

BRITISH MEDICAL JOURNAL

THE JOURNAL OF THE BRITISH MEDICAL ASSOCIATION

Editor

HUGH CLEGG, M.A., M.D., F.R.C.P.

Deputy Editor

J. W. P. THOMPSON, M.A., M.B., D.P.H.

VOLUME II, 1957

JULY TO DECEMBER

LONDON

BRITISH MEDICAL ASSOCIATION

TAVISTOCK SQUARE, W.C.1

INDEX TO VOLUME II FOR 1957

Original articles, leading articles, annotations, parliamentary news, and correspondence are indicated by the use of the symbols (O), (L), (A), (P), and (C), respectively. Some subjects dealt with under various main headings in the Journal—e.g., "Annotations," "Leading Articles," "Parliament," etc.—are also set out under these headings.

- ABBOTT, J. D.:** Ionizing radiations and leukaemia, 41
- Abdomen:** *Management of Abdominal Operations*, 2nd ed. (Editor: R. Mainiot), 148
- obscure pain, 1169 (A)
- ABELS, J.:** Influenza epidemic, 1112 (C)
- Relief of Stokes-Adams syndrome after cholecystectomy, 709 (C)
- ABER, G. M., NEALE, F. C., and NORTHAM, B. E.:** Binding of haemoglobin, 1368 (C)
- ABERCHROMBIE, M.:** Cytology and pathogenesis of cancer, 697
- Aberdeen University.** See Universities, Aberdeen
- Abnormalities, congenital, relation to attempted abortion,** 248
- Abortion, attempted, and foetal malformation,** 248
- habitual, due to insufficiency of internal cervical os; preliminary report of seven cases treated by modified Shirodkar technique (V. B. Green-Armstrong and J. C. McC. Browne), 128 (O); 299 (C), 352 (C), 469 (C), 589 (C), 714 (C), 767 (C)
- ABRAHAM, J. J.:** *Surgeon's Journey. The Autobiography of J. Johnston Abraham*, 511
- Abstracts and digests of medical papers,** 705
- ABT, L. E.:** See BROWER, D., 32
- Accidents in the home, notification,** 1555 (P)
- injuries resulting from road accidents, 231
- Acetazolamide, effect in sickle-cell disease,** 231
- ACHESON, R. M.:** Morbidity in old men from cardiovascular disease, 818
- Testosterone in dwarfism, 996 (C)
- Achondroplasia,** 931 (A)
- Acne, early, treatment of,** 478
- problems of, 990 (A)
- scars, abrasive treatment, 837
- vulgaris, 225
- Acro-osteolysis, familial ulcers, and mutilating lesions of extremities (L. van Bogaert),** 367 (O), 400 (A)
- A.C.T.H. See Corticotropin**
- ADAMS, J. Bodkin, fined on 14 charges of forgery and drug offences (medico-legal note),** 303
- ADAMS, J. C.:** *Outline of Fractures Including Joint Injuries*, 396
- ADAMS, R.:** Recent developments in cerebrovascular diseases, 287
- ADAMS, W.:** Blood films of persons living in the unsewered suburbs of Georgetown, 761
- Adder bite, antivenal for,** 56 (C)
- ADDERLEY, D. J.:** Drug firm representatives, 1243 (C)
- Addison's disease and adrenal cortical steroids,** 1010
- occurring in sisters (P. H. Hewitt), 1530
- treatment (J. D. N. Nabarro and G. Walker), 17 (O)
- Adenomatosis, pancreatic islet, with hypoglycaemic episodes (H. Garland),** 969 (O)
- Adenovirus: Pharyngo-conjunctival fever; school outbreaks in England during the summer of 1955 associated with adenovirus types 3, 7, and 14 (E. J. C. Kendall and others),** 131 (O)
- ADERHOLD, K. See SIERING, H., 454**
- Adiposis dolorosa, treatment,** 1381
- ADLER, G. See READ, Sir Herbert, 630**
- Adolescence: In Their Early Twenties: A Study of Glasgow Youth (T. Ferguson and J. Gunnison),** 203
- *Youth at Work. A Five-year Study by an Appointed Factory Doctor (M. E. M. Herford),* 511
- Adoption, effect on fertility,** 719, 1008 (C), 1322 (C)
- Adrenaline, accidental fatal injection (medico-legal note),** 1443
- fate in the body, 1226 (L)
- ADRENALS:**
- Cortex:** aldosterone, function in metabolism of sodium and water in pregnancy (M. G. Rinsler and Barbara Rigby), 966 (O); 1239 (C), 1436 (C)
- secretion in man (G. W. Thorn, E. J. Ross, Jean Crabbé, and W. Van't Hoff), 955 (O)
- corticosteroid therapy in the elderly, complications, 1559
- dysfunction; diagnosis of (J. D. N. Nabarro, Audrey Moxham, and G. Walker), 1018 (O)
- hazards of Soffer's test, 823 (C)
- effects of steroids on intermediary metabolism (G. W. Thorn, A. E. Renold, and A. I. Winegrad), 1009 (O)
- hyperactivity in patient with bronchial carcinoma and diabetes mellitus (F. D. Rosenthal), 139 (O)
- ADRENALS (continued):**
- Cortex: The Adrenal Cortex (I. C. Jones),** 1039
- treatment of insufficiency (J. D. N. Nabarro and G. Walker), 17 (O)
- Relationship to thyroid glands, 41
- Adrenocorticotrophic hormone. See Corticotropin**
- Advertisements in medical journals, editorial responsibility for,** 704
- Advertising: Subliminal advertisement,** 928 (L)
- Acrosols, infected, liberated in opening screw-capped bottles (A. J. H. Tomlinson),** 15 (O)
- Africa: Nutrition Research in Africa South of the Sahara,** 871 (L)
- *Report of the C.C.T.A. Inter-African Nutrition Conference,* 871 (L)
- Age, old. See Old age**
- AGER, J. A. M., and LEHMANN, H.:** Haemoglobin L; a new haemoglobin found in a Punjabi Hindu, 142 (O)
- Agranulocytosis and anaemia associated with disseminated tuberculosis (P. E. R. Tattersall),** 1351
- associated with infective hepatitis (F. E. Dische and J. R. Golding), 738 (O)
- with recovery, during promazine therapy (J. A. Cook, A. G. Melrose, and J. R. Roy), 276
- Air ambulance service, Scotland; tribute to crew and nurse of crashed plane,** 1053 (C)
- AIRD, I.:** *Companion in Surgical Studies*, 2nd ed., 87
- AITKEN, T. H. G.:** Viral studies in Caribbean, 761
- AKENSIDE, Mark, doctor and poet (Sir John Charles),** 222, 1449 (O)
- Albinism, inheritance of,** 94 (A)
- Alcohol: Calories from alcoholic drinks,** 1502
- effect in peptic ulcer, 1064
- medicinal, prescription of, 360 (P), 1122 (P)
- ALCOHOLISM:**
- Alcoholic psychoses, incidence,** 164 (P)
- Alcoholism (Editor: G. N. Thompson),** 453
- Alcoholism: A Manual for Students and Practitioners (L. Williams),** 453
- Aldosterone, function in metabolism of sodium and water in pregnancy (M. G. Rinsler and Barbara Rigby),** 966 (O); 1239 (C), 1436 (C)
- hyperaldosteronism and potassium deficiency, 964
- measurement in urine, 956
- secretion in man (G. W. Thorn, E. J. Ross, Jean Crabbé, and W. Van't Hoff), 955 (O)
- ALEXANDER, F.:** *Psycho-analysis and Psychotherapy: Developments in Theory, Technique, and Training,* 1532
- ALEXANDER, G. L.:** Intoxicated children, 885 (C)
- Poliomyelitis in West Africa, 1241 (C)
- Alexander Pigott Werner Memorial travelling fellowships in ophthalmology and otology,** 363
- Alkaptonuria, two cases (A. W. McKenzie, J. A. Owen, and J. H. R. Ramsay),** 794 (O)
- All-India Institute of Mental Health,** 428
- ALLANBY, K. D., and TROUNCE, J. R.:** Excretion of mecamylamine after intravenous and oral administration, 1219 (O)
- ALLEN, C.:** Clinic for homosexuals, 715 (C)
- Allergy: Third international congress of allergology,** 534
- vasculitis, allergic, 36 (L)
- ALLISON, A. C., and ap REES, W.:** Binding of haemoglobin by plasma proteins (haptoglobins); its bearing on the "renal threshold" for haemoglobin and the aetiology of haemoglobinuria, 1137 (O); 1164 (L); 1368 (C)
- ALLISON, R. S.:** Walking-aid for paraplegics, 350
- Altitude, effects on patients with emphysema, bronchitis, and coronary disease,** 1007
- Ambulance, air, in Scotland; tribute to crew and nurse of crashed plane,** 1053 (C)
- Amenorrhoea, ovarian and endometrial grafting for,** 105 (C)
- American Board of Surgery: History of the American Board of Surgery, 1937-1952 (J. S. Rodman),** 630
- American Diabetes Association, meeting,** 40
- American Gout Association: Van Meter prize,** 1558
- American Society of Clinical Pathology, joint session with Association of Clinical Pathology,** 349
- Amidopyrine purchased abroad, fatal effects,** 826 (C)
- Aminophylline, objective comparison with two recent neutral theophylline compounds (D. N. Phear),** 74 (O); 489 (L)
- Amphenazole and bemegride in treatment of acute primidone poisoning (G. Dotevall and B. Herner),** 451

- Amnesia; spontaneous recovery in long-term personality amnesia,** 1175 (C)
- sudden loss of memory (A. Kennedy and J. Neville), 428 (O)
- Amnion implantation; results in peripheral vascular disease (H. D. Moore),** 1350 (O)
- AMPURAN, J. C.:** Tropical pulmonary eosinophilia, 1304 (C)
- Amputees: Ministry of Health booklet on rehabilitation of amputees,** 169
- Amylobarbitone sodium and bemegride, effect of oral administration in psychiatric patients,** 1516
- trial in psychoneurosis, 64
- Amyloidosis, diagnosis and prognosis,** 365
- leukaemia, and renal vein thrombosis in irradiated ankylosing spondylitis (J. B. Penfold and R. D. S. Rhys-Lewis), 1034 (O); 1176 (C)
- ANAEMIA:**
- And agranulocytosis associated with disseminated tuberculosis (P. E. R. Tattersall),** 1351
- Aplastic, due to phenylbutazone (G. R. Venning),** 146, 354 (C)
- microspectrographic diagnosis, evaluation of (K. W. Keohane and W. K. Metcalf), 981 (O)
- Cancer anaemia; nature and bearing on immunological theory of cancer (H. N. Green, June Wakefield, and G. Littlewood),** 779 (O)
- Haemolytic, congenital; complicated by megaloblastic anaemia of pregnancy (M. I. Drury and F. Geoghegan),** 393 (O)
- Megaloblastic, and vitamin-B₁₂ deficiency after anticonvulsant therapy; report of two cases (P. Kidd and D. L. Mollin),** 974 (O)
- due to anticonvulsants, 412 (C)
- of infancy, treated with folic acid (F. Walt, S. Holman, and P. Naidoo), 1464 (O)
- of pregnancy, complicated by congenital haemolytic anaemia (M. I. Drury and F. Geoghegan), 393 (O)
- treatment with folic acid (Jean M. Scott), 270 (O)
- Pernicious; College of General Practitioners survey,** 307
- dosage of cyanocobalamin, 309
- Sickle-cell disease, new method of treatment; preliminary report (G. Hilkovitz),** 266 (O)
- Sickle cells and salmonellae, association between,** 1537 (A)
- Treatment: radioactive iron-dextran complex, metabolism in human subjects (A. J. Grimes and M. S. R. Hutt),** 1074 (O)
- ANAESTHESIA AND ANALGESIA:**
- Analgesic action of bethidine-levallorphan mixtures in man (A. Herxheimer and C. Sanger),** 802 (O); 1051 (C)
- Association of Anaesthetists: silver jubilee,** 1445, 1423 (A)
- Breathing apparatus, draft standard for,** 952
- Buthalitone sodium; assessment (P. H. Simmons and May S. Blandhard),** 1347 (O)
- Caudal analgesia, continuous, clinical trial in prolonged labour (G. T. Johnson),** 386 (O), 763 (C)
- Death on the table; coroners' criticisms,** 885 (C), 1175 (C)
- Department of anaesthetics, Royal College of Surgeons,** 245
- Draffin bipod, modification to (D. F. N. Harrison),** 233
- Endotracheal intubation, complications,** 690 (A)
- Fatalities in relation to use of relaxants, 224**
- "Fluothane": report to Medical Research Council by Committee on Non-explosive Anaesthetic Agents,** 479 (O), 514 (L); (correction, 592), 641 (C), 762 (C)
- General anaesthesia as aid to therapeutic hypothermia (J. Parkhouse),** 751
- Halothane, use in closed circuit (H. R. Marrett),** 331 (O), 515 (L), 526 (C), 762 (C)
- In dystrophia myotonica,** 1174 (C)
- In hepatic disease,** 776, 1008 (C)
- Manual of Anesthesiology for Residents and Medical Students (H. Schwartz, S. H. Ngai, and E. M. Papper),** 563
- Muscle Relaxants in Anesthesiology (F. F. Földes),** 687
- Nitrous oxide anaesthesia,** 712 (C), 884 (C)
- dangers, 1293 (A); 1438 (C), 1293 (C)
- Obstetrical anaesthetic deaths,** 1306 (C)
- Premedication in children,** 469 (C)
- Respiratory and cardiac arrest in children (E. H. Rainer and J. Bullough),** 1024 (O)
- S.C.T.Z., new cerebral depressant,** 152 (A)
- Second World Congress of Anaesthesiologists,** 113
- Suxamethonium chloride and muscle pain,** 527 (C)
- Techniques for the single-handed practitioner,** 477

JULY-DEC., 1957

INDEX

ANA-ASH 3

- Analgesia. See Anaesthesia and Analgesia**
- Anaphylactic shock after immunization,** 775
- Anatomy: Anatomical Atlas of the Human Brain and Spinal Cord (M. Stelmasiak),** 33
- *Atlas Illustrating the Topographical Anatomy of the Head, Neck, and Trunk (J. Symington),* 33
- *Synopsis of Surgical Anatomy, 8th ed. (A. L. McGregor),* 1532
- ANDERSON, C. R.:** Viral studies in Caribbean, 761
- ANDERSON, Frederick Jasper, obituary of,** 1439
- ANDERSON, I.:** *T. violaceum infection of the scalp,* 1221
- ANDERSON, O. W.:** *Voluntary Health Insurance in Two Cities: A Survey of Subscriber-Households,* 986
- ANDERSON, T.:** Antibiotics in fungous diseases, 348
- *Exploring in the northernmost Andes (H. B. Jule),* 519
- ANDREWS, B. E. See KENDALL, E. J. C., 131**
- ANDREWS, M. M. See REID, J., 1071**
- ANDREWS, R. H.:** Pneumonia and bronchial vesicular association with herpes zoster; with reference to other visceral associations of zoster, 384 (O)
- ANDRIA, O. J., and SINCLAIR, W. D.:** Chemical boiling test for proteinuria, 1114 (C)
- Androgens and erythropoiesis,** 1422 (A)
- Anencephaly,** 818
- Aneurysm, traumatic, treated by excision, and the effect of chlorpromazine (A. M. Wiley and G. M. Boyes),** 1160, 1366 (C)
- ANGEL, J. H.:** Pachydermo-periostosis (idiopathic osteoarthritis), 789 (O)
- Angina, effect of glyceryl trinitrate overdosage,** 1382
- Animal experiments: Humane Technique in the Laboratory,** 1343
- inquiry into law, 241 (P)
- Stephen Paget memorial lecture, 1363
- Ankle injury: damages increased (medico-legal note),** 1123
- ANNING, S. T.:** Neurodermatitis, 226
- review of *Ulcers of the Legs*, by P. P. Luchs, 32
- ANNOTATIONS:**
- Abdominal pain, obscure,** 1169
- Achondroplasia,** 931
- Acne, problems of,** 990
- Air pollution,** 1358
- Albinism, inheritance of,** 94
- Androgens and erythropoiesis,** 1422
- Antibiotics in chronic bronchial infection,** 459, 713 (C), 826 (C), 1050 (C)
- tissue distribution, 1484
- Anxious patient and worried doctor,** 1483
- Art and mental illness,** 210
- Association of Anaesthetists, jubilee,** 1423
- Atomic reactor, accident at Windscale,** 991, 1166
- Botulism,** 1537
- British Council and medicine,** 1228
- Award of Gold Medal, 210
- Meeting at Newcastle, 39
- Scientific exhibition, 1958, 992
- British National Formulary,** 758
- Cambridge Regius Professor, 154**
- Cancellous strip grafting,** 759, 999 (C), 1052 (C)
- Candida napkin rashes,** 1229, 1492 (C)
- Cardiac arrest, elective,** 1104
- Cement dust,** 94
- Chlorpromazine jaundice,** 635
- Chronic sick, care of,** 1421
- Crash helmets on trial,** 636
- Cyanosis in infancy,** 1045, 1309 (C), 1544 (C)
- Cysticercosis, cerebral,** 516, 714 (C)
- Deafness, detection of,** 153
- Depopulation of a rural area,** 517
- Doctors off duty,** 1295
- Doctors' questionnaire,** 1360
- Drug addiction,** 210, 413 (C), 468 (C), 643 (C)
- Drugs for private patients; parliamentary Bill,** 403
- Endotracheal intubation, complications,** 690
- Environment and congenital malformations,** 208
- Eugenics Society,** 1358
- First chair of paediatric surgery,** 932
- General practitioners, diagnostic centre in Edinburgh,** 875
- Genetics; effects of desoxyribonucleic acid on ducks,** 873
- Haematiic pneumoconiosis in Cumberland miners,** 1423
- Hepato-lenticular degeneration,** 283, 528 (C)
- Household spending,** 1102
- Hypertension in pregnancy; symposium,** 153
- Hypotonia, congenital, benign,** 931
- Influenza epidemic,** 757, 939 (C), 1045
- local prophylaxis, 1421
- vaccination, 38
- vaccines, 1482
- Interferon,** 1102
- Iodine compounds in plasma,** 93
- King Edward's Hospital Fund, 60th annual report,** 460
- Klinefelter's syndrome,** 1294
- Knee-joint injuries in miners,** 1101
- Lightning shock,** 1168
- Liver: British Medical Bulletin symposium,** 345, 470 (C)
- cirrhosis, deaths from, 1538
- Lung cancer in women,** 458
- changes during methonium therapy, 345, 466 (C)
- Measure to maid,** 346

- ANNOTATIONS (continued):**
- Medical education in Scotland; working under difficulties,** 567
- Medical Journal of Australia,** 636
- Medicine in India and Canada,** 569
- Meningitis, listerial,** 209
- Mental deficiency in Scotland,** 517
- disease, chronic, 691
- health of students, 567, 710 (C), 823 (C), 940 (C)
- Myxoedema, circumscribed,** 285, 471 (C)
- N.H.S.: Disciplinary procedure,** 1103
- in 1956, 1359
- Nervous disease, trophic lesions in,** 400
- New scholarship for doctors' sons,** 814
- Nitrous oxide, dangers of,** 1293, 1438 (C), 1491 (C)
- Nobel Prize in Medicine and Physiology awarded to Daniel Bovet,** 1045
- Nurses' examinations,** 39
- Obstetrics in Nigeria,** 635, (correction, 776)
- Opticians Bill,** 1360
- Paternity, false admissions of,** 401
- Peptic ulcer, acute haemorrhage from,** 693, 941 (C)
- Pink disease,** 402
- Pneumoconiosis in coal workers,** 346
- Poliomyelitis; American vaccine banned,** 38
- and sanitation; dangers of sewage contamination, 402
- vaccine dosage, 1229
- Polymyalgia rheumatica,** 1483
- Portuguese man-of-war,** 692
- Pregnancy, effect on colitis,** 151, 524 (C)
- President of Royal College of Surgeons,** 154
- Principal at Bangor,** 403
- Psychiatrist as administrator,** 284
- Psychopaths,** 1536
- Radiations, ionizing, protection against; code of practice,** 1535
- Renal calculi in severe paralysis,** 759
- Respiratory diseases, acute, in young children,** 1228, 1434 (C)
- virus vaccines, 813, 821 (C), 881 (C)
- Salicylate, pharmacology of,** 812
- Sarcoidosis, syndrome of,** 634
- Scottish presidents,** 1484
- S.C.T.Z., new cerebral depressant,** 152
- Seeing in the dark,** 347
- Sickle cells and salmonellae, association between,** 1537
- Smokers' lungs,** 692
- Sports and world culture,** 874
- Stenosis of sphincter of Oddi,** 1044, 1179 (C)
- Strontium-90 in bone,** 1104
- Student looks at the curriculum,** 930, 1053 (C)
- Tetanus, prevention and treatment,** 930, 1053 (C)
- Tranquilizers, hazards of use,** 92, 299 (C), 300 (C)
- Tropical jubilee,** 1230
- Tuberculosis in Scotland,** 93
- Vitamin-D intoxication,** 813
- Waiting-lists,** 152
- Wasp stings,** 757
- Welfare foods,** 284, 654 (C)

 BRITISH MEDICAL ASSOCIATION: ANNUAL MEETING, NEWCASTLE UPON TYNE: PROCEEDINGS:
 Plenary Sessions:
 Care of the dying (I. D. Grant, A. G. R. Lowdon, C. J. L. Thurgar, R. B. Scott, and Bishop of Durham), 286
 Management of hypertension (R. Coope, J. McMichael, E. G. Tuckwell, and J. H. Hunt), 211
 Present status of prophylactic immunization (R. Cruickshank, J. Grant, T. Francis, C. H. Stuart-Harris, and P. M. D'Arcy Hart), 212
 Round-Table Conferences:
 Injuries resulting from road accidents, 231
 Low back pain (W. Mills, D. R. L. Newton, S. Josephs, I. N. Maciver, and N. M. Roberts), 230
 Some pregnancy alarms (W. Walker and C. K. Warrick), 230
 Section of Anaesthetics:
 Barbiturate toxicity and coma (E. Nilsson, T. J. Thomson, I. W. Dundee, P. H. Simmons, and B. R. M. Johnson), 290
 Deaths related to anaesthesia (J. Gillies, H. J. V. Morton, W. D. Wylie, and A. R. Hunter), 224
 Section of Cardiology:
 Rheumatic carditis in children (W. Brigden), 225
 Role of quinidine in treatment of the arrhythmias (P. Wood), 225
 Survival after cardiac infarction (F. Jackson), 225
 Treatment of resistant heart failure (O. Brenner), 224
 Use and abuse of the electrocardiogram (C. Bain), 224
 Colour film: The jugular venous pulse (P. Mounsey), 225
 See also Sections of Medicine, Surgery, and Cardiology
 Section of Child Health:
 Collagen disorders: round-table conference (G. A. Rose, C. O. Carter, A. Hill, and Barbara Ansell), 293
 Iatrogenic disease in childhood (A. W. Franklin, Mary Crosbie, Alice Stewart, and K. Cameron), 293
 Sections of Child Health and General Practice:
 Acute respiratory infection (D. Court, J. Fry, J. F. Goodall, C. H. Stuart-Harris, and A. J. Laidlaw), 290
 See also Sections of Preventive Medicine, Child Health, and Obstetrics and Gynaecology
 Section of Dermatology:
 Acne vulgaris (A. J. Rook), 225
 Neurodermatitis (S. T. Anning), 226
 Vesicular eruptions of the hands and feet (S. Gold and A. G. Fergusson), 226
 Sections of General Practice and Preventive Medicine:
 Illness of the school child (R. W. Eldridge, G. K. Hodgkin, E. G. Brewis, A. Model, and G. S. Robertson), 226
 See also Sections of Child Health and General Practice, and Sections of Obstetrics and Gynaecology
 Section of History of Medicine:
 Cholera epidemics in Newcastle (J. Boyes), 223
 The De Dissectione of Charles Estienne (C. E. Kellie), 222
 Influence of Leyden upon the Edinburgh Medical School (D. Guthrie), 223
 John Snow's place in history (M. H. A. Davison), 223
 Mark Akenside (Sir John Charles), 222
 Section of Medicine:
 Cortisone in general practice (G. A. Smart, S. J. Hartfall, I. W. B. Grant, and R. B. Thompson), 215

BRITISH MEDICAL ASSOCIATION: ANNUAL MEETING, PROCEEDINGS (continued):

Sections of Medicine, Surgery, and Cardiology:
 Arterial embolism (W. Evans, Sir James Learmonth, C. Rob, H. A. Dewar, A. A. Klass, Catherine C. Burt, and M. M. Suzman), 214

Section of Neurology:
 Symposium on cerebral vascular disease (R. Adams, J. M. Holmes, J. Bull, M. Falconer, and F. A. Elliott), 287
 Symposium on epilepsy (D. Williams, D. Hill, H. Merritt, W. Penfield, and Lord Cohen of Birkenhead), 228

Section of Obstetrics and Gynaecology:
 Placental insufficiency (G. T. Johnson), 216
 Prolonged labour (W. C. W. Nixon, K. Vartan, and A. S. Duncan), 217
 Some causes of public alarm and anxiety: round-table conference (W. Walker and C. K. Warrick), 230
 Unusual uses of the flying squad (F. Stabler and R. A. Tennent), 217
 See also Sections of Preventive Medicine, Child Health, and of Obstetrics and Gynaecology

Sections of Obstetrics and Gynaecology and General Practice:
 The G.P.'s responsibility in gynaecology (A. J. G. Newton, J. K. Russell, and E. D. Forster), 155
 Pre-eclampsia (Kate Harrower, O. V. Jones, and J. H. Fisher), 155
 Section of Occupational Health:
 Management of pneumoconiosis in general practice (A. Meiklejohn, J. C. Gilson, R. A. Trevethick, and F. Lishman), 221

Section of Ophthalmology:
 Cataract surgery under chlorpromazine hydrochloride (H. V. Ingram), 222
 Chiasmal disease (N. Dott, A. I. Mooney, J. McClelland, C. F. Rolland, and J. S. Robertson), 222
 Ocular changes in the leukaemias (P. D. T. Roper), 222
 Section of Orthopaedics:
 Fractures of the patella (J. V. Todd), 228
 Pain in the arm (R. Roaf, J. K. Stanger, and M. Kremer), 227
 Reconstructive surgery of the upper limb following poliomyelitis (A. Miller), 228
 Section of Oto-rhino-laryngology:
 Epistaxis (J. P. Stewart, H. A. Dewar, and R. H. Moore), 292
 Presenting symptoms and signs of malignant disease of the upper respiratory tract (W. A. Mill, R. D. Owen, and J. I. M. Black), 292
 Scope of surgery in the management of deafness (I. B. Thorburn and F. McGuckin), 291

Section of Physical Medicine:
 Low back pain: round-table conference (W. Mills, D. R. L. Newton, S. Josephs, I. N. Maciver, and N. M. Roberts), 230
 Results of rehabilitation of injured miners (A. N. Zinovieff), 294
 Symposium on painful feet (G. Beauchamp and A. T. Richardson), 294
 Symposium on steroid therapy in the rheumatic diseases (G. R. Fearnley, J. Cyriax, and M. Thompson), 294
 Section of Plastic Surgery:
 Haemangioma (D. N. Matthews), 228
 Investigation of children with speech defects (J. S. Canan), 228
 Repair of hand injury (M. H. Shaw), 228
 Sections of Preventive Medicine, Child Health, and Obstetrics and Gynaecology:
 Puberty and its problems (L. Banks, D. V. Hubble, and T. N. MacGregor), 218
 See also Sections of General Practice and Preventive Medicine

Section of Psychiatry:
 Symposium on tranquillizers (D. R. Laurence, L. C. Cook, and E. H. Kitching), 219
 Sections of Radiology and Surgery:
 Radiological investigation of the biliary tract (S. D. S. Park, J. D. Dow, J. D. Rose, and A. D. Wright), 289
 Section of Surgery:
 Diagnosis and treatment of carcinoma of the stomach (J. Gilmour, G. A. S. Lloyd, H. Taylor, R. O. K. Schade, and D. Chamberlain), 219
 See also Sections of Medicine, Surgery, and Cardiology; Sections of Radiology and Surgery

CLINICAL TRIALS OF INFLUENZA VACCINE

THIRD PROGRESS REPORT TO THE MEDICAL RESEARCH COUNCIL BY ITS COMMITTEE ON CLINICAL TRIALS OF INFLUENZA VACCINE*

In November, 1951, the Medical Research Council set up a Committee on Clinical Trials of Influenza Vaccine. In its First Progress Report (M.R.C., 1953) details were given of a small-scale trial in the winter of 1951-2 designed to assess by serological methods the comparative value as antigens of certain influenza A vaccines, and of a larger controlled field trial in the winter of 1952-3 of an influenza A vaccine containing equal proportions of a threefold concentration of F.M.1 (U.S.A. 1947 strain) and of the Liverpool (1951) strain. The incidence of clinical influenza in the volunteers was low, but there appeared to be a reduction of some 40% in the vaccinated as compared with the control group.

In its Second Progress Report (M.R.C., 1955) were described the results of investigations in 1953-4 into the comparative antibody responses and clinical reactions with saline and emulsion (oil-adjuvant) vaccines. Three vaccines were under investigation containing the same antigen (A/England/1/51). Two were of the emulsified type—from mouse-adapted and egg-adapted viruses, respectively—and the third, from a mouse-adapted virus, was of the saline type adsorbed on aluminium phosphate. The emulsified vaccines gave a greater and more sustained antibody response than the saline vaccine although they contained only one-tenth of the amount of virus antigens, but a decrease in the antibody levels was found in all vaccinated groups after one year. Abnormally severe local reactions occurred in two volunteers out of 268 given the emulsified vaccines.

In the winter of 1954-5 a further field trial was arranged with the object of assessing the comparative value in the prevention of influenza of two emulsified vaccines, prepared from an egg-adapted and a mouse-adapted virus respectively, and a saline vaccine containing mouse-adapted virus. All three vaccines were prepared from the same strain A/Eng/1/54. Trials with the same vaccines were also carried out with a view to measuring the serological responses as a background to the trial of protection.

In the absence of epidemic virus A influenza in 1954-5 the period of observation of the inoculated volunteers was continued in the next winter, 1955-6. In addition a further field trial was organized. It was decided not to employ emulsified preparations because of the rather

high proportion of delayed local reactions with these vaccines in the previous winter's investigation. Saline vaccines with aluminium phosphate were accordingly used, and the trial was arranged to compare the value of a monovalent vaccine from a recent virus A strain (A/Eng/19/55) with a polyvalent vaccine from three older strains—namely, P.R.8, F.M.1, and Swine viruses. Concurrent serological trials with the same vaccines were carried out on a limited scale in two age groups—25 years of age and under, and 30 years and over—to establish the relative responses with each vaccine and in the two different adult age groups.

The results of the trials in the winters of 1954-5 and 1955-6 are given in detail in the sections of the report which follow.†

I. SEROLOGICAL TRIALS. COMPOSITION OF THE VACCINES AND SEROLOGICAL TRIALS OF THEIR ANTIGENICITY

Trial I, 1954-5

The vaccines used in the field trials of 1954-5 were also tested for their antigenic properties by inoculation into a small number of volunteers. The vaccines were prepared by Dr. F. Himmelweit of the Wright-Fleming Institute of Microbiology by methods previously described (Reports to the M.R.C., 1953, 1955). They were:

W.—A saline vaccine made from the egg-adapted line of A/Eng/1/54 virus and concentrated approximately threefold from the original allantoic fluids. Each dose of 1 ml. contained 20,000 haemagglutinating units of virus adsorbed on to 10 mg. of aluminium phosphate.

X.—A water-in-oil emulsion containing "bayol F" and "arlacel" (Salk et al., 1952). Each dose of 0.25 ml. contained 1,000 haemagglutinating units of the egg-adapted A/Eng/1/54 virus.

Y.—A similar water-in-oil emulsion containing 1,000 haemagglutinating units of the mouse-adapted line of the A/Eng/1/54 virus.

Z.—A saline vaccine made from the Lee strain of influenza virus B and containing 20,000 haemagglutinating units adsorbed on to 10 mg. of aluminium phosphate in each dose of 1 ml.

Vaccines X and Y contained only half the content of haemagglutinating units of the earlier emulsified vaccines and had only one-twentieth of the virus content of the saline vaccine (W). The Lee strain from which vaccine Z was made yielded infected allantoic fluids of high titre, but both egg and mouse lines of the A/Eng/1/54 virus gave poor yields of virus in eggs, those of the mouse-adapted strain being the lower. The adjuvant vaccines were inoculated intramuscularly and the saline vaccines were given by deep subcutaneous inoculation.

†The various strains of influenza virus used in these trials are summarized as follows. Influenza A: Swine 1931; P.R.8 1934; F.M.1 1947; A/England/1/54 and A/England/202/56, Scandinavian group; A/England/19/55—Eire 55 group. Influenza B: Lee 1940; B/England/9/54.

Serological Responses

Medical students at St. Mary's Hospital, London, and at the Universities of Aberdeen, Birmingham, Durham, Liverpool, and Sheffield volunteered for the inoculation of vaccine and the collection of blood before and at one month, three months, and one year afterwards. A number of volunteers could not be bled after the inoculation, but the loss amounted to only 20% at one year. Table I shows the results of haemagglutination-inhibition tests on the individual sera from 103 students inoculated originally; geometric mean titres and rises of antibody are shown. The egg-adapted line of the A/Eng/1/54 virus was the only strain of virus A used in the laboratory tests, because the mouse-adapted line proved difficult to use owing to its undue sensitivity to inhibition *in vitro*. The B/Eng/9/54 virus was used in addition to the Lee strain of influenza virus B in tests on sera from volunteers inoculated with the vaccine Z. All the antigens for the tests were made at the Wright-Fleming Institute of Microbiology with the same lines of virus as those from which the vaccines were prepared. The tests shown in Table I were carried out at the Wright-Fleming Institute of Microbiology, at the Virus Research Laboratory of the University of Sheffield, the Virus Reference Laboratory, Colindale, and the World Influenza Centre, Mill Hill.

Table I shows that the virus A vaccines behaved as expected. After inoculation with the saline vaccine W, volunteers developed an antibody response reaching a peak at one month. The adjuvant-containing vaccines X and Y produced a peak in antibody response three months after inoculation which was greater than that produced by the saline vaccine. The adjuvant vaccine Y gave a smaller antibody response than vaccine X, and this result contrasts with that obtained in 1953, when the mouse-adapted virus proved a better antigen than the egg-adapted line of the same strain (Report to the Medical Research Council, 1955). Apart from this, however, the adjuvant vaccines gave remarkably similar responses in amount and duration to those obtained in 1953 (Table II) and the saline vaccine W also behaved in much the same manner as the saline vaccines of 1951 (Report to the Medical Research Council, 1953).

The serological responses were intended to furnish a background to the trials of protection against influenza in the field. There was no general outbreak of influenza A, but influenza B was unusually prevalent in the winter of 1954-5 following the inoculation. The virus B vaccine had been included in the trial for control purposes. It produced the expected serological response against the Lee virus, and the antibody levels were slightly higher three months after inoculation than at one month. But when the sera were tested against a newly isolated strain of influenza B (B/Eng/9/54), it was found that a much smaller antibody response had been engendered against this strain. This may explain why the vaccine conferred little protection against influenza in the field (see below). The virus A vaccines had produced antibody levels which were still substantially higher one year after inoculation than those present before inoculation, and a follow-up of those inoculated in the field trials was therefore continued during the winter of 1955-6.

TABLE I.—Serological Trials, 1954-5. Results of Tests on Individual Serum Samples

Vaccine	Strain of Virus in Vaccine	Strain of Virus in Test	Geometric Mean Titres				Fol. Rises of Antibody		
			1 Before Inoculation	(1 Month)	(3 Months)	(1 Year)	1-2	1-3	1-4
W (saline)	A/Eng/1/54 Egg-adapted	A/Eng/1/54 Egg-adapted	5.5 (23)	26.9 (23)	20.4 (23)	14.3 (20)	4.9	3.7	2.6
X (oil-adjuvant)	A/Eng/1/54 Egg-adapted	A/Eng/1/54 Egg-adapted	5.7 (22)	62.4 (22)	142.2 (22)	89.9 (19)	10.9	24.9	15.0
Y (")	A/Eng/1/54 Mouse-adapted	A/Eng/1/54 Egg-adapted	6.2 (21)	38.2 (20)	74.3 (20)	50.6 (19)	6.2	11.8	7.8
Z (saline)	Lee (B)	Lee B/Eng/9/54	16.9 (37)	74.2 (37)	78.0 (35)	57.5 (23)	4.4	4.6	3.1
			16.4 (26)	37.5 (26)	40.6 (24)	45.4 (13)	2.3	3.4	2.3

Figures in parentheses give the number of samples of serum tested.

TABLE II.—Comparison of Antibody Responses to Influenza Virus A Vaccines used in Various Serological Trials

Year of Trial	Virus Strain	Type of Vaccine	Haemagglutinating Units per Dose	Maximum Recorded Fold Rise*	Interval after Inoculation
1951 (Nurses and university students)	A/Eng/1/51	Saline	19,200	3.2	2 weeks
	A/Swe/50	"	64,000	4.9	
	"	"	12,000	2.9	
1952 (University students)	A/Eng/1/51	Saline	20,000	9.4	2 weeks

* In geometric mean titre.

Trial II, 1955-6

Three more vaccines were tested during the winter of 1955-6 in the field, and the two which contained influenza virus A were also tested serologically. The vaccines, again prepared by Dr. Himmelweit, were:

S.—A monovalent influenza A saline vaccine made from the A/Eng/19/55 strain recovered from a local outbreak of influenza in the spring of 1955. It contained 20,000 haemagglutinating units of virus adsorbed on to 10 mg. of aluminium phosphate in a dose of 1 ml.

T.—A polyvalent influenza A saline vaccine made from equal amounts of the three viruses P.R.8, F.M.1, and Swine. The total virus content of 20,000 haemagglutinating units was adsorbed on to 10 mg. of aluminium phosphate in a dose of 1 ml.

U.—A control saline vaccine made from the Lee strain of influenza B and containing 20,000 haemagglutinating units and 10 mg. of aluminium phosphate in a dose of 1 ml. This vaccine was used in the field trial but was not tested serologically.

All vaccines were administered by deep subcutaneous injection.

Purpose of the Trial

The serological trials undertaken in 1956 were partly designed to serve as a background to the trial of protection in the field against influenza. This was particularly important because of the different composition of the two vaccines and the need to compare the relative antibody response produced with each vaccine with the degree of protection. Secondly the relative serological response in persons of different ages was measured because of the work of Davenport and Hennessy (1956) in the U.S. These authors have suggested that the serological response to an influenza vaccine is partly dependent on the age of those who are inoculated. They showed differences in the antibody responses in young subjects compared with those in older persons to the same monovalent vaccines which they attributed to previous experience of the older subjects to antigenic stimuli during epidemics in their youth.

Serological Results

Two groups of volunteers were assembled. Those who were 25 years of age or less were from the R.A.M.C. Depot and Training Establishment, Crookham. Industrial workers of 30 years and over provided the second group. The serological responses to the two vaccines were determined separately in two groups of 80 volunteers consisting of 40 from each age group. Two serum samples were collected, one before and the other one month after inoculation, from each volunteer. Twenty pairs of sera from each group were distributed to each of the four laboratories named above, where the individual serum samples were each tested against virus antigens prepared and distributed by the Wright-Fleming Institute. Each of the strains of virus used to prepare the vaccines was included in the tests and so also was a newly isolated strain of influenza virus A recovered in January, 1956, from an outbreak in Lancashire. Table III shows the geometric mean titres obtained with the various viruses in each laboratory separately. The titres found at Colindale were all higher than those reported by the other laboratories. The difference, which was thought to be due to technical variations, did not affect the antibody rises, and these are shown in parentheses in Table IV, which also sets out the geometric mean titres based on the results of the three other laboratories.

The accompanying Chart shows the geometric mean titres rearranged so as to demonstrate as clearly as possible the changes in the antibody levels to the various viruses in each group of persons.

The initial antibody titres present before inoculation against the P.R.8 and Swine viruses differed in the young from those in older subjects. Thus lower levels of antibody were present against the Swine virus and higher levels against the P.R.8 virus in the sera from the young subjects. Antibody titres against the F.M.1, 1955, and 1956 viruses were, however, similar in both age groups.

Antibody responses were obtained against all the viruses used in the laboratory tests with both vaccines and in both age groups, but there were certain differences. Thus the monovalent vaccine produced a greater antibody response in young persons than that engendered by the polyvalent vaccine against all of the virus strains except the Swine virus. In older persons, the monovalent vaccine also produced a greater antibody rise than did the polyvalent vaccine against the F.M.1, 1955, and 1956 viruses but was inferior to the polyvalent vaccine against the P.R.8 and Swine viruses.

The general effect of the polyvalent vaccine was the same in persons belonging to both age groups, and essentially consisted of a reinforcement of the antibody levels present before inoculation. The monovalent vaccine in the older people appeared to raise the antibodies to a uniform level against all the viruses excepting the 1956 strain, but produced an exceptional response to its own antigen. In the younger subjects the monovalent vaccine again produced a rather uniform level of antibodies except for the defective response against the Swine virus. The final level of antibodies against the most recently isolated virus (1956 strain) was, however,

lower than that of the F.M.1 and 1955 viruses with both vaccines and in both age groups.

Discussion

It has already been shown that the antibody pattern to various strains of the influenza viruses differs in young and old persons both in those resident in the U.S.A. and those resident in Britain (Davenport *et al.*, 1955). The results obtained in the present trials show similar differences in the

Chart showing antibody responses in two age groups of volunteers.

initial antibody titres in those of different ages. After vaccination the antibodies against both P.R.8 and Swine viruses maintained their relative proportions in both young and old in spite of the different composition of the two vaccines. It thus appears that the antibody response to an influenza vaccine is partly dependent on age and presumably, therefore, on the antigenic experience during past epidemics as suggested by Davenport and Hennessy (1956).

The present data emphasize, however, the importance of the composition of the vaccine on the antibody response likely to be obtained. Appleby, Himmelweit, and Stuart-Harris (1951) compared the antibody response to two different virus A vaccines prepared from the P.R.8 virus and a strain recovered in 1949 in tests on groups of Servicemen. They concluded that the antibody response to a monovalent vaccine was likely to be relatively specific. Davenport and Hennessy (1956) measured the antibody response to monovalent vaccines and attributed antibody rises to heterologous viruses antigenically remote from the strain contained in the vaccine, to previous infection with these viruses or with strains like them. The present monovalent (1955) vaccine seemed to be little inferior to the polyvalent vaccine in stimulating antibodies to the older viruses, and was more effective in producing antibody against the most recent strains. The polyvalent vaccine was particularly defective

in stimulating antibodies against the most recent viruses (A/Eng/19/55 and A/Eng/202/56) in the older persons. In view of the fact that these latter viruses differ antigenically from each other (Isaacs, 1956) it is perhaps hardly surprising that the monovalent vaccine made from the A/Eng/19/55 strain produced a poorer antibody response against the heterologous 1956 strain than against itself.

II. FIELD TRIALS

The procedures followed in the field trials—the method of allotting the vaccines, the keeping of inoculation registers, and the recording of sickness—were the same as those described in the report on the previous trial (1953). In both winters the inoculation of volunteers was carried out at the end of November and beginning of December.

In these trials, reliance had once more to be placed on a clinical diagnosis unaided by laboratory tests. However, a special influenza-spotting scheme was arranged with the help of the Public Health Laboratory Service and certain other laboratories, and a number of general practitioners. The aim of the scheme was to determine the probable date of appearance and disappearance of influenza in the local areas and to give some indication of the proportion of infections due to virus A and virus B. The results of these investigations are published elsewhere.

1954-5

The trial was organized in 69 centres in England and Wales, Scotland, and Northern Ireland, all of which were industrial communities of various types. In all, 14,708 volunteers took part. Four vaccines were used, of which the details are given in Section I.

A low incidence of influenza was experienced, and in the early weeks of 1955 the infection was mainly due to virus B. As cases of virus A infection were discovered in March the period of observation was extended from the end of March to the end of May, but no general epidemic of influenza A developed. The absence rates for the recorded illnesses in the four groups of vaccines are shown in Table V.

TABLE V.—Influenza Vaccine Trial, 1945-55. Number and Percentage of Persons Absent from Work with an Illness for Two Days or More

Diagnosis	Virus A				Virus B			
	Vaccine W Saline (3,715 Persons)	Vaccine X Oil-adjuvant (3,613 Persons)	Vaccine Y Oil-adjuvant (3,666 Persons)	Vaccine Z Saline (3,714 Persons)	Vaccine W Saline (3,715 Persons)	Vaccine X Oil-adjuvant (3,613 Persons)	Vaccine Y Oil-adjuvant (3,666 Persons)	Vaccine Z Saline (3,714 Persons)
	Absences No. %	Absences No. %	Absences No. %	Absences No. %	Absences No. %	Absences No. %	Absences No. %	Absences No. %
Influenza	186 5.0	197 5.5	213 5.8	209 5.6	186 5.0	197 5.5	213 5.8	209 5.6
Other respiratory	229 6.2	218 6.0	227 6.2	231 6.2	229 6.2	218 6.0	227 6.2	231 6.2
Non-respiratory	304 8.2	318 8.8	323 8.8	335 9.0	304 8.2	318 8.8	323 8.8	335 9.0
All illness	719 19.4	733 20.3	763 20.8	775 20.9	719 19.4	733 20.3	763 20.8	775 20.9

This table shows that the absence rate for influenza was practically the same in each group of vaccine, and ranged from 5.0 to 5.8%. Low rates were found for other respiratory sickness, and there were only small differences in the sickness experience of the four groups.

An examination of the regional distribution of the factories taking part in this inquiry showed that throughout the country the influenza experience was similar and there were no geographical variations of any importance in the incidence of influenza. As regards seasonal incidence, the highest absence rates were during December and January, and the trend of the rates was similar for each vaccine.

The influenza-spotting scheme definitely established that outbreaks were due to influenza B in certain areas (P.H.L.S. Report, 1957). The absence rates for the factories situated in these areas during the period when influenza B was being found are shown in Table VI.

TABLE VI.—Influenza Vaccine Trials, 1954-5. Absences Attributed to Influenza During the Epidemic Period in Areas where the Spotting Scheme Indicated that Outbreaks of Influenza B Occurred

Vaccine	No. Exposed	No. of Absences	Percentage Absence Rate
Virus A:			
W (Saline)	1,336	46	3.4
X (Oil-adjuvant)	1,356	59	4.4
Y (")	1,349	44	3.3
All virus A vaccines	4,041	149	3.7
Virus B (Z, saline)	1,333	39	2.9

These figures suggest that vaccine Z gave a very slight degree of protection against influenza B compared with the other vaccines, but the difference between the absence rates is not statistically significant. The lack of definite protection from the vaccine containing virus B was attributed first of all to the low incidence of influenza and secondly to the fact that the infecting virus was antigenically different from the Lee strain of virus B incorporated in the vaccine. A similar lack of protection was found by Davenport, Hennessy, Houser, and Cryns (1956) in the winter of 1954 during an influenza B outbreak when the vaccinated persons had received an adjuvant vaccine containing the Lee virus.

Reactions

In view of the more severe local reactions with the emulsified vaccines which had been reported earlier from the U.S.A. and of the two cases previously referred to which occurred in the serological investigations with this type of vaccine in 1953-4, special attention was paid to the local and general reactions in the field trial under discussion. It was necessary to consider separately the reactions which occurred during the first few days after inoculation from those occurring at a later date.

Immediate reactions occurred in much the same percentage of volunteers as with previous vaccines except in those receiving the saline W vaccine. Reactions due to the other vaccines were also more numerous in proportion than those from the oil-adjuvants X and Y, but were less than those with W. No cause for the excessive number of reactions encountered with the latter vaccine was obvious, but it will be recalled that this vaccine was made from low-titre allantoic fluids, which were therefore concentrated to a greater extent than usual.

The delayed reactions were local areas of nodule formation often accompanied by swelling and tenderness of the arm. They sometimes yielded collections of fluid which required surgical treatment. They were similar to the sterile abscesses recorded by Philip, Bell, Davis, Beem, and Beigelman (1954) in subjects receiving influenza virus vaccines containing aralcel and "drakeol." The nodules were noted at various times from one month up to twelve months after inoculation. Their number and distribution by vaccine is shown in Table VIII.

In those cases that occurred with the saline vaccines, W and Z, which contained alum, the nodules were temporary; they disappeared relatively quickly compared with those due to the oil-adjuvant vaccines. With the latter the nodules tended to be larger and to spread down the arm, while the pain and tenderness were more marked. There was

TABLE VIII.—Delayed Reactions

Vaccine	Numbers with Marked and More Persistent Local Reactions	Percentage of Total Inoculated
Virus A:		
W (Saline)	3	0.08
X (Oil-adjuvant)	7*	0.19
Y (")	17†	0.47
B-Z (Saline)	2	0.05

* Includes 3 particularly severe reactions, of which 2 required surgical intervention.
† Includes 10 particularly severe reactions, of which 7 required surgical intervention.

usually, also, degeneration of tissues in the centre, and resolution was delayed for as much as a year to eighteen months and sometimes longer. The symptoms were not particularly serious except in 3 cases with X (0.08%) and 10 cases with Y (0.28%). Of these, approximately two-thirds required surgical intervention before they cleared up. In those cases which were incised, a greenish-yellow pus was usually evacuated, which was sterile on culture and was apparently a product of tissue degeneration.

In order to ascertain, if possible, the precise constituent of the oil-adjuvant vaccine responsible for these local reactions and to seek to establish some means by which individuals likely to react adversely to an oil-adjuvant vaccine could be detected beforehand, further investigations were made. These consisted first of inquiries by industrial medical officers to ascertain if any of the cases with marked local reactions with the emulsified vaccines gave a history or evidence of an allergic condition. The results of these were negative. Secondly, cutaneous sensitivity tests were made on a limited number of those who had developed nodules and of others who had received adjuvant vaccine without local effect. These were carried out by patch-testing with pure aralcel applied to one arm in each case and control, and a normal saline fluid to the other. Scratch tests in the same individuals with the vaccine (X or Y) rubbed into a scratch in one arm, and normal saline fluid into a scratch in the other, were also done. Although a few instances were encountered where aralcel solution applied as a patch test gave a local reaction, this was an inconstant phenomenon. A hypersensitivity to aralcel or other constituents of the vaccine did not appear to be the cause of local nodule formation.

1955-6

In addition to the follow-up of 12,890 volunteers from the trials held in 1954-5, a new field trial of three vaccines described above (S, T, and U) was arranged to begin in November, 1955. The inoculated volunteers in this trial, like those in the trial begun in 1954, were observed until the middle of April, 1956. 7,495 volunteers in industry, nearly half of whom were employed by the National Coal Board, and 5,278 volunteers in the Royal Air Force took part. The vaccinated persons were located in areas of Great Britain and Eire which differed largely from those in which the persons inoculated in 1954 were resident. The incidence of local and general reaction to the vaccines was of the same order as that encountered previously. None of the vaccines caused an undue proportion of reactions such as that found in 1954 with the W vaccine.

An epidemic of influenza started early in January, and by the end of the month there was evidence of an increasing

INFLUENZA IN THE UNITED KINGDOM, 1953-6

REPORT TO THE MEDICAL RESEARCH COUNCIL COMMITTEE ON CLINICAL TRIALS OF INFLUENZA VACCINE BY THE PUBLIC HEALTH LABORATORY SERVICE*

In association with influenza vaccine trials organized by the Committee during the winter of 1954-5 and 1955-6 special arrangements were made for the detection of influenza virus infections in various parts of the United Kingdom. In these trials vaccines containing both influenza virus A and virus B strains were used (M.R.C., 1957). As it was not practicable for diagnostic laboratory tests to be carried out on the inoculated volunteers it was considered important to collect information on the prevalence of influenza in those areas in which most of the volunteers lived or worked. It was hoped that this would enable an estimate to be made of the date of appearance and disappearance of influenza in the trial areas and of the proportion of infections due to virus A and to virus B. No attempt was made to assess the proportion of the population attacked by influenza.

This report is based on data from three main sources: a special influenza-spotting scheme undertaken at the request of the Committee, surveys of acute respiratory illness in the Royal Air Force, and returns from public health and other laboratories of results of routine diagnostic tests. The last report of laboratory evidence of influenza in England and Wales was for the winter of 1952-3 (Public Health Laboratory Service, 1953). In order that a continuous record should be available, results of routine diagnostic tests reported by public health and other laboratories during the winter of 1953-4 are also included in this report.

The special spotting scheme was put into operation in or near 17 large cities in 1954-5 and 19 cities in 1955-6. The centres were in various parts of the United Kingdom, and were chosen because the majority of the inoculated volunteers lived in or near them. In England and Wales the medical officer of health and the director of the local public health laboratory in each centre found about six general practitioners willing to collaborate. In Scotland and Northern Ireland similar arrangements were made with the help of university and other laboratories and the appropriate health authorities. The practitioners agreed to send blood specimens taken during the acute stage and the convalescent stage from suspected cases of influenza each week for a five-months period from the beginning of December to the end of April. In addition many of the doctors—59 in 1954-5 and 58 in 1955-6—kept a record of the number of new cases of influenza diagnosed clinically each week during the same period. In the Royal Air Force survey of 1954-5 paired sera were collected from a sample of acute respiratory illnesses in 10 units scattered throughout Britain. In the survey of 1955-6 the number of units was increased to 24 and a very much larger number of paired specimens—some 1,400 in all—were tested. Information from the third source—routine diagnostic tests—was obtained from the weekly epidemiological reports of pathologists in public health, hospital, and

university laboratories to the Director of the Public Health Laboratory Service. In the results given below no distinction is made between information obtained from the three main sources.

The serological tests for influenza referred to in this report were all done by the complement-fixation method. Antigens were prepared in fertile hen eggs, partially purified soluble antigens being used for viruses A and B and untreated infected amniotic fluid for virus C.

Results

Between July 1, 1953, and December 31, 1956, 2,266 cases of influenza, diagnosed serologically or by virus isolation, were reported. Of these, 1,097 were due to influenza virus A, 1,146 to virus B, and 23 to virus C. The weekly numbers of positive tests for virus A and B infections in the United Kingdom as a whole are shown in the accompanying Chart. The corresponding figures for England and Wales in 1952-3, extracted from the earlier report (P.H.L.S., 1953), are included. The 23 cases of virus C infection are not shown, as comparatively few laboratories have tested for this agent until recently.

Influenza A

After the epidemic in January and February, 1953, no cases of influenza A were reported until February, 1954, when there was an outbreak among the staff of a hospital in Essex. The first case was in a student nurse who became ill while on holiday in Germany; she travelled back while still ill, went on duty, and then had to take to her bed. Subsequent cases in the hospital were almost confined to student nurses, the attack rate among foreign nurses being almost five times higher than among British nurses. The excess was mainly due to a very high attack rate in a group of Jamaican nurses. This episode was followed in March by an isolated case in Birmingham and minor outbreaks in Berwick-on-Tweed and neighbouring towns and villages. In April sporadic cases were confirmed in Skipton, Sheffield, and Carlisle, and in a home for old people in Ipswich. In May there was an outbreak of great intensity in a mental deficiency hospital in the Midlands (Andrews and McDonald, 1955), and in June a further case was confirmed in an associated mental hospital in the same area. Further evidence of importation of influenza A infection from abroad was found during the early summer of 1954, when a number of ships in which outbreaks had occurred arrived from South Africa. Influenza A was epidemic in South Africa at the time, and a virus strain was isolated from one passenger on the day of arrival in this country. There was, however, no general spread from any of these sources of infection.

During the winter of 1954-5 influenza A, though less prevalent than influenza B, behaved in an interesting manner. Sporadic cases were detected, mainly in the Midlands, in December, January, and February. In March an outbreak occurred in South Wales and Monmouthshire. Towards the end of March and the beginning of April there were sharp outbreaks in towns and villages in Carmarthenshire. At the same time, and within a remarkably small number of days of one another, small numbers of cases were detected in many parts of Britain. Once again no epidemic spread took place, but sporadic cases continued to be reported until the end of July.

There was no further laboratory evidence of influenza A in the country until the end of November, 1955, when two cases were detected, one in London and one in Stafford. Soon afterwards infection became widespread. Although the dates when the first and last cases were found in different regions varied considerably, in each region the weeks of highest incidence were at the end of January and in February, 1956. There was a moderate rise in the number of first claims for National Insurance sickness benefit and in the number of patients with clinical influenza seen by general-practitioner "spotters." National Insurance figures showed

no special rise in London, South Wales, or the Midlands, and few cases were confirmed by laboratory tests in these areas. Since the epidemic came to an end a small number of sporadic infections have been detected.

Influenza B

During the first half of 1953 small numbers of cases of influenza B had been reported almost every week (P.H.L.S., 1953). There was no further evidence of this infection until the spring of 1954, when there was a series of localized outbreaks in the Midlands involving three schools, a mental hospital, and a children's home, and a small number of sporadic cases mostly in South Wales. After a gap during the late summer there followed a protracted epidemic that continued until the end of the first quarter of 1955. First signs were noted in October in North Wales and in North and North-East England during November. The epidemic continued to grow slowly during December, involving South-East Scotland and the Midlands, and then spread rapidly during January and February to most other parts of Britain. Rural districts and small towns appeared to be attacked earlier than large cities, and in most areas outbreaks in children, especially of school age, tended to precede the peak incidence in adults, among whom the infection may have been less prevalent. Morbidity figures from the general-practitioner "spotters" and from the Ministry of Pensions and National Insurance showed a rise of the same order as that in the influenza A epidemic of the following year. This was probably the largest epidemic of influenza B since that of 1945-6 (Stuart-Harris, 1953). In over 18 months since it came to an end only 10 sporadic cases have been reported.

Virus Strains

Influenza virus A strains isolated during 1954 were all of the Scandinavian group except that from the passenger on arrival from South Africa. This strain was of the Liverpool group which was prevalent in South Africa at the time. Most of the strains isolated in 1955 were also Scandi-

navian, but others showed new antigenic characteristics and resembled strains isolated in Eire, India, and New York State. These were designated "Eire '55 strains by Isaacs (1956). In the outbreaks in Carmarthenshire both Eire '55 and Scandinavian strains were obtained on the same day from patients in the same neighbourhood. During the 1955-6 winter 101 virus A strains were examined at Colindale (Hatch, 1957). Forty-four of the strains were from a single outbreak, but the remainder were isolated at different times in various parts of the United Kingdom. All but four were of the Scandinavian group. Two were similar to the Eire '55 strains and two appeared to belong to yet another antigenic variety, referred to as Dutch '56 strains (Isaacs, 1956).

The influenza virus B strains isolated during the 1954-5 epidemic differed antigenically from earlier strains of this group, for which the American Lee strain is the prototype (C. H. Andrewes, 1955, personal communication). Their relationship to strains isolated more recently in this country is not known.

Summary and Conclusions

Morbidity and mortality statistics taken in conjunction with laboratory results suggest that no severe epidemic of influenza occurred in the United Kingdom during the three winters 1953-6, though influenza B was prevalent in most parts of the country during the winter of 1954-5 and influenza A during the winter of 1955-6. Localized outbreaks and sporadic cases of influenza A were detected fairly often during the first half of 1954 and the first half of 1955. Sporadic cases and small outbreaks of virus B infection were detected during the late winter of 1953-4 and less frequently since the large epidemic that followed.

The great majority of the virus A infections during the period under study were probably due to virus of the

Chart showing laboratory evidence of influenza A and B in the United Kingdom, 1952-6.

*Prepared by Dr. J. C. McDonald and Dr. B. E. Andrews, of the Central Public Health Laboratory, Colindale, London, N.W.9.

Scandinavian group. Infections associated with Eire '55 and Dutch '56 viruses occurred, but were much less prevalent. Influenza virus B strains isolated during the 1954-5 epidemic differed antigenically from earlier strains of this group.

The frequency with which respiratory illnesses associated with influenza A and B infections were detected between epidemics in the period studied appears compatible with the hypothesis that both diseases are endemic in this country. Evidence of actual and potential importation of infection from abroad was also found.

This report was made possible by the work of many people—medical officers of health, laboratory workers, Service medical officers, and especially those general practitioners who took part in the influenza-spotting scheme. We should like to acknowledge in particular the help given to the Public Health Laboratory Service by the university laboratories in Aberdeen, Bristol, Edinburgh, and Glasgow, and by the Central Laboratory, Belfast. We are indebted to the Medical Research Council for a grant towards expenses of the special influenza vaccine trial spotting scheme.

INCIDENCE OF TUBERCULOSIS AMONG WORKERS IN MEDICAL LABORATORIES

BY

D. D. REID, M.D., Ph.D.

Reader in Epidemiology and Vital Statistics, University of London

From the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine

Although the hazards of handling certain types of infectious material in the medical laboratory are well documented in the literature, the presence of an unduly high risk of contracting tuberculosis while employed in hospital or public health laboratories has never been firmly established. There is, however, evidence which suggests that tuberculous infections, quite apart from obvious skin lesions, may result from exposure to laboratory conditions. Lurie (1930), for example, has noted the presumed airborne spread of tuberculosis among animals caged separately in the same animal-room. Meade (1948) reported a decrease in tuberculin skin-test conversion rates and in the incidence of tuberculosis among medical students after they were forbidden to handle fresh post-mortem material from tuberculous patients. An excessive incidence of tuberculosis among medical students, particularly during the course in pathology, has been remarked upon by both Hedvall (1940) in Sweden and Morris (1946) in the United States.

In Düsseldorf, Koch (1951) reported that the frequency of tuberculosis among pathologists was five times higher than among physicians; four times higher than among oto-rhino-laryngologists, bacteriologists, and public health workers; and twice as high as among the

staff of infectious diseases units; there were no cases among surgeons. Despite other evidence of a similar nature, Gruber (1949) found it difficult to convince authorities in Germany that a real hazard existed: and it is certainly true that neither of the German studies takes any detailed account of the numbers and characteristics of those exposed to risk. Similar difficulties were encountered in the survey of all types of laboratory infections by Sulkin and Pike (1951), who had doubts about the completeness of case-reporting. In this country, Stewart Smith (1953) was unable to find convincing evidence that the necropsy room presented a health hazard so far as tuberculosis was concerned; and this doubt is commonly expressed by many pathologists.

The difficulties of measuring the incidence of tuberculous laboratory infections are obvious. Although laboratory experiments such as those of Sloan (1942) may indicate the possibility of aerial dissemination of bacilli from incised pathological material, complete conviction can come only from a demonstration of an appreciably higher incidence of clinically evident tuberculosis among laboratory staffs employed on tasks exposing them to infection than among the working population as a whole. Unlike infections such as psittacosis or Q fever, tuberculosis is endemic in our population and its appearance in a laboratory worker is in no way remarkable. On the other hand, the attack rate is so low that a laboratory staff of 20 people could well go on for more than a generation without a naturally occurring case arising among them. To obtain an experience large enough a wide-scale survey is clearly required.

Preliminary Observations

Under the provisions of the Industrial Diseases and Injuries Act, laboratory workers of all grades can apply for the increased rates of sickness benefit awarded to those whose disability might be attributable to their occupation. The Minister of National Insurance encourages all who are members of the Health Service to make application, although acceptance of attributability by no means necessarily follows. Reports on these claims for the period 1953-5 inclusive were made available, and "claim" rates, which are minimum estimates of the incidence of disabling tuberculosis, were calculated by relating these claims to the number of individuals in the corresponding Health Service occupational group given in returns to the Ministry of Health. Table I shows that pathologists, like chest physicians and surgeons, had much higher claim rates than did men in other specialties. Similarly, laboratory technicians had higher claim rates than other medical auxiliaries working in hospital.

Clearly, there are major difficulties in the interpretation of such data. Quite apart from the possibility that claims are not equally often pressed by individuals suffering from tuberculosis in different occupational

TABLE I.—Crude Tuberculosis Claim Rates for Hospital Staff (M.N.I. 1953-5 Inclusive)

	Cases	Man-years Exposure	Rate per 1,000 p.a.
Pathologists	12	2,193	5.47
Chest physicians and surgeons ..	10	2,489	4.02

Laboratory technicians	33	11,593	2.85
Other auxiliary staff	34	32,152	1.06

groups, the age-and-sex structure of these groups may vary widely. Again, laboratory staffs may have better facilities for prompt recognition of tuberculous infection. Finally, occupational self-selection may result from men and women of poorer physique or with a family history of tuberculosis preferring the physically less arduous life of the laboratory to the rigours of general practice or other specialties. To try to meet these difficulties surveys of morbidity among clinical laboratory workers in general and mortality of pathologists in particular were carried out.

The Morbidity Survey

With the help of Sir Samuel Bedson, Chairman of the Central Pathological Committee of the Ministry of Health, and Dr. G. S. Wilson, Director of the Public Health Laboratory Service, directors of all official pathological and bacteriological laboratories were asked to provide information both about the work and the routine practices of health care in their laboratories and about the occupation and health history of every individual who had worked in each laboratory during the period 1949-53 inclusive.

The first questionnaire dealt with the laboratory conditions. The size of staff in relation to the number of rooms was taken as a guide to the crowding of the working space and risk of human contacts at work. The main function of the laboratory—for example, blood transfusion or public health bacteriology—gave some indication of the nature of any infective hazards; while the frequency of x-ray examination and tuberculin skin-testing at entry or at regular intervals thereafter was elicited to determine the standards of health care in different laboratories.

A personal record was also required for every individual who had worked in the particular laboratory for any time during the period 1949-53. Names were excluded to make this report completely confidential: references in later correspondence were made by code numbers or initials. The data requested included age, sex, occupational status in laboratory—for example, chief technician or student—the nature of the duties undertaken—for example, medium preparation or animal care—and possible contacts with tuberculous material, such as sputum or infected animals, in the preceding 12 months. Questions were also included about the results of pre-employment tuberculin skin-tests and chest x-ray examinations and any history of being offered and accepting B.C.G. vaccination. In general, the information on health care could be given accurately only for present members of staff, and analysis of these data has been restricted to those from that group.

A history was also obtained of tuberculous infection arising at any time between January 1, 1949, and December 31, 1953, during the period of employment in the reporting laboratory. For these cases the type, pulmonary or other, and date of onset of first absence from work were to be given. Comments on known human contacts, at work or at home, were also included.

Of the 368 heads of laboratories approached 345, or 94%, gave all the information they could obtain. Considering the impersonal nature of postal inquiry and the emotions which the subject can engender, this was a most gratifying response. Follow-up questions on doubtful points were answered equally effectively.

Method of Analysis

In the analysis of the data, the number of cases of tuberculosis reported in any particular group of laboratory workers compared with the number to be expected in a group of the same age and sex structure had they experienced the contemporary age-sex-specific tuberculosis attack rates prevailing in a standard population. This method depends for its accuracy on (1) the completeness of case-reporting, (2) the propriety of the standard rates used, and (3) the complete and accurate reporting of the numbers and charac-

teristics of the populations exposed to risk in each subdivision of the laboratory staffs.

To take the last first, the adequacy of the description of the population derived from the survey was tested by comparing the numbers and age distribution of pathologists at the end of 1953 and the total numbers of laboratory technicians estimated from the survey with data from official sources. In both instances there was satisfactory agreement with the Ministry of Health return for that year. The checks on the two other aspects of the method are considered incidentally in the discussion of the results.

The age-sex-specific notification rates for pulmonary tuberculosis for the United Kingdom during the years 1949-53 have been used as a standard. The total "exposure to risk" was obtained by adding the number of months each person spent in each laboratory during the course of the survey period to obtain the total number of person-months in each age, sex, and occupational or other group.

Results of Morbidity Survey

Among the average number of persons working in the laboratories (4,824) during the five years, 151 cases of tuberculous infection were reported. Of these, 55 were excluded from the analysis for the following reasons: 16 had non-pulmonary lesions; 10 had minimal pulmonary lesions not severe enough to cause absence from work; 1 attempted suicide by intravenous inoculation; and 28 had recurrent or continuing infections where the date of first onset of absence from work was before the beginning of the survey in 1949 or where the absence, although reported by one laboratory, had begun in another and was thus included already. The remaining 96 cases formed the basis of the subsequent analysis.

Table II shows the detailed comparison of observation and expectation at the national notification rates in the two sexes, at all ages and in each grade within the laboratory staffs. Small though the numbers in any one group are, the trend of the results is clear. Among male workers, pathologists, junior and student technicians, and post-mortem attendants appear to contract disabling pulmonary tuber-

culosis far more frequently than might have been expected at national age-sex-specific notification rates. Similarly, women pathologists, student technicians, and cleaners appear to fare badly compared with women in the country as a whole.

When the laboratory population is grouped according to the nature of the possible contacts with tuberculous infection the results obtained appear as in Table III. Although one man may do several tasks and no clear-cut comparisons are

possible, the general ranking of risks in males does suggest that the handling of post-mortem material, from either human or animal sources, is associated with a higher relative incidence of pulmonary tuberculosis. Among women, on the other hand, bacteriological work ranks above contacts with necropsy material as a possible hazard. Of particular importance from the viewpoint of method, however, is the close agreement between the numbers of cases expected among laboratory staff with no contact with infective material (9) and the number actually reported (8). The comparative immunity of women doing sensitivity tests, based though it is on small numbers, is not readily explicable. When the attack rates according to duration of employment in medical laboratories are plotted as in Fig. 1 a peak incidence appears about two years after beginning laboratory work. This peak, which is more marked among males than among females, cannot be entirely explained by the exposure of young susceptibles to the increased number of infective contacts usual when a youth begins work. Some of the cases in the peak period were male post-mortem attendants who had taken up laboratory work in middle life. Again, although there is some appearance of excessive morbidity from tuberculosis among young Service men shortly after joining the Army (Rosenbaum, personal communication), this is almost entirely the result of the routine initial medical examination, and there is no rise in incidence in the next two years of Army service.

Suggestive though this evidence is, it should not be too readily accepted. As already noted, the standard rates may not be appropriate to an urban group of the same social class as laboratory workers. Some pathologists have suggested that overcrowding in laboratories may increase the

FIG. 1.—Incidence by length of employment.

risk of effective transmission of infection in the normal contacts of daily life, particularly if pathological laboratory work has attracted an unduly high proportion of individuals who have had active disease. Others may go into the laboratory because of poor physique or a family history of tuberculosis. A preoccupation with infection and unusual opportunities for bacteriological and radiological diagnosis may increase the likelihood of the detection and reporting of pulmonary lesions which might otherwise have been unrecognized.

The appropriateness of the general method adopted was tested by applying the standard national notification rates to civil servants coming from much the same social background as the main grades of laboratory workers and also employed mainly in towns throughout the country during the same period 1949–53. Male professional engineers and scientific officers in the General Post Office are roughly comparable in education and social background to pathologists; and male and female clerical officers, like laboratory technicians, are largely drawn from the grammar schools. The rate of routine mass miniature x-ray examinations is similar in the two groups. The relatively low ratios, seen in Fig. 2, obtained by applying the standard rates to the group of professional engineers (0.7), are quite consistent with the indications given by the low standardized mortality ratio (64%) for Social Class I in 1951 (Registrar-General, 1954). Similarly, the ratio of observed to expected cases among clerical officers of both sexes (0.9) suggests that these standard rates are appropriate to a group, such as civil servants, where all absences from work due to pulmonary tuberculosis are routinely reported. Since these were the criteria and methods of reporting and standardization used in the survey, the excessive morbidity reported among pathologists and technicians becomes more significant.

The low tuberculosis incidence rates for secretarial and other staff not exposed by their jobs to much infection make it less likely that overcrowding in the laboratories may explain some of the excessive morbidity among the rest of the staff. Nevertheless, this possibility was further investigated by comparing the experience of laboratories where the total number of the staff, and presumably the risk of work contact with a human carrier, was much the same but the number of rooms in the laboratory was either above or below the average. There was no suggestion in these data that the more crowded laboratories have in fact a consistently higher attack rate. It proved difficult to obtain complete histories of human contact either at home or at work for the 96 cases; but of the total, a known work contact was reported for 15 to 16%, and home or other contacts with an infectious case for 12 to 13%. These proportions are difficult to interpret because of the many unknown sources of infection, but they do not suggest that increased risk of contact with a human source at work is unusually common in clinical laboratories.

Time charts of the dates of onset of absence because of tuberculosis in the laboratories showed that, although there were 20 instances when two or more cases appeared in the same laboratory during the survey, only 8, or 8%, of the 96 cases recorded followed a previous case in the same

FIG. 2.—Tuberculosis in laboratory and G.P.O. staffs (1949–53). (Compared with U.K. notification rates.)

laboratory within between two and twelve months. Even if these were all true secondary infections, they would not suggest an unusual risk of human case-to-case transmission.

To avoid any risk of anxiety or resentment among laboratory staff no questions were asked about previous personal histories of tuberculous infections: only illnesses arising for the first time during service in the reporting laboratory at some time between 1949 and 1953 were included. Thus no data on the relative frequency of previous clinically evident infection are available. Some indication of the frequency of previous contact with infection can be obtained, however, from the percentage of positive Mantoux test results among young entrants to the laboratory service. Table IV shows rates which are quite compatible with rates of 60–75% for 18-year-olds in towns of more than 50,000 population found during the Medical Research Council's National Tuberculin Survey in 1949–50 (M.R.C., 1952). It should be emphasized, however, that only 40% of the entrants were skin-tested on recruitment and that many individuals with a clear previous personal history of tuberculosis might not have been examined for this reason. But for the remainder, these figures do not support the view that the younger recruits accepted for service in laboratories have had more contact, familial or other, with tuberculosis than have other urban children of the same age.

TABLE IV.—Tuberculin Skin-Sensitivity-Test Results for Laboratory Recruits (1949–53)

Age	Male		Female	
	No.	Obs. % Positive	No.	Obs. % Positive
<16	41	70.7	65	49.2
17–18	78	66.7	169	68.0
19–20	9	88.9	39	56.4

Note.—At age 18, rates in both sexes in M.R.C. 1949–50 National Tuberculin Survey ranged from 60 to 75% for towns of more than 50,000 population.

As for the relevance of diagnostic facilities to high reported incidence rates, three comments are pertinent. Firstly, one might assume that diagnostic standards would apply equally to all members of the laboratory staff; yet there is a clear rise in infection rates with increasing contact with infected material. Secondly, all minimal lesions have been excluded and all cases reported and used in this analysis have been obvious and severe enough to require absence from work. Finally, pre-employment x-ray examination and regular examinations thereafter formed a routine practice in only 60%, and skin-testing in 40%, of the laboratories at the time of the survey.

Two questions remain. Has the suggested occupational hazard been a constant feature of pathological or bacteriological work in this century? Is there any evidence that pathologists as a group are selected in any way on grounds of physique? To try to answer these questions a survey was made of the mortality experience in this century of a group of doctors concerned in some way with pathology and its allied subjects.

The Mortality Study

Data and Analysis

The honorary officers of both the Pathological Society of Great Britain and Ireland and the Association of Clinical Pathologists gave access to the records of their membership since their foundation in 1906 and 1927 respectively. It was assumed that membership of these learned societies implied a decided interest in this branch of medicine although not necessarily an intention to practise clinical pathology and bacteriology. The number of years lived by each of these society members until his death or his survival until January 1, 1955, was then totalled and the numbers of man-years lived in each age group in each ten-year period from 1906 to 1954 were tabulated. Particulars of the date of death and the certified cause were obtained from the files of the General Medical Council, to whom the Registrars-General are statutorily obliged to furnish a copy of the death certificate of all registered medical practitioners dying in this country or in Eire. By tracing each member through successive Medical

Directories it was possible to limit those included to men who had lived here all their working lives.

To these "exposures-to-risk" in each age group in successive decades were then applied the corresponding age-specific death rates for the social class to which all medical practitioners belong (Registrar-General, 1912, 1927, 1936, 1954).

Summary of Results

The numbers of deaths from each of the main causes expected at Social Class I rates are compared in Table V with the numbers actually observed. These results suggest

TABLE V.—Comparison of Deaths Observed Among Members of the Pathological Society, 1906–53, With Numbers Expected at National Social Class I Rates

	Cause of Death							Total
	Pulm. Tub.	Non-Pulm. Tub.	Suicide	Cancer	Cardio-vascular	Respiratory	Other	
Observed	17	2	18	34	120	29	80	300
Expected	15	1	5	42	108	32	79	282

that men whose leaning towards laboratory work has led to membership of one or other of the appropriate societies may share a tendency to suicide, but in other respects they are, so far as mortality is a measure, as robust as other males in the same social class.

There is, however, little if any excess mortality from tuberculosis in the groups as a whole. But the whole membership could be divided, on the basis of appointments held according to *Medical Directories* current in their lifetimes, into those obviously practising hospital pathology or diagnostic bacteriology and those, working perhaps as consulting physicians or engaged in specialized experimental work, who were less likely to be exposed to tuberculous infection. Only men between 25 and 64 working during the period 1925–53, when all but one of the cases occurred, have been included. When the experiences of these two subdivisions of the society membership are compared, as in Table VI, it is clear that, although the two are alike in respect

TABLE VI.—Comparison of Deaths Observed Among Members of the Pathological Society, 1925–53, With Numbers Expected at National Social Class I Rates

	Cause of Death			Total
	Pulmonary Tuberculosis	Suicide	All Other Causes	
Presumed hospital pathologists:

Expected	6	2	66	74
Other members:				
Observed	4	6	42	52
Expected	4	2	57	63

of suicide and other causes of death, the hospital workers appear to have an excess in mortality from pulmonary tuberculosis.

An increasing degree of specialization within the profession has been a marked feature of medical practice in this century; and, even within specialties such as pathology, the nature of the work has changed very considerably. For these reasons a further subdivision of the comparative experience of hospital pathologists and others in successive decades seems justified. Despite the small numbers thus produced, there is in Table VII a suggestion, albeit a very tenuous

TABLE VII.—Time Trends in Tuberculosis Mortality Among Members of the Pathological Society

Decade	Presumed Hospital Pathologists			Other Members		
	Obs.	Exp.	Ratio	Obs.	Exp.	Ratio
1925–34	1	1.6	0.6	0	1.5	—
1935–44	4	2.6	1.5	3	1.1	2.7
1945–53	5	1.9	2.6	1	0.8	1.3

one, that the adverse mortality from pulmonary tuberculosis has appeared among hospital laboratory workers largely in the last decade.

Discussion

The certain recognition of pulmonary tuberculosis as an important occupational hazard to workers in pathological and bacteriological hospital laboratories is by no means easy. There have been very suggestive incidents: two research workers in the same laboratory were found to be suffering from pulmonary tuberculosis due to the type-specific strain which they had been investigating. Dramatic though such laboratory outbreaks may appear, some of the multiple cases observed in these circumstances are quite likely to arise from the ordinary personal contacts with an infective carrier in the same occupational group. The demonstration of a general raising of the incidence of pulmonary tuberculosis above the endemic levels in the community requires the type of large-scale survey here described.

The 94% response rate achieved ensures that the results are closely representative of the national hospital or public health laboratory experience: even though there were no cases in the remaining 6% of laboratories, it would make little difference to the results obtained. These results agree surprisingly closely with the crude preliminary indications, based on claims made for compensation, of the striking divergence between the two specialties where excessive exposure to tuberculosis might be anticipated (pathologists and chest physicians and surgeons) and the remainder of the medical staff in the hospital branch of the Health Service. Even on the scale of this five-year survey, the total number of cases is quite low, but, although no one item of the evidence presented is irrefutable, there is an internal consistency in the pattern of results which makes it seem likely that a real occupational hazard exists. Cross-checks on the accuracy of the data and the appropriateness of the methods used give added confidence to the conclusions derived from the analysis.

Compared with other workers in the laboratory or men and women of similar age and social status outside, laboratory workers exposed to post-mortem material or sputum from tuberculous patients suffered about a threefold increase in the incidence of disabling pulmonary tuberculosis. Attack rates reached a peak in the third year of laboratory employment. None of the likely alternative explanations for this excess proved satisfactory. Indeed, the demonstration that members of the pathological societies have no raised death rates from other physical diseases makes occupational self-selection of the less robust unlikely. The slight suggestion in the mortality experience of hospital pathologists that the excessive incidence of tuberculosis is a fairly recent phenomenon would be quite consistent with the development of specialized pathological and bacteriological techniques in the last two decades.

Strong though such circumstantial evidence is, it simply indicates that a hazard exists without determining whether air-borne dissemination or contact contamination is the only or even the more important mode of transfer of infection. There is thus a clear need for detailed bacteriological studies of technical procedures as a source of infection. In this way, more specific prophylactic measures can be added to more obvious hygienic precautions.

Summary and Conclusions

Examination of the frequency of claims for sickness benefit for pulmonary tuberculosis made under the Industrial Diseases and Injuries Act suggested that pathologists shared with chest physicians and surgeons much higher claim rates than other hospital consultants. Laboratory technicians also made relatively more claims than other types of medical auxiliary. A survey was therefore made of tuberculous morbidity experience in the laboratories of the National Health Service and the Public Health Laboratory Service during the five-year period 1949-53 inclusive. Data on the work and accom-

modation of the laboratory, methods of pre-employment examination or medical supervision, and individual records of work and exposure to tuberculous material and the incidence of tuberculosis were provided by 94% of the directors of laboratories approached. At the same time a study was made of the mortality experience, during the present century, of the membership of the two major societies for pathologists and bacteriologists.

Analysis of these data suggested that:

1. The apparent gross excess in tuberculous morbidity noted in the compensation claim rates was equally obvious in the results of the special morbidity survey.

2. This excess was greatest among individuals employed in laboratory and mortuary tasks which exposed them to the risk of contact with infected pathological material. The incidence was highest in the second and third years of such employment. For such occupational groups, the attack rate from pulmonary tuberculosis severe enough to cause absence from work was about three times above the rate for non-exposed laboratory staff.

3. Both pathologists and laboratory technicians had in general a much higher incidence of disabling tuberculosis than socially comparable groups of General Post Office professional engineers and clerical officers of the same age working in this country at the same time under regular medical supervision. For males in both grades the excess was threefold, and for female technicians twofold.

4. The analysis of the limited pre-employment examination results available suggests that young recruits to laboratory work had no unduly frequent previous contact with tuberculosis. No adequate data were available for pathologists.

5. The mortality investigation showed that members of the pathological societies were not physically self-selected in that they had in general no excessive mortality from all causes of death other than suicide. There was, however, a slight suggestion, based on very small numbers, of excessive tuberculous mortality among presumed hospital pathologists, particularly in recent years.

Consideration of various alternative explanations led to the conclusion that in laboratory work on the pathology and bacteriology of tuberculosis there was a considerable environmental hazard from pulmonary forms of the disease.

I am indebted to the National Association for the Prevention of Tuberculosis for suggesting this investigation and for a generous grant towards its cost. The honorary officers of the Pathological Society and of the Association of Clinical Pathologists, the staffs of the Ministry of Health, and the national officers of the General Medical Council helped in obtaining some of the information. Miss D. Bobby, Miss L. M. Colwell, Mrs. B. M. Hunt, and Mrs. S. King were responsible for the secretarial and computing work. I am particularly grateful to all the laboratory directors and staffs who provided the bulk of the data.

INFECTED AIR-BORNE PARTICLES LIBERATED ON OPENING SCREW- CAPPED BOTTLES

BY

A. J. H. TOMLINSON, M.B.

Public Health Laboratory Service, County Hall, London

The problems of the risk of laboratory infection have been investigated over the past few years. Wedum (1953) and Wedum and Reitman (1956) have shown that infected particles are liberated into the air during the performance of many of the procedures commonly carried out in bacteriological laboratories. The techniques used by laboratory workers to perform the same operation often differ widely, and it has been possible to believe that, with a perfect technique, the risk of producing infected aerosols becomes infinitely small, and that laboratory infections arise only from carelessness or indifferent technique.

Some of the techniques used in the routine laboratory diagnosis of tuberculosis in Britain were not included in the American investigations, and in particular the danger of infected aerosols arising from the use of screw-capped bottles for bacterial cultures are not mentioned. Partly for the reason that there appeared to be no likely technical variation in the removal of caps from screw-capped bottles and partly because such bottles are commonly used in routine diagnostic laboratories in Britain, the present investigation was confined to the removal of screw caps from bottles containing slope cultures of various organisms.

Methods

A slit-sampler sampling 20 cu. ft. (0.566 cu. m.) of air per minute was used for the detection of infected aerosols. A slit-sampler is usually used to sample air equally from all directions: for the first experiments it seemed desirable to limit the air entering the sampler to air from a fairly narrow sector, since this might be expected to increase the recovery of infected aerosols. For this purpose a paper hood was fitted over the air intake: this had an opening in a vertical plane of approximately 6 by 7 in. (15 by 17.5 cm.) through which air flowed at a velocity of about 70 ft. (21.3 m.) per minute (just detectable on the hand). The bottles were opened about 2 in. (5 cm.) in front of the centre of the opening in the hood. In some experiments the agar plate was allowed to rotate in the usual manner and a number of bottles were opened in rapid succession: in other experiments the infected aerosol formed on opening individual bottles was detected by closing two of the four slits, and starting and stopping the motor so that the infected particles liberated appeared as a line of colonies across the agar plate. This cut down the air flow by about one-half, but did not otherwise interfere with the working of the apparatus.

Infection of the mouth of the bottle was detected by running a sterile loop over the rim and plating on to nutrient agar; an alternative method that was quicker and more economical was to bring the surface of an inverted agar plate down on to the exposed rim of the bottle and then incubate the plate.

Screw-capped bottles of different sizes were used in different experiments; any bottle in which the sloped medium came above the shoulder of the bottle was discarded. The majority of the experiments were carried out using *Chromobacterium prodigiosum* as the test organism, but essentially similar results were obtained with *Staph. aureus* and *Salm. typhimurium*.

First Experiment

A number of preliminary experiments were carried out on groups of 12 or 25 slope cultures in screw-capped bottles. In all of these experiments some infective airborne particles were detected, and in one experiment the colonies appeared on the agar plate in a way that suggested that they had all been liberated at one time. An experiment was therefore carried out in which the bottles were opened individually; at the same time cultures were made from the bottle rims and a record was kept regarding whether the rims were obviously wet or dry (Table I). This was not always easy to determine, since the amount of fluid was often small; some inaccuracies must therefore be expected in this last observation.

TABLE I.—*Infected Aerosols Formed on Opening 1-oz. (14-ml.) Screw-capped Bottles of Slope Culture of Chr. prodigiosum. Each Bottle opened Once Only*

Apparent State of Rim	No. of Bottles with Rim Infected			No. of Bottles with Rim Not Infected			Total
	Aerosol +	Aerosol -	Total	Aerosol +	Aerosol -	Total	
Dry	8	1	9	0	65	65	74
Wet	35	13	48	1	74	75	123
Total	43	14	57	1	139	140	197

It will be seen that the majority of bottles with infected rims produced a bacterial cloud on opening. Bottles with apparently dry rims were rarely infected. The number of colonies recovered varied from 1 to 50 a bottle. The figures in Table I refer to the first opening of each bottle; in some experiments bottles were opened several times. The results were consistent in that bottles with uninfected rims did not produce aerosols. Bottles with infected rims generally produced aerosols, but the number of colonies recovered did not bear any direct relation to the number of times the bottle had been opened. On two occasions bottles with infected rims that had not given a demonstrable aerosol on first opening did so subsequently.

Second Experiment

It seemed desirable to confirm under rather different conditions the observation that infected air-borne particles were formed when bottles with infected rims were opened. Two experiments were carried out in a closed chamber of 300 cu. ft. (8.5 cu. m.) capacity. Twenty-five bottles with infected rims were opened on a bench and the air was sampled by a slit-sampler (20 cu. ft. (0.566 cu. m.) per minute) approximately 6 ft. (1.8 m.) away with its air intake about 2 ft. (60 cm.) above the bench. The slit-sampler was run for four periods of two minutes, after each of which half a minute was spent changing the plates. Bottles were opened during the second two-minute period. The results are given in Table II.

TABLE II.—*Aerosol Formation on Opening 25 Screw-capped Bottles: Rims Infected with Chr. prodigiosum*

No. of colonies per 40 cu. ft. of air (1.13 cu. m.)	Time in Minutes			
	0-2 (Control Period)	2½-4½ (Bottles Opened)	5-7	7½-9½
Exp. A	0	11	14	7
Exp. B	0	9	20	10

Infected particles began to appear when the bottles were opened and persisted until the end of each experiment. Assuming no natural "die away," that recovery by slit-sampler was complete, and that no air was sampled twice, 50 bottles gave rise to 71×300/120 infected particles=3.5 per bottle. This is clearly a minimum figure.

Third Experiment

It seemed clear that the infected rim was the source of the aerosol infection on opening the bottle. The following

experiments were carried out to try to find the source of this infection. Half-ounce (14-ml.) screw-cap bottles containing agar slopes were inoculated by the following methods:

Method A.—The tip of a straight wire was infected by touching a colony of *Chr. prodigiosum* and the slope inoculated by a single touch at the bottom. Great care was taken to avoid touching the rim of the bottle.

Method B.—About $\frac{1}{4}$ in. (2 cm.) of a straight wire was infected by passing it through a stab culture. The slope was inoculated as a single streak from the bottom. It was found practically impossible to avoid touching the rim with the wire during this procedure.

Only one out of 24 bottles inoculated by Method A had an infected rim; after inoculation by Method B, 22 out of 24 bottles had infected rims.

The fluid on the rims of uninoculated bottles gave a strong ninhydrin reaction and was presumably a transudate of nutrient agar—that is, nutrient broth. Twelve bottles were inoculated by method B, the rims of alternate bottles were swabbed, and the viable organisms were counted. Four bottles gave a count of fewer than 30, one of 60, and one of 450. After overnight incubation the remaining six bottles were examined in the same way, and all gave counts greater than 4 million. Clearly bacterial growth occurs in the fluid on the rims.

A number of bottles inoculated by method B were flamed after inoculation before the caps were replaced; the bottle necks were held in the Bunsen flame for five seconds. In the control series of unheated bottles, 31 out of 36 had infected rims; of the flamed bottles 4 out of 36 had infected rims. Flaming for periods up to 10 seconds with rapid rotation did not invariably sterilize the necks: a number of bottles were broken as a result of heating.

When Pasteur pipettes were used to inoculate slopes by as scrupulous a technique as possible, 8 out of 24 bottles had infected rims. In another series, flamed as before, 4 out of 24 rims were infected. As a check on individual technique, three competent technicians familiar with this work were asked to inoculate twelve slopes each with a Pasteur pipette; 9 out of 36 bottles had infected rims. Inoculated bottles with uninfected rims were completely inverted, incubated for four hours, and re-examined. All rims were infected.

Further Experiments

Dr. O. M. Lidwell, of the Air Hygiene Laboratory, Colindale, has estimated the size of the infected particles liberated when screw-capped bottles are opened with a new sampling device (Lidwell, in preparation) which separates the air-borne cloud into four ranges of particle size. He reports: "In each of two experiments, 25 bottles were opened in our experimental chamber. At least 30%, and probably nearly 50%, of the approximately 60 bacteria-carrying particles recovered from the air are estimated to have had diameters of 4 microns or less. Such particles will be small enough to penetrate into the lung, a fact which may be of consequence when considering risks from handling cultures of *Myco. tuberculosis*. Many other clouds of airborne bacteria consist in the main of much larger particles."

If, when opening the bottles, it was possible to avoid breaking the film of bacterial growth on the rim, no infected aerosol would be produced. The most promising material for sealing bottles is "parafilm" (Gallenkamp); this material forms a good seal on the neck of the bottles with the warmth of the hand, and bottles can be opened by piercing the film with a hot wire and resealed with a fresh piece of parafilm. We have used parafilm on one-half of our routine cultures for *Myco. tuberculosis* for six months with satisfactory results: no attempt was made to sterilize the parafilm, which was applied to the bottles of Löwenstein-Jensen media immediately after they were inoculated with sputum concentrates. The great disadvantage of the material is that, after autoclaving discarded cultures sealed with parafilm, it is difficult to remove the sticky mass from

the neck. Bottles containing slope cultures of *Chr. prodigiosum* inoculated by method B and sealed with parafilm have been opened with a hot wire. Only one infected air-borne particle was detected when 30 bottles were opened, although at least 23 had infected rims. In a control series of the same bottles using screw caps, 15 out of 28 gave a demonstrable infected aerosol. In another experiment in the closed chamber of 300 cu. ft. (8.5 cu. m.) capacity, 11 infected particles were detected in three periods of two minutes when 25 screw-capped slope cultures were opened, but none when a similar series of bottles sealed with parafilm were opened with a hot wire.

Discussion

These experiments were carried out to try to assess some of the risks that are involved in handling cultures of *Myco. tuberculosis* in a routine diagnostic laboratory. For much of this work screw-capped bottles are commonly used, and it is clear that opening these bottles when they contain a slope culture may cause infected airborne particles to be liberated. The way in which this comes about appears to be the accidental infection of fluid on the rim at the time of inoculation, and the multiplication of the organisms in this fluid. When the bottle is opened, the film of broth culture on the rim is broken and some of the resulting droplets are small enough to form aerosols. A high proportion of the infected particles formed in this way are of such a size that if inhaled they would penetrate to the alveoli of the lung.

No attempt has been made to demonstrate the formation of infected aerosols on opening bottles containing cultures of *Myco. tuberculosis* because of technical difficulties, but there do not appear to be any reasons why the findings reported above, using *Chr. prodigiosum*, should not apply to cultures of *Myco. tuberculosis*. The rims of a group of cultures of tubercle bacilli were cultured, and it was found that 7 out of 197 were infected and therefore presumably capable of producing an infected aerosol when the bottles were opened.

It is possible with a very careful inoculation technique to avoid infecting the rim of the bottles, but if the bottle is inverted or handled in such a way that the infected water of condensation comes into contact with the cap, the rim will become infected and the result of the careful inoculation technique will be nullified. Competent technicians appear to infect about one-quarter of the bottles they inoculate with a Pasteur pipette; this is a common method of inoculating sputum concentrates when culturing for *Myco. tuberculosis*. Intense flaming of the neck of the bottle after inoculation does not appear to be a complete safeguard, and one must assume that, in spite of the most careful techniques in inoculation and subsequent handling, a proportion of cultures will give rise to infected aerosols on opening.

The use of a plastic seal may offer a solution to this particular problem, but there are other manipulations in the work of a routine diagnostic laboratory which have not been investigated and which may be more important sources of infected air-borne particles.

It is difficult for laboratory workers to assess the risk involved in their own laboratory; the results obtained by other workers, often under rather different circumstances, cannot be repeated because the necessary apparatus for sampling air is not readily available. Cultures made from the rims of inoculated bottles may enable this risk to be estimated, since all bottles with infected rims can be assumed, from the present experiments, to be potential if not actual sources of infected aerosols.

Summary

Infected air-borne particles are liberated when some screw-capped bottles containing slope cultures of *Chr. prodigiosum* are opened.

A mechanism accounting for this observation is suggested.

A possible solution to the problem is discussed.

My thanks are due to Dr. O. M. Lidwell for his determination of particle size and to Dr. R. E. O. Williams for the loan of the slit-sampler and for his help and co-operation in the experiments in the closed chamber.

TREATMENT OF ADRENAL CORTICAL INSUFFICIENCY

BY

J. D. N. NABARRO, M.D., F.R.C.P.

AND

G. WALKER, M.B., M.R.C.P.

The Institute of Clinical Research, the Middlesex Hospital, London

Prior to 1951 patients with Addison's disease could be maintained only with difficulty on the replacement therapy available. Since cortisone and hydrocortisone have been in use these patients have been able to lead normal lives, and it has also been possible to perform total adrenalectomy in selected cases of malignant disease and Cushing's syndrome. Addison's disease is a rare condition, and it is not surprising that there have been differences of opinion about the place of cortisone in its treatment in relation to deoxycortone and extra salt. However, the performance of total adrenalectomy has provided an opportunity for the study of a larger group of patients who have what is in effect severe Addison's disease. Detailed observations have been made on nine patients with Addison's disease and on 30 after total adrenalectomy. The former have been seen at regular intervals for up to seven years and the latter for up to three years. Particular attention has been given to the place of 9 α -fluorohydrocortisone in the treatment of chronic adrenal insufficiency.

Hormones of the Adrenal Cortex

The two most important hormones produced by the adrenal cortex are hydrocortisone and aldosterone. Hydrocortisone is sometimes referred to as a "glucocorticoid" hormone because it stimulates gluconeogenesis; it has, however, other more important actions. If the level of circulating glucocorticoid drops abruptly, the blood pressure falls, glomerular function is impaired with reduction of glomerular filtration rate, and sodium tends to leave the extracellular fluid and enter the cells and possibly bone (Hills *et al.*, 1953; Mendelsohn and Pearson, 1955). Cortisone is not secreted by the adrenal glands, but there is interconversion of hydrocortisone and cortisone in the body and the actions of the two are similar. Aldosterone is the main "mineralocorticoid" hormone of the adrenal cortex. It maintains the body sodium by limiting renal excretion and has a less conspicuous effect in increasing potassium output. Cortisone and hydrocortisone have some mineralocorticoid action, and in large doses may produce sodium retention and oedema or potassium loss and hypokalaemia.

The other hormones of the adrenal cortex are not necessary for maintaining life. Corticosterone (compound B) has mineralo- and glucocorticoid properties, but in humans it is produced in only very small amounts. In both sexes the adrenal cortex secretes significant quantities of androgens and traces of oestrogens.

Replacement Therapy Available

Hydrocortisone is the most important hormone secreted by the adrenal cortex, and tablets of hydrocortisone or cortisone acetate are essential for adequate replacement therapy. Maintenance of sodium equilibrium is less simple because aldosterone is not yet available. In many patients the weak mineralo-corticoid action of hydrocortisone or cortisone is sufficient provided the salt intake is high. There are two powerful salt-retaining steroids that can be used. Deoxycortone was introduced for the treatment of Addison's disease in 1937 (Simpson, 1938). It must be given by frequent intramuscular injection or implantation of pellets; the sublingual route has been used, but absorption is uncertain. Microcrystalline suspensions of deoxycortone trimethyl acetate may be given by injection at monthly intervals (Thorn *et al.*, 1953). The long-acting preparations (pellets and microcrystalline suspensions) have the disadvantage that their action is not constant throughout the intervals between implantation or injection. An important practical advance in salt-retaining steroids is the fluorine-substituted 9 α -fluorohydrocortisone. Its glucocorticoid activity is twenty times that of the parent compound, whereas sodium-retaining power is increased more than one hundred times (Garrod *et al.*, 1955). Fluorohydrocortisone is readily absorbed from the alimentary canal.

Of the remaining hormones, androgens if indicated can be given in the form of methyltestosterone by the sublingual route. There is no evidence that corticosterone or oestrogen replacement is necessary.

Practical Experience

Hydrocortisone production in a normal subject may be assessed by studies with isotope-labelled steroid (Peterson and Wyngaarden, 1955), or by measurement of urinary glucocorticoid excretion (Moxham and Nabarro, 1956). The adrenal glands of a normal adult secrete 20–25 mg. of hydrocortisone a day, which is equivalent to about 25–37.5 mg. of cortisone acetate. Patients who have had total adrenalectomy and those with severe Addison's disease can usually be maintained on 37.5 mg. of cortisone a day. Because of its rapid absorption and conjugation after oral administration, cortisone should be given as evenly spaced doses of 12.5 mg. When adrenalectomy has been performed for malignant disease 50 mg. of cortisone a day is often prescribed, and the slight excess of glucocorticoid is undoubtedly beneficial in causing an increased sense of well-being and appetite. In some patients it may lead to excessive weight gain.

In many cases the cortisone will also maintain sodium balance provided the salt intake is high. If an excess of

FIG. 1.—Case 1. Total adrenalectomy for carcinoma of breast. Development of sodium-depletion crisis.

FIG. 2.—Case 1. Subsequent progress when 9α-fluorohydrocortisone given in addition to cortisone.

cortisone is given—for instance, 50 mg. a day instead of the physiological 37.5 mg.—with 3 g. of additional salt, sodium depletion is unusual, but it may occur.

Case 1.—A housewife of 49 had a radical mastectomy for carcinoma of the right breast in 1947. In 1953 there was evidence of diffuse involvement of the left breast, and this was treated by deep x-ray therapy. By April, 1955, she had a left pleural effusion and widespread skin infiltration over the left side of the chest. Oophorectomy and adrenalectomy were performed in May by Mr. J. H. Lees Ferguson. She was seen rather infrequently because she lived a considerable distance from the hospital, but her condition was satisfactory, the pleural effusion did not return after pre-operative aspiration, and the skin infiltration regressed. Six months after the operation her practitioner informed us that she was not well enough to attend, and he thought that she had developed visceral metastases. She was, however, brought up, and biochemical studies suggested that her extreme weakness and nausea were due to salt depletion (Fig. 1). Additional salt-retaining steroid was given, and it was found that to maintain sodium equilibrium she needed 0.25 mg. of fluorohydrocortisone and 3 g. of salt a day in addition to 50 mg. of cortisone. She lived for a further year after this episode (Fig. 2). It will be noted that she received 0.5 mg. of fluorohydrocortisone a day initially and after seven weeks had developed hypokalaemia (2.4 mEq/l.).

It is not easy to detect the patients with Addison's disease or following adrenalectomy who are unable to maintain sodium balance on a programme of cortisone and extra salt. The chief symptoms of sodium depletion—weakness and loss of weight—may be masked if 50 mg. a day of cortisone is being given; or if the patient has carcinoma they may be attributed to its progress. Reduction of blood pressure may be a useful guide, but most important are rises of the blood urea and plasma potassium. It could be argued that if the patient feels well there is no need to undertake biochemical studies or to modify replacement therapy on account of a raised blood urea or plasma potassium. We cannot agree with this, because two of our patients, who appeared to be still in remission following operation, died at home after a very brief illness. Their recent biochemical tests had not been completely satisfactory, and it would appear that chronic mild sodium depletion makes the patient more liable to develop acute adrenal insufficiency if any intercurrent illness arises.

When a patient develops clinical or biochemical evidence of sodium depletion the additional salt is increased to 6 g. and, if necessary, to 9 g. a day. Intakes in excess of this are apt to cause troublesome thirst and polyuria. The question of absorption of the extra salt is also considered. Most

patients prefer the 1-g. enteric-coated tablets to capsules, but in one case we found that they were not digested (Nabarro *et al.*, 1956). If the patient has been taking tablets a change to capsules may be tried, but when a modest increase of salt intake fails to correct the clinical or biochemical abnormalities 9α-fluorohydrocortisone should be given.

Case 2.—A married woman aged 55 had a radical mastectomy performed in June, 1955. There was evidence of involvement of the internal mammary glands and, a few months later, of the paratracheal glands. In September Mr. D. H. Patey performed oophorectomy and adrenalectomy. She has remained very well since these operations and there has been no further progress of the malignant disease. Changes in weight and blood chemistry are shown in Fig. 3. The rising blood urea was partly controlled by increasing the salt intake, but fluorohydrocortisone proved more effective and allowed the cortisone dose to be reduced to 37.5 mg. a day. This patient is now receiving 37.5 mg. of cortisone and 0.2 mg. of fluorohydrocortisone but no salt tablets.

FIG. 3.—Case 2. Sodium depletion after adrenalectomy while receiving cortisone (50 mg. a day) and extra salt (3 g. a day). Partial response to increased salt intake; further improvement on fluorohydrocortisone.

FIG. 4.—Married woman aged 52 treated for Addison's disease. Attempt to substitute a greatly increased salt intake for fluorohydrocortisone. (The steady loss of weight in this period was the result of dieting.)

We have studied one patient who had had Addison's disease for 18 years.

This patient had been receiving 25 mg. of cortisone a day and monthly injections of deoxycortone trimethyl acetate (Fig. 4). Fluorohydrocortisone was substituted for the latter, but the dose given (0.0625 mg. a day) was barely adequate. An attempt was made to replace the salt-retaining steroid by a greatly increased salt intake, but although the dose reached 15 g. of additional salt a day the results were disappointing. The patient subjectively was much less well and had thirst and nocturia. She is now well balanced on the same dose of cortisone and 0.125 mg. of fluorohydrocortisone a day.

Tables I and II show the most satisfactory replacement therapy in nine patients with Addison's disease and 30 who had undergone total adrenalectomy. In the case of the adrenalectomized patients it will be noted that, of those receiving 37.5 mg. daily of cortisone, two out of seven needed salt-retaining steroid; of those receiving 50 mg. a day it was two out of 23. In the smaller group of patients

TABLE I.—Replacement Therapy in Addison's Disease

Cortisone Dose (mg./day)	Extra Salt (g./day)	Salt-retaining Steroid*
25 mg. (3 patients)	3–5 g. (2) Nil (1)	Nil F.F. 0.2 mg./day
37.5 mg. (6 ")	3 g. (1) 10 " (1) Nil (4)	Nil F.F. 0.1–0.2 mg./day (3) D.C.T.M.A. 50 mg. every 2 months (1)

* F.F. = 9α-fluorohydrocortisone. D.C.T.M.A. = Deoxycortone trimethyl acetate.

TABLE II.—Replacement Therapy in Total Adrenalectomy

Cortisone Dose (mg./day)	Extra Salt (g./day)	Sodium-retaining Steroid
37.5 mg. (7 patients)	3 g. (4) 6 " (1) Nil (2)	Nil F.F. 0.2 mg./day
50 " (23 ")	3 g. (18) 6 " (3) Nil (2)	Nil F.F. 0.2 mg./day

Indications for adrenalectomy—disseminated carcinoma of breast (21 cases), of prostate (3 cases); malignant hypertension (2 cases); Cushing's syndrome (4 cases).

with Addison's disease, five out of nine were better with sodium-retaining steroids in addition to cortisone. When fluorohydrocortisone is given it is usually possible to stop the extra salt tablets. The dose varies between 0.1 and 0.2 mg. a day; bigger doses have resulted in hypokalaemia (Case 1), and two other patients complained of excessive weight gain and headache while taking 0.25 mg. a day.

Androgens have been used in a few patients in this series. Four men are included in the Addisonian group; all have been tried on methyltestosterone (5–10 mg. a day), but only one has felt any benefit. A few of the women adrenalectomized for carcinoma have been given methyltestosterone if severely troubled by hot flushes or where there was evidence of further progress of the growth. The results were disappointing.

Discussion

The findings in these patients confirm that cortisone acetate in "physiological" amounts (25–37.5 mg. a day) is suitable replacement therapy for patients with chronic adrenal insufficiency. It is, however, clear that some of these patients require a very high salt intake if they are to remain in sodium balance. When a patient with Addison's disease is becoming sodium-depleted there will be weakness, loss of weight, hypotension, and biochemical abnormalities. Increasing the dose of cortisone has little influence on the sodium depletion and by stimulating cellular catabolism may aggravate the biochemical disturbances. Increasing the salt intake may lead to some improvement, but additional sodium-retaining steroid in the form of oral 9α-fluorohydrocortisone has proved most satisfactory. Our results in cases of severe Addison's disease and in patients who have undergone total adrenalectomy suggest that about

one-third of those receiving 37.5 mg. of cortisone daily and one in ten of those receiving 50 mg. daily are benefited by additional fluorohydrocortisone.

Adrenalectomized patients treated with cortisone who develop the "salt-depletion syndrome" seem to do so between three and six months after the operation. The earliest definite evidence is a rise of the blood urea, and we have found it advisable to see all patients who have undergone total adrenalectomy at monthly intervals for the first twelve months. In addition to the usual clinical examination, weighing, and blood-pressure recording, the plasma sodium and potassium and the blood urea are estimated. As well as taking these precautions against the development of a sodium-depletion crisis, we advise the patients or their doctors about the need for extra cortisone if any intercurrent infection occurs. The patients are all given cards similar to those carried by diabetics taking insulin but stating that the patient has undergone total adrenalectomy and must have regular replacement therapy.

Summary

The hormones produced by the adrenal cortex and the preparations available for replacement therapy in adrenal cortical insufficiency are reviewed.

Experiences with nine cases of Addison's disease and 30 patients who had undergone total adrenalectomy are described.

Oral cortisone acetate, 37.5 to 50 mg. daily, was the basis of replacement therapy. It was found that about one-third of those on 37.5 mg. and one-tenth of those on 50 mg. a day became sodium-depleted.

The addition of oral 9α-fluorohydrocortisone, 0.1 to 0.2 mg. a day, was found to be an effective way of correcting this salt depletion.

Attention is drawn to the importance, following total adrenalectomy, of making regular biochemical examinations for the detection of sodium deficiency.

We thank the following surgeons for allowing us to study their patients: Mr. D. H. Patey, Mr. R. S. Handley, Mr. J. H. Lees Ferguson, Mr. L. P. LeQuesne, and Mr. B. J. Harries. Many of the biochemical estimations were performed in the routine laboratories of the Courtauld Institute of Biochemistry, and we are grateful to them for their help. We are indebted to the Medical Research Council and E. R. Squibb and Sons, London, for supplies of 9α-fluorohydrocortisone, and to Mr. V. K. Asta for the charts. We thank the Clinical Research Committee of the Middlesex Hospital for the provision of laboratory facilities and for a personal grant to one of us (J. D. N. N.).

Three new films have recently been presented to the B.M.A. film library. They are: "Allergic Diseases in Man," by Dr. C. J. C. Britton (presented by C. L. Bencard Ltd.); "Haemorrhoids or Piles," by Mr. A. Lawrence Abel (presented by William R. Warner & Co. Ltd.); and "The Medical Witness," by the American Medical Association and the American Bar Association (presented by Riker Laboratories Ltd.). The first two are in colour, and are suitable for undergraduate and postgraduate audiences. "The Medical Witness" deals with conditions in an American court in an interesting and entertaining way. All the films have a sound track. The films may be hired on application to the Secretary of the Association, B.M.A. House.

THE OPTIMUM AGE FOR MASS B.C.G. VACCINATION IN ENGLAND AND WALES*

BY

T. M. POLLOCK, M.B., Ch.B.

Tuberculosis Research Unit, Medical Research Council

Three years have passed since B.C.G. vaccination of 13-year-old schoolchildren was first authorized in England and Wales, and, although this is not a long period in the epidemiology of tuberculosis, further information now available about vaccination, as well as the probable reduction in the risk of tuberculous infection since 1953, makes it of interest to inquire whether 13 years is the most suitable age at which to give the first, and in most cases the only, anti-tuberculosis vaccination under present conditions. To make an assessment of this kind, the current proportion of children infected with tubercle bacilli by the age of 13, the results of tuberculous infection acquired before that age, the risks of infection at puberty and adolescence, the duration of protection conferred by vaccination, and some other factors all need to be considered.

Frequency of Tuberculin Sensitivity in 13-year-old Children

During 1955 the adoptive scheme for the B.C.G. vaccination of 13-year-old schoolchildren (Ministry of Health, 1953) was being undertaken by more than half of the 145 local health authorities in England and Wales. Seventy-three of

TABLE I.—Tuberculin Sensitivity in 13-year-old Schoolchildren, 1955 (Summary of Results of Skin-testing by 73 Local Authorities in England and Wales*)

Method of Skin Testing	Smallest and Largest No. of Children Tested by Each Method	No. of Authorities Total Using Each Method†	According to the Proportion of Children found to be Tuberculin-positive		
			11-20%	21-30%	31-40%
Mantoux 10 T.U.‡ old tuberculin	100-2,459	8	3	1	4
Mantoux 10 T.U. purified protein derivative	94-11,287	38	15	18	5
Mantoux 100 T.U. old tuberculin as final test	388 and 657	2	0	0	2
Heaf multiple puncture (2 mg. purified protein derivative per ml.)	320-4,315	15	8	7	0
Heaf multiple puncture (undiluted old tuberculin)	88-3,152	6	1	3	2
Mantoux 10 T.U. and Heaf multiple puncture at different times	1,287-8,481	4	1	2	1
Total		73	28	31	14

* In one further area the results for 1955 were unaccountably high (77%). This area is not included.

† Four authorities used two different tests and reported the results separately. The lower proportion only is given in the Table.

‡ T.U. = tuberculin units.

the local authorities known to have begun the scheme have supplied details of the tuberculin tests employed and of the proportion of children found to be tuberculin positive immediately before vaccination in 1955. These results are summarized in Table I.

When the results of all tests are compared they show a wide variation, the range in the proportions with positive

*Based on a paper read in the Section of Diseases of the Chest at the Annual Meeting of the British Medical Association, Brighton, 1956.

reactions being from 11% to 40%. This is partly the result of the diversity of tests, but there are sufficient differences among areas using the same test to suggest that the frequency of infection with tubercle bacilli varies considerably in different areas. None the less, it is evident that in England and Wales at the present time substantial proportions of children have been infected with tubercle bacilli by the age of 13, and cannot benefit from a vaccination scheme at that age. The morbidity which results from childhood infection is thus of special relevance. An indication of the extent of this morbidity may be obtained from the new notifications of tuberculosis in the age group 0-14 years, but cases which are never notified and those which arise later in life have also to be taken into account.

Morbidity from Tuberculous Infection Received Before the Age of 14

Notified Cases in the Age Group 0-14 Years

In 1955 the notifications of new cases in the 0-14-year group in England and Wales were: respiratory, 3,614; meningeal, 337; other organs, 1,171; total 5,122 (Registrar-General, 1956).

A case of notifiable tuberculosis is defined as one which "because of tuberculous infection may infect others: or a person who is suffering from an active tuberculous lesion which calls for medical treatment or for some modification of the patient's normal course of living" (Ministry of Health, 1951). The above notifications thus represent cases of various grades of severity and are difficult to assess in medical and social terms.

The serious nature of most non-respiratory disease in childhood is self-evident; so also is "adult type" pulmonary disease at this period of life. However, most respiratory tuberculosis notified in the 0-14-year group is probably associated with primary disease—considered for the present purpose to be those lesions in which a primary complex is visible radiographically. Reports of the course of primary lesions show great variation, depending on the ages of the patients and whether the cases studied were those admitted to hospital or attending out-patient clinics.

Thomas and his colleagues (1954) followed up cases of primary disease which appear to be representative of those notified. Their study was of 298 cases of primary tuberculosis, each with a radiographically evident pulmonary complex, attending Swansea Chest Clinic. Most would be notifiable as cases of respiratory disease, and the majority were under 13 years of age. Seventy-three per cent. were treated at home under supervision and the remainder were admitted to hospital. The majority required bed rest for four months, were not allowed to attend school for six to nine months, and were subsequently supervised for three years. Sixteen per cent. of the total cases developed serious complications. Although there may be variation in the practice of chest clinics in different parts of the country, this experience suggests that the notified cases in the 0-14-year group may represent serious morbidity, having regard to the interruption of normal activities and the medical care required in childhood. Moreover, primary lesions which appear to have healed in childhood sometimes precede further morbidity in later life.

Unnotified Cases in the 0-14-year Age Group

Evidence of the frequency of unsuspected tuberculosis among children about to pass out of the age group 0-14 years was observed in the Medical Research Council's (1956) clinical trial of tuberculosis vaccines. In that investigation, in which 14-year-old entrants had a chest radiograph, 134 previously unsuspected cases of tuberculosis requiring close observation or active treatment were found on entry among approximately 56,000 participants. Almost all of these cases were of pulmonary tuberculosis. The fact that primary infection in childhood may result in lesions of clinical importance which escape notification is also emphasized in the notable study from High Wood Hospital (Bentley *et al.*, 1954). Some

cases of non-respiratory tuberculosis may also remain unnotified in childhood (Wallis, 1955).

A primary tuberculous lesion causing minor or no symptoms and remaining undiagnosed and unnotified in childhood may produce morbidity later, not only through tuberculosis but also as a result of non-specific structural damage—for example, segmental or lobar collapse with subsequent bronchiectasis—or infertility due to pelvic changes.

Bronchiectasis.—Collapse of a pulmonary lobe or segment results not infrequently from primary tuberculous infection. Bentley *et al.* (1954) estimated that segmental lesions often associated with collapse occurred in 5-10% of all primary infections. About 6% of segmental lesions studied in the High Wood survey were found to result in bronchiectasis of a sufficient degree to come to notice; the incidence was much higher than this in lesions of the middle and lower lobes. The frequency with which bronchiectasis occurs among primary pulmonary lesions which are discovered suggests that it may also occur, though perhaps less commonly, among primary pulmonary lesions which remain undetected. Bronchiectasis from primary infections may give rise to serious morbidity much later in life (Brock, 1950).

Infertility.—Pelvic tuberculosis has been reported (Sutherland, 1956) to be the cause of infertility in more than 5% of patients attending a fertility clinic. The serious nature of morbidity of this type is not always generally appreciated, but should not be underestimated; infection at puberty is especially dangerous in this respect (Barns, 1955). In most cases a manifest extragenital lesion precedes the discovery of genital tuberculosis, but in some the initial lesion gives rise to few symptoms and is unlikely to be notified before the age of 14.

Respiratory Tuberculosis and Tuberculosis of Other Organs in Later Life

The frequency with which tuberculous infection in childhood produces tuberculous disease manifest only in later life is not known. In the M.R.C. trial (see above) a relatively high incidence of tuberculosis (1.45 per 1,000 annually), including pulmonary lesions and tuberculosis of other organs, was found during a two-and-a-half-year follow-up among those who were tuberculin-positive on entry at the age of 14 but with no radiological evidence of disease at that time. The incidence was higher among those who were tuberculin-sensitive to 3 T.U. (1.75 per 1,000 annually) than among those who were tuberculin-negative to 3 T.U. but positive to 100 T.U. (0.74 per 1,000). Such a high incidence may not continue in later life, but the possibility requires serious consideration.

The subsequent incidence of tuberculosis in the tuberculin-positive groups aged 13 years in the current B.C.G. vaccination scheme for schoolchildren might be less than among those found to be tuberculin-positive at 14 in the M.R.C. trial, since a higher proportion in the latter inquiry would have been infected during the susceptible period of adolescence. On the other hand, most of the tuberculin tests preparatory to the vaccination of 13-year-old schoolchildren are performed with doses of tuberculin less than the final test of 100 T.U. used in the M.R.C. trial (Table I). The tuberculin-positive groups determined by such tests will therefore contain a higher proportion of the more highly sensitive and vulnerable individuals than the tuberculin-positive group in the M.R.C. trial: this would tend to result in a higher future incidence among the positive group in the current vaccination scheme than in the M.R.C. investigation.

From all the above considerations there is no doubt that the morbidity arising from infection received before the age of 13 is still a serious matter—indeed, more than would appear from the notifications in the 0-14-year group. This suggests that B.C.G. should be given before 13 years of age. On the other hand, doubts about the duration of protection conferred by vaccination make it desirable that the vaccine should be given shortly before a period of increased risk from tuberculous infection begins, if the period of risk is likely to extend over several years.

Risks from Infection at Puberty and Adolescence

It is generally accepted that between 5 and 10 years of age the immediate dangers of a primary tuberculous infection are less than at other periods of life, while at puberty and adolescence morbidity resulting from primary infection increases. By 14 years, for example, an appreciable prevalence of tuberculosis was found among entrants to the M.R.C. trial. It would be reasonable to try to forestall the effects of natural infection at this period by vaccination at, say, 10 years. Vaccination at this age has been advocated by Griffiths and Gaisford (1956).

However, a single vaccination at 10 years instead of 13 might reduce the benefit to those infected after 13 years of age if protection from the vaccine lasted only a very few years, since exposure to tuberculosis might be more frequent at work during late adolescence after the protection conferred by vaccination had declined, than between the ages of 10 and 13 during school life. Much thus depends upon how long protection from vaccination may be expected to last.

Duration of Protection Afforded by B.C.G. Vaccination

The period of protection conferred by B.C.G. vaccine under present conditions in Britain will not be known until the M.R.C. trial has continued for some further years. There was no evidence of a decline in protection in that investigation four years after the vaccine was given. In a clinical trial among American Indians of various ages by Aronson and Aronson (1952), protection lasted for 10 years, although there was a suggestion that it might wane thereafter. Hyge (1956) has reported the result of a follow-up of schoolchildren infected in a tuberculosis epidemic in a school, first reported in 1941. In this instance B.C.G. was shown to confer considerable protection against the development of post-primary tuberculosis for at least 12 years after exposure to a natural infection sustained shortly after vaccination.

Whatever the final outcome of these investigations, it should be borne in mind that B.C.G. might not confer the same duration of protection at all ages or in all types of community. If protection in Britain lasts for a decade or more, vaccination at 10 instead of 13 years of age would appear to offer definite advantages. But even if protection should last for a shorter period vaccination at 10 years might still be a sound policy, since tuberculous infection appears to be declining; the current 10-13-year group may be at greater risk from disease now than by the time they reach late adolescence.

Thus an assessment of the information at present available suggests that the advantages of vaccination at 10 years are likely to outweigh the risk of a relatively early fading in protection. If vaccination much earlier in life—for example, in infancy—were thought to be desirable revaccination at 10 years would have to be considered.

Vaccination in Infancy

Although there is general agreement in Britain about the need for mass vaccination in adolescence and also for the vaccination of infants in known contact with the disease, there are widespread doubts about the desirability of vaccinating infants who are not contacts. The main issue is whether tuberculosis is frequent enough in early childhood to justify the vaccination of approximately half a million infants each year. This consideration is, however, sometimes obscured by doubts about the number and severity of the complications after infant vaccination. There is also the fear that the loss of the tuberculin test in infancy might seriously impede the control of tuberculosis at the present time.

Complications of Infant Vaccination.—The frequency and severity of the complications due to infant vaccination in Britain have been reported by Gaisford and Griffiths (1954) and by Purser (1954). These studies suggest that, provided due attention is paid to technique and dose, the frequency of significant complications and their severity are not greater

than in older children. Complications were later shown by Gaisford (1955) to be greatly reduced when half the adult dose of vaccine was given; such a dose produced no constitutional upset in premature infants.

Loss of the Tuberculin Test

Vaccination in infancy would certainly entail the loss of the tuberculin test, and so, by interference with case-finding and epidemiological investigation, affect the control of tuberculosis.

Reports by MacDougall, Mikhail, and Tattershall (1953), Cuthbert and Randall (1954), Ritchie, Calwell, and Barr (1955), and Davies (1955) illustrate the value of the tuberculin test as a case-finding measure. The cases discovered, however, represent the final result of much tuberculin-testing and follow-up work. It is doubtful whether this way of finding sources of tuberculosis can be widely and consistently put into practice in many areas at the present time, because the numbers of tuberculin-positive children are still high enough to make the follow-up of the potential sources of their infection a considerable undertaking. There are obvious future possibilities, however, of increasing the use of the tuberculin test as a case-finding measure when the frequency of infection has declined further.

It is not easy to assess the extent to which the loss of the tuberculin test would obstruct the control of tuberculosis if a long-term view is taken of the practical value of the information obtained. It should, however, be remembered that, so far as tuberculin surveys are concerned, the findings are generally of most value when the results from different surveys can be usefully compared. In practice, variation in the tests used limits the conclusions which can be drawn from such comparisons. The control of tuberculosis is certainly assisted if regular and accurate estimates of the decline in tuberculous infection can be made; for this purpose mass radiography surveys of some social groups, carried out intensively at intervals of a few years, might be used as a substitute for tuberculin surveys. A comparison of the prevalence of radiographically evident pulmonary tuberculosis would enable an estimate of the decline in tuberculous infection to be made. Such an estimate would probably be sufficient for practical purposes, although less sensitive than the findings of co-ordinated tuberculin surveys. The number of radiographic examinations required would not materially increase the annual number of radiographic examinations undertaken throughout the country.

If the above considerations are taken into account it appears probable that at the present time the control of tuberculosis in England and Wales would not be seriously impeded if the tuberculin test was no longer available, although this might not be true in future.

Frequency of Tuberculous Infection in Infancy

The most important objection to infant vaccination is that the frequency of natural tuberculous infection in infancy may be insufficient to warrant vaccination of non-contacts.

Tuberculin-testing of infants of 5 years and less has not been done on a scale approaching the 13-year-old group; knowledge of the frequency of infection in infancy is in consequence very incomplete. In a few local tuberculin surveys in this country between 1950 and 1954 it was found in the main that between 3 and 5% of children of 5 years of age were tuberculin-positive (Coles, 1952; Palmer *et al.*, 1954; Carstairs, 1955; Jarman, 1955). It seems likely that in many areas the proportion will now be less than this.

TABLE II.—Tuberculosis (All Forms): Notification Rates Per 100,000 Living, Age Group 0-5 Years, 1950-5, England and Wales

Year	Males	Females	Year	Males	Females
1950	86	72	1953	72	66
1951	81	78	1954	57	53
1952	79	74	1955	49	48

The rate at which tuberculous infection is declining is not known, but a general indication can be obtained from a study of the tuberculosis notification rates for recent years. These rates for the age group 0-5 years from 1950 to 1955 are shown in Table II. During the last few years a decline in the rates is evident, and it seems not unlikely that this decline will be sustained and may become accelerated.

The numbers of new cases notified in the age group 0-5 years in 1955 were: respiratory, 1,165; meningeal, 155; tuberculosis of other organs, 295. The new notifications for all ages were: respiratory, 34,192; meningeal, 532; other forms, 4,151 (Registrar-General, 1956). Thus pulmonary notifications in the 0-5-year group represent a rather small proportion of the notifications for all ages; and, although notifications of meningitis in infancy constitute more than a quarter of the meningitis for all ages, the total number judged on a national scale is small; the latter consideration also applies to the notifications of other non-respiratory tuberculosis.

These figures, of course, leave out of account the cases of tuberculosis which are not notified; also the serious nature of tuberculous infection in infancy should be borne in mind. But despite these considerations it is doubtful whether the amount of disease consequent upon infection in infancy justifies widespread vaccination at this age in the present circumstances. Similar observations have influenced opinion in Scandinavia, where the wisdom of continuing to vaccinate infants who are not contacts has been questioned (Wallgren, 1956).

The results in Table I suggest that the frequency of tuberculous infection before 5 years may be unduly high in some areas. Thus, although a national scheme for infant non-contacts is not indicated, the results of tuberculous infection in early childhood are serious enough to encourage tuberculin surveys of school entrants, aged 5, in any area where the frequency of tuberculous infection may be much higher than the national average. Local authorities might then decide whether an adoptive scheme for infant non-contacts was justified in the particular area concerned.

Conclusions

During 1955 a substantial proportion of school-children in England and Wales had already been infected with tubercle bacilli by the age of 13.

The morbidity arising from infection received before the age of 13 is considerable, and is greater than appears from tuberculosis notification rates.

Puberty and adolescence is a relatively dangerous period to sustain a first tuberculous infection, and it is desirable that children should be protected by vaccination before entering this period.

The available evidence suggests that protection from B.C.G. vaccine may last for a considerable period. Thus vaccination at 10 years of age may make a greater contribution to the prevention of tuberculosis in England and Wales than vaccination at 13 years.

Widespread vaccination of infant non-contacts does not appear to be justified on a national scale. The indications for local schemes deserve investigation.

I thank Dr. B. Benjamin, Dr. F. J. Bentley, and Dr. A. M. Sutherland for their advice on various points; the General Register Office, London, who supplied the figures for Table II; and the many medical officers of health who provided the information on which Table I is based.

FIRST FIELD TRIAL OF 377 C 54, A NEW ANTIMALARIAL COMPOUND

BY

L. J. BRUCE-CHWATT, O.B.E., M.D., M.P.H.

AND

L. J. CHARLES, M.B., M.P.H., D.P.H.

Federal Malaria Service, Nigeria

The action of modern antimalarials is such that they provide a reasonably satisfactory range of chemotherapeutic weapons at the disposal of the clinician. The public health worker in endemic malarious areas is less fortunate.

Difficulties encountered in many parts of Tropical Africa in achieving malaria eradication have renewed the interest in possibilities of mass chemotherapy, and several recent W.H.O. malaria conferences recommended that drugs be used in conjunction with residual insecticides wherever this combined attack may lead to the rapid elimination of malaria.

Mass chemotherapy of malaria with drugs available at the present time has two disappointing features. One is the possibility of development of resistant strains to otherwise excellent protective drugs such as proguanil and pyrimethamine. The other is the fact that all available antimalarials are excreted relatively rapidly and have a short "carry over" value. Thus any "mass treatment" of malaria aimed at elimination of the infection in the community and consequent interruption of transmission must be based on giving the drug at intervals of one to four weeks but not greater than one month (Bruce-Chwatt, 1956).

The more frequent the regimen the greater the chances of its irregularity, also the greater the difficulties and the higher the costs of correct administration over large areas with a low population density, poor communications, primitive educational level, and inadequate rural health service organization. The length of action of the drug required for mass chemotherapy of malaria should be at least equal to the "carry over" period of pentamidine, which when administered in a dose of 200-250 mg. will protect an individual from trypanosomiasis for three to six months.

The ideal antimalarial combining the virtues of causal prophylaxis, suppression, rapid and complete curative action, sporontocidal effect and inability to create parasite resistance, absence of toxic effects, slow excretion, palatability, and (last but not least) low cost is still wait-

ing to be discovered. Any new advances of synthetic chemistry applicable to chemotherapy of malaria are therefore of considerable practical importance.

The finding of Rollo and Duffin (1957) that the compound known under a code number, 377 C 54, belonging to a series of hydroxynaphthalenes, has a pronounced action against malaria parasites is of particular interest. It introduces an entirely new group of drugs and opens for the synthetic chemist the possibility of many variations on the main theme in the hope of producing, if not an ideal antimalarial, an improvement on present drugs.

Characteristics of 377 C 54

Coatney and his associates (1952), who tested nearly 4,000 chemical compounds for antimalarial activity, reported that naphthalene derivatives had some effect on the experimental infection of chickens with *P. gallinaceum*. Nevertheless in the final table of tested products with a significant therapeutic index, the halogenated naphthalene aminoalcohols occupied only a modest place in the middle of the range of just over 200 chemical compounds.

377 C 54, a new compound, synthesized recently in the laboratories of the Wellcome Foundation in London, is 2:5-bis(cyclo-hexylaminomethyl)naphthalene-1:6-diol dihydrochloride. It belongs to a series of mono- and dihydroxynaphthalenes which were first tested for antimalarial activity against *P. gallinaceum* infections in young chicks and *P. berghei* in mice (Rollo and Duffin, 1957). In further trials use was made of *P. cathemerium* in canaries and *P. knowlesi* in a rhesus monkey.

Screening tests showed that the activity of 377 C 54 against the two avian plasmodia was of a high order. In *P. gallinaceum* infections the median effective dose was about twice that of chloroquine. The therapeutic index of the new compound, calculated according to the method used by Coatney *et al.* (1952), is of the order of 60-70, and thus in the first third of the American table of compounds with a significant plasmodicidal activity. In single-dose experiments the speed of action of the new compound was of the same order as that of chloroquine. Its action on a virulent strain of *P. knowlesi* in the rhesus monkey was fast and complete.

The early pharmacological tests of 377 C 54 on chicks and man showed that the drug is rapidly absorbed; it appeared that its excretion is slow owing to retention in the liver and lungs. Its toxicity in laboratory animals and in man seemed to be low.

Method of Field Trial

Prior to the large-scale field trial of the new drug it was taken by each of us for seven days at the daily dose of 600 mg. This high dosage having produced only nausea and fatigue, it was decided to use the drug for a field trial.

The method of the trial was that used for the past five years for several similar investigations (Bruce-Chwatt, 1951; Archibald, 1951; Bruce-Chwatt and Archibald, 1953; Charles and Bruce-Chwatt, unpublished). It was based on a selection of two or more volunteer groups of African schoolchildren naturally infected with malaria. Preliminary screening was followed by the administration to each group of a suitable therapeutic dose of the tested drug. The speed of disappearance of parasitaemia in each group was used as an indication of the respective activity of the tested drug and its dosage. It is fully realized that this method has its disadvantages. It cannot serve as a substitute for a well-controlled laboratory experiment in which all the variables of the infection are well assessed and the toxicity of the drug can be gauged during the investigation. Nor can this trial claim to give more information than a true therapeutic trial on non-immune patients with acute clinical malaria.

The method adopted by us stands half-way between the two mentioned above. It provides rapidly a good deal of

information on the comparative value in human malaria of drugs known to be active and non-toxic. Moreover, it uses reasonably good samples of subjects naturally infected with a variety of species and strains of the parasite and, after a judicious preliminary screening, permits us to standardize to some extent the composition of each group, though at times a random sampling might be preferred. Furthermore, this method approximates the conditions under which mass administration of antimalarials is most likely to be carried out in a given area.

The present investigation was carried out on 316 African children attending five elementary schools in the Mushin-Shomolu suburban area of Lagos. Its purpose was carefully explained to the teachers, to the parents, and to the children, and it was made clear that taking part in the trial was voluntary. It is a tribute to the intelligence of the teachers and parents and to the confidence of the children that refusals to take part in the trial were extremely rare.

After an initial screening the children were divided into two series of three groups, each to be given 377 C 54 at the following regimens: (I) single dosage at 300 mg., 200 mg., and 100 mg. respectively; (II) repeated dosage for two consecutive days at 300 mg., 200 mg., and 100 mg. respectively. In addition, one separate group was given a single dose of 100 mg. of chloroquine, and one small group of 20 children, given a placebo, served as control. All the drugs were administered by one of us and, apart from the initial selection for positive parasitaemia, the children were allotted at random to the six treatment groups. The observations were made at the height of the rainy season during the period June to October.

Thick blood films were collected daily from D-day to D+3 and weekly thereafter to week 4, stained with Giemsa, and examined for 200 microscopical fields on each occasion. A parasite density index was computed on the basis of grouped parasite densities per c.mm. (Bruce-Chwatt, 1951), parasite counts being made from the parasite/leucocyte ratio. Spleen and liver palpation was made a few days before D day at the time of the preliminary survey and again at the end of the observations at week 4.

The usual malarimetric indices were calculated for each group from the results of these investigations. The time of disappearance of the initial parasitaemia (exclusive of crescents) in each group of children was calculated as a "mean clearance time" and used for comparison of schizontocidal activity of the investigated drug.

Results of the Investigation

The preliminary screening of children showed that the two main series and the two additional groups were malarimetrically comparable in all major respects (Table I). Their overall mean age was 7.2 years; liver enlargement rate, 31.3%; spleen rate, 75.3%; average enlarged spleen 1.54; parasite density index, 3.31; mean weight of children, 45 lb. (20.4 kg.).

As usual in Southern Nigeria, the predominant parasite species was *P. falciparum*, which occurred in 96.5% of the selected positive sample. *P. malariae*, generally in associa-

tion with *P. falciparum*, ranged between 20.7 and 32.2% in the group parasite formula, while *P. ovale* occurred irregularly with an overall frequency of 2.1%.

The gross parasite densities, which because of the general low counts of *P. malariae* and *P. ovale* principally reflect *P. falciparum*, centred around 500-1,000 parasites per c.mm. to give an overall parasite density index of 3.31. Gametocytes of *P. falciparum* were evenly distributed among the various groups at a comparatively high overall rate of 36.4%.

Effects of Treatment

The effects of the several regimens of the compound 377 C 54 and that of chloroquine are described here mainly with reference to parasite findings in the peripheral blood.

Disappearance of parasitaemia (exclusive of crescents) was complete in Series I only for the 300-mg. group. Failure of such clearance was recorded in five children (11.4%) of the 200-mg. group, while only 21 of 44 children (47.7%) were cleared in the single-dose 100-mg. group. In these two groups failure of clearance occurred both against *P. falciparum* in single infections and against *P. falciparum* and *P. malariae* in mixed infections. The parasite density of these failures did not differ from that of the groups as a whole. Where one species only was cleared in a mixed infection it was included in calculating the clearance time for that species. In Series II all three regimens of 377 C 54 produced total clearance, as also did the single 100-mg. dose of chloroquine. No change was noticeable in the control group, the 100% parasite rate of which remained at this level throughout the investigation.

TABLE II.—Clearance Time Obtained in Two Series of Children Given 377 C 54 Compared with One Group on Chloroquine

	No. of Infections	Percentage Cleared	Clearance Time (Mean Days ± S.E.)		
			Gross	<i>P. falciparum</i>	<i>P. malariae</i>
377 C 54 Series I:

200 " " "	45	100.0	2.51 ± 0.34	1.77 ± 0.08	4.66 ± 0.98
100 " " "	42	100.0	3.78 ± 0.51	2.15 ± 0.07	5.68 ± 0.95
Chloroquine 100 mg. Single dose	37	100.0	2.53 ± 0.24	2.08 ± 0.12	2.77 ± 0.97

Clearance time set out in Table II is shown for all species combined and for the two main species separately. As previously observed by us (Charles and Bruce-Chwatt, unpublished) in relation to chloroquine and amodiaquine, the relatively prolonged gross clearance times recorded here are due principally to the persistence of fully grown pre-segmenters of *P. malariae*. These parasites with poorly staining cytoplasm and clumped pigment were seen in the peripheral blood for upwards of a week without any evidence of further development.

The irregular nature of this phenomenon is reflected in the long mean clearance times (2.42 ± 0.68 to 6.50 ± 1.55 days) and the large standard error of the means recorded for *P. malariae* alone.

TABLE I.—Malarimetric Findings on 316 Children Taking Part in the Field Trial

A.E.S. = Average enlarged spleen. P.D.I. = Parasite density index.

Against *P. falciparum* the clearance times observed for 377 C 54 were generally less than two days. In both series the speed of clearance appeared to be directly proportional to dosage, ranging from 1.41 to 1.90 days for 300 mg. and 100 mg. respectively in Series I, and from 1.51 to 2.15 days for the same doses in Series II. In both series analysis of this relationship by the chi-square test suggested the improbability of this finding occurring by chance alone ($P < 0.001$). The apparent faster action of the single-dose regimens in Series I than that of the corresponding repeated dose regimens in Series II was in no instance statistically significant. The difference between the fastest (1.41 days) *P. falciparum* clearance time for 377 C 54 and that for chloroquine (2.08 days) was, however, highly significant $P < 0.001$.

All but one of the nine *P. ovale* infections included in the groups were cleared by D+1, and that exception was cleared by D+2.

Analysis of the speed of clearance of *P. falciparum* in relation to the pre-treatment density of that species per c.mm. was made for Series II. For this purpose the usual 10 parasite density groups were consolidated into two groups below and above the level of 500 parasites per c.mm. There was no significant association of clearance time with the parasite density.

Reappearance of Parasitaemia.—In assessing the time of reappearance of parasitaemia, the small number of *P. malariae* pre-segmenters persisting from the original infections were discounted in both series, and in Series I only those children in whom total clearance had been attained were taken into consideration. The results of these observations are summarized in Table III and illustrated in the graph. Most of the recurrences were due to

TABLE III.—Weekly Parasite Rates Following Initial Therapeutic Clearance of Parasitaemia

Parasite rates in African schoolchildren all infected with malaria prior to administration of 377 C 54. The drug was given in three doses of 100 mg., 200 mg., and 300 mg. once (Series I) or twice (Series II). The graph shows the different speed of the reappearance of parasitaemia after a clearance on week 1 or week 2.

P. falciparum, but a small number (five and six) pertained to *P. malariae* and *P. ovale* respectively. In the 200-mg. and 300-mg. groups of Series I the first reappearance of parasites was observed by week 2. Although by week 4 approximately half of the children in these two groups showed positive blood films, 90% of the 100-mg. group were already positive.

Gametocytocidal Action.—Although 377 C 54 appeared to act on all the erythrocytic forms of *P. malariae* and *P. ovale*, it had no immediate and direct action on the gametocytes of *P. falciparum*. There was evident, however, a gradual and indirect reduction of crescents over a period of time after clearance of the asexual forms (Table IV).

TABLE IV.—*P. falciparum* Gametocyte Rates in Seven Groups of Treated Children and One Control Group

	D	D+1	D+2	D+3	Wk 1	Wk 2	Wk 3	Wk 4
377 C 54 Series I:								
300 mg. ..	34.9	44.2	29.5	34.9	38.1	31.7	19.5	12.5

TABLE V

	Before Drug Administration	5 Days After Receiving 300 mg. of 377 C 54
No. of <i>P. falciparum</i> gametocytes	180/c.mm.	40/c.mm.
No. of <i>A. gambiae</i> infected on 10th day	3 out of 10 dissected	1 out of 9 dissected
Total No. of oocysts of <i>P. falciparum</i>	14	2

Thus in Series II, where all asexual forms of *P. falciparum* were cleared by D+3 in all three groups, crescents were still found in about 10% of children at week 4, though about 40% of the children showed them at the start of the observation period.

Sporontocidal Action.—Four children with *P. falciparum* gametocytes varying in density between 80 and 180 per c.mm. were each exposed to bites of 20-30 *A. gambiae*. Immediately after this they were each given a single dose of 300 mg. of 377 C 54. On the fifth day after receiving the drug the children were again examined for crescents and exposed to bites of new batches of *A. gambiae*. The mosquitoes were dissected for oocysts and sporozoites

between the 9th and the 11th day after the infective meal. Infections were obtained from three children before the drug administration and from one child after it. The results pertaining to this child aged 6 are shown in Table V. The result suggests that 377 C 54 is not a sporontocidal drug, but that it acts indirectly on gametocytes, decreasing their number by attrition, similarly to the 4-aminoquinolines.

Effects on Splenomegaly.—No significant changes in spleen rate or average enlarged spleen were observed in any of the groups under review.

Toxic Effects.—Among 259 children treated with the dosage regimens described above, nausea and vomiting, usually within two hours after taking the drug on an empty stomach, was reported by eight. No other side-effects were noted, although many of the youngest children, having to crush the tablets before swallowing, were obviously conscious of the bitter taste of the drug.

Discussion

The results of these first field trials indicate that the compound 377 C 54 has an appreciable schizontocidal action on *P. falciparum*, *P. malariae*, and *P. ovale* infections.

Of the *P. falciparum* infections cleared by 100 mg. of 377 C 54, the speed of clearance did not differ statistically from that for chloroquine. But at the higher single doses of 200 and 300 mg. respectively the clearance times for the new drug was significantly faster ($P < 0.001$) than that for chloroquine at 100 mg. This is of particular interest, since in a previous field trial the clearance times for single-dose chloroquine at 100, 200, and 300 mg. respectively did not differ significantly one from another (Charles and Bruce-Chwatt, unpublished).

Judging by the comparative clearance rate with single doses of the new drug and of chloroquine it appears that 377 C 54 is approximately one-half to one-third as active on *P. falciparum* as chloroquine. This is reasonably consistent with the experimental findings of the activity of 377 C 54 against *P. gallinaceum*.

The fact that at week 4 there was no evidence of a significant decrease of the spleen rate or of the average enlarged spleen in any of the six dosage groups of 377 C 54 suggests that the action of the drug is not as complete as that of 4-aminoquinolines given at single doses of 200 or 300 mg. (Charles, in print). Apart from the single doses of 100 mg. and 200 mg. of 377 C 54 which did not completely clear the parasitaemia in the respective groups, the clearance time for the other dosages was directly proportional to the amount of the drug administered. The steepness of the dose response curve on human malaria parasites is of interest and in accordance with experimental findings in *P. gallinaceum*. The rate of reappearance of parasitaemia indicates that 377 C 54 is a quick-acting and rapidly excreted antimalarial.

Summary

The results of the first field trial on African children of 377 C 54, a new antimalarial compound belonging to a series of mono- and di-hydroxynaphthalenes, indicate that the drug has a pronounced schizontocidal effect on *P. falciparum*, *P. malariae*, and *P. ovale*. There is no evidence of any direct gametocytocidal or sporontocidal action on *P. falciparum*. The new compound is well tolerated in a dosage of about 30 mg. per kg. given in two days.

We are grateful to Sir Samuel Manuwa, Chief Medical Adviser to the Federation of Nigeria, for permission to publish this paper; and to Dr. R. S. F. Hennessey, Director of the Wellcome Laboratories of Tropical Medicine, London, for supplying the new compound and for his valuable suggestions.

Which Way Now? is a leaflet issued by the National Association for Mental Health for parents of mentally handicapped children. The leaflet describes how such children, for whom ordinary schools are unsuitable, are placed under "supervision" by a mental welfare officer or a health visitor, who will help and advise the parents as necessary. Occupation centres, which are similar to special schools, may be provided by the local health authority. If there is no occupation centre the health authority may employ a "home teacher" at regular intervals. This leaflet (price 3d. net), and others also concerned with the training of mentally handicapped children, are obtainable from the National Association for Mental Health, 39, Queen Anne Street, London, W.1.

ANTIVENENE REACTION FOLLOWING
ACCIDENTAL SEA-SNAKE BITE

BY

H. A. REID, M.B., M.R.C.P.Ed., D.T.M.&H.

Specialist Physician, General Hospital, Penang, Malaya

The following personal experience illustrates some problems in snake-bite and its treatment.

Case Report

On September 23, 1955, sea-snakes were being manipulated to obtain venom. At that time the technique used was to grasp the neck of the sea-snake with a long pair of forceps and lift it from the glass bowl in which the snakes swam. The snake was then laid on a table and seized by the left thumb and index finger either between the head and forceps or just behind the forceps (depending on how near the forceps were to the head). The forceps were then released and venom was taken on a plastic spoon. An adult *Enhydryna schistosoma* (Daud)—total length 810 mm. (32 in.)—was being held thus by forceps on the table, but as my finger approached to grasp the snake, it managed to turn its head quickly (with far greater speed than I thought possible in this usually sluggish species) and bite the tip of my finger. This was at 2.50 p.m.

The snake was rapidly returned to its bowl and the index finger, bleeding slightly, sucked with much dismay. Amputation was considered, but the means were not immediately to hand. It was therefore decided to "take a chance." At the same time, I thought that if the chance did not come off, inactivity would not appear—even posthumously—to have been masterly. Without faith in the procedure, antivenene therapy was therefore given as follows: 3.10 p.m., 250 mg. of cortisone by intramuscular injection; 3.20 p.m., 10 ml. of antivenene intramuscularly; 3.25 p.m., a further 10 ml. of antivenene together with 1,000 units of hyaluronidase intramuscularly. The antivenene was polyspecific against *Naja naja*, *Bungarus coeruleus*, *Vipera russelli*, and *Echis carinatus* and concentrated by sulphate. It has negligible *in vitro* neutralizing power against *E. schistosoma* venom (Savoor, 1955).

Until 6 p.m. there were no symptoms suggesting sea-snake poisoning. The bite mark was painless and there was no objective sensory loss over the index finger. Neurological and general physical examinations were negative. Routine venom-taking was resumed, the *E. schistosoma* specimen which bit me giving an unusually high yield (after drying, it weighed 27 mg.; the average maximum for this species is 15 mg.). At 6 p.m. generalized aches, stiffness, and some muscular weakness started. Sleep that night was disturbed, but no further symptoms of sea-snake poisoning developed. The next morning the stiffness was much better although still present. Both palms were red and swollen. On September 25 and 26 I felt quite well but had a pricking sensation at the site of the bite. X-ray examination showed an opacity in the finger pulp. With the help of a dissecting microscope I extracted a grooved fang.

On September 27 urticaria started, the next day general aches, and on September 29 lip-swelling and conjunctival congestion developed. Promethazine, 50 mg. twice daily, temporarily relieved these symptoms, but malaise remained severe. At 6 p.m. on September 30 the neck was stiff and painful. At 9 p.m. twinges were passing down both arms. At 1 a.m. on October 1, I was woken by violent shooting pains down the arms and over the left buttock: they were agonizing and were not significantly relieved by 100 mg. of promethazine and 8 tablets of aspirin. Further sleep was impossible. Throughout that day severe pains continued despite 8 codeine compound tablets and 100 mg. of pethidine. Nausea was constant.

On October 2 root pains had diminished, but pain and, later, moderate swelling of the joints of both ankles, knees, elbows, and wrists, and of the fingers started. A scarlatiniform rash appeared over the trunk and limbs. There were fever, general weakness, and exhaustion. At 10.30 a.m. 200 mg. of cortisone was taken orally, and by 1 p.m. all pains had disappeared. The relief was dramatic. At 4.30 p.m. ankle-joint pains recurred and 100 mg. of cortisone was taken. Weakness in the left arm was first noticed. At 8.30 p.m. there was no pain, but I was now quite unable to lift the left arm. A papulo-vesicular rash had appeared round the knees.

On October 3 I felt much better and resumed work. The legs ached on standing and there was inability to abduct the left arm and difficulty in lifting the right arm. Oral cortisone, 25 mg. thrice daily, was continued. On October 5 general aches and root pains recurred. Prednisolone, 20 mg. daily, was substituted for the cortisone, but weakness and aching pains increased. The latter were constant in the left shoulder and upper arm, with exacerbations there, in the buttocks, and sometimes in the right arm. Momentary acute jags, like adhesive plaster being torn off the skin, occurred in various sites. These symptoms continued more or less unchanged during the next two weeks. They were always worse at night and were eased by codeine tablets. After October 13 prednisolone was reduced as it did not seem to be of much benefit, and was stopped on October 17. By October 26 the pains were less severe and the strength of the left arm and shoulder had improved so that the hand could now be used to brush the hair. Power in the right arm seemed almost normal.

On November 3 the remaining symptoms were an aching pain on sustained elevation of both arms, more severe on the left, occasional paraesthesiae across the shoulders and right knee, and stiffness of the right ankle. A visiting neurosurgeon found weakness and wasting of the left deltoid, infraspinatus, biceps, and (slightly) triceps. The tendon reflexes of the left arm were depressed. There was altered sensation over the left fifth cervical and right third lumbar dermatomes. During the following year these symptoms gradually diminished, and in August, 1956, an objective neurological examination was essentially negative. Prior to the antivenene, no horse serum had been injected. Previous and family histories were not relevant.

Discussion

Personal experience of the ailments we try to treat is often revealing. The literature on snake-bite contains few accounts by medical victims. Day (1869) described being bitten by *E. schistosoma* whilst wading off the Orissa coast. The snake bit his heel so tenaciously it had to be shaken off, leaving two clear fang marks, but no symptoms of poisoning followed. Haast recovered from a bite by *B. coeruleus* after neurotoxic symptoms (Haast and Winer, 1955). During the preceding five years he had been inoculated with *Naja* venoms—but these antigens would not raise his immunity to *Bungarus* poisoning. Herpetologists are not infrequently bitten (Minton, 1950; Benn, 1951; Watt *et al.*, 1956). Carelessness is usually the main factor in such accidents, sometimes even bravado (Forné, 1888; Tidswell, 1906). As a result of being bitten, my technique was modified (Reid, 1956).

The symptoms from September 27 onwards were typical of a serum reaction and were not related to the venom. Poisoning due to the venom was limited to stiffness and weakness starting three hours after the bite and lasting 24 hours. The triviality of these symptoms is remarkable when one considers that an hour after biting me the specimen yielded 27 mg. of venom, the equivalent of about 14 lethal doses for an adult (Reid 1956). It is true that my finger was pulled away swiftly, but, if there was time for a fang to be left behind, this should be sufficient for the injection of 2–3 mg. of venom. Taking venom from different species of sea-snakes, I have often seen it deposited instantaneously. This experi-

ence supports my belief (Reid, 1956) that venom ejection is primarily dependent on instantaneous secretion rather than a syringe-like expulsion of what happens to be "in store."

Snake-biting of mankind is a defensive act; the stimulus to reflex secretion is weak and rarely results in a "business bite." Otherwise it is difficult to understand why the mortality from bites of poisonous snakes should be so low considering their potential lethality. For example, M'Kenzie (1820) reported 15 sea-snake bites without a death. In a recent survey of fishing villages, several fishermen recounted to me bites in which, as in the case of Day (1869), the sea-snake stuck like a limpet yet few symptoms of poisoning followed. Only slight poisoning was observed by Lamb (1904) in 8 out of 11 patients bitten by identified *N. naja*. Martin (1907) recorded the case of a snake-charmer who was bitten on many occasions by *Notechis scutatus* (the most poisonous land snake in the world). Ferguson (1926) reported that out of 88 patients bitten by Australian neurotoxic snakes 23 victims had no symptoms of poisoning whatsoever. Jutzy *et al.* (1953) reported 55 cases of snake-bite in the Panama Canal zone, and 32 of these had no evidence of poisoning. In six of the latter the snake was identified as poisonous. One of their fatal cases was a herpetologist who had been bitten on some 20 previous occasions. Watt *et al.* (1956) reported the case of a herpetologist bitten on 10 occasions by American pit vipers: in six of these incidents symptoms were minimal.

First-aid Measures

Absorption of venom is rapid. Active first-aid measures short of immediate radical excision or amputation are ineffective (Reid, 1956). It is interesting to contrast theory—for some time prior to being bitten I had been critically considering the problem of first aid in snake-bite—with personal practice. I did nothing. The outcome may well have been due to luck, but, regardless of whether customary first-aid measures are effective or not, my point here is, are they practical?

If effective antivenene is available the sooner it is given the more likely will it help the patient. It was therefore of great interest to note afterwards how long it took before antivenene was given. Although the bite occurred in hospital, where a "snake-bite treatment box" with polyspecific antivenene, cortisone, adrenaline, and sterile syringes is immediately available in the hospital dispensary, antivenene injection was not completed until 35 minutes after the bite. This made me wonder what the delay was with ordinary patients. It emphasized how essential it is that patients coming to hospital with snake-bite should be regarded as medical emergencies.

Doubts of Efficacy of Antivenene

Grave doubts have recently been expressed regarding the practical efficacy of "neurotoxic" antivenene at present available (Reid, 1956). In many hospitals (probably most) antivenene is given to all victims of snake-bite even when there is no evidence of poisoning or the patient was bitten so long ago that no benefit would result. Sometimes the antivenene given is virtually useless for the particular varieties of snake-bite in the area concerned. It is therefore important to consider the harm antivenene may do. Serum reactions are commonly of two types—anaphylaxis, which occurs immediately (if within a few minutes it may be fatal), and serum sickness, which starts later, usually 7–10 days after the injection. Records of anaphylaxis attributed to antivenene are not common, but many accounts of snake-bite describe symptoms highly suggestive of such reactions. For example, Efrati and Reif (1953) reported 65 cases of viper bite in Israel with a high proportion of allergic symptoms ascribed to the venom. Shannon (1953) remarks that such symptoms are often regarded as due to the venom when they are in reality due to the antivenene.

Whilst hypersensitivity to snake venom may well occur, it is significant that the patient reported by Watt *et al.* (1956)

showed no signs of it despite repeated bites from each of three species of pit vipers. Faraker (1924) described a near-fatal reaction starting whilst refilling the syringe for the second half of antivenene. In this case, even the diagnosis of snake-bite was doubtful. Jörg (1935) recounted the case of a patient dying from pulmonary oedema 15 minutes after 20 ml. of antivenene injected intravenously. Flecker (1952) reported a case needing adrenaline and promethazine, which did not entirely prevent reactions. Grasset and Christensen (1947) recorded that serum reactions with South African antivenene were not rare even though the antivenene was concentrated by sodium sulphate. Minton (1952) has seen several severe reactions probably more dangerous and unpleasant than the snake-bite. Shannon (1953) mentions "several authenticated fatalities." The incidence of antivenene anaphylaxis in U.S.A. must be greatly diminished by the custom there of using the subcutaneous route.

In Penang General Hospital intravenous injection of 20 ml. of antivenene used to be a routine procedure. Anaphylactic reactions occurred more often than not. Some were so severe that doctors in the out-patient department became afraid of snake-bite cases mainly because they would have to give antivenene. These reactions became exceptional when combination with hyaluronidase and change to the intramuscular route were adopted. But were fewer antivenene reactions accompanied by a corresponding loss of therapeutic effect? The incidence and severity of anaphylaxis are directly proportional to the speed and quantity with which the antigen serum reaches its "target." Almost certainly the therapeutic efficacy bears the same relation. One is faced with the Scylla of anaphylaxis and the Charybdis of delay nullifying benefit to the patient. Two outstanding clinical problems are the indications for antivenene in snake-bite and effective dosage in relation to the time elapsed since the bite with snake-poisoning.

Serum Sickness

There are few records of late serum reactions following antivenene. Reid and Flecker (1950) described mild serum sickness seven days after *N. scutatus* antivenene. Miller and Stanton (1954) reviewed the literature of neurological complications of serum treatment without mentioning antivenene as a possible cause. Pacheco e Silva (1933) reported a case of serum sickness following scorpion antivenene. The patient had radiculitis almost identical to mine. I have been unable to find a previous record of neuropathic serum sickness due to snake antivenene. Miller and Stanton remark that "the patient is rarely treated for the complication by the physician who gave the original injection: the relation between inoculation and subsequent neurological symptoms may pass quite unrecognized." This would apply to serum sickness generally, and many instances following snake-bite may be overlooked. Swaroop and Grab (1954) estimated that about half a million people in the world were bitten each year by snakes. According to Laurent and Parish (1952), the incidence of serum anaphylaxis may not have been appreciably reduced by modern processing, whereas serum sickness has fallen from 40-60% of injections with crude serum to 20-30% with ammonium and sodium sulphate concentration and to 5% with enzyme refining.

If a quarter of a million victims are given antivenene each year, the incidence of serum sickness might well be 100,000, as few antivenenes are enzyme-refined. Neurological syndromes would, of course, be much rarer. They include cerebral, meningeal, myelitic, radicular, and neuritic forms, but much the commonest is a neuropathy of the fifth and sixth cervical roots. The large size of these roots relative to their intervertebral foramina makes them susceptible to compression. Miller and Stanton (1954) think that many roots may be involved in the reaction, but symptoms are confined to the few with anatomical factors in addition. If this is true and cortisone relieves the radicular swelling, it should prevent the ensuing paralysis. However, it failed in my case. Although, on October 2, 300 mg. of cortisone relieved root pains dramatically, paresis started later that

day and progressed rapidly to paralysis. Possibly, if cortisone had been taken at the onset of root pains, paralysis would not have occurred. As 75 mg. daily failed to prevent the pains on subsequent days, higher dosage would be needed for a period which presumably could be determined only by trial reduction and, if pains recur, resumption. Without cortisone, recovery occurs within a few months to two years, but 20% have residual weakness. Deaths are rare.

Prevention and treatment of serum reactions in general are admirably dealt with by Laurent and Parish (1952) and Williams (1955). Payling Wright and his colleagues (Littlewood *et al.*, 1954) have shown that, once injection of horse serum has been given, with second or subsequent injections the serum is likely to be removed so rapidly from the circulation by the liver that prophylactic effectiveness is curtailed. Therapeutic effectiveness would presumably be nil. However, they were referring to tetanus intoxication, which slowly increases over several days and therefore needs a persistent antibody for effective prophylaxis. Snake-poisoning is a sudden intoxication in which the venom circulates for a period before becoming fixed to susceptible structures. If antivenene is also circulating during these few minutes or hours—the fixation time of venom has not been investigated by modern methods—it should be able to neutralize significant amounts of venom. But if the patient has had a previous injection of horse serum there will be a race between the venom and the patient's horse-serum-precipitating antibodies for a coupling with the antivenene. The higher the concentration of the anti-horse-serum antibodies the more quickly would antivenene be destroyed.

Research is needed to decide if destruction occurs so rapidly that therapeutic efficacy would be impaired or nullified. If the latter proves to be the case it will be pointless to give antivenene obtained from horses to persons who have previously received an injection of any horse-serum antitoxin. Active immunization, as suggested for fishing folk exposed to risk of sea-snake bite (Reid, 1956), would be indicated. Whether such a procedure could be effective and practical is a matter requiring investigation.

Summary

A personal experience of neuropathic serum sickness following antivenene given for accidental sea-snake bite is recounted.

One hour after the bite the sea-snake yielded venom equivalent to 14 adult lethal doses, yet minimal poisoning followed the bite. The significance of this is discussed.

Contrast in theory and practice of first-aid measures is mentioned.

In the experience reported, the effects of treatment were much worse than those of the snake-bite. Antivenene is not harmless. It should not be regarded as mandatory in every case of snake-bite coming to hospital.

I wish to thank Professor G. Payling Wright for reading the manuscript and for his most helpful and stimulating advice; Mr. Douglas Miller, of Sydney, Australia, and Dr. Henry G. Miller, of the Royal Victoria Infirmary, Newcastle upon Tyne, for examining me; and the Director of Medical Services, Federation of Malaya, for permission to publish.

SYSTEMIC TREATMENT OF TRICHOMONAL INFECTIONS

BY

R. D. CATTERALL, M.R.C.S., L.R.C.P.

Registrar to the Whitechapel Clinic, London Hospital

AND

C. S. NICOL, M.D., M.R.C.P.

Physician in Charge, Special Treatment Centre, St. Thomas's Hospital, London

It is generally agreed that the treatment of trichomonal infections is unsatisfactory. The claims made for various therapeutic agents are frequently conflicting, and this may be due to varying standards of diagnosis and criteria of cure as well as to faulty assessment arising from a high incidence of defaulters and difficulty in arranging a satisfactory series of controls. Recent work has established the fact that the parasite is often present in the urinary tracts of both male and female patients (Kean, 1955; Whittington, 1956, personal communication), and it seems reasonable to suppose that reinfection of the vagina after apparently successful local treatment may occur from this source. The ideal remedy for the disease would be a drug which would be effective when administered systemically and so would eradicate the parasite not only from the vagina in women and the urethra in men but also from other parts of the genitourinary tract not accessible to local treatment. The investigation and treatment of sexual partners is also essential to eliminate another possible source of reinfection.

Recently claims have been made for two drugs which are said to be effective when administered by mouth. The object of this investigation was to test these claims and assess the place of these preparations in the treatment of trichomonal infections.

The first of these drugs was "trichomycin," an antibiotic isolated from *Streptomyces hachijoensis* in Japan by Hosoya *et al.* (1950, 1952). Reports from Japan indicated that it was effective against trichomonads both *in vitro* and *in vivo*. It was also claimed to be effective against *Candida albicans* (Magara *et al.*, 1955). Shortly afterwards another preparation, acinitrazole (2-acetyl-amido-5-nitrothiazole; "tritheaton"; "trichorad"), was used in the United States (Cuckler *et al.*, 1955) and claimed to be effective when given by mouth in the treatment of trichomonal infections (Plentyl *et al.*, 1956).

Previously Bushby and Copp (1955) had demonstrated that certain of the amido-nitrothiazoles were more active *in vitro* against *Trichomonas vaginalis* than acetarsol; and Bushby, Catterall, and Williamson (1955) had shown that forminitrazole (2-formamido-5-nitrothiazole), a related compound, was effective in suppressing symptoms and causing the parasite to disappear rapidly when used as vaginal pessaries.

Diagnosis and Tests of Cure

In cases in the female, diagnosis was established by examination of wet smears and by cultures of vaginal secretions. Specimens of vaginal exudate were obtained, using the vaginal spoon method described by Jackson *et al.* (1948). Some of this material was inoculated into tubes of the liquid liver medium of Feinberg and Whittington (1957, in press). Samples of urine were obtained and the centrifuged deposit was examined microscopically and cultured in the same medium. In cases in the male, urethra scrapings were examined by dark-ground microscopy and cultures were also made. Centrifuged deposit of urine was also examined microscopically and cultures were taken. The patients were re-examined in the middle of the course of treatment and at the end of treatment, and the same tests applied. Samples of urine were obtained from a small number of patients on the last day of treatment and the antitrichomonal effect of the urine was assayed against standard cultures of trichomonads. In a few cases samples of blood serum were obtained before, during, and at the end of treatment, and the trichomonocidal effect was assayed. In many of the cases the blood haemoglobin was estimated and total white and differential cell counts were made before and after treatment.

Trichomycin

The first available supplies of trichomycin were in the form of vaginal pessaries containing 50,000 units of the antibiotic in each pessary. *In-vitro* tests of this substance against a standard culture of trichomonads showed that it was actively trichomonocidal in low concentration (Table I) and that its activity compared favourably with that of acetarsol (Table II).

TABLE I.—*In-vitro* Tests with Trichomycin

Twenty-three women were treated, each by the vaginal insertion of one pessary of trichomycin every night for 14 nights. As controls, 23 patients were treated with acetarsol, using two pessaries nightly for 14 nights. Eleven patients defaulted, of whom five were receiving trichomycin and six acetarsol. The remainder were followed for three months. Trichomonads disappeared from the vaginal secretions rapidly in both groups, but subjective relief of symptoms was more rapid in the group treated with acetarsol. One patient receiving trichomycin complained of vulval and vaginal soreness but completed the course of treatment. After follow-up for three months 17 of the patients treated with trichomycin had relapsed, eight of them within the first three

weeks following treatment. On the other hand, only eight of the patients treated with acetarsol had relapsed (Table III).

Ten women were treated systemically by giving one trichomycin tablet of 5,000 units orally three times a day for 10 days. In 9 of the 10 cases trichomonads were found in the urine before treatment, by microscopical and cultural methods. In all 10 cases trichomonads were found in the vaginal secretion, before, during, and at the completion of

trichomonal or antimonial activity was observed in the urine after doses of over 4 million units, and no increased antitrichomonal activity was discovered in the blood serum after similar doses. It is probable, therefore, that the drug is either not absorbed from the intestine or that it is metabolized in the body to an inactive compound.

Acinitrazole

This product is already available to physicians in several countries and has been widely advertised in the medical press. It is presented in enteric-coated tablets each containing 100 mg. of the active principle. The dose recommended by the manufacturers is one 100-mg. tablet three times daily after meals for 10 days.

In the first trial 10 women suffering from trichomonal infections were treated with the drug in this dosage for 10 days, and a control series of 10 women received one 5-gr. (300-mg.) tablet of calcium lactate by mouth three times daily for 10 days. In all 20 cases trichomonads were present in the vaginal secretions throughout treatment and after the completion of treatment. One patient receiving acinitrazole tablets complained of nausea and abdominal pain during treatment, which was therefore discontinued. No significant changes in the haemoglobin or white cells of the blood were noted in any of the patients at the end of the course of treatment.

It was suggested by one of the manufacturers of acinitrazole that this drug should be used concurrently with local treatment with "penotrane" (phenylmercuric dinaphthylmethane disulphonate) in vaginal pessaries. Accordingly nine women were treated with 100 mg. of acinitrazole by mouth three times daily for 10 days and one penotrane pessary vaginally twice daily. All but one of these patients relapsed within one week of completing treatment and the remaining patient defaulted after one week of follow-up (Table IV).

TABLE IV.—Results of Treatment with Acinitrazole

Dosage	No. Treated	Cures	Failures	Defaulter
Control: Cal. lactate 3 tabs. daily × 10	10	0	10	0
300 mg. daily × 10	26	0	26	0
300 " " × 10 + penotrane pessaries	9	0	8	1
Total	35	0	34	1

Finally, 16 patients (6 men and 10 women) were treated with acinitrazole in dosage of 100 mg. three times daily for 10 days. No controls were used in this series in view of the uniformly poor results obtained earlier. Trichomonads were present in the vaginal or urethral secretions, before, during, and at the completion of treatment in all 16 cases, and 10 patients (5 men and 5 women) had trichomonads in the urine, before, during, and after treatment. In 10 cases the urine was investigated for antitrichomonal activity at the end of the course of treatment, but no such activity could be demonstrated. Blood serum was examined for antitrichomonal activity in four cases, and no increased activity was detected during or at the completion of treatment.

Thus acinitrazole, although actively trichomonacidal *in vitro* (Table V), did not produce any therapeutic effect on trichomonal infections in men or women when given systemically in the dosage recommended. The drug has

TABLE V.—*In-vitro* Tests with Acinitrazole

Final Concentration	After 1 Hour		After 6 Hours		After 24 Hours	
	Micro. Exam.	Culture	Micro. Exam.	Culture	Micro. Exam.	Culture
50 mg./ml.	—	—	—	—	—	—
5 " "	—	—	—	—	—	—
0.5 " "	—	—	—	—	—	—
Control	+	+	+	+	+	+

and after treatment. Samples of urine were examined for trichomonacidal activity on the last day of treatment in four cases and all were found to be without such activity.

The dose of trichomycin was then increased to 15,000 units three times a day for 10 days. Four patients (two men and two women) were so treated. In none of these cases was any therapeutic effect apparent, and trichomonads were present in the urine or in urethral or vaginal secretions throughout the period of treatment.

In view of these disappointing preliminary results, the dosage was increased to 300,000 units a day given in the form of two tablets, each of 50,000 units three times a day for 14 days. Twenty women were treated with this dosage; 2 defaulted during treatment and 17 failed to respond to treatment, trichomonads being found in the vaginal secretions during and at the end of treatment. In the other case there were no trichomonads in the vaginal secretions at the end of treatment, but the patient then discontinued attendance. Six men suffering from trichomonal urethritis, of whom four were contacts of women under treatment, were also treated with 300,000 units of trichomycin daily for 14 days. In all six cases trichomonads were found in the urine and in urethral scrapings during and at the completion of treatment (Table III).

Samples of urine were obtained on the final day of treatment from 18 patients who had taken 300,000 units of trichomycin daily for 14 days (total dose 4,200,000 units). The urine was tested against a culture of *T. vaginalis* in 8 cases and against a culture of *C. albicans* in 10. No antitrichomonal or antimonial effect was observed in any of the samples of urine. Samples of blood serum obtained from six patients, before, in the middle of, and at the end of treatment were examined for antitrichomonal activity, and in none of the samples was any increased antitrichomonal activity detected.

Four women were treated with combined systemic and local trichomycin, each receiving 300,000 units of trichomycin daily by mouth for 14 days and one vaginal pessary containing 50,000 units inserted each night for 14 nights. All four patients had trichomonads present in the urine before treatment. The organism disappeared from the vaginal secretions during treatment but was still demonstrable in the urine by cultural methods. At the end of one month all four patients had relapsed with trichomonads present in the vagina.

It thus appears that trichomycin, although active against *T. vaginalis in vitro*, had no therapeutic activity when given systemically in high doses. Local vaginal treatment suppressed the infection temporarily, but relapses were very frequent. Serious toxic effects were not found. No anti-

been made available to practitioners and widely advertised in the medical press, and it seems very unfortunate that this should have been done without detailed clinical trials to confirm the claims made for this preparation.

Summary

Treatment of trichomonal infections by local applications has proved unsatisfactory and the nature of the disease is probably such that treatment will continue to be unsatisfactory until a remedy is found which is effective when administered systemically.

An antibiotic, trichomycin, which has not been marketed in Britain and which has pronounced trichomonacidal activity *in vitro*, was supplied for investigation. Groups of patients were treated locally, systemically, and with combined local and systemic treatment. Local treatment was not satisfactory in preventing relapse and was less effective than the standard remedy, acetarsol. Systemic treatment was ineffective in eradicating the infection in 44 cases, and tests for antitrichomonal activity were negative in blood serum from six of these patients and in urine from 12.

Acinitrazole, which is also an effective trichomonacidal drug *in vitro*, was without therapeutic activity in 35 cases treated systemically. Samples of blood serum from four patients and urine from 10 patients showed no antitrichomonal activity at the end of the course of treatment.

A plea is made that new drugs should not be put on the market and advertised to physicians until adequate trials have been carried out and the results confirmed on repetition.

We thank Mr. A. J. King for permission to publish these results and Miss Joan Whittington and Dr. J. E. Middleton for the laboratory investigations. We also thank Dr. G. R. Fryers, the laboratory investigations. We also thank Dr. G. R. Fryers, Messrs. Wyeth and Bro. Ltd., for arranging for the supplies of trichomycin and Messrs. Ward, Blenkinsop and Co. Ltd. for supplying acinitrazole. Part of this work was done on a grant from the United States Public Health Department on behalf of the working party on non-specific urethritis of the Medical Research Council.

Medical Memorandum

Stab Wound of Heart with External Bleeding and Tamponade; Suture; Recovery

Reports of successful surgical treatment of stab wounds of the heart are extremely rare in British literature, only four having been published in recent years. The following case presented certain features differing from those previously recorded.

CASE REPORT

A married woman aged 25 was admitted to hospital on August 23, 1953, having sustained a stab wound of the pericardium with a pocket-knife half an hour previously. She was extremely shocked, having bled copiously externally,

though the wound itself was small. She seemed too ill for radiological examination, but physical examination revealed no evidence of intrapleural bleeding or pneumothorax. There was a suggestion of jugular distension, but external bleeding seemed sufficient to account for the degree of shock. She was given 2 pints (1,140 ml.) of dextran followed by 2 pints (1,140 ml.) of blood in three hours. Her pulse became perceptible and was paradoxical: blood pressure was 75 mm. systolic, no diastolic reading being obtainable. Jugular distension was now definite, and there was slight peripheral cyanosis. Haemopericardium with tamponade was diagnosed; operation was decided upon and was begun four hours after admission.

Operation.—The incision was L-shaped, centred on the stab wound, which was excised. The fourth left costal cartilage, which was found to have been severed, was resected, and the pleura was entered; it contained no blood, but the pericardium was bulging, blue, and tense. On opening the pericardium much clot and fluid blood was evacuated; a 4-in. (2-cm.) linear wound on the pulmonary conus of the right ventricle was spouting blood during each systole. The heart was "palmed" in the left hand, the thumb and index compressing and controlling the wound on the anterior aspect (Sauerbruch and O'Shaughnessy, 1937). Three silk sutures tied without tension effected satisfactory closure. The pericardium was loosely approximated with interrupted catgut, and the chest wall was closed in layers, with closed drainage of the pleura for 24 hours. Immediately after closure of the heart wound the blood pressure rose to 110/70, and remained at this level without further transfusion.

The post-operative course was relatively uneventful; a slight pericardial effusion developed on the fifth day, and disappeared after a week's bed rest and systemic chloramphenicol. Six months later the patient was symptom-free and her electrocardiogram was within normal limits.

COMMENT

Contrary to popular belief, stab wounds of the heart are by no means always fatal. Although rare in Britain, this type of injury seems relatively common in America and Europe: several large series of cases treated surgically have been reported in American literature, with a survival rate of over 50%. Patients reaching hospital alive must of necessity have small wounds; research (Brockman *et al.*, 1953) has shown that large wounds are almost immediately fatal.

Blalock and Ravitch (1943) recommend transfusions at first, to raise the venous pressure and counteract tamponade. Aspiration of the pericardium is usually ineffective because of clot. Most authors recommend surgical intervention. The approach used in the above case was adequate, speedy to make, and simple to close. Wilson (1951) stresses the friability of ventricular muscle, not noted in the above case, and advises that the pericardium be left partly open to prevent recurrence of tamponade.

Most recorded cases have presented features of either tamponade or exsanguination; the first occurs if there is no free exit of blood from the pericardium, the second if such exit is present. The case reported here presented as one of exsanguination from external bleeding, and it was not until 5 pints (2,840 ml.) of intravenous fluid had been given that signs of tamponade became apparent.

I thank Mr. C. M. Pearce, under whose care the patient was admitted, for permission to publish this case; Dr. E. A. Milner, whose skill as an anaesthetist made the operation possible; and the theatre and ward staff for their co-operation and unremitting care.

Reviews

LEG ULCERS

Ulcers of the Legs. By P. Piulachs. (Pp. 574+xxv; illustrated. £5 17s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

Benjamin Bell in the preface to his book on ulcers published in 1789 wrote: "There are many surgical diseases which are neither so well understood, nor so accurately treated, as we might otherwise have expected. This seems, in a great measure, to proceed from the fame and reputation commonly acquired by success in the more capital operations of Surgery; which having a greater effect with the public than the most successful treatment of complaints not evidently of so much consequence, has naturally prevented practitioners from paying to diseases of this nature that attention which they certainly deserve." These remarks have remained true until recent years in regard to leg ulcers, although they occur so frequently and are the cause of much disability. It is true that in the eighteenth and nineteenth centuries a few monographs appeared on the subject, but only during the last few decades has interest in the condition quickened. This is partly owing to the rise of vascular surgery, which has no doubt been stimulated by the wars waged during that period. Though concerned primarily with the effects of injury and of cold, and though concentrating especially on arterial disease and the arterial supply of blood, vascular surgeons have become interested in the peripheral circulation as a whole, including its venous aspects.

Barcelona is one of the centres of vascular surgery, and the publication of the first large-scale monograph on ulceration of the legs, written by the chief professor of surgery in the faculty of that city, is of importance to all those interested in the peripheral vascular system. Professor Piulachs's book has been translated from the Spanish and suffered in the process. No doubt because of the time taken to produce an edition in English the book is already a little out of date. Most references quoted are of 1949 or earlier, and only Spanish references are as late as 1953. Cockett's anatomical investigations and the tracer studies of Helen Payling Wright, which are of fundamental importance to this subject, are not mentioned. Furthermore, the English translation is not always happy and is sometimes cryptic. Nevertheless this is an important book which gives us the author's very original views on a difficult subject, based on extensive investigations, and it opens up the European literature, some of which is difficult of access to English readers.

Three aetiological types of leg ulcer are considered—arterial, venous, and neurotrophic. The author deals first with venous ulcers, and considers at length the problem of venous insufficiency which may arise from obstruction or from valvular incompetency of a deep vein resulting from thrombophlebitis or hereditary defect. He is surely correct when he writes: "In cases complicated by a venous ulcer, it may be said that insufficiency of the deep veins is practically constant." The pathophysiology of the venous return from the lower limb is considered, and the part played by arteriovenous shunts in the aetiology of varicose veins discussed. 90% of leg ulcers are the result of thrombophlebitis. Moreover, the author believes that ulceration associated with chronic venous insufficiency should be attributed to the repeated blows of the retrograde wave of venous hypertension due to effort (as with a hydraulic ram). In the section on arterial ulcers a large variety is considered, such as those associated with arteriosclerosis, thromboangiitis obliterans, Raynaud's disease, arteriovenous aneurysms, Malta fever, perniosis, nodular vasculitis, and livedo reticularis. Polyarteritis nodosa is not mentioned as a cause of livedo reticularis.

The author's views on treatment are clearly based on great experience. It is, however, surprising to find the local application of penicillin, sulphonamides, and streptomycin

recommended. He believes that lumbar ganglionectomy is not indicated for venous ulcers, and that extirpation of the ulcer and immediate grafting is the best method of treatment. He also discusses the treatment of varicose veins, including the injection of sclerosing fluids and the stripping operation. In certain patients ligation of the popliteal or the superficial femoral vein is recommended.

This book is of value for those who take a special interest in peripheral disease rather than for the general practitioner (unless as a work of reference). It is profusely illustrated and most of the photographs are good. The author is to be congratulated on producing a book on leg ulcers which is likely to become the standard work on the subject.

S. T. ANNING.

CLINICAL PSYCHOLOGY IN THE U.S.A.

The Clinical Psychologist. By William A. Hunt, Ph.D. (Pp. 206+xii. 42s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956. *Progress in Clinical Psychology. Volume II.* Edited by Daniel Brower, Ph.D., and Lawrence E. Abt, Ph.D. (Pp. 364+vi. \$7.75.) New York and London: Grune and Stratton. 1956.

Though *The Clinical Psychologist* ostensibly deals with the training and functions of the clinical psychologist and the future of clinical psychology, a British reader will obtain very little information from it on these subjects. Psychiatric practice in America seems very different from that in this country, and the relations between psychiatrists and clinical psychologists are certainly radically different. Relations indeed seem so strained that the author has devoted most of his book to examining "the current tension between clinical psychology and medicine," saying how this tension has arisen and providing suggestions to remedy it. We are told that "in the early years of this century when psychiatry operated within an organic framework there was relatively little friction," but "as psychiatry has become the primarily dynamically and developmentally oriented discipline it is to-day" friction has arisen because psychiatrists are operating "within a framework which has little to do with the physiological, organic orientation of medicine proper" but are "more and more . . . drawing upon the formal knowledge of psychology." This leads to what one would call, in trade-union terms, a demarcation dispute, or, as the author calls it, a boundary dispute; and he is reminded of the friction between medicine and dentistry over the boundaries of the alveolar process.

The author thinks that a legitimate function of the clinical psychologist is psychotherapy, and he discusses the types of psychotherapy that he would regard as coming within his province, in both hospital and private practice. "Client-directed psychotherapy," for example, can be practised by the clinical psychologist. He thinks "it worth noting that the psychologist's incursion into the field of therapy with the ill has never extended to clearly medical techniques such as surgical [sic] and pharmaceutical interference," and that "insulin shock, metrazole, E.C.T., topectomy, lobotomy, etc.," are "techniques which the clinical psychologist is not prepared to handle." That the author should have felt the necessity to make these disclaimers indicates more clearly than any description the differences between British and American practice; and anyone who wants an insight into American psychiatry to-day will find this book fascinating.

Progress in Clinical Psychology, Volume II, follows the pattern of Volume I published in 1952, and covers developments since then over a very wide field of projection tests, psychotherapy, special applications of clinical psychology to correctional institutions, rehabilitation of the physically handicapped, statistics, and neurophysiology of higher processes. Recent progress in these fields is covered very adequately, and the book comes up to the high standard of its predecessor and will be invaluable as a work of reference. A point of interest is that the authorship of this book underlines what has been said above about the functions of the clinical psychologist in America; of the twelve chapters dealing with progress in therapy, only three are by psychiatrists.

FLIOT SLATER.

TUBERCULOSIS

Symposium of Tuberculosis. Edited by F. R. G. Heaf, M.A., M.D., F.R.C.P. (Pp. 755+xvi; illustrated. £5 5s.) London: Cassell and Co. Ltd. 1957.

With the suppression of malaria, tuberculosis has become the major public-health problem in most underdeveloped countries. A new and comprehensive volume on the subject is therefore by no means out of place. The contributions to this symposium come from 14 specialists. The emphasis is mainly on the clinical and epidemiological aspects of tuberculosis, particularly from the practical point of view. Most of the authors deal thoroughly with their subjects. In the sections on epidemiology there is a natural emphasis on the experience of this country, including perhaps more of the history of British legislation than may hold the interest of overseas readers. Nevertheless, there is an admirably sensible chapter by Dr. P. V. Benjamin on the problems of tuberculosis in the tropics. Non-respiratory tuberculosis is well covered and there is an interesting chapter on tuberculosis in animals. Research in therapy is proceeding so rapidly that, by the time of publication, most authors of textbooks will regard their views on treatment as archaic. Although in some chapters a valiant last-minute effort seems to have been made to bring the treatment section up to date, the general impression must be quite different from what the authors would now wish to convey. This is particularly true of non-respiratory tuberculosis. Nevertheless, the book contains a mass of information, and few will fail to learn a great deal from it. It would be useful in another edition if each author could summarize at the end of his chapter the main practical conclusions to be drawn from the large volume of facts he has assembled. The symposium could then become of even greater value, not only as a useful reference book, but as a practical handbook for the post-graduate student.

JOHN CROFTON.

SURGERY OF RECTUM, ANUS, AND THORAX

Operative Surgery. Under the general editorship of Charles Rob, M.C., M.Chir., F.R.C.S., and Rodney Smith, M.S., F.R.C.S. Volume 3—*Rectum and Anus—Thorax*. Part IV (pp. 96). Part V (pp. 215); index; illustrated. £5 10s. London: Butterworth and Co. (Publishers) Ltd. 1957.

The third volume of this magnum opus is composed of two parts, each of which has its own pagination. There are 96 pages devoted to diseases of the rectum and anus, and 215 pages in which are described operations on the thorax. The list of contributors includes many well-known names, and the accounts of the various operations are very concise, sometimes almost too concise. The section on operations on the heart and great vessels is of extreme importance inasmuch as many of the operations are of quite recent introduction. Mitral valvulotomy and the suture of atrial septal defects are well illustrated, and many other operations which would have astonished surgeons of the last generation are dealt with as established procedures. The standard of illustration is well maintained, but not every artist sufficiently realizes that for teaching and demonstrative purposes artistic finish is not so necessary as adequate contrast.

ZACHARY COPE.

MEDICAL BACTERIOLOGY

Medical Bacteriology, including Elementary Mycology and Parasitology. By Sir Lionel Whitby, C.V.O., M.A., M.D., F.R.C.P., D.P.H., and Martin Hynes, M.D., M.R.C.P. Sixth edition. (Pp. 540+vi; illustrated. 30s.) London: J. and A. Churchill Ltd. 1956.

It is interesting to compare the latest edition of this well-known book on medical bacteriology with the earlier editions. The essential character of the book has been preserved, but in the actual details of the wording, and even the arrangement of the chapters, little of the original is left.

The first nine chapters deal with the general properties of bacteria, sterilization, the cultivation of bacteria, methods of examining bacteria, infection and resistance, the basis of immunity, hypersensitivity, practical applications of immunology, and chemotherapy and antibiotics. The last is a new chapter which includes a short glossary of antibiotics and chemotherapeutic substances. This contains many of the newer drugs, but naturally not those which have been developed in the last year or two. On page 128 there is a table indicating the therapeutic range of chemotherapeutic substances and antibiotics. This is a useful table, though it is debatable whether it is wise to classify antibacterial drugs rigidly into bactericidal and bacteriostatic agents. Such hard-and-fast subdivisions may be comforting to some students on some occasions, but it is questionable how sound they are in principle and to what extent they should be relied upon as a guide to treatment.

In a book of this calibre, now in its sixth edition, it is disappointing to find no discussion of the great advances that have been made in recent years in bacterial genetics and chemical microbiology on the one hand and in preventive and epidemiological bacteriology on the other. There is no serious account of the bacteriological methods now available in the control of epidemics and of the kind of work carried out by an efficient Public Health Laboratory Service. The book can in fact be described as traditional in its approach. It will be found useful by many medical students and others interested in the application of bacteriology to clinical problems. In that restricted sense it can be said to give a balanced and accurate account of orthodox medical bacteriology.

R. KNOX.

ANATOMICAL ATLASES

An Atlas Illustrating the Topographical Anatomy of the Head, Neck, and Trunk. By the late Johnson Symington, M.D., F.R.C.S., F.R.S. Edinburgh and London: Oliver and Boyd for the Anatomical Society of Great Britain and Ireland. 1956.

Anatomical Atlas of the Human Brain and Spinal Cord. By Mieczyslaw Stelmasiak, M.D. (Pp. 226; illustrated. No price.) Warsaw: Polish State Medical Publishers. 1956.

The reprinting of the atlas of the head, neck, and trunk, by the late Johnson Symington, will be welcomed not only by anatomists but also by radiologists. The atlas consists of a series of 36 life-size sections of the body and seven reconstructions. All the sections are viewed from above. The reconstructions show the plane of the sections. Professor Symington is remembered not only as a distinguished topographical anatomist, but also as one who was especially interested in the use of x rays in the teaching of anatomy. His department was one of the first in this country in which an x-ray plant was installed. It is indeed appropriate that this atlas should now be found to be of great value to radiologists who wish to determine the relationships of structures as seen in transverse sections. No alterations have been made from the first edition.

The Warsaw atlas of 241 photographs and drawings is for students, physicians, and neurologists; it deals mainly with the neurology from the topographical aspect. Many of the illustrations are typical of those found in other atlases; a few are of an unconventional nature. Different types of nerve cells are clearly illustrated and labelled. An attempt has been made to make an atlas on the grand scale, but has been unsuccessful. Many of the illustrations—for example, Figs. 210, 213, and 217—are very crude and of little value. There is little new in this volume.

W. J. HAMILTON.

The Britannica Book of the Year, 1957 (Encyclopaedia Britannica Ltd., 11, Belgrave Road, London, S.W.1; pp. 532; illustrated, 6 guineas), covers the important events of 1956. It contains 29 articles dealing with medical subjects, including an account of radiation hazards, and articles on all the major specialties in the medical and surgical fields.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JULY 6 1957

NATURAL BACKGROUND RADIATION

One consequence of the increasing use of x rays and nuclear radiations in medicine, science, and industry is that human beings are now exposed to a greater dose of ionizing radiation than at any time in the past. The increment of dose above that due to naturally occurring radiation is not precisely known, but the estimates so far made have given rise to much discussion of the harm which may possibly be caused to the health of both present and future generations.^{1,2} Ionizing radiation is considered to be damaging to living tissues because when it is absorbed the energy imparted either removes an electron from an atom or at any rate so excites it that chemical change and biological damage are likely consequences. However, the significance of radiation dosage at levels approaching those of the natural background is hard to assess. Long-term genetic and carcinogenic effects are possible, but the rate in man of mutation induced by radiation is unknown, and the limited data on human carcinogenesis due to radiation relate to comparatively high dose rates and large doses. It is therefore most important at this time to compare the doses of man-made radiation with those known to be received by human beings from natural sources.

The tissues of the human body receive radiations from natural sources in two ways: from such external sources as terrestrial radioactivity and cosmic rays, and from internal radioactivity acquired by the body from air, food, and water. Under most circumstances the larger fraction of the external radiation is contributed by the local background of gamma rays due to radioactive elements in the earth's surface and in building materials. Indoors this component depends upon the construction of the building, being lowest where wood is used and highest where—for example, in some parts of Sweden and India—unusually radioactive shale or sand is used in the building materials. Although the local gamma radiation is less out of doors, its amount depends on the type of

surface rock. It can be very low over chalk and high over granite. Cosmic rays make the next important contribution to the dose of external radiation, and there is a further very small addition from radon escaping into the atmosphere from the radium in the earth's crust. The radiation dose to the soft tissues of the body from internal sources is nearly all due to potassium-40, a naturally occurring radioactive isotope present with the potassium of the tissues. Bone contains an amount of radium which is approximately known, and the radiation it receives from this source may be augmented by contributions from other naturally occurring radio-elements whose presence in bone has been postulated but not yet confirmed. In all tissues very small additional doses arise from carbon-14 and probably also from the inhalation of radon and thoron and their airborne products of disintegration.

While the tissues at risk in the genetic sense are the gonads, all the tissues of the body are presumably susceptible to the carcinogenic action of radiation. Nevertheless, scientific interest in carcinogenesis has so far centred chiefly on bone and bone marrow, though cancer induced by radiation has long been recognized clinically in the skin. The unavoidable background dose to the gonads of the inhabitants of Great Britain amounts to about 3 rad³ in a "generation" time of thirty years. Nearly 30% of this dose is due to cosmic radiation, 20% to potassium-40, and some 45% is delivered by gamma rays from local surroundings. The remaining 5% is due to the various other small sources already mentioned. Partly because the gonads are to some extent shielded from external radiation by overlying tissues, and partly because a considerable fraction of the day is spent indoors, the variation in gonad dose from one locality to another is less marked than might at first be expected. It has been shown, for example, that the inhabitants of granite houses in Aberdeen might receive about 20% more radiation than those in brick houses in Leeds, and that people living in the chalk areas of the south of England might get some 20% less. Although the evidence is incomplete, it would appear that great differences in radiation dose are not to be expected in the areas of Great Britain where most people live. On the other hand, in some types of Swedish house, in localities where the rock radioactivity is high, the average dose to the gonads may be 50% higher than in Great Britain, and in some coastal areas of India the figures may be as much as five times as great owing to a local gamma-ray background roughly ten times that in Britain. Finally, the intensity of cosmic rays increases with altitude, and at 15,000 feet the cosmic ray dose may be some six

times as great as at sea level, giving a total gonad dose over rock of average radioactivity perhaps two to three times as great.

The dose to tissues within bone is less easily determined, partly through lack of knowledge of all the natural radioactive elements present and of their distribution on a microscopic scale, and partly because radium, and possibly other elements, irradiate bone with alpha particles, the biological effect of which differs from that of gamma rays and beta particles. The dose to bone may be up to 20% greater than that in soft tissues if radium alone is present, and as much as 60 to 120% greater if bone contains the recently postulated amounts of mesothorium and radium D; the actual dose values will depend on the factors assumed for the relative biological effectiveness of the alpha particles. There is only a slight correlation between the body's content of radium and the radioactivity of drinking-water, because the main source from which radium is ingested is food. It has also been shown that very little of the radioactivity of "raw" water reaches the household tap. For these reasons the background radiations to the body tissues of inhabitants of spas are unlikely to differ greatly from the average for other parts of the country. The dose to bone marrow, which in general will not be irradiated appreciably by alpha rays from elements incorporated in mineral bones, is roughly the same as that to other soft tissues in the body. One tissue in particular is possibly subject to a greater radiation dose than others. Owing to inhalation of radon, thoron, and their decay products, the upper respiratory tract and lungs may receive about three times the dose to the gonads. But this estimate, which applies to "average" atmospheric radon and thoron levels, depends very much on assumptions about the fate of the decay products after inhalation rather than on the established fact. By comparison, the dose of radiation received by the gonads in human beings from caesium-137 at its present level (acquired from fission product fall-out) is a little less than 1% of that from the natural background. The dose to bone from the present level of strontium-90 in children (about 1 micro-microcurie of strontium-90 per gramme of calcium) is about 2% of the background dose, if the skeletal distribution is assumed to be uniform as a consequence of slow continuous uptake during bone growth.

The authors of Appendix N of the Medical Research Council's report on the hazards of radiations⁴ recommended that the maximum allowable concentration of strontium-90 should not exceed 100 micro-microcuries per gramme of calcium, and suggested that immediate consideration of the stron-

tium-90 hazard would be needed if the body burden of this fission product rose to ten times its level in 1956. Their conclusions were based chiefly on the human evidence gained in cases of radium poisoning and not directly on considerations of dosimetry. The implication, however, is that the proposed maximum allowable concentration corresponds to a dose rate of about 200% above background radiation, and that the risks would need to be carefully reconsidered if the dose rate to bone increased by 20%. The main finding of the report is that the total dose of man-made radiations to the gonads should not exceed twice that from the natural background. Usually an increase in the dose to the gonads will be accompanied by a similar increase in the dose to bone, and therefore a maximum increment to the gonad dose of twice the background dose implies an increment of the same order to the bone dose. The dose rate to bone corresponding to the maximum permissible level for strontium-90 thus agrees with the dose rate to bone implied by the recommendation on the maximum permissible gonad dose, and the level at which the need for reconsideration is suggested corresponds to an increase in dose rate of about 20% above the background dosage. Many problems on the effects of radiation on man wait to be resolved, but the elucidation of the role which background radiation has played and is playing in human evolution promises to be one of exceptional significance to his well-being.

TUBERCULOSIS IN LABORATORY WORKERS

Accidental infection in the post-mortem room or laboratory is a special risk to pathologists. Indeed, a notable number of them have succumbed to it, and only recently has it become compensatable under the Industrial Diseases and Injuries Act. Certain specific infections, such as streptococcal septicaemia among pathologists and rickettsial and brucella infections among bacteriologists, are known to present particular hazards, possibly owing to the small infective dose and high incidence of the pathogens concerned. Tuberculosis as a laboratory infection has been a controversial subject among pathologists, but because this infection is common in the general community an association between it and the laboratory has been difficult to prove. The chemotherapy of tuberculosis, requiring the cultivation of sputum and other suspected material for diagnosis and sensitivity testing of the tubercle bacilli, has introduced fresh dangers, as has the greatly increased activity in the field of experimental tuberculosis.

¹ *British Medical Journal*, 1956, 1, 1472.

² *Ibid.*, 1957, 1, 752.

³ The "rad" is the unit of absorbed dose of any ionizing radiation and is defined as 100 ergs per gramme of tissue; the röntgen, commonly used in radiology, is approximately equivalent to 100 ergs/g. of aqueous tissue irradiated by "hard" x rays and gamma rays, but the actual value depends upon the quantum energy of the radiation.

⁴ *The Hazards to Man of Nuclear and Allied Radiations*, Medical Research Council, H.M.S.O., 1956.

The time seemed ripe for an objective assessment of tuberculosis as an occupational hazard for the laboratory worker, and Dr. D. D. Reid, with encouragement from the National Association for the Prevention of Tuberculosis, has undertaken the task. His report appears at page 10 of the *Journal* this week. He first analysed the claims for additional sickness benefits under the Health Service and found that pathologists, like chest surgeons and chest physicians, had claim rates for incapacitating pulmonary tuberculosis greatly in excess of other medical men, while laboratory technicians had much higher rates than other medical auxiliaries. Because of possible fallacies in these data Dr. Reid next sought the help of pathologists and bacteriologists in obtaining information by a carefully planned questionnaire about the incidence of tuberculosis among scientific and technical staff in the hospital laboratories of the N.H.S. and in the Public Health Laboratory Service during the five years 1949-53. Analyses of the collected data showed that the incidence of incapacitating pulmonary tuberculosis was, for different laboratory categories adjusted for age and sex, two to nine times greater than the corresponding national notification rates. Similarly, the rates for pulmonary tuberculosis among pathologists and technicians were shown to be two to three times greater than the notification rates for Post Office groups of similar social and economic status.

The possibility was examined that these adverse rates might be due to such factors as overcrowding in the laboratories, poor physique of the pathologists, and more complete notification rather than to environmental exposure from handling tuberculous material, but these factors were not found to operate significantly. The increased incidence of tuberculosis among laboratory staff reaches its peak two to three years after entry, and there is a suggestion of an increasing hazard in recent years.

If, then, this environmental hazard is accepted, we need to examine the technical procedures to find where the danger lies. Two recent studies have indicated new and unexpected sources of infection. It is known that only very fine particles, of 5 μ diameter or less, can reach the lung parenchyma, and as this is the most likely mode of infection in pulmonary tuberculosis any fine spray or aerosol released during laboratory manipulations of tubercle-infected material might be dangerous. This hazard, as Dr. A. J. H. Tomlinson shows in the *Journal* this week (p. 15), may be associated with the opening of the screw-capped bottles which are commonly used for the collection and homogenization of tuberculous

sputum and as containers of medium on which to cultivate tubercle bacilli. Apparently the film of fluid round the rim of the bottle can easily be contaminated when a slope of culture medium is being inoculated; the bacteria grow in this unusual site during incubation of the medium, and when the cap is unscrewed a shower of fine infective particles is released. Another hazard has been described by F. Whitwell and his colleagues,¹ who found that when screw-capped bottles which might contain homogenized tuberculous sputum are spun in an angle centrifuge a spray of material is distributed over a distance of 3-4 ft. (1 metre) from the machine. It seems that the rim of the bottle is again the source of danger, but in this case the fluid collects between the outside threads of the tube and the screw-cap. With both the angle and the swing-out centrifuges the outside of the bottle and the bucket become contaminated during centrifugation.

There are other hazards in handling tuberculous material, some of them recognized—for example, the spray that follows incisions into tuberculous lesions and the cage dust of tubercle-infected laboratory animals—but others are doubtless undetected. In America special studies have been made of laboratory hazards and documentary films have been prepared to illustrate them. Pathologists need to be made fully aware of these dangers so that specific precautions can be taken, in particular against tuberculosis. All new laboratory staff should be tuberculin-tested and B.C.G. vaccination offered to the negative reactors; they should have chest x-ray examination on entry and at regular intervals afterwards; and only experienced staff should handle suspected tuberculous material, preferably in a separate room and, when appropriate, under a hood. Our pathological services, perhaps the finest in the world, offer satisfying careers to scientific and technical staff. We must take care to preserve the health of those who serve in them.

ALLERGIC VASCULITIS

Some work of great interest to clinicians has recently been reported by R. P. McCombs, J. F. Patterson, and H. E. MacMahon.¹ They describe a group of thirty patients in whom the presence of vasculitis was established during life by skin or muscle biopsy or both. In none of these thirty cases has it been necessary as a result of prolonged clinical observation or post-mortem study to change the diagnosis to diffuse lupus erythematosus or polyarteritis nodosa, though the symptoms were sometimes similar and the pathological features have points in common. In view of the frequent occurrence of vasculitis in conditions

known to be due to hypersensitivity, they call the condition "allergic" vasculitis, leaving the word "allergic" in inverted commas because proof of an allergic response as the basis of the vasculitis is not always found.

In reviewing the literature leading up to their own study, McCombs and his colleagues trace the evolution of present-day knowledge of the vascular changes met with in allergic states from the observation of E. L. Opie² in 1924 that vasculitis occurred in the Arthus phenomenon of sensitized animals. Other workers then observed vasculitis in such diverse conditions as diffuse lupus erythematosus, experimental serum sickness, polyarteritis nodosa, dermatomyositis, and thromboangiitis obliterans. P. M. Zeek³ considered that a variety of different conditions were being erroneously labelled as polyarteritis nodosa and proposed the term "necrotizing angiitis" to embrace vascular lesions characterized by fibrinoid necrosis and inflammatory reactions involving all three coats of the vascular wall. She recognized five types of necrotizing angiitis, one of them being "hypersensitivity angiitis." In her own patients this diagnosis implied a rapidly downhill course, with death occurring within one month. By contrast with Zeek's patients, only four of the 30 observed by McCombs and his colleagues have died, all because of renal failure. Of the remainder, fifteen have completely recovered, the causative factor having been recognized and eliminated in twelve of them. Another seven patients were wholly relieved of symptoms by cortisone; but relapse occurred in five of them after stopping this therapy, and maintenance treatment has been found necessary. Of the remaining four patients, three continue to have symptoms due to irreversible changes produced by the vasculitis, and one suffers from urticaria which is controlled by antihistamines.

These thirty cases were found by carrying out biopsies of skin and muscle as diagnostic procedures in patients with obscure diseases. The symptoms associated with the finding of vasculitis on biopsy were diverse, and patients showed one or several of the following features: arthralgia, purpura (sometimes associated with gastro-intestinal haemorrhage), oedema, fever, loss of weight, pleurisy or pneumonitis, subcutaneous nodules, dermatitis, muscle tenderness, urticaria, and neuritis. The laboratory findings were also diverse. Anaemia occurred only in those patients who had uraemia or gastro-intestinal haemorrhage.

⁴ Polley, H. F., *British Medical Journal*, 1956, 2, 1253.

⁵ Hargraves, M. M., Richmond, H., and Morton, R., *Proc. Mayo Clin.*, 1948, 23, 25.

⁶ Harvey, A. M., Shulman, L. E., Tumulty, P. A., Conley, C. L., and Schoenrich, E. H., *Medicine (Baltimore)*, 1954, 33, 291.

Leucocytosis was uncommon and leucopenia did not occur. Eosinophilia was common, but was severe in only four patients. More than half the patients showed a raised erythrocyte sedimentation rate, in some cases above 100 mm. in 1 hour (Westergren). A third of the patients had abnormal serum proteins, usually with a rise of globulins and fall of albumins. Haematuria and albuminuria were noted in eleven patients, and in six of these renal failure developed. In the twelve cases in which a definite causal factor could be recognized and removed, drugs and antibiotics were the most common offending agents, followed by infections; in one case a malignant tumour was the cause.

Cortisone and other adrenal steroids had an almost specific effect on the vascular lesions and promoted healing and sclerosis, the only cases with a bad prognosis being those with renal damage. However, cortisone itself may act as an antigen if given for long periods, and "allergic" vasculitis is one of its complications. H. F. Polley⁴ recently described in this *Journal* five such cases in an article on the present therapeutic status of cortisone; he included a photomicrograph of characteristic panarteritis found on muscle biopsy in a patient with rheumatoid arthritis who was experiencing severe hypercortisonism. In these circumstances, when cortisone is the offending agent, it is its removal which is beneficial.

Not everybody will agree with McCombs and his colleagues in distinguishing this group of patients as a unity because they showed evidence of vasculitis. Nevertheless, for the practising physician the implication of their work is plain. It is that skin and muscle biopsy should be carried out in a variety of obscure illnesses, so that if vasculitis is found treatment with cortisone can be given and the causative agent sought with a view to its elimination. It is possible that these cases are quite common, for in the last decade the numbers of patients diagnosed as suffering from diffuse lupus erythematosus have greatly increased since M. M. Hargraves and his colleagues⁵ described the characteristic L.E. cell (lupus erythematosus) phenomenon and thus furnished a simple test for its recognition. Furthermore, we have learned that diffuse lupus erythematosus does not carry so gloomy a prognosis as was once thought, provided the diagnosis can be made before renal damage is severe and provided corticoid therapy is promptly and adequately administered.⁶ In the nineteenth century the morbid anatomist was responsible for great advances in medical progress by his post-mortem studies. In the present age he can contribute greatly to early diagnosis and effective treatment if he is provided with suitable biopsy material.

VACCINATION AGAINST INFLUENZA

From the very extensive laboratory and field work on influenza during the past thirty years it seems that vaccination is the only method of control that offers any hope of success. The results of vaccine research, bedevilled by repeated antigenic variations in virus A and by practical difficulties in clinical assessment, have been disappointingly few and not straightforward. Most of the successful trials have been those in which the vaccine used was prepared from a virus strain antigenically similar to that causing the epidemic; and most of the failures have been associated with vaccines not meeting this requirement. If virus A is capable of infinite variation there is little chance of producing from an epidemic strain enough vaccine to protect more than a small proportion of the population in the short time available. That there is any chance of this at all is mainly due to the rapid identification of new viruses and exchange of epidemiological information made possible by the World Health Organization. A more hopeful hypothesis favoured by T. Francis and other American workers is that the degree of variation in virus A so far observed represents a rearrangement of components rather than a complete gain or loss of basic constituents. On this assumption a satisfactory vaccine with wide application might be prepared from a number of different strains selected to cover as many antigenic components as possible. Comparison of this type of vaccine with one prepared from a single recent virus strain has been a principal objective in recent field trials undertaken by the Medical Research Council and reported in the opening pages of this issue. During the small epidemic of 1955-6 similar protection was given by both types of vaccine. However, the virus responsible for the epidemic was neither identical with that in the monovalent vaccine nor entirely different from one of the strains (F.M.1) included in the polyvalent preparation. The question is therefore still unanswered, but the ideal opportunity for investigating it may soon occur, though not in time to help in the present difficulty.

The report confirms further confirmation of the economy in antigen made possible by emulsified vaccines containing mineral-oil adjuvant—about ten times as many doses being obtained from a given virus pool. Unpleasant local reactions have been experienced with some batches of oil-adjuvant vaccine, but this trouble may now have been overcome, and in a real emergency this slight risk could probably be neglected. Another possible means of economy is the nasal instillation of vaccine containing killed or living attenuated virus. The method has been tried extensively in Russia and Poland; though promising, it is unlikely that it could be of immediate practical value in this country.

So long as the present epidemic of Asiatic influenza remains mild, vaccination is unnecessary and perhaps even unwise. But should the disease show signs of increasing virulence, how much could then be expected from a vaccine? Although the assessment of a polyvalent vaccine containing older virus strains remains an important object of research, present efforts are presum-

ably being concentrated on the manufacture of vaccine from Asiatic virus. It is too soon to say how suitable the strains isolated so far will be for vaccine production, and the rate at which vaccine could be manufactured if all available resources were used is quite uncertain. But unless exceptional steps are taken it seems doubtful whether the needs of even priority groups in Britain could be met before the end of the year. There are no better grounds for optimism in forecasting the protective value of the vaccine. Success in the past may have been achieved because those vaccinated had been infected at an earlier date with similar virus; no such secondary response can be counted on in the present situation. Another disturbing possibility is that a change in virulence might be associated with a further antigenic change in the virus, against which even vaccine containing Asiatic virus might be useless. Even so, assuming the trial vaccines made from Asiatic virus pass their preliminary tests, it would be only prudent to make plans for emergency manufacture on a large scale.

AMERICAN POLIO VACCINE BANNED

Last week the Minister of Health announced¹ that he had "accepted the expert medical advice that Britain should not run the risk of importing poliomyelitis vaccine." He was thus obliged to dispose of an issue that is at once technically complex and of great moment to many people, especially to those living in areas where poliomyelitis is at present on the attack. The decision overrides the wishes of many private individuals, a few of whom are known to have obtained supplies of vaccine from the U.S.A., and is not in conformity with the views of at least some medical men who have a knowledge of the facts. Obviously no Government action is going to please everyone, and medical men have a cherished reputation for differing among themselves, but a full explanation ought to accompany an important decision that may affect the health of many, and makes it impossible for doctors to provide protection against poliomyelitis for those of their patients for whom British vaccine is not available.

To be effective in the earlier part of this summer, any American vaccine imported would have to be used without being tested in Britain. While it would be up to the standards imposed by the U.S. public health authorities, there are risks in using it here, discussed in these columns a month ago.² The tests which it undergoes are said not to be so strict as those imposed in Britain, or not so rigorously controlled, and an additional risk lies in the use of the Mahoney strain for the type-1 antigen instead of the Brunenders strain as in Britain. Again, the antigenic potency of some batches of American vaccine has been too low; 6 million doses recently had to be withdrawn because the batch failed to meet minimum requirements, for instance.³ The British vaccine is in several ways a more desirable product (though not every batch of that has passed its tests), but there is

¹ *The Times*, June 27, 1957.
² *British Medical Journal*, 1957, 1, 1229.
³ *Ibid.*, 1957, 1, 1537.

not enough of it at present. The individual doctor or parent therefore asks himself, with some reason, why the Government forbids the importation of a vaccine which, whatever its failings, has been given in well over 100 million doses with hardly any serious ill-effects—certainly fewer than are accepted as the inevitable risk of vaccination against smallpox. The apprehensions that stir the public mind, and the doubts among medical men about the pros and cons of the American vaccine, are unlikely to fade away in response to a few brief remarks from the Minister of Health when he opened the annual conference of the National Association for Maternity and Child Welfare.

Importation of poliomyelitis vaccine is subject to the Therapeutic Substances Act, 1956, which provides that a licence must be obtained from the Ministry of Health. It may be presumed that the Ministry would not grant a licence to a private individual seeking one, so a virtually complete ban on the American vaccine exists in this country. While we realize that the Minister must accept the medical advice given to him, he must nevertheless be aware of the anxiety that is widely felt on this issue. The medical profession has a right, we submit, to know just what was the expert medical advice that bans the importation of the American vaccine—a ban that prevents doctors giving apparent protection against poliomyelitis to those of their patients not able to receive the British vaccine because it is in short supply. It is difficult to believe on the evidence available that the safety of poliomyelitis vaccine as used now in the U.S.A. is seriously questioned. If its antigenic potency is in doubt, some doctors might well like to give their patients the benefit of this doubt.

NURSES' EXAMINATIONS

In a profession where devotion counts for so much, as it does in nursing, the problem of intellectual standards is inevitably controversial when candidates are fewer than the country needs. Since the only measure of a candidate's intellectual ability commonly available is her school record, some weight has to be attached to the exams she passed or did not pass there. Training schools vary in the academic requirements they demand of candidates applying for entry to them. Some require the general certificate of education in two or three subjects, for instance, while others do not insist on the possession of it—though they might prefer to do so. It seems a natural conclusion that girls with the general certificate would, on the whole, do better at the nursing exams than girls without it. Their ultimate quality as nurses might not be so readily forecast, but now it seems to be fallacious to assume even that they do better in the exams.

The results of an investigation in the Oxford area, published last week,¹ are surprising. A. Barr, I. James, and Honor M. V. Smith obtained data from four training schools, and found that students without school certificates passed the final of the State preliminary examina-

¹ Barr, A., James, I., and Smith, H. M. V., *Monthly Bull. Minist. Hlth (Lond.)*, 1957, 16, 94.

tion in less time than those with school certificates. They also found, tentatively, that older students on the average completed their finals more quickly. The authors conclude that "the lack of entrants to nurse training schools with school leaving certificates is frequently lamented, but if the results of this survey are typical it would seem that those holding school leaving certificates do not have any outstanding advantages over those with no certificates."

As many other investigators of nurse training have done, these report a high rate of wastage during the training course. It amounted to about 10% a year, giving a loss of about 30% in three years, and they pick out two main remediable causes of this loss. The first is ill-health, "which appears to be widespread." In four years about 9% of those who left went for that reason, and many people would agree that more care of these students' health is needed. The second is home-sickness and other vague though related complaints. Nearly 40% of the leavers were in this category. It no doubt included some who, on gaining a knowledge of nursing, came to the conclusion they had made the wrong choice of career. Among these were probably most of those students who gave dislike of hospital discipline as their reason for leaving. But among other reasons given were poor social and recreational facilities, food, and the volume of domestic duties they were required to undertake.

THE MEETING AT NEWCASTLE

Next week Newcastle will see the beginning of the Annual Meeting of the B.M.A. Notwithstanding the two recent Special Representative Meetings in London, the agenda of the A.R.M. (see last week's *Supplement*) is a long one, and Dr. Ian Grant, the chairman, is likely to have his hands full for the five days allotted to the meeting. On Monday, July 15, Mr. Weldon Watts will deliver his presidential address, and on the following day the scientific sections will begin their work in earnest. Several distinguished medical men from Canada, the U.S.A., and Sweden will be taking part in the discussions, and there will be many representatives from overseas Divisions and Branches and delegates from kindred associations all over the world.

Apart from the plenary sessions, round-table conferences, and section meetings, there will be a number of scientific diversions. Pride of place among these must be given to the annual scientific exhibition, with 37 exhibitors this year. The exhibition of pharmaceutical products is sure to be a popular place for those with half an hour or so to spare, for the manufacturers always put on a lively display from which much can be learned. A novelty this year will be a series of closed-circuit colour television programmes, and there will also be several showings of films from the B.M.A. film library. In fact there is so much to hear and see and do that visitors will have a difficult choice in deciding which meetings and social functions to attend. But whatever they decide they can be certain of a warmly hospitable welcome from their colleagues in Newcastle.

TUBERCULOSIS IN RUSSIA

MOSCOW MEDICAL CONGRESS

[FROM A SPECIAL CORRESPONDENT]

The Sixth All-Union Congress of Tuberculosis was held in Moscow from June 9 to 16. It was attended by more than a thousand specialists from the U.S.S.R. and by about sixty foreign physicians from more than twenty countries, including four from the United Kingdom. Simultaneous translation was provided into English and French, and we were given English summaries of the main papers. We were able to supplement what we learnt about Soviet methods in the conference proper by visits to institutions and private discussions with our Russian colleagues.

Tuberculosis Services

The Congress dealt with the organization of the tuberculosis services in Russia, and the epidemiology, prevention, chemotherapy, and surgery of the disease. The primary unit in the tuberculosis services is the dispensary or chest clinic, which undertakes prevention, diagnosis, and treatment. In Moscow, at least, this service is highly developed, dispensaries serving populations of 100,000 to 300,000 people, an individual doctor within the dispensary being in charge of a sector of about 30,000. In general a dispensary has up to 100 beds of its own, from which most patients are sent on to sanatoria or, in difficult cases or in those requiring excisional surgery, to hospital. When the patient resumes work, at first part-time, he spends the remainder of the day at a "day sanatorium" attached to the dispensary, where he receives meals and possibly also chemotherapy. Miniature radiography is used on a large scale; 49 million people were x-rayed in the U.S.S.R. in 1955, and about a million in Moscow in 1956. A yearly chest x-ray examination is compulsory for teachers and others dealing with children, and for food-handlers, shop-assistants, and bus-conductors, among others. Schools, factories, and offices are regularly covered, but community surveys, we understood, are only now being undertaken. B.C.G. is given extensively to infants, children, and adolescents; some six million received the vaccine in 1956.

A number of delegates from the peripheral republics made it clear in their contributions, however, that they lagged considerably behind the standards of the more highly developed areas. In general the type of organization aimed at seemed to be that already outlined, though there were suggestions of local variations such as treatment centres attached directly to collective farms. In the better centres brisk percentage falls in mortality and morbidity were reported. In the whole U.S.S.R., hospital deaths were said to have decreased by 30% since 1949 and new cases by almost the same amount. Few actual rates were mentioned. In conversation this was attributed to the fact that there has been no census since 1939 and the size of the population is uncertain. One mortality rate of 42.1 per 100,000 for 1954 was reported from Lithuania, and, in conversation, an estimated and unofficial mortality rate of 20 per 100,000 for Kiev in 1956. When we visited a dispensary in Moscow we were given absolute figures and rates for a district with a population of 300,000 containing the university and many factories. Mortality had fallen from 57 per 100,000 in 1949 to 14 in 1954 and 13 in 1956. Morbidity had shown a remarkable reduction from 905 notifications in 1949 to 235 in 1956.

Oral B.C.G. and "Phthivazide"

Discussion on prevention mainly centred in B.C.G. and its methods of application. Oral vaccination is extensively practised in infants. Older children are vaccinated intradermally. A total of 6 million were vaccinated in 1956. One of the points discussed was the possible application of the method of large and repeated oral doses advocated by Brazilian authors. Trials of this technique were in progress, but it did not appear that any firm conclusions had yet been reached. No controlled trials seemed to be in progress.

The discussion on chemotherapy lasted about two days. In Russia isoniazid is seldom used, being replaced by "phthivazide," a drug with comparable effect, approximately twice the molecular weight of isoniazid, and given in doses of 1-2 g. a day. The rather surprising merit claimed for phthivazide is its lesser toxicity. In general the speakers were employing combined therapy; usually daily phthivazide with P.A.S., thiosemicarbazones, or intermittent streptomycin. Recently many centres have begun using "prolonged" chemotherapy, which in most cases seemed to consist in treatment continuing for from four months to a year, seldom longer; the results appeared to be commensurate. These sessions were remarkable for an admirable review of potential drugs for tuberculosis by Professor PERSHIN, of the Institute for Chemical Pharmacy in Moscow, and a brilliant summary of United States practice by Dr. CORWIN HINSHAW.

In the sessions on surgery it appeared that resection was now being used extensively, and with considerable success, in the larger centres. Series were reported with low mortalities and a high proportion of satisfactory results. Extrapleural pneumothorax seems to be fairly often employed. A much wider use of surgery was advocated. Incidentally artificial pneumothorax, though less popular than formerly, is still employed far more frequently than in Britain; for instance, in 34% of admissions to one Moscow sanatorium in 1956.

General Impression

To sum up, it was clear that in the U.S.S.R., at least in its more highly developed areas, preventive measures are being more intensively applied than in Britain. Considerable progress is being achieved in reduction of morbidity as well as mortality. On the other hand, our Russian colleagues have something to learn from us in therapy. Scientifically some experimental work appeared to be good, especially in the preparation of new drugs and their experimental use in animals. In the techniques of clinical research in tuberculosis Britain is probably ahead of other countries, and certainly the U.S.S.R. could benefit from our experience.

The standard of hospitality was of the highest order, and we particularly valued the opportunities for informal discussion with our Russian colleagues.

HORMONE STUDIES

[FROM A SPECIAL CORRESPONDENT]

Here are recorded a selection from the papers read at the recent meetings of the Endocrine Society and the American Diabetes Association, held in New York from May 30 to June 2. The papers have been grouped by subject and are not necessarily in the order of their delivery.

Studies on Diabetes and Insulin

At the Diabetes Association's meeting Dr. S. A. BERSON and Dr. R. S. YALOW (New York) reported their further investigations on insulin antibodies produced by insulin administration. The sera of most diabetics who had received insulin for periods longer than three months contained these antibodies, and studies on the kinetic aspects of the insulin-antibody reaction showed, they said, that there were at least two types of insulin-antibody complex. Drs. H. RIFKIN and S. LIEBERMAN (New York) discussed the role of the adrenal cortex in diabetic retinopathy and nephropathy. A series of 30 patients with these diabetic complications had been studied by means of blood and urinary corticoid estimations, including the response to corticotrophin, and by following the fate of intravenous hydrocortisone. No clear evidence of increased adrenal cortical activity was found in these cases. The effect of experimental kidney disease on induced diabetes in rats had been studied by Dr. N. KALANT and his co-workers (Montreal). They presented evidence in support of the view that the nephrotic syndrome led to improvement in the diabetes and a

reduction in insulin requirement. The reason for this was not known, but it was not due to a decrease in food intake or to increased insulin sensitivity.

Insulin labelled with radioactive iodine (^{131}I) has been used as a tracer of insulin metabolism, but Dr. G. W. SCOTT and his co-workers (Baltimore) suggested that it had marked limitations as an accurate tracer. Changes in the insulin molecule occurred during iodination which resulted in altered behaviour on electrophoresis, and the turnover rate determined from previous studies was probably incorrect. By the techniques they used the biological half-life of insulin was about 24 minutes and its space of distribution, 26% of body weight, approximately the same as that of the extracellular fluid.

Studies on insulin metabolism were also reported at the Endocrine Society's meeting. Dr. G. W. THORN's group from Boston drew attention to the marked and rapid rise of adrenaline in the plasma following the intravenous administration of insulin. However, in patients who received intravenous insulin for longer than two to three weeks this response was gradually extinguished. No explanation for this finding could be offered.

Evidence that glucose circulates freely between intracellular and extracellular fluid in the liver was presented by Dr. G. F. CAHILL, jun., and his colleagues (Boston). They concluded from their studies that the current concept of insulin exerting a peripheral action on the penetration of glucose into the cells was inapplicable to its action in the liver.

Interrelationships Between Thyroid and Adrenals

Among the other papers at the Endocrine Society's meeting there were several on the relationships between the thyroid and adrenal glands. A group of workers from the University of Minnesota reported that, in dogs, the peripheral catabolism and adrenal secretion of 17-hydroxycorticoids were accelerated by analogues of thyroxine. They showed that the intravenous administration of triiodothyroacetic acid significantly increased the output of 17-hydroxycorticoids in the adrenal vein within an hour of its injection. The response was of the magnitude of the adrenal secretory response to exogenous corticotrophins. Dr. N. B. ACKERMAN and his co-workers from Detroit discussed the effect of hydrocortisone on thyroid secretion. Forty-eight hours after the administration of radioactive iodine (^{131}I), serial blood samples for protein-bound iodine were obtained from the femoral arteries and thyroid veins of dogs. Infusion of hydrocortisone produced no appreciable change in the levels of protein-bound iodine in the thyroid vein, while infusion of thyrotrophin (T.S.H.) accelerated its release from the thyroid. However, if hydrocortisone was infused during the period of action of the thyrotrophin, the output of thyroid hormone was diminished.

Dr. E. KNÖBL and Dr. J. B. JOSIMOVICH (Boston) reported studies on pregnant rats whose thyroids had been inactivated by propylthiouracil. The administration of thyroxine and triiodothyronine prevented the formation of goitres in the foetuses, a finding that indicated their transfer across the placenta. Thyroxine was twice as effective as triiodothyronine, which suggested special facility in the former's placental passage. Dr. R. E. PETERSON (Bethesda) reported that in myxoedema, despite normal pool and plasma hydrocortisone levels, the metabolism of infused hydrocortisone was delayed, but after thyroid therapy its rate of metabolism reverted to normal.

Oestrogen Metabolism, Growth Hormone, and Hypoparathyroidism

Dr. A. A. SANDBERG and Dr. W. R. SLAUNWHITE (Buffalo) discussed the metabolism of oestrogens. The metabolites of oestrone or oestradiol were re-excreted in large amounts in the bile and continuously reabsorbed from the intestine, whence they were re-excreted in the bile or urine. This hepato-enteric circulation was a significant cause of their slow urinary excretion. Dr. H. MILLS (Bethesda) spoke on hydrocortisone metabolism in pregnancy. He presented

evidence that during pregnancy circulating hydrocortisone was not metabolized by the liver at a normal rate. He thought the increased oestrogen secretion of pregnancy was a causative factor, as a similar change could occur in subjects given oestrogen during cortisone administration.

The effect of human growth hormone in hypophysectomized patients was described by Dr. O. H. PEARSON and his co-workers (New York). A preparation of growth hormone from human pituitaries was administered to three women with secondary deposits in their bones from breast cancer whose disease appeared to be in remission following hypophysectomy. Growth hormone induced prompt and sustained nitrogen retention, as well as retention of phosphorus and potassium in amounts commensurate with tissue synthesis. In one patient there was a rise in urinary calcium and a deterioration in her clinical condition.

Dr. S. LITVAK and his colleagues (Boston) reported that, in some post-operative hypoparathyroid patients on vitamin D, the urinary calcium was quite high (165 to 491 mg. per day) in spite of the serum calcium remaining low. Investigation suggested that vitamin D might lower the renal threshold for calcium excretion. The speaker emphasized that the resulting hypocalcaemic hypercalciuria constituted a serious complication in the treatment of hypoparathyroidism.

LEUKAEMIA AND GENETIC HAZARDS FROM RADIOTHERAPY

[FROM A SPECIAL CORRESPONDENT]

A most successful innovation at the annual meeting of the Faculty of Radiologists this year was a panel discussion by the therapy section on "Genetic and Leukaemogenic Hazards of Radiotherapy." Dr. CONSTANCE WOOD was in the chair for this session, which was held at the Royal College of Surgeons on the first day of the meeting, June 21. The Faculty met for two days under the presidency of Dr. WHATELY DAVIDSON, of Newcastle upon Tyne.

Ionizing Radiations and Leukaemia

In reply to the opening question by Professor B. W. WINDEYER (Middlesex Hospital), who acted as question-master, Dr. W. M. COURT BROWN (M.R.C. Group for Research on the General Effects of Radiation, Edinburgh) said that from the evidence of the Japanese atomic bomb casualties, the apparently high death rate amongst radiologists, and the recent survey of patients irradiated for ankylosing spondylitis it must be accepted that ionizing radiations were leukaemogenic. Population surveys showed that the incidence of leukaemia was higher in those who had been irradiated, though the parts played, if any, by diagnostic and background irradiation were difficult to assess. Evidence on this was unlikely to be available for some time; at the least a 10-year survey of a population of 50,000 would be needed, particular attention being paid to lower dose levels than those studied so far. For the present, one was forced to extrapolate from curves for leukaemic patients.

Dr. J. D. ABBATT (General Electric Company) referred to the finding that the incidence of leukaemia in 13,000 patients with ankylosing spondylitis treated by irradiation was ten times higher than that in the unirradiated population. But it was hard to gauge the effect of background dose, and further study of the aetiology of leukaemia would be required before the part played by irradiation in its production could be fully understood. Dr. Court Brown thought that leukaemogenesis was purely a question of mutation, that there was no threshold dose for it, and that a latent period of 3 to 4 years occurred after stimulation before the malignant cells proliferated. Neither he nor Dr. ALICE STEWART (Oxford) thought that the latent period was related to the age of the patient. Dr. Court Brown presumed that the greater the volume of red marrow irradiated the greater the risk of leukaemia; and, although not ruling out the possibility, because of the scarcity of data, he did not believe

that ankylosing spondylitis in itself was associated with a raised incidence of leukaemia. Dr. Abbatt, however, was not yet satisfied about the absence of any relationship, irrespective of treatment, between certain types of "rheumatism" and leukaemia. Dr. Alice Stewart suggested that all benign conditions for which patients are sometimes treated by irradiation should be reviewed to make sure that such therapy carried no extra risk of leukaemia.

Gene Mutation

Dr. ALMA HOWARD (B.E.C.C. Radiobiology Unit, Mount Vernon Hospital) said that in animals and plants gene mutation was proportional to the dose of ionizing radiation. The fact that gene mutation had not been demonstrated after radiotherapy in man did not invalidate the view that it could occur. If leukaemia was induced by somatic mutation, then it was likely to be proportional to a dose higher than the first power, possibly to the square of the dose. It was also important to determine whether or not chromosome mutations were produced by radiations of higher densities than those of x or gamma rays such as neutrons or protons.

The irradiation of males and females was genetically equally hazardous, though permanent sterilization occurred at lower doses in females than in males. Over the population as a whole the average dose to the gonads from radiotherapy was only a few per cent. of the natural background dose; but the effective *genetic* dose must be very much less, since a high proportion of patients receiving radiotherapy had a low reproductive capacity on account of the nature of their disease and its often fatal outcome. The hazard was certainly smaller than that due to many other procedures. Provided reproductive potential was equal, the genetic effects of dosing one person with 500 r were the same as exposing 500 people to 1 r.

The cytological type of leukaemia induced by irradiation was also of interest, Dr. Howard continued. Chronic lymphatic leukaemia was uncommon among those exposed to the atomic bombs in Japan, though this was also true of the Japanese race as a whole. In Dr. Court Brown's own series there was a deficiency of this type of the disease, and Dr. Stewart had no cases to report in children. It was, however, difficult to believe that irradiation of lymphatic tissue would not produce leukaemia.

Referring to reports from Chicago of carcinoma being induced by irradiation of the thyroid, Dr. COURT BROWN said that he had found no case of carcinoma in a series of between four and five hundred thyrotoxic patients treated by radiotherapy, but he did not state the duration of their follow-up. Dr. STEWART mentioned that in the years 1953-5 not a single case of carcinoma of the thyroid gland in children under the age of 10 had been notified in Great Britain. Dr. L. H. GRAY (B.E.C.C. Radiobiology Unit, Mount Vernon Hospital) reminded members of the panel that some carcinogenic effects of ionizing radiations were dependent upon their association with certain irritants. A combination of both these factors might be essential for the induction of cellular changes. Many chemical substances on their own were not only carcinogenic but also strongly mutagenic.

Dr. RHYS LEWIS (Colchester) raised the point that the total dosage from background radiation received by man throughout his evolution must be very high, and, by comparison, his therapeutic dosage relatively insignificant. In reply Dr. M. W. B. agreed that this was so, but stressed the fact that his germ plasma to-day would have become highly selected as a result of mutations in the past, and consequently ran a greater hazard from mutations. This point must be taken into account when assessing the current risks. It might be that we were already operating at too high a mutation rate.

Brief reference was made to the maximum permissible dose for workers with ionizing radiations. Dr. STEWART doubted if any dose could be regarded as absolutely safe, though, as with the risk of infection by bacteria, some risk had to be accepted.

Reports of Societies

**JUBILEE MEETING OF THE ROYAL SOCIETY
OF TROPICAL MEDICINE AND HYGIENE**

The Royal Society of Tropical Medicine and Hygiene held its fiftieth annual general meeting on June 20 at Manson House, London. Financially and numerically the Society remains strong, the count of Fellows at the end of March showing a rise to 2,054. After the induction of the new president, Brigadier J. S. K. BOYD, F.R.S., by his predecessor, Professor R. M. GORDON, of Liverpool, and the completion of the official business, the Chalmers medal for 1957 was presented to Dr. A. J. HADDOW, of the Virus Research Institute, Entebbe. The medal is awarded every second year to a person under the age of 45 for outstanding research in tropical medicine or hygiene. Dr. Haddow then addressed the meeting on "The Changing Background to Research Work in Uganda."

Virus Research in Uganda

Until 1950 the virus research centre at Entebbe was a branch of the international health division of the Rockefeller Foundation, said Dr. Haddow, and in those days most of its work was concerned with the epidemiology of yellow fever. When he joined the staff in 1942 there was a field station about 200 miles away near the Congo border, and from it collections of mosquitoes and various animals from the surrounding forest areas were regularly sent to Entebbe. Large numbers of African workers could be employed and transport costs were not very heavy. But with the rise of prices during and after the second world war this system of working had had to be radically altered. No longer was it possible to employ large staffs or undertake long and expensive journeys; the field station had been closed; and now work was concentrated around the shore of Lake Victoria near Entebbe and on some of the islands in the lake.

Since 1950 the centre had come under the control of the East African High Commission, and its field of work had been extended to include not only viruses suspected of affecting man but also those that attacked his stock.

The introduction of very young mice as test animals had led to the isolation of large numbers of viruses, many, however, of doubtful significance. This phase of isolating new viruses in almost every experiment seemed now to be ending, and with the help of workers in other countries, particularly in America, the identification of groups of viruses was becoming more accurate. Dr. Haddow mentioned some special investigations which had been carried out by members of the staff of the centre, such as the investigation by Dr. W. H. R. Lumsden of an outbreak of a dengue-like illness in southern Tanganyika. Only by grants from such organizations as W.H.O. could these investigations be completed to-day.

Hampering Effect of Local Suspicion

In the earlier years of his service in Uganda, and still in some of the remoter areas, such as Karamoja, near the Sudan border, the co-operation of unsophisticated African people was freely given; but Dr. Haddow illustrated by several examples how this had changed, and how to-day many Africans, especially around Entebbe itself, were suspicious of all the activities of Europeans. The increasing nationalist political feeling made them suspicious of those working under an inter-territorial organization such as the East Africa High Commission. So there was the paradox of increasing co-operation internationally in virus research work and decreasing local co-operation from the people in the area where the research was done. Dr. Haddow concluded his address by showing some beautiful colour photographs of Uganda.

Correspondence

Dangers of Cigarette-smoking

SIR,—Your annotation on dangers of cigarette-smoking (*Journal*, June 29, p. 1518) leads up to the demand (p. 1520) that these hazards "must be brought home to the public by all the modern devices of publicity." That is just what some of us with research interests are afraid of. In recent wars, for example, we have seen how unscrupulously the "modern devices of publicity" are liable to be used under the impulsion of fear; and surely the "yellow peril" of modern times is not the mild and soothing weed but the organized creation of states of frantic alarm.

A common "device" is to point to a real cause for anxiety, such as the increased incidence of lung cancer, and to ascribe it in urgent tones to what is possibly an entirely imaginary cause. Another, also illustrated in your annotation, is to ignore the extent to which the claims in question have aroused rational scepticism. The phrase (p. 1519), "in the presence of the painstaking investigations of statisticians that seem to have closed every loophole of escape for tobacco as the villain in the piece," seems to be pure political rhetoric, even to the curious practice of escaping through loopholes. I believe I have seen the sources of all the evidence cited. I do see a good deal of other statisticians. Many would still feel, as I did about five years ago, that a good *prima facie* case had been made for further investigation. None think that the matter is already settled. The further investigation seems, however, to have degenerated into the making of more confident exclamations, with the studied avoidance of the discussion of those alternative explanations of the facts which still await exclusion.

Is not the matter serious enough to require more serious treatment?—I am, etc.,

Cambridge.

RONALD A. FISHER.

Tumour-Host Relationships in Cancer

SIR,—Your recent annotation on hormone-dependent cancer (*Journal*, March 23, p. 694) has prompted us to draw the attention of your readers to other apparently less well-known, yet perhaps equally important, aspects of neoplasms and hormones, and some possible mechanisms of tumour-host relations.

In referring to the interpretation of data on oestrogen formation in cancer cases, you remark, Sir, that "some endocrine abnormality may be determined by the nature of the disease present at the time." We would like to draw attention to several careful studies in man and animals, indicating that widespread changes in endocrine balance are in fact common, even in the presence of tumours not arising from endocrine glands, and, moreover, that there is quite a body of evidence indicating that neoplasms may themselves secrete substances having metabolic effects hardly distinguishable from those of "normal" endocrine glands. For example, Greenstein, Jenrette, and White¹ showed that subcutaneously implanted hepatic tumours or sarcomas produced profound diminutions in hepatic catalase and that resection of these tumours was followed by return to normal of the concentration of this enzyme in the liver. They considered this biochemical change, induced in a distant organ by the tumours, as due to the action of some circulating "toxin" elaborated by the tumours. Further, Albright and Reifstein² initially, and more recently Myers,³ as well as Plimpton and Gellhorn,⁴ all disclosed the frequency of hypercalcaemia in patients with cancers—even in the absence of osseous secondaries. These findings led these investigators to suggest that many cancers may secrete a hormone with parahormone-like actions.

Hyperglycaemia has also repeatedly been shown to be extremely common in association with malignant neoplasms,⁵ while Jacobson⁶ had earlier demonstrated the frequency of

combined diagnosis of cancer and diabetes to be statistically significantly higher than would be expected in the general population. On the other hand, diminution both in glycosuria and insulin requirements has also been reported in diabetics who developed cancers, with relapse to the *status quo ante* on successful treatment of the tumours. More recently, too, McFadzean and his co-workers⁷ have revealed the frequency of hypoglycaemia in patients with primary hepatic cancers—a phenomenon recently confirmed by us,⁸ and attributed by these workers to the unabated appetite of the liver cancers for carbohydrates. Severe hypoglycaemia and even hypoglycaemic convulsions (as a presenting sign) have not infrequently been reported in patients with non-pancreatic cancers, while prolonged relief from such hypoglycaemias, with recurrence when metastases appeared, have also been noted in the literature—and not infrequently.^{10 11}

Our own clinical studies of the value of alloxan in treating patients with otherwise hopeless liver cancers,^{12, 13} as well as the still unpublished results of our experimental work on the prophylactic and therapeutic effects of alloxan on transplantable sarcomas in rats, have together elicited several facts of considerable interest and perhaps even of some importance, particularly in elucidating that fundamental aspect of oncology—namely, the mechanisms involved in tumour-host relation. We now know, from our own investigations in some 18 cases, that repeated intravenous injections of alloxan in doses known to be diabetogenic for several other mammalian species fail to provoke diabetes in human subjects harbouring neoplasms of various types—a reaction which we have also adequately established for tumour-bearing rats. We have shown in rats, too, that this is not an “apparent” protection, due to the diabetes being masked by the demonstrable hypoglycaemic effects of the tumours implanted into normal or diabetic rats.” On the contrary, that these “protective” effects of cancers against the diabetogenic actions of alloxan are “real” was clearly demonstrable in our experiments by the fact that subsequent resection of the sarcomas, implanted intra-abdominally prior to alloxan injections, was not followed by diabetes but merely by a rise of the blood sugar from hypo- to normoglycaemic values.

Furthermore, Sir, we have now repeatedly confirmed, in rats, the observations of Goranson and his co-workers,^{14, 15} and subsequently of Ingle,¹⁶ that: (1) a pre-existing diabetes significantly retards the growth of implanted tumours, while (2) even the limited growth of tumours in diabetic animals exerts marked ameliorating effects on the hyperglycaemia and/or glycosuria. We have now shown this to be a property of sarcomas as well as of carcinomas.

Tumours are known to alter profoundly the retention and use of nitrogen, phosphate, and other nutrients by their hosts, to abolish the normal diurnal fluctuations in metabolic rate, and to alter in many ways the chemical composition of the blood. Tumours must, of necessity, eke out from their hosts the raw materials for their own energy requirements, and especially perhaps the amino acids so essential for the protein synthesis implicit in their growth. It is not unexpected, therefore, that malignant tumours should have some means of diverting from the normal metabolic channels of their hosts the materials required by both tumour and host. It seems feasible, too, that the loss of weight, frequently without increased nitrogen excretion, so characteristic even in the presence of small cancers, and before marked changes in appetite ensue, like all the other peculiarities outlined above, may merely represent aspects of the overall effects of some "endocrine" actions rather than "toxic" effects of malignant neoplasms on their hosts.

Bearing all the above in mind, it would seem that the attention of clinicians and endocrinologists should not be confined so closely to alterations in steroid hormone metabolism alone in cancer, but that a broader perspective and wider clinical attack on this problem are now long overdue. In such work, moreover, it seems to us that attention to the carbohydrate metabolism of both tumours (*in vivo*)¹ and of their hosts merits pride of place, not only because of the

already demonstrated effects in man and rats of the close interrelations between carbohydrate metabolism of the host and tumour, but also because tumour growth can apparently, both in man and rats, be altered profoundly by the presence of diabetes in the host. Moreover, there is a considerable body of *in vitro* and *in vivo* (clinical) data suggesting the apparent marked dependence of malignant tumours on glucose being made freely available by their hosts. Of particular interest perhaps is the recent disclosure that insulin markedly influences the carbohydrate metabolism and especially the synthesis of ribonucleic acid, phospholipid, and protein in cultured tumour cells.¹⁷ Experimental evidence, at any rate, has adequately disclosed the possible value of chemically or surgically induced diabetes in inhibiting the growth even of advanced cancers.

While we are still far from convinced of the value of alloxan injections in the treatment of advanced cancer in man, we do, nevertheless, feel that there is more than enough experimental evidence and even sufficiently provocative clinical information to merit more work on this aspect of neoplasia by others, probably better qualified than we and certainly with better facilities for metabolic and follow-up studies on human material than presently available to us. There would also seem to be more data justifying attack on advanced cancers by altering the carbohydrate metabolism of both hosts and tumours than the rather slender evidence originally available when clinicians first attempted complicated operations such as adrenalectomies, hypophysectomies, and other endocrine ablations which seem, even to-day, to be rather unpredictable in their effects on the hormone metabolism of their hosts as well as on the growth and spread of malignant tumours.—We are, etc.,

Blood Group Chimeras

SIR,—This problem, reviewed in the annotation in the *Journal* of June 22 (p. 467), and further illustrated by Dr. P. B. Booth and his colleagues (p. 1456) and Dr. J. W. Nicholas, Dr. W. J. Jenkins, and Mr. W. L. Marsh (p. 1458), is of great interest to all pathologists. Injecting Rhesus-positive blood into a newborn baby in the hope of giving it "immunological tolerance" would be very dangerous. To be really effective the baby must be injected with the appropriate red cells at some period—not properly defined—during the stage of gestation—i.e., *in utero*. It seems likely that the baby must not be "injected" too early in life, and most certainly not too late. All pathologists have been puzzled by the occasional Rhesus-negative woman with a homozygous husband who is the father of all her children, who produces six, seven, or eight or more children (all Rhesus-positive) but does not develop any antibodies. These women are rare, but they do exist. I have often wondered if the maternal grandmother in these large families may not be Rhesus-positive. The theory is that the grandmother may have introduced some Rhesus-positive cells into the circula-

tion of the mother during gestation, choosing the appropriate phase of intrauterine life for the operation. The prospective multipara is thus made "immunologically tolerant" before birth, and the benefit is shown when she is grown up and married and in her child-bearing stage of life. We have been looking for such a grandmother, but so far have not been able to contact her. We are still trying.—I am, etc.,

Epping, Essex.

FRANK MARSH.

Society and Mental Disorder

SIR,—With reference to your second leading article, "Society and Mental Disorder" (*Journal*, June 8, p. 1349), this states: "The special legal function of the medical superintendent vanishes, and his duties will come to resemble closely those of the superintendent of a general hospital."

I have previously been under the impression that in general hospitals the principle of equal tripartite administration with the lay secretary as the designated head of the hospital was the recommended practice. That where one is named as the chief the others cannot be equal is beside the point. Is there in fact such a being as the superintendent of a general hospital? I can only write with assurance on the conditions within a mental-deficiency hospital, and there appears no doubt that, in the therapeutic community which such hospitals should be, a doctor must be the designated leader and head of a team which covers psychology, social science, education, and training, nursing and business management, as well as medicine. A close reading of the Royal Commission's report¹ would seem to imply that the legal functions of the medical superintendent, rather than vanishing, will become somewhat more difficult and arduous. That many of the old functions will disappear is, however, admitted.

At a time when "medical superintendent" has joined "gilt-edged" among the dirty words in the English language, I hope that the lot of those of us who administer the lives of our unfortunate patients will not be made harder by suggestions that unlike things can be treated as though they were alike.—I am, etc.,

Prudhoe-on-Tyne.

Hanging Bladder Stones

SIR,—In searching the literature for certain surgical curiosities, examples are sometimes hidden away and not easily found under obscure headings, or even not indexed at all.

In the second edition of my book *Stone in the Urinary Tract*¹ I referred to and illustrated a case I had dealt with some years previously; at the same time I quoted another case from the literature.² I do not doubt that this type of case is far less common than it used to be, when, perhaps, unabsorbable suture material was in more frequent use for the repair of the uterine incision in cases of caesarean section. In the last two years, in another journal, three cases of hanging bladder stone have been reported as though they were exceptional rarities.^{3,4} I think in the past they were not so uncommon.—I am, etc.,

Range of Movement of Testicle

SIR,—I am very grateful to Dr. J. Shegog Ruddell for his account (*Journal*, June 1, p. 1304) of the way in which sepoys arrange their testicles before periods of stress. I suppose they keep them up by a tight loin-cloth, and so avoid the very debilitating drag on the posterior extra-peritoneal tissue and the nerves it contains which would

otherwise occur, particularly in a hot country where the supporting muscles tend to relax. The tone of the other letters shows the well-recognized change from the first greeting of something new as complete nonsense to the second stage, in which it is asserted that everyone has known it all the time.

I believe that the knowledge of the arrangements of the fibres of the areolar tissue in this region will: (1) avoid parental worry, "waiting to see what happens," hormone injections, and operations in about 70% of those cases which are now called undescended testicles; in only about 5% is the diagnosis difficult; (2) enable the undescended testicle to be locked in the scrotum more firmly and comfortably than by any of the classical methods; (3) diminish greatly the present heavy incidence of atrophy after operation.

Those who recommend me to be content with a description that has not altered for a hundred years may: (1) consider the muddle caused by describing tendons like the fascia lata and the white line or tendinous arch of the pelvic fascia by the same term as areolar tissue like the fascia of Scarpa and of Zuckerkandl; (2) consider the queerness of classing certain anatomical facts as belonging to topographical anatomy and others to surgical anatomy. For an example of what results, look up the volume of Cunningham¹ to which I have been referred by Dr. R. D. Lockhart (*Journal*, June 1, p. 1304). The vessels from which children bleed to death after tonsillectomy, the paratonsillar vein, is in "Topographical Anatomy" but not in "Surgical Anatomy"; (3) With the abdomen empty of bowel at a necropsy, pull on the testis. Fibres will be seen to spring up under the peritoneum of the posterior wall. They are the suspensory ligament of the testicle (cf. Arbuthnot Lane's phrase, "the organization of lines of force"). These fibres are the key to the freeing of the undescended testicle at operation. They are in neither topographical nor surgical anatomy.² (4) Look for the internal spermatic fascia of the textbooks; it will not be found; no fibres from the transversalis fascia enter the cord. (5) At an operation on a misplaced testicle insert a frame retractor into the wound and lift the superficial tissues all round it. An open space will spontaneously appear without dissection, leading down into the neck of the scrotum, with on its floor tough fibrous tissue superficial to the pubic bone. This tissue is the key to retaining the freed testicle in position.³ (6) Find a testicle that moves in and out of the external ring, the kind that is described in my original paper⁴ as "emergent." All these need operation, as this movement is only possible if the testicle is slipping about in a hernial sac. Before operation note that, though the testicle is easily palpable while it is outside the external oblique (in the pouch), it cannot be felt at all once it is in the canal. Confirm this at operation. This is the most instructive and misleading of all the varieties of maldescent; since surgeons, having felt the testis before operation, and having found it in the canal when the child was under an anaesthetic, imagine it was in the canal when they felt it. It was not. (7) Look for the nerve supply of the dartos muscle in textbooks. (8) Check the coefficient of contraction of such muscle as the cremaster.—I am, etc.,

Myringoplast

SIR,—I was gratified to read Mr. G. A. Moulden's letter (*Journal*, June 15, p. 1419) and his comments on the myringoplast. I should like to assure him that, before publishing the details of the instrument (*Journal*, May 25, p. 1240), I tested it exhaustively. The original version (the present is the fourth) was fitted with the trigger below the shaft, revolver-fashion. There was always some difficulty in controlling a certain tendency of the end-plate to ride up as one approached the tympanic membrane in the final stage

of patching. With the trigger above the shaft, however, it is relatively easy to grasp the butt of the instrument between the proximal phalanx of the thumb and the second metacarpal, and to operate the trigger with the tip of the index finger. The latter is the most precise and versatile digit in the human hand, particularly when the otologist performs delicate manoeuvres in the external auditory meatus.

Mr. Moulden also refers to the use of moistened cotton-wool plaques to assess the efficiency of the ossicular chain and cochlear reserve. I should draw his attention to the fact that the mere introduction of additional moisture into an ear for the purpose of testing the ossicular chain can lead to fallacies. There is no doubt, however, that such a procedure does help one to assess the cochlear reserve.

In the course of my research I have found thin sheets of polythene far superior to any other material for patching the tympanic membrane in the diagnosis of infective derangements of the middle ear. A detailed account of my experience in this respect has been accepted for publication by the *Journal of Laryngology and Otology*.—I am, etc.,

London, S.E.1.

FRANCE ROHAN.

Vaccine Against Poliomyelitis

SIR,—Mr. P. G. Gray's letter (*Journal*, June 22, p. 1473) raises important points which were carefully studied by the Medical Research Council's committee on poliomyelitis vaccines in preparing its report on the assessment of poliomyelitis vaccine (*Journal*, June 1, p. 1271). One of the features which contributed to the decision that bias was unlikely in the group of "defaulters" who had been born in the months selected for vaccination, but who received no injections, was the uniformity in the proportion of such "defaulters" among those registered for vaccination. Of the registered children born in March, 1951–4, 18.3% received no injections, and of the registered children born in November, 1947–50, 16.0% received no injections. The incidence of paralytic poliomyelitis in these groups was very similar to that in unvaccinated children born in months which were never selected for vaccination (three cases were observed compared with 3.2 expected). Among registered children born in November, 1951–4, 17.6% received no injections, a proportion very similar to that in the other selected groups of March, 1953–4, and November, 1947–50, in which there was no excess incidence. Furthermore, this proportion of defaulters in young November-born children was very similar for the separate years of birth—16.5% for 1951 births, 17.6% for 1952, 16.7% for 1953, and 20.2% for 1954. As Mr. Gray suggests, with such uniformity in these proportions the appreciable variation in the attack rate between the years 1 to 5 would not be a factor contributing to any bias.

The six cases of paralytic poliomyelitis observed in young November-born defaulters (to be compared with 1.4 expected at rates for unvaccinated children born in unselected months) were scattered throughout the years of birth, 2 in 1951, 3 in 1952, and 1 in 1954. Geographically they came from six different local authority areas which were in no way remarkable for unusually high or low incidence of poliomyelitis in 1956. It was these various observations that led to the conviction that the high incidence in this one group of defaulters was due only to chance.—I am, etc.,

J. KNOVELDEN,

Secretary,
M.R.C. Poliomyelitis Vaccines Committee.

Operations for Varicose Veins

SIR,—Mr. R. R. Foote's implication (*Journal*, June 1, p. 1305) that the technique described in our original paper¹ is the same as in the early attempts at subcutaneous ligation suggests that he may not have read this article. Why he condemns the method so strongly without having the opportunity to compare the results in a suitable series is not clear.

Granted, as he says himself, that no surgical method guarantees permanent success, and granted also that the stripping operation has great value, yet it is felt that subcutaneous ligation well done with good instruments has much to offer. If collaterals with incompetent communicating veins are left "the river spreads the waters into the surrounding fields" regardless of whether the main vein was ligated or removed. On the other hand, subcutaneous ligation offers the great advantage of picking up collateral as well as main vein, and in areas where these are abundant tandem ligation may be extended at several levels, thus reducing or removing the downward pressure which contributes so greatly to recurrences. If "pseudo-surgical," the method is not easier and certainly not less time-consuming than ligation and stripping. Because it is tedious it will probably be slow to be adopted, but for cases of recurrence, of extensive varicosity, or where cosmetic results are important it may well be a method of choice.

Since the appearance of our first report modifications in materials and technique have been introduced which will be the basis of a further report together with a survey of cases treated up to the present.—I am, etc.,

Sydney, N.S., Canada.

Hospital Confinement

SIR,—I have been surprised and disappointed that Dr. D. S. Foster's letter (*Journal*, May 11, p. 1121) has not evoked any constructive correspondence. Surely his proposals are sound and worthy of notice. They appear likely to benefit not only the mother, her infant, and the household, but also the hospital, district midwife, general practitioner, and the Exchequer. I for one would actively encourage any steps taken in this direction. Who will make a move?—I am, etc.,

Dartford, Kent.

G. F. TRIPP.

Post-maturity

SIR,—Professor F. J. Browne has been misled by the annual reports of the Liverpool and Birmingham Maternity Hospitals for 1953, which he quotes in his letter (*Journal*, June 22, p. 1472) to support his thesis that surgical induction of labour for post-maturity is a useless procedure. One of us was concerned with the preparation of each of these reports, and, as the fault for the misunderstanding may be due to our presentation, we would take this early opportunity of making the facts clear.

First, surgical induction of labour for "maturity" (using the term to cover all inductions performed at 40 weeks or later in which the duration of pregnancy was the only indication), far from being rarer at Liverpool than Birmingham, was in fact performed 238 times in 1953, an incidence of 8.4% compared with 1.1% at Birmingham. The Liverpool figures for induction were omitted from the original binding and were issued as a supplement at a later date. Possibly Professor Browne has not seen this. It should also be borne in mind that the standard maternity hospital report does not, at present, record inductions of labour for maturity by oxytocin drip, a method increasingly used. The second misinterpretation lies in the assumption that a direct comparison between the perinatal mortality figures of the two hospitals is possible, though each of the hospitals concerned is the main obstetric teaching hospital for its own city, their clientele differs in many respects. The Birmingham hospital, with a smaller number of beds, serves a large population and as a result the proportion of abnormal cases is higher, as can be seen from a comparison of the various tables in the reports. Normal primigravidae were not booked for hospital confinement in Birmingham in 1953, whereas they were in Liverpool. Another illustration will perhaps confirm the differences—in Liverpool approximately 40 medical students every year perform 20 normal deliveries each in the Liverpool Maternity Hospital, whereas at Birmingham

there are only sufficient normal deliveries to supply the midwives in training. In 1953 the medical students had to obtain their normal deliveries in other hospitals, and attended the Birmingham Maternity Hospital only to witness abnormal obstetric cases.

It is clear that whatever value maternity hospital annual reports may have this does not extend to the solution of the problem of post-maturity, in the investigation of which perusal of individual case sheets is essential and study of the actual cases preferable. Even then the pitfalls are many.—We are, etc.,

Liverpool, 3.

D. N. MENZIES.
J. S. SCOTT.

The H-bomb

SIR,—While it would be gross injustice to describe Mr. Norman Capener's letter (*Journal*, May 25, p. 1246) or Dr. W. V. Cruden or Dr. Rachel Hunter's letters (*Journal*, June 8, p. 1362) as high flown or highfalutin, it might be fair to contend they show a lack of realism, or for that matter any sense of practical national urgency. Indeed, there is no doubt the success of the recent tests has accelerated the progress of the current disarmament talks, which themselves can now be conducted in a more realistic manner.

There is one further aspect of the matter that so far seems to have been completely overlooked—namely, that this specialized experimentation for the purpose of self-defence has, and will, yield useful results in the harnessing of atomic power for peaceful uses to a much greater extent than ever occurred with the development of now old-fashioned, but still conventional, instruments of war. Since man is fallible, this world must be insecure and must be accepted as such, so that risks have to be run anyway, and to be strictly consistent we should be worrying over equally pressing problems, such as the danger of world overpopulation, whose implications in their own way are no less sinister. If overpowering force and potentiality for destruction must be in anyone's hands, let it be in our own as well as in others, as this in itself will solve all sorts of problems, even simple ones like having armed forces of a friendly country in our own land, and yet not answerable to our own laws.—I am, etc.,

London, S.W.1.

ROBERT CUTLER.

Speed Warning Device

SIR,—Dr. Allen Glenn (*Journal*, March 23, p. 705) asks for a speed warning device that would attract the attention of drivers who now pay little heed to their speedometers. Such a gadget is now quite popular in America. It is a plastic image of St. Christopher, the patron saint of travellers. When the speedometer reads 60 miles an hour this little figure lights up and a sound track clearly records "O.K. Brother, you are on your own now."—I am, etc.,

Birmingham, 15.

WILLIAM GISSANE.

Anonymity in Broadcasting

SIR,—A few weeks ago I was invited to participate in an I.T.V. programme "Thou Shalt Not Kill." I accepted on condition that complete anonymity was assured; this condition was agreed to and faithfully honoured by I.T.V.

However, on leaving the train on my return to London I was stopped by reporters from the *Daily Express*, who requested my name and address. This I refused, and reiterated my refusal after further pressure. In spite of this, by some means unknown to me, these particulars were obtained and published in the issue of the *Daily Express* of June 27, 1957. You will thus see that, in defiance of my wishes, anonymity was destroyed, and I have sent a letter to the Editor of the *Daily Express* protesting at the publication of my full name and area of practice.—I am, etc.,

Plympton, Devon.

S. NOY SCOTT.

Obituary

W. J. PEARSON, D.S.O., M.C., D.M., F.R.C.P.

Dr. W. J. Pearson, formerly senior physician at the Hospital for Sick Children, Great Ormond Street, and physician in charge of the children's department at University College Hospital, died at Cromer on June 27, aged 73.

Wilfred John Pearson was born on June 23, 1884, and was educated at Rugby and at University College, Oxford. Going on to University College Hospital for his clinical training, he graduated B.M., B.Ch. in 1911. Eight years later he proceeded to the D.M. and took the M.R.C.P., becoming a Fellow of the College in 1928. After graduation he held a number of house appointments at University College Hospital and then became first assistant in the children's department at King's College Hospital, and, later, physician in charge of the children's department at Charing Cross Hospital. He was also physician to the Cheyne Hospital for Children, Chelsea.

During the first world war he served with great gallantry in the R.A.M.C., attaining the rank of major. In 1917 he won the Military Cross for working under heavy shell fire for 50 hours without rest while in charge of the evacuation of wounded from a sector of the front. In the following year he was awarded the D.S.O. During the second world war he was head of one of the London sectors of the Emergency Medical Service.

Dr. Pearson's main work as a paediatrician was done at University College Hospital, where he followed the late F. J. Poynton as head of the children's department, and at the Hospital for Sick Children, where he was first physician to out-patients, then full physician, and finally senior physician. A popular teacher at both hospitals, he was author, with W. G. Wyllie, of *Recent Advances in Diseases of Children* (third edition, 1935). He also wrote, with A. G. Watkins, a short book entitled *The Infant: A Handbook of Management*, the first edition of which appeared in 1933 and the third in 1945.

Dr. Pearson is survived by his widow, formerly Miss Charlotte Warrack, whom he married in 1909, and by two daughters.

B. E. S. writes: To the students who went to University College Hospital in the years which followed soon after the first world war, Wilfred Pearson had already become a legend. An Oxford graduate was rare in those days at this hospital, and it was even more remarkable for an R.M.O. to be visited by his wife and children. Hospital messes were more monastic, and the "family quarters" atmosphere so customary now would have horrified any of our predecessors coming down to breakfast after a residents' party. Pearson, we told each other, had had a fine war record. Mentioned in dispatches and with an M.C. and D.S.O., he was recalled from the front line to a staff appointment usually reserved for Regulars in the Army of those days. But he soon tired of a "cushy" job and succeeded in being sent back to the fighting.

This spirit for adventure was not to remain dormant for long when he returned to civilian life, and was quickly rekindled during the General Strike. The authorities had some difficulty in containing him when, as a special constable and armed with a truncheon, he set forth as a volunteer to the most disturbed areas in order to show the arm of the law and demonstrate it forcibly if required. He was a fine-looking man and conducted his life with that *sprezzatura* so often seen in people of his era. This was particularly noticeable in the various games he played, at all of which he excelled. He was a good doctor and taught many generations of students sound medicine. University College Hospital owes the children's department to his drive and administrative ability after he was elected as its first paediatrician. Soon he became vice-dean in the

medical school, and when the second world war broke out his previous record left little doubt that he was the man to play an important role with the Emergency Medical Service and he was appointed Group Officer, Sector IV.

No one could have been kinder to his junior colleagues, and the assistance he gave to smooth the way of his successor will always be gratefully remembered. At the same time it would only be fair to say he took dislike to people too easily and often without good reason magnified them into enemies. This unfortunately darkened the latter part of his life, which should have ended so brilliantly. In some ways Pearson lived outside his time. His instincts were those of a crusader: his early marriage would now be the accepted custom among most young doctors, and his unorthodox ideas on child physiology, which were thought absurd when they were first expressed, now in the "age of electrolytes" seem to have more sense. Even his political views and Cassandra-like warnings, so important to him and absurd to us, are becoming the keynote of half the world's fears. If only his anxieties had not become obsessions he could have been counted right and we would have been proved wrong. Whatever judgment is passed, to those who knew him well he will always remain one of the striking figures of his time.

G. P. McCULLAGH, M.D., B.Sc., D.P.H.

The death of Graham Patterson McCullagh, fellow and senior tutor of Queens' College and senior lecturer in pathology in the University of Cambridge, has prematurely terminated a career of outstanding benefit both to his college and to the university.

Graham McCullagh was born in Belfast in 1904, the son of a well-known medical practitioner in that city. After winning a scholarship to Campbell College he later became a scholar of Queen's University, Belfast, and graduated M.B., B.Ch., B.A.O.(Hons.) in 1927 and B.Sc.(Hons.) in 1928. He proceeded to the M.D. in 1931 and took the D.P.H. in 1932. In Belfast he held both surgical and pathological hospital appointments and later became a lecturer in pathology at Queen's University. While in Ireland he was a prominent yachtsman, and was vice-commander of the Queen's University Sailing Club.

In 1935 McCullagh was appointed university demonstrator in pathology at Cambridge and in 1937 was elected to a fellowship at Queens' College. His quite exceptional talents for helping and advising both students and colleagues were quickly recognized; he was appointed a tutor of Queens' in 1938 and became senior tutor of his college on his return from the Navy in 1945. In 1930 he had joined the Royal Naval Volunteer Reserve as a medical officer; he rose to the rank of surgeon commander by 1941. Even before the outbreak of hostilities in 1939 he was called away from Cambridge for whole-time naval service, which lasted unremittingly until the end of 1945. During the war he acted as specialist pathologist in naval hospitals, and later as the principal medical officer for the Suez Canal. While in the Middle East his health suffered considerably, and, after a severe corneal ulceration, he was posted to England. Thereafter he was engaged on extensive experiments carried out by the Admiralty on the effects of subaqueous blast on animals. McCullagh's ability, ingenuity, and tireless energy played a large part in the success of this work. By 1945, however, his health was seriously threatened by duodenal haemorrhage; he was demobilized and then returned to his teaching and administrative duties at Cambridge. He was awarded the naval Volunteer Reserve Decoration in 1945.

K. C. D. writes: Dr. McCullagh was a man of wide and catholic interests, being well read and a lover of music, besides possessing a remarkable breadth of knowledge in his own subject. He brought to pathology the mind and hands of an able surgeon. His work on experimental hypertension in rabbits, produced by denervation of the carotid

sinus, early demonstrated his outstanding skill as an operator. He maintained a highly efficient and beautifully equipped operating theatre for work on experimental pathology. It was characteristic of his nature that of recent years more of his experimental work was directed to promoting the researches of his juniors than towards publications in his own name. His important work on guinea-pigs fed with cholesterol established that gross enlargement of the liver and spleen follows excessive intake of this lipid; he showed that this splenic enlargement may be accompanied by the accumulation of macrophages bloated with lipid and that this condition constitutes an experimentally produced histiocytic lipidosis. More recently he worked on necrosis of liver and found that protein may be retained with pertinacity by liver cells killed by carbon tetrachloride.

Post-war Cambridge utilized McCullagh's varied talents to its lasting benefit. His magnetism of personality made him loved equally by his pupils and his colleagues, as well as by the technical staff in the department of pathology. His administrative ability, however, resulted in big demands being made on any free time he could use for research. He was first elected to the council of the Senate in 1947, and he served the university on this and numerous other committees in a most valuable manner. He devoted great care to devising a new schedule for the conditions of employment of university assistants which remains as a memorial to his efforts in their welfare.

In his college he was the loved and valued friend and counsellor of all his pupils. The college athletic clubs particularly prized his presence at their dinners, where his speeches were noted for clarity of exposition as well as for the sparkle of his wit. He loved a good story and none could tell one better than he. On his return to full work, after a few months' absence due to severe illness, the joy and relief so plainly visible on the welcoming faces of students, colleagues, and assistants testified to the deep affection in which he was held. As a teacher and as an examiner he required and maintained high intellectual standards, but he always endeavoured to rectify errors by a characteristic bright and constructive sympathy for the young.

In 1938 he married Miss Margaret Janet Dick; there are two daughters and one son of the marriage. The continued happiness of Graham McCullagh's home life contributed in no small manner to his outstanding success as a college tutor; this was also dependent on his own unique capacity for radiating enthusiasm and good will into the daily work and objectives of his students.

G. CLARK TROTTER, M.D., D.P.H.

Dr. G. Clark Trotter, who was for many years medical officer of health for the metropolitan borough of Islington, died on June 21, aged 81.

George Clark Trotter was born at Partick, Lanarkshire, on February 28, 1876. About 10 years later he went with his parents to New Zealand, where he attended Auckland Grammar School. Returning to Scotland for his university education, he had an exceptionally successful student career at Edinburgh. After graduating M.B., Ch.B. in 1902, he obtained the Aberdeen D.P.H. in 1903, and proceeded to the M.D. three years later with a thesis in which he compared the public health methods of London and Paris. It was while he was working at the Pasteur Institute that he collected material for this thesis. Clark Trotter's first post in the public health service was that of assistant medical officer of health in Devon, but he soon moved to Paisley, where after a few years as an assistant he became medical officer of health. This gave him all-round experience, for he was chief clinical tuberculosis officer, child welfare officer, medical superintendent of the fever, smallpox, and tuberculosis hospitals, and police surgeon. A member of the council of the Incorporated Sanitary Association of Scotland for a number of years, he was elected to serve a term as president of the association.

At the end of the first world war he followed the example of many other Scots who have distinguished themselves in the public health service and came south. His first appointment was that of medical officer of health for the metropolitan borough of Deptford, but he did not stay there long, for in 1921 he was selected for the important post of medical officer of health for Islington in succession to Dr. A. E. Harris. He remained there until he reached the retiring age in 1941.

Islington is one of the largest of the metropolitan boroughs and has many public health problems. Trotter threw himself with great vigour into their solution. He was always specially interested in environmental hygiene and wrote a valuable paper on the collection and disposal of household refuse. Islington abounded in voluntary organizations engaged in health and social work: they remember with gratitude the private advice and official support which he gave them. Soon after his retirement he was called back to the public service as medical officer of health for Hampstead while Dr. Leslie Oldershaw was on military duty.

Trotter was an inveterate attendee at meetings, especially those of the metropolitan branch of the Society of Medical Officers of Health, the Section of Epidemiology and Preventive Medicine of the Royal Society of Medicine, and the Royal Institute of Public Health and Hygiene. He was an active member of the council of all three, continuing in the case of the latter two until within a few weeks of his death. He was a tall and commanding figure, but was no orator and intervened only when he had something worthwhile to contribute. His remarks were always shrewd and based on real knowledge. A member of the B.M.A. for 55 years, he took an active part in the work of the Association: he was a member of the Council from 1923 to 1938, of the old Dominions Committee from 1924 to 1938, and of the Public Health Committee from 1919 to 1933. He also represented his Division at the Annual Representative Meeting on a number of occasions, and locally he was chairman of the City Division in 1925-6. Clark Trotter was one of those people who, without ever aspiring to presidential chairs or even chairmanships, exercise great influence behind the scenes. He was often consulted and his advice was always sound, though given with a quite charming diffidence. He always took a close interest in the Mildmay Memorial Hospital, and was its honorary consulting physician, and from 1948 a member of its house committee. At one time he was lecturer on public health and hygiene in the medical school of Charing Cross Hospital.

He married late. His wife, Dr. Margaret Trotter, though much younger than he was, predeceased him by seven years. He relied much on her and felt her loss deeply. They had four daughters, one of whom is medically qualified.—W. A. D.

R. A. SLESSOR, M.B., D.P.H.

Dr. R. A. Slessor, who died at his home at Fraserburgh on June 9, aged 81, was probably the oldest and one of the best-known practitioners in the north-east of Scotland.

Robert Alexander Slessor was born at Methlick, Aberdeenshire, on November 13, 1875, and was educated at Aberdeen University, where he graduated M.B., Ch.B. in 1900, taking the D.P.H. three years later. After graduation he was for a time demonstrator in anatomy and lecturer in osteology in the university and a resident surgeon in the Royal Aberdeen Hospital for Sick Children. During 1901-2 he was a civil surgeon with the South African Field Force, being medical officer to a cavalry column. He took up general practice in 1903 in Fraserburgh, where he built up an extensive town and country practice, only giving up in April of this year. For many years he was partnered by his elder son, Dr. James Slessor, whose death with startling suddenness in June, 1956, was a terrible blow to him and no doubt hastened his end.

Medical Notes in Parliament

GOVERNMENT ACTION ON SMOKING AND LUNG CANCER

The Government's response to the advice of the Medical Research Council that a major part of the increase in the deaths from lung cancer is caused by smoking was given on June 27 by Mr. J. K. VAUGHAN-MORGAN, Parliamentary Secretary to the Ministry of Health, in the absence through illness of the Minister.

The Government consider, he stated, that the facts should be made known to all those with responsibility for health education. Local health authorities would be asked to take appropriate steps to inform the general public, and in this task they would have the assistance of the Central and Scottish Councils for Health Education. Once the risks were known everyone who smoked would have to measure them and make up his or her own mind, and must be relied upon as a responsible person to act as seemed best.

The Medical Research Council were supporting an extensive programme of work designed to discover the way in which tobacco smoke exerted its effect and the relative importance of other factors, such as atmospheric pollution, which might also play a part in the causation of lung cancer. The recent expansion of this programme has been greatly assisted by a substantial grant made in 1954 by a leading group of tobacco manufacturers. The work at present in progress consisted largely of chemical and biological studies of the many different constituents of tobacco smoke and of atmospheric pollution. In addition, surveys of the role of atmospheric pollution and of specific industrial hazards in the causation of the disease were being undertaken. The M.R.C. had established three new research groups in Exeter, London, and Sheffield, where long-term studies of different aspects of the problem were being carried out.

Dr. EDITH SUMMERSKILL (Warrington, Lab.) welcomed the statement as containing a warning that was rather overdue. She was told by Mr. VAUGHAN-MORGAN that the Ministry would use the local authorities as the agents for disseminating information; and he added in reply to Mr. M. LIPTON (Brixton, Lab.) that they would receive an Exchequer grant of 50% towards their expenditure. Publicity material would be supplied by the Central Council for Health Education.

Prohibition of Smoking

Much of the initial reaction was directed to proposals for the prohibition of smoking. Dr. R. BENNETT (Gosport and Fareham, Con.) suggested notices banning smoking in places of public assembly. Mr. H. C. USBORNE (Birmingham, Yardley, Lab.) wanted a ban in public vehicles, notably the Underground, at any rate at peak hours, and more non-smoking carriages in trains. Mr. R. FORT (Clitheroe, Con.) said that health authorities had power to stop smoking in cinemas, and thereby to bring Britain into conformity with almost every other civilized country. Mr. M. STEWART (Fulham, Lab.) questioned whether central and local government authorities and public corporations should continue to accept advertisements for smoking.

The other aspect was research. Mr. A. BLENKINSOP (Newcastle upon Tyne, East, Lab.) was given the assurance that no line of research was being neglected for lack of funds. The limiting factors, Mr. VAUGHAN-MORGAN said, were personnel and ideas. The M.R.C. expenditure had risen substantially and was now approximately £40,000 a year—quite apart from expenditure on cancer research generally. Mr. D. WADE (Huddersfield, West, Lib.) asked if they would consider the comparative effect of different qualities of tobacco, and the effect of saltpetre in cigarette paper. He was told that the Council would bear these points in mind.

Medico-Legal

POSSIBLE DANGER FROM RESERPINE

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Miss Lavinia Joyce Higgitt, aged 31, was a voluntary patient in All Saints' Mental Hospital, Birmingham, suffering from schizophrenia, as a result of which she was very simple and facile and very hallucinated. In March, 1957, she was treated with reserpine to diminish the restlessness and hallucinations. When dosage is large it sometimes makes patients apathetic and produces physical symptoms of weakness, sometimes amounting to helplessness. Miss Higgitt had her reserpine at first orally, taking three 1-mg. tablets three times daily. This seemed to have no marked effect, and on May 9 she was given intensive treatment which continued up to May 30. In addition to the oral dose she had injections of 2.5 mg., which increased to 5 mg. Up to 15 mg. is used in intensive treatment. The dosage was then reduced because her family thought she was better although very tired, and wanted her home for a holiday. On June 5 Miss Higgitt had her tablets, and at 6.15 p.m. had an injection of 2.5 mg. She was seen at intervals during the night, at first asleep and then awake and then again asleep, and at all times was quite quiet. At 4.45 a.m. on June 6 she was found in her bed lying on her stomach with her arm over her head and her face into the pillow, dead.

At the inquest held by the Birmingham coroner on June 7 evidence was given by Professor J. M. Webster, who performed the necropsy, that the cause of death was asphyxia due to closure of the external orifices of respiration. There were no marks of violence, and no pressure marks on the face, mouth, or nose. He felt that the deceased either had a fit unassociated with the reserpine, or else had a fit following the administration of it.

Dr. McPherson, medical officer of the hospital, said in evidence that the patient had never shown any traces of epilepsy. There had, however, been two occasions in the hospital when patients had had very violent epileptic fits while under reserpine treatment.

In his summing-up the coroner directed the jury that if they were satisfied that the drug was the cause of the fit which led to her death they should say so when bringing in their verdict. But in returning their verdict of accidental death they did not do so.

In a letter published recently in this *Journal*¹ Dr. George A. Kernohan reports the case of a 20-year-old girl suffering from simple schizophrenia who fell into a condition of stupor during intensive reserpine treatment, but recovered with restorative treatment. She later had smaller doses of reserpine with a beneficial effect. This report, coupled with the evidence at the inquest, suggests that there may be risks incidental to intensive reserpine treatment which have not hitherto been fully recognized.

¹ Kernohan, G. A., *British Medical Journal*, 1957, 1, 1475.

FATE OF A CHILDREN'S HOSPITAL

Another phase in the conflict between local feeling for, and the best use of, a hospital assumed almost the proportions of a full-dress debate in the House of Lords on June 26, where it attracted 15 speakers and occupied three hours. The issue was the future use of the Princess Louise Kensington Hospital for Children. The motion, by Lord BALFOUR OF BURLEIGH, called attention to a proposal recently accepted by the governors of St. Mary's Hospital, Paddington, to convert the Princess Louise from a wholly children's to a wholly adult hospital; and asked the Government to study means by which "this modern, well-equipped children's hospital of 76 beds, with all its specialist services, including a cerebral palsy unit," should be preserved as a children's hospital serving the needs of the densely populated working-class area of North Kensington.

He is an alderman of Kensington, and he claimed that he was voicing the united opinion of the borough council, irrespective of party: "Deprivation of our hospital, built with our money, for our children, will, if it is proceeded with, cause burning resentment." He quoted a resolution from the Kensington and Hammersmith Division of the B.M.A.: "Being satisfied as to the continuing needs of sick children in the area, the medical practitioners of the Kensington and Hammersmith district ask the Minister of Health to give serious consideration to the necessity for the Princess Louise Hospital to continue as a children's hospital serving the needs of the area. We should further like to impress on the Minister that these needs should take priority over the teaching requirements of St. Mary's Hospital." He also cited the report of the Royal College of Physicians on the care of children in hospital.

The story of proposals and discussions which Lord Balfour told began in January, 1955, and in essence arose from the need of St. Mary's Hospital for a greater proportion of adult beds. He accepted that this difficulty was a real one, but argued that it was largely of St. Mary's own creation, resulting from their amalgamation in 1946 not only with the Princess Louise Hospital but with the Paddington Green Children's Hospital. He claimed that in both cases St. Mary's had bound themselves by agreement to retain those hospitals as children's hospitals. Finally he declared that, if the Minister of Health, by any misfortune, should come to what Kensington would regard as a wrong decision, it was highly probable that its legality would be tested in the courts.

Lord WEBB-JOHNSON, expressing his regret at seeing this great teaching hospital being driven to such straits as to urge the destruction of "a gem of a children's hospital," said the difficulties and needs of St. Mary's could be met only by a bold scheme. He urged the governors to "think big," and the Minister to realize the need and back a bold plan.

Changing Needs of Children

Lord COHEN, a governor of St. Mary's, said the board would not have put forward these recommendations if they had not believed that to be their duty under the Act. A convincing reason was the change in the relative needs of children and adults, since the Princess Louise Hospital was built. The waiting-list at St. Mary's at the end of May was 1,580 adults, compared with a total of 320 children, only 64 of whom were not on the E.N.T. list.

Lord COTTESLOE, chairman of the north-west regional board, said that in West London there were more children's beds than were now needed. Within reasonable reach of North Kensington there were 350 children's beds, a considerable number of which might be closed without any harm. The regional board had come to the conclusion, after consultations, that if the Princess Louise were offered to the board they would be prepared to take it over, integrating it with the St. Charles' as the paediatric department of the hospital, and closing the children's beds in St. Charles' and perhaps some in the Paddington General. That would be a beneficial arrangement; it would relieve

St. Mary's of their paediatric incubus, reduce the total of children's beds in the area, and give the Princess Louise the benefit of integration with a large general hospital. But it would not give St. Mary's the additional beds for obstetrics and other specialties it needed for teaching. The board would be prepared to go further, and had expressed their willingness to make available to St. Mary's, although it would not be easy, 50 beds at St. Charles'. There was no way in which St. Mary's could obtain beds under their own control for teaching purposes except by building, and he hoped the Minister would find the means of doing it.

Lord AMULREE was among other speakers who thought Lord Cottesloe's suggestion a good one.

Lord MORAN, formerly dean of the medical school at St. Mary's, said that if the Health Service Act laid down no other principle it did lay down that all hospitals and their beds were to be reviewed to see whether they were serving the public need. That must mean a change of function in beds at some hospitals. It inevitably always resulted in a tremendous outcry when local feelings were outraged. But it was important that they should not give way to sentiment, however laudable. That there were too many children's beds now was established—children's diseases were falling rapidly—and the only question was which should be converted. If in Kensington many of these beds were redundant it would not be sensible blindly to carry out an undertaking given in totally different circumstances 11 years ago.

On the suggestion made by Lord Cottesloe he commented that, though it would afford valuable clinical material, from the point of view of teaching it had serious disadvantages. Without administrative control, the cases admitted could not be controlled. If Lord Cottesloe said, "You can have administrative control," he would have no more to say; he would accept it. At St. Mary's they were saturated with beds of which they had not administrative control.

The blunt and brutal truth was that the Princess Louise Hospital was no longer needed. Co-ordination of the hospital service was unpopular. Last year there was a tremendous outcry in the East End of London. Before that there was the agitation at Kingston. He had the thankless task of contending for principles against emotions. He appealed to the House to put sentiment on one side and concentrate on the real job that faced the Ministry and support them in it—taking each institution and seeing whether it was really serving the needs of the public as it should.

Government Reply

The Government reply, made by Lord STRATHCLYDE, Minister of State at the Scottish Office, was that the arguments on both sides would receive the earnest and sympathetic consideration of the Minister of Health.

Scottish Hospital Dispute

Mr. A. C. HUTCHISON (Edinburgh, South, Con.) asked the Secretary of State for Scotland on June 25 whether, in view of his having seen a widely representative deputation on June 14, he had any statement to make on the appointment of a consultant physician at the Bruntsfield and Elsie Inglis Hospitals, Edinburgh. Mr. J. S. MACLAY replied that he felt bound to maintain his previous decision that he would not be justified in intervening in a matter which had been entrusted under statute to the discretion of the regional board.

Scottish Prescriptions Inquiry

Mr. MACLAY announced that the Scottish Committee to inquire into the factors governing the cost of the pharmaceutical services provided under the National Health Service in Scotland had been set up under the chairmanship of Mr. J. B. Douglas, chairman of the Scottish Milk Marketing Board.

The members of the committee are: Professor S. ALSTEAD, professor of materia medica, Glasgow University; Professor R.

HUNTER, professor of materia medica, St. Andrews University; Dr. J. C. KNOX, Aberdeen, retired senior administrative medical officer, North-eastern region; Dr. E. V. KUENSSBERG, general practitioner, Edinburgh; Dr. J. R. LANGMUIR, general practitioner, Glasgow; Dr. D. McCALL, Scottish Secretary of the Pharmaceutical Society of Great Britain; Dr. J. O. McDONAGH, general practitioner, Perthshire; Dr. E. G. OASTLER, senior physician, Southern General Hospital, Glasgow; Professor T. B. SMITH, professor of Scots law, Aberdeen University; Mr. J. C. STEWART, chartered accountant, Glasgow; and Dr. A. STEWART HENDERSON, formerly general practitioner, now in charge of the student health service of Glasgow University.

Asian Influenza

Mr. V. COLLINS (Shoreditch and Finsbury, Lab.), questioning the Minister of Health on July 1 about the type of influenza rife in south-east Asia, asked if any cases had been notified in this country, and, if so, whether any had proved fatal. He said there was some anxiety that there might not be sufficient supplies of vaccine available should there be a large number of cases, and asked if an assurance could be given on that point. Mr. J. K. VAUGHAN-MORGAN, Parliamentary Secretary to the Ministry of Health, stated that a number of persons suffering from influenza had arrived and were awaiting laboratory confirmation of what particular variety of influenza they were suffering from. Vaccine was being produced on a laboratory scale. It was being tested for efficacy, and the result would be known about mid-July. But it should not be assumed, in view of the rather mild nature of the disease, that vaccination would necessarily be appropriate.

Sir FRANK MEDLICOTT (Norfolk, Central, Nat. Lib. and Con.) asked if the Minister's attention had been drawn to the fact that there was some similarity between the symptoms of Asian influenza and those of poliomyelitis; and what steps were being taken to guard against the difficulties and complications which might arise as a result of such similarity. Mr. VAUGHAN-MORGAN said he was advised that differentiation between two virus infections of this kind might at first present some difficulty, but that this should not continue for long in a particular case. Medical officers of health had been asked to inform general practitioners of the clinical signs caused by this type of influenza, and laboratory facilities were available to assist in diagnosis.

German Measles

Dr. EDITH SUMMERSKILL (Warrington, Lab.) asked whether the Minister of Health would consider adding German measles to the list of notifiable diseases. Mr. VAUGHAN-MORGAN replied that he had considered this, and had been advised that since it could not be effectively controlled there was no epidemiological purpose in making it notifiable. Dr. SUMMERSKILL said that many authorities believed there was a relationship between German measles and congenital defects. In view of that there should be a national record of German measles. Mr. VAUGHAN-MORGAN said he was advised that German measles did have certain consequences in certain conditions, but also that in the present state of knowledge the degree of risk could not be assessed with certainty.

Schizophrenia Research

Mr. C. MAYHEW (Woolwich, East, Lab.) said in a question that highly qualified scientists were leaving Great Britain to take up schizophrenia research in other countries; and asked what grants were made for schizophrenia research by the Medical Research Council in the years 1952-7 inclusive. Mr. VAUGHAN-MORGAN replied that an isolated instance was known of the acceptance of a post abroad by a scientist working in experimental psychiatry, but he was not aware that there was any significant exodus of trained workers. Between 1952 and 1957 the annual value of grants increased from £3,000 to £11,000 and totalled about £37,000.

Mr. MAYHEW said he could quote other names of scientists leaving to take up schizophrenic research in other

countries. There was a widespread feeling that the small amount of research being done was due to the negative and traditional attitude of the Medical Research Council. Mr. VAUGHAN-MORGAN said that if Mr. Mayhew liked to ask specific questions about the lines of research being pursued he would be surprised. It was not fair to say that the M.R.C. were neglecting any opportunities in this matter.

Vital Statistics

Smallpox in England

Two cases of smallpox in the London region were detected last week. A 6-year-old boy, unvaccinated, was found on June 23 to have a febrile illness and a rash of macular spots. By June 27 the rash was vesicular, apparently typical of smallpox, and the boy was seriously ill. The diagnosis has been confirmed by laboratory tests. When this case was detected inquiries showed that the boy's grandmother had had a febrile illness and rash which began on June 8. The rash was atypical, but some vesicles developed. She was a part-time hospital cleaner. Laboratory tests were not completed at the time of going to press, but the diagnosis is presumed to be smallpox. The patients were isolated at Long Reach Hospital, Dartford. Inquiries have not yet revealed the source of infection, though it is believed to have been brought in by a traveller from abroad.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1948-56 (influenza, 1952-6) are shown thus -----, the figures for 1957 thus ————. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

Infectious diseases were less prevalent in England and Wales during the week ending June 15, and the falls in the number of notifications included 1,497 for measles, from 23,290 to 21,793, 200 for dysentery, from 657 to 457, 152 for whooping-cough, from 1,523 to 1,371, and 42 for scarlet fever, from 589 to 547.

83 cases of acute poliomyelitis were notified, and these cases were 7 fewer for paralytic and 16 more for non-paralytic than in the preceding week. The largest returns were Essex 12 (Colchester M.B. 3, Tendring R.D. 3), Kent 11 (Maidstone M.B. 7, London 9 (Islington 3, Wandsworth 2), Devonshire 8 (St. Thomas R.D. 5, Exeter C.B. 2), Worcestershire 6 (Redditch U.D. 3).

A fall of 100 or more in the number of notifications of measles was recorded in 10 counties. The large exceptions to the general decline in measles were rises of 249 in Lincolnshire, from 692 to 941, and 167 in Sussex, from 251 to 418. In the former county the largest rise was 87 in Louth M.B., from 43 to 130, and in the latter 53 in Brighton C.B., from 107 to 160. Very little variation was reported in the local trends of scarlet fever. The largest decline in the number of notifications of whooping-cough was 43 in Lancashire, from 153 to 110. 8 cases of diphtheria were notified, being 4 more than in the preceding week; 2 cases were notified in Birmingham C.B.

The largest centres of dysentery were Lancashire 93 (Liverpool C.B. 20, Blackpool C.B. 13), Surrey 51 (Croydon C.B. 37), London 38 (Islington 11), Yorkshire West Riding 36; Durham 27; Northumberland 22 (Newcastle upon Tyne C.B. 10).

Week Ending June 22

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 357, whooping-cough 1,592, diphtheria 4, measles 22,144, acute pneumonia 312, acute poliomyelitis 105, dysentery 489, paratyphoid fever 7, typhoid fever 3.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending June 15 (No. 24) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1957					1956				
	Eng. & Wales	London	Scotland	N. Ireland	Eire	Eng. & Wales	London	Scotland	N. Ireland	Eire
Diphtheria	8	2	3	0	2	3	0	1	0	0
Dysentery	457	38	194	6	1	1,246	168	193	9	1
Encephalitis, acute	5	1		0		4	0			0
Enteric fever:

Medical News

Travelling Fellowships for General Practitioners.—Applications are invited from members of the College of General Practitioners, resident in the United Kingdom, for fifteen Upjohn travelling fellowships of £200 each. The fellowships are to provide for not less than two weeks' postgraduate study at the practitioner's old teaching hospital or at any other hospital, clinic, or health centre of his choice in the British Isles. These fifteen travelling fellowships are to be presented annually by Messrs. Upjohn of England Ltd. to members of the College of General Practitioners in the following proportions: England, 10; Scotland, 3; Wales, 1; Northern Ireland, 1. They must not overlap with Ministry of Health grants for postgraduate study. Applications for the 1957 fellowships, with a brief account of the postgraduate work to be undertaken, should be sent to the chairman of the postgraduate education committee of council, College of General Practitioners, 54, Sloane Street, London, S.W.1, before September 1. The names of successful applicants will be announced at the annual general meeting of the College on November 16.

King Edward's Hospital Fund.—At its sixtieth annual meeting on June 28 the council of King Edward's Hospital Fund for London unanimously adopted a proposal to allocate a further £250,000 in grants to mental and mental-deficiency hospitals during the three-year period 1958-60. The meeting was held at St. James's Palace under the chairmanship of the Fund's president, the DUKE OF GLOUCESTER. Referring to this proposal, the Duke said it would bring the total of the Fund's assistance to mental and mental-deficiency hospitals over a very few years to about £630,000. This was a large draft on the Fund's resources, but they now had much detailed knowledge of the needs of such hospitals. Examples of two recent grants the Fund had made in this field were £8,000 to provide an occupational therapy unit for male patients at Oakwood Hospital, Maidstone, a large mental hospital, and £12,500 for an industrial training unit at Leavesden Hospital, Abbots Langley, a mental-deficiency hospital. A number of improvements recommended by the Fund's catering and advisory service, and financed wholly or in part by the Fund, had recently been completed, said the Duke, and during the last few years there had been a marked improvement in catering in many of the mental hospitals with which the Fund's officers had been in touch. For the first time a group of physician superintendents from mental and mental-deficiency hospitals had spent a month at the Fund's staff college, last February, examining afresh the work of mental hospitals. The Fund had made a grant of £10,000 to the British Student Tuberculosis Foundation towards the cost of a sanatorium for university students with tuberculosis in the grounds of Grove Park Hospital, London. A new home was being built at a cost of about £38,000 in the grounds of St. Benedict's Hospital, Tooting, to receive aged patients fit for discharge from hospitals of the Wandsworth Group. This was the eleventh such home the Fund had given, and a twelfth was being built in the grounds of St. Leonard's Hospital, Shoreditch. Sir ERNEST ROCK CARLING reported two grants from the radiotherapy fund: £20,500 to finance new work at the Royal Marsden Hospital's laboratories at the Downs, Sutton, on measuring the intake of radioactive material in man; and £3,000 to St. Thomas's Hospital, London, to provide improved facilities for the radiotherapy of cancer in an atmosphere rich in oxygen.

Medical Sickness, Annuity, and Life Assurance Society, Ltd.—The society's 72nd annual meeting was held in London on June 25. Mr. R. J. McNEILL LOVE, chairman of the board of directors, paid a tribute to the late Dr. A. HOPE GOSSE, the Society's chief medical officer for 30 years, and announced the appointment of Dr. T. C. HUNT in his place. Dr. Hunt had also been elected to the board. 1956 had

been a most successful year, said Mr. McNeill Love. The new life business, with sums assured of nearly £2m., had been a record, and the sickness business had equalled the high standard of previous years. The satisfactory position of the fund had allowed the directors to declare a bonus of 40s. per annum on life assurances. The sickness insurance fund now stood at £2.5m., and the life assurance fund at £4.5m. The wholly owned subsidiary, the Medical Sickness Finance Corporation Ltd., had experienced some reduction in its hire-purchase business owing to Board of Trade restrictions last year, but these had since been relaxed; £650,000 was the amount invested in this subsidiary at the end of 1956. The Society's directors, besides Mr. McNeill Love, the chairman, are Sir Cecil Wakeley (vice-chairman), Dr. A. H. Douthwaite, Dr. T. C. Hunt, Dr. G. Roche Lynch, Dr. S. P. Meadows, and Mr. Bertram Sutton, F.C.I.I. Its offices are at 3, Cavendish Square, London, W.1.

West London Medico-Chirurgical Society.—Dr. C. L. COPE presided at the annual banquet, held at the Apothecaries' Hall on June 27, and his health and that of the Society was proposed by Sir CHARLES READ, P.R.C.O.G. Describing the early history of the Society, Sir Charles said that ever since it had been founded 75 years ago it had been noted for a high standard of oratory and for the farsightedness of its policy. The Society's journal first appeared in 1890, and its library was also founded then. In more recent times the Society had been fortunate in its officers and executive committees, and especially in having Dr. Cope as its president this year. Replying to the toast, Dr. Cope reviewed the activities of the Society during the previous year, and appropriately commented on some of the circumstances of Harvey's life and work in the light of the present day. Harvey delayed nine years before publishing his discovery; he thought that no surgeon should operate without the approval and direction of a physician; and he had views on the value of hypothermia, for when sleepless he walked about in his nightshirt until he was cool. Dr. Cope said that another revolution in thought was proceeding at the present time: the concept of the circulation of atoms in the body. Turning to the function of societies such as the West London Medico-Chirurgical Society, Dr. Cope thought that the most important one was to promote fellowship and good will among medical men. Harvey's own words for this were "Mutual love and affection among ourselves." Dr. CHARLES NEWMAN proposed the health of the guests, and Sir HARRY PLATT, P.R.C.S., replied.

Colouring Matter in Food.—Regulations coming into force by stages over the next two years will make it illegal to add any colouring matter to food unless it is named in a prescribed list. These regulations—the Colouring Matter in Food Regulations, 1957, made jointly by the Minister of Agriculture, Fisheries, and Food and the Minister of Health, under powers conferred by the Food and Drugs Act, 1955—replace earlier regulations which relied on a "forbidden" list of colouring materials. Besides certain colours of natural origin, 30 others are scheduled as permissible under the new regulations, the list being open to revision in the light of further knowledge. The regulations apply to England and Wales only, but corresponding regulations for Scotland are shortly to be made by the Secretary of State.

Professor J. J. Elkes is resigning from the chair of experimental psychiatry at Birmingham on September 30 to take up an appointment as head of the Clinical Neuropharmacology Research Centre of the U.S. National Institute of Mental Health, Washington. Professor Elkes is 43. After education in private schools in Lithuania and Switzerland, he qualified in medicine in 1941, proceeding M.D. (Birmingham) with honours in 1949. He was Sir Halley Stewart research fellow (1942-5), successively lecturer (1945-8) and acting head (1948-50) of the department of pharmacology at Birmingham, and visiting fellow (1950) at New York University and the New England Medical Center, Boston. In 1951 he was appointed to his present chair. He is also consultant psychiatrist to the United Birmingham Hospitals.

C.M.S. Honours Sir Henry Holland.—The Church Missionary Society held a reception in London on June 19, in recognition of Sir HENRY and Lady HOLLAND's "fifty years' distinguished service on the North-West Frontier." Sir Henry Holland, who is now 82, went to India as a medical missionary in 1900, serving in the C.M.S.'s Punjab mission until his retirement in 1948. His work as an ophthalmologist at the C.M.S. Hospital, Quetta, won world-wide renown. He himself performed over 60,000 operations for cataract alone. Since their retirement, Sir Henry and Lady Holland have made six return visits to the Punjab.

Dr. Paul White at R.C.P.I.—On June 24 Dr. PAUL DUDLEY WHITE, of Boston, received the honorary fellowship of the Royal College of Physicians of Ireland. He was introduced by Dr. EDWARD T. FREEMAN, a past-president, and admitted by the president, Dr. F. J. O'DONNELL. Dr. WHITE addressed the College on the subject of "Hypertension and Coronary Thrombosis," and a vote of thanks was proposed by Professor LEONARD ABRAHAMSON, a past-president, and seconded by the vice-president, Dr. BRIAN PRINGLE.

Society of Medical Officers of Health.—Dr. H. D. CHALKE, M.O.H. for the metropolitan borough of Camberwell, has been elected president for 1957-8. Dr. C. METCALFE BROWN, M.O.H., City of Manchester, was re-elected chairman of council for a fourth year.

U.S. Advice to Curtail Mass Radiography.—According to a report from Washington, the U.S. Public Health Service has recommended the curtailment of mass radiography programmes in order to reduce the dangers of exposure to radiation (*New York Herald Tribune*, June 29). The Service suggested, according to the report, that future programmes should be concentrated on those exposed to "the highest risks of contracting tuberculosis, such as persons in hospitals and other institutions and low-income groups."

New Zealand Study on Leukaemia.—At a recent conference of the New Zealand Society of Pathologists in Auckland it was agreed to undertake a co-operative study of all cases of leukaemia in the Dominion. Between 120 and 140 new cases occur there each year, it is stated. The mortality rate for leukaemia in New Zealanders aged 65-75 was 39.7 per 100,000 in the period 1949-53.

Treloar College, Alton.—The Minister of Education, Lord HAILSHAM, opened new buildings for the Lord Mayor Treloar College at Alton on June 26. The college provides a grammar-school boarding education for handicapped boys. It was, in fact, said Lord Hailsham, the first special school for able boys with physical handicaps. The only road to a happy and useful adult life for handicapped children, Lord Hailsham continued, was devoted teaching of the right kind. The degree of success achieved in the Treloar College and other schools like it was a measure of the debt which children, parents, and society in general owed to the teachers.

Harveian Society.—The annual summer meeting of the Harveian Society of London was held on June 23. The traditional pilgrimage was made to the tomb of William Harvey at Hemstead parish church, Essex, where more than 60 members and guests of the Society attended a service in the presence of the Lord Lieutenant of the County and the Bishop of Colchester. Dr. R. COVE-SMITH gave the address. Afterwards an inscribed gold medallion was presented to Mr. A. DICKSON WRIGHT, president of the recent Harvey Tercentenary Congress, by Dr. COVE-SMITH and Mr. W. E. TUCKER on behalf of the Society's council.

Contact Lens Society.—This society, with a membership consisting of ophthalmologists and opticians, held its tenth annual meeting recently at the Institute of Ophthalmology, London. The meeting was under the chairmanship of the society's president, Mr. L. H. LAKE, clinical teacher in ophthalmology at Durham. The society concerns itself with the interchange of experience and the promotion of research in its field, ethical standards, and the advancement of this branch of practice. The society publishes a list of members

who fit contact lenses which is available to the public on application. Further details about the society are obtainable from the secretary, Mr. W. GUMMER, 316, Vauxhall Bridge Road, London, S.W.1.

Liverpool University.—Dr. J. W. DUNDEE and Dr. W. E. KERSHAW have been promoted to senior lectureships in, respectively, anaesthetics and medical parasitology. Both were previously lecturers. Their new appointments will take effect from October 1.

Surgeon Lieutenant-Commander D. G. Dalgliesh, R.N., leader of the advance party of the Royal Society's Antarctic expedition, has been awarded a clasp to his polar medal.

COMING EVENTS

"From Incapacitation to Independence."—Three-day residential course organized jointly by the British Council for Rehabilitation and University College of North Staffordshire, at Keele, Staffs, July 15-17 (fee for course, £1 17s. 6d.; supplementary fee for residence, £3 3s.). Details from the general secretary, British Council for Rehabilitation, Tavistock House (South), Tavistock Square, London, W.C.1.

Royal Medical Benevolent Fund.—Annual general meeting, July 31, 5 p.m., at the Medical Society of London, 11, Chandos Street, London, W.1.

Institute of Diseases of the Chest.—Clinical demonstrations, open to medical practitioners without fee, will be continued at the Institute (in the grounds of the Brompton Hospital, Fulham Road, London, S.W.3) on Fridays at 5 p.m. throughout the summer.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Tuesday, July 9

SOCIETY FOR THE STUDY OF ADDICTION.—At 11, Chandos Street, W., 8 p.m., annual general meeting. Symposium by Dr. E. L. Williams, Dr. A. A. Macdougall, and Dr. M. M. Glatt: Group Therapy in Alcoholism.

Wednesday, July 10

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—3 p.m., Sir Charles David Read: Reflections on Pelvic Excitation.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor A. K. Saha: Zero-position of Glenohumeral Joint—Its Recognition and Clinical Importance.

Thursday, July 11

INSTITUTE OF NEUROLOGY.—5.30 p.m., Professor H. Houston Merritt (New York): Patho-physiology of Convulsive Seizures.

Friday, July 12

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. G. Scadding: clinical demonstration.
ROYAL SOCIETY OF HEALTH.—At Nottingham, 10 a.m., symposium: Social Breakdown in the Elderly. Papers by Dr. Patricia H. S. Shaw and Dr. D. Macmillan.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Dalgliesh.—On June 18, 1957, at Farnborough Hospital, Kent, to Marjorie (formerly Heyworth) and Kenneth Dalgliesh, a daughter—Elaine.
Hamilton.—On June 19, 1957, at the Garrett Anderson Maternity Home, London, N.W., to Angela (formerly Brooks), M.B., B.S., wife of Mark Hamilton, a son.
Littlewood.—On June 12, 1957, at Whiston Hospital, Prescott, Lancs, to Christina, wife of A. H. M. Littlewood, F.R.C.S., a daughter—Claire Magdalen.
Robinson.—On June 25, 1957, at Singapore, to Barbara (formerly Hammond), wife of Dr. Keith Wallace Robinson, a daughter—Claire Elizabeth.

DEATHS

Cohen.—On June 18, 1957, at One Ash, Stoke Lane, Gedling, Notts, Julius Cohen, T.D., M.R.C.S., L.R.C.P., aged 59.
Dale.—On June 14, 1957, at Little Acre, Chestnut Grove, Westfield, Woking, Surrey, Aston Ridley Dale, M.C., M.R.C.S., L.R.C.P., Major, R.A.M.C., retired.
Dixon.—On June 18, 1957, at the Old School House, Bingley, Yorks, Robert Garside Dixon, O.B.E., M.B., Ch.B.
Gordon.—On June 18, 1957, in a hospital, London, William Hadden Gordon, M.B., Ch.B., D.P.H., D.O.M.S., aged 65.
Hamlyn.—On June 16, 1957, David Desmond Hamlyn, M.B., B.S., F.F.A.R.C.S., of Castle House, Wembury, Devon.
Huntley.—On June 18, 1957, at Victoria, British Columbia, Canada, Edgar Huntley, O.B.E., M.B., B.S., aged 89.
Seawin.—On June 12, 1957, at 101, Coronation Road, Bristol, Harold Willis Seawin, O.B.E., M.R.C.S., L.R.C.P.
Stewart-Billings.—On June 13, 1957, Grace Harwood Stewart-Billings, M.B., B.S., of 84, Eveham Road, Cheltenham, Glos., aged 84.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Boosting Polio Immunization

Q.—What boosting is needed for a boy of 10 who had three injections of Salk vaccine in Canada in 1955?

A.—When vaccination against poliomyelitis was first started in North America the initial immunizing course was two doses of vaccine a week apart followed by a third dose four to five weeks later. As the antigenic response is just as good after two doses four to six weeks apart, this latter schedule is the one now most widely used. However, the complete course of immunization consists of the initial injections coupled with a booster dose six to twelve months later.

If this boy received three injections as his initial course another booster dose should be given now. If the third dose was given six months or more after the first two there is no necessity to give him another booster for at least another two years.

Allergy and Polio Vaccine

Q.—What is the frequency of allergic reactions to the British Salk-type poliomyelitis vaccine, and to what constituents are they mostly due? Is the vaccine safe to give to allergic or asthmatic children, and, if so, are any special precautions indicated?

A.—The report to the Medical Research Council on the first 200,000 children to be given British polio vaccine¹ mentions that six children were reported to have become ill shortly after vaccination; in none of these was the illness allergic in type nor could it be related definitely to the preceding injections on clinical or laboratory grounds. In the United States,² up to May, 1957, when more than 140 million doses of vaccine had been issued, 25 probable instances of allergic reaction had been reported, 17 occurring within 24 hours and eight more than 24 hours after inoculation. The three commonest symptoms and signs in order were: urticaria or other skin lesions, oedema of the mouth, lips, or periorbital region, and fever. The constituent of the vaccine most probably responsible was penicillin or some related derivative.

A history of allergy or asthma would not by itself be a contraindication for polio vaccine. A previous violent reaction to penicillin would justify caution. A method that has been used successfully in adult subjects with a previous history of acute violent reaction to penicillin requiring hospital admission is to administer diphenhydramine 50 mg. and ephedrine 15 mg., three times a day, on the day before and the day of injection, and the day afterwards, and to divide the dose of vaccine into an initial 0.3 ml. followed after four hours by the remaining 0.7 ml.

- ² Unpublished information.

Menopausal Osteoporosis and Endocrine Therapy

Q.—Is the presence of osteoporosis a contraindication to the use of hormone therapy for menopausal disorders?

A.—No. In fact the presence of osteoporosis is an indication, rather than a contraindication, for endocrine therapy of the menopause and post-menopausal state. Oestrogen stimulates osteoblastic activity and therefore encourages the deposition of calcium phosphate in bone. Androgen is protein-anabolic and encourages the laying down of protein to form the bony matrix.

So-called "senile" or menopausal osteoporosis is largely due to lack of these two hormones, and its presence calls for

replacement therapy. It is difficult to devise objective assessment of the degree of osteoporosis and its response to treatment, and there are therefore no accurate criteria to indicate optimal dosage. It is probably higher than that recommended for the relief of menopausal symptoms. So far as oestrogen therapy is concerned reasonably large doses—say, stilboestrol 3 mg. daily (or its equivalent)—are indicated, provided the oestrogen is not given continuously but for three weeks out of every four. This may give rise to withdrawal bleeding, but, provided this is scanty and of short duration and appears during the week when no oestrogen treatment is being given, it is unnecessary to attribute any sinister significance to it. Androgen therapy may be administered in the form of oral methyltestosterone, 10 mg. daily for two months out of every three. It is claimed that other preparations, such as methylandrosterone, are equally "protein-anabolic" and less androgenic. Certainly in higher doses this is not true. It may take several years to correct a degree of osteoporosis which is clearly evident on x-ray examination, though some of the accompanying symptoms, such as pains in the afflicted bones, may be relieved shortly after treatment is instituted.

Calculating the "Safe Period"

Q.—A mechanical calculator is now available which on the basis of information about a woman's menstrual pattern is claimed to be able to predict the days in her cycle when pregnancy can and cannot occur. (1) Is the "fertile period" sufficiently regular to permit this kind of calculation? (2) How safe would contraception be if based on a "safe period" estimated in this way?

A.—The recognition of fertile and safe periods of the menstrual cycle depends on the fact that ovulation ordinarily takes place 14±2 days before the next menstrual episode. Allowance has to be made for the survival times of spermatozoa and ova, and for variations in the length of the cycle which occur in the most regularly menstruating women.

In a woman who menstruates regularly every 28±2 days, the fertile period is generally said to be the 8th to 18th days; the safe period comprises the remainder of the days in the cycle. Working to this rule, the safe period is remarkably safe in certain women, but it is only relatively safe. Some authorities regard the fertile period as the 7th to the 21st days, and they reduce the safe period accordingly. It is obvious that the fewer the days placed in the safe period the safer it becomes. Even so, it is reported that amongst women who avoid coitus during the 7th to 21st days of the cycle the risk of pregnancy is still as high as 3 to 4 per 100 "woman-years." For women whose cycles are shorter or longer than 28 days, the calculations must be adjusted, but, if the cycle is less than 21 days or more than 35 days, or if it is grossly irregular, no phase can be regarded as safe. It may be added that the safe period cannot be reckoned for any woman until she has recorded her menstrual period over several months.

The mechanical calculator now on the market does not surmount these difficulties, nor does it make the safe period more safe; it merely removes the element of human error in the calculations. The claims made for it depend essentially on the supposition that in certain cases where conception has occurred during what was regarded as a safe period the woman did in fact make a wrong reckoning.

Chronic Proteus Urinary Infection

Q.—What treatment is advised for a chronic *Proteus* urinary infection where the patient, a young woman, suffered from vestibular disturbance and deafness on streptomycin? Full urological investigation has shown evidence of only chronic cystitis. At present the patient's life is severely restricted.

A.—It should first be verified that the strain of *Proteus* has the sensitivities to drugs other than streptomycin normal for this species: it is presumably resistant to the latter if the patient has unsuccessfully been given enough

streptomycin to cause eighth nerve damage, a most unusual effect from the comparatively short course indicated for this purpose.

The most promising antibiotic is penicillin. Most strains of *Proteus* are inhibited by about 5 units per ml., and far higher concentrations than this are attained in the urine on only moderate dosage. A sustained effect is desirable, and to give the treatment the best chance sodium penicillin should be administered by injection not less than four times a day in fairly large doses, say 500,000 units each; this should produce a urinary concentration of about 1,000 units per ml. (assuming 60% excretion and a daily urinary output of 1,200 ml.; fluid intake can with advantage be restricted to produce this). After three or four days the urine should be sterile, and the dose of penicillin can then be reduced; it would probably suffice to give 120 mg. penicillin V orally four times a day. To prevent recurrence this treatment should be continued for at least one month: a possible alternative at this stage is a small dose of a sulphonamide if the strain is sulphonamide-sensitive.

Few other antibiotics are of value in this infection, and treatment by mandelic acid is precluded by the breakdown of urea to form ammonia producing a degree of alkalinity which no acid drug can reverse. Neomycin is effective, but out of the question in this case because of its action on the eighth nerve. *Proteus* is the only coliform bacillus sensitive to novobiocin, but so little of this antibiotic is excreted by the kidney that its usefulness in urinary tract infections is doubtful.

Cleft Palate and Mental Defect

Q.—Why is deformity of the palate so often associated with mental deficiency?

A.—The incidence of cleft palate among imbeciles and idiots does indeed appear to be appreciably higher than in the general population. In a series of some 1,915 cases of severe mental defect in children examined during the past 10 years 19 instances of obvious cleft palate were recorded, a proportion of 0.992%. This compares with an incidence of 0.057% in children examined in general hospitals in England.

Cleft palate is merely one of the many somatic abnormalities the incidence of which is increased in children with abnormally developed brains. Other instances are syndactyly and polydactyly. It is known that abnormalities both of the brain and of the palate can be produced in animals by restricting the diet of the mother. Other unfavourable circumstances during early intrauterine life may also damage the palate as well as the brain. Genetic factors may be operative, but in the great majority of cases there is no clear family history of such a defect.

In feeble-mindedness there are certain special considerations. Any marked impairment of articulation associated with cleft palate may lead to educational retardation, poor test performance, and emotional maladjustment. The sum effect of these factors may be such as to cause a child to be classed as educationally subnormal or as feeble-minded after leaving school. The question of the intelligence of children with cleft palate was discussed in a recent annotation.¹ The evidence reviewed suggested that such children tend to be below average intelligence.

Lead Hazard from Burning Paint

Q.—Does burning off paint with a blow-lamp, or the burning of painted objects in a fire, cause any appreciable volatilization of lead from the paint? If so, do the fumes constitute an acute or chronic hazard to those engaged in such operations?

A.—The extent to which volatilization of lead from painted objects will occur when burning off paint with a blow-lamp depends upon the temperature produced by the blow-lamp flame and on the lead content of the paint. For example, the lead-poisoning which occurs among ship-breakers results from the cutting of steel plates weather-proofed by red-lead paint with oxyacetylene (3,500° C.), oxyhydrogen (2,800° C.),

or oxy-coal-gas (2,200° C.) blowpipes, whereas the temperature reached at the hottest part of a paraffin blow-lamp flame is only 1,100° C. and in a spirit blow-lamp 900° C. Burning off or dry rubbing-down of surfaces painted with a lead paint constitutes a risk of lead absorption which may lead to intoxication, particularly if these procedures are carried out in confined, badly ventilated spaces.

With regard to the possible harmful effects of burning painted objects in a fire, it would be necessary to know much more about the nature of the objects, the type of paint, and the conditions under which the objects would be burned. The use of scrap batteries as domestic fuel gave rise to an outbreak of lead-poisoning among children in Rotherham in 1954. This, however, was attributed to ingestion of the residual ash and not to inhalation of fume.¹

NOTES AND COMMENTS

Antivenin for Adder Bite.—Dr. G. A. BALLANCE (Knighton, Radnorshire) writes: The second paragraph of your expert's answer ("Any Questions?" April 20, p. 961) begs the essential question—when indeed is one to expect the "remission of symptoms" to commence? That is just the problem of the isolated doctor, and it becomes more urgent when one remembers the little boy who recently died from the remedy, not the disease.

OUR EXPERT replies: I mentioned in my answer that fatalities following the bite of *Vipera berus* are fortunately rare, though small children may be severely affected. The timing of the expected recession of symptoms naturally depends on the severity of the case, but many patients show improvement within a few hours or on the following day. It is by no means uncommon to find that, when the country doctor obtains the serum urgently, he refrains from using it because the patient is already so much better. The recent fatality due to serum received considerable publicity in the lay press. It must be appreciated that the use of antivenin carries the same hazards as any other serum, and ideally one should carry out measures analogous to those recommended by Parish *et al.*¹ in connexion with the injection of tetanus antitoxin. Although it is unusual in practice to delay the main dose of antivenin for a sensitivity test, perhaps in the case of bites from *Vipera berus*—an adder that is not very poisonous—inquiries should be made about previous injections of horse serum of any kind and about allergic conditions, especially asthma and infantile eczema. What the doctor then does is a question of balancing the various risks in the particular case.

REFERENCE

¹ Parish, H. J., Laurent, L. J. M., and Moynihan, N. H., *British Medical Journal*, 1957, 1, 639.

Corrections.—In the description of Case 4 in the paper by Dr. Robert P. Warin and his colleagues on the subject of "Reticulohistiocytosis (Lipoid Dermato-arthritis)" (June 15, p. 1387) it was stated that: "A chest skiagram in April, 1957, showed diffuse mottling throughout both lungs." We regret that this sentence was misplaced: it should, in fact, have appeared at the end of the paragraph discussing the results of the x-ray examination of Case 2.

Dr. E. ASHWORTH UNDERWOOD writes: In my obituary note on Edgar Goldschmid (June 22, p. 1478) I regret that by a slip of the pen I wrote *Geschichte* instead of *Entwicklung* in the title of his main work. The correct title should therefore read *Entwicklung und Bibliographie der pathologischen-anatomischen Abbildung*.

We regret an error in the list of those admitted F.R.C.P.I. in our issue of June 22 (p. 1481). The D. J. O'CALLAGHAN concerned is of Cork, not Kilgarvan, Co. Kerry.

THE ERYTHROMYCIN GROUP OF ANTIBIOTICS

BY

LAWRENCE P. GARROD, M.D., F.R.C.P.

Bacteriologist, St. Bartholomew's Hospital; Professor of Bacteriology, University of London

The comparative value of a new antibiotic depends not only on its therapeutic usefulness but also on its relationship to others already in existence. If it differs little from them its discovery may not be of major importance: if it has entirely new properties it may represent a major advance. The discovery of erythromycin in 1952 must unquestionably be placed in the second of these categories. This antibiotic has a similar range of activity to that of penicillin, but there is no relationship between the two, or between it and the tetracyclines. It can hence be used when these earlier antibiotics are contraindicated either by reason of sensitivity in the patient (particularly to penicillin) or resistance in the organism (notably in staphylococci). Unfortunately staphylococci can also become resistant to erythromycin itself, and where it has been extensively used, particularly in the United States, resistant strains have become prevalent, even causing fatal infections on which no antibiotic had any effect (Martin, Nichols, Wellman, and Geraci, 1954). In the hope of preventing or delaying the development of such a situation in this country, it has been suggested that the use of erythromycin be restricted to really necessary indications. This warning has had an unprecedented effect, and has so far almost completely achieved its purpose.

Since 1952, several other antibiotics have been produced which stand in close relationship to erythromycin: they have a similar "spectrum" of activity and exhibit at least some degree of cross-resistance with it. These therefore require to be considered from two points of view: their therapeutic merits relative to those of erythromycin, and the possible effect of their use on bacterial sensitivity to it. If complete cross-resistance occurred, as between the three tetracyclines, any restrictive policy in the use of erythromycin should clearly also be applied to these others. In the order of their discovery these are:

Carbomycin.—This antibiotic is practically identical in its range of activity with erythromycin, but at a considerably lower level. Cross-resistance is close if not complete. Carbomycin, besides being less active, also attains lower concentrations in the blood (Hewitt and Wood, 1953) and, as would be expected from these two facts, is decidedly inferior in therapeutic action (Finland, Purcell, Wright, and Love, 1953). Hence it is not a serious competitor, at least for the treatment of most bacterial infections.

Spiramycin.—This antibiotic was discovered in France and appears to have been used there more than

anywhere else, although it has also undergone trials in the United States and is commercially available in this country under the name "rovamycin." Its *in vitro* activity is decidedly inferior to that of erythromycin: although the same species are susceptible, the relative degrees of activity differ somewhat: thus the approximate factors by which the activity of erythromycin is superior are $\times 16-32$ for *Staphylococcus pyogenes*, $\times 8$ for *Streptococcus pyogenes*, and $\times 4-8$ for *Streptococcus pneumoniae* (Garrod and Waterworth, 1956). There is cross-resistance with erythromycin when strains of staphylococci are habituated *in vitro* (Chabbert, 1955), but Hudson, Yoshihara, and Kirby (1956), in examining 117 strains of staphylococci, found only two resistant to both of these antibiotics, one resistant to spiramycin only, and 11 resistant to erythromycin but sensitive to spiramycin. It appears from these findings that cross-resistance is the exception rather than the rule in strains which have presumably become resistant *in vivo*.

Oleandomycin.—This antibiotic was first described under the designation P.A.105 by Sobin, English, and Celmer (1954-5), and for two years little more was heard of it. Recently it has appeared on the market under three names and in two forms: as pure oleandomycin ("matromycin," Pfizer; "romicil," Hoffmann-La Roche) and as a mixture with twice its weight of tetracycline ("sigmamycin," Pfizer).

The range of activity of oleandomycin, so far as it has been ascertained, corresponds closely to that of erythromycin, and cross-resistance between them in strains of staphylococci habituated in the laboratory was found by Sobin *et al.* (1954-5), by Fust, Böhni, Zbinden, and Studer (1956), and by Noyes, Nagle, Sanford, and Robbins (1956). On the other hand, according to Ross (1955-6) 22 erythromycin-resistant strains were "either quite sensitive or moderately sensitive" to oleandomycin; and Needham and Geraci (1956) found 54 out of 75 erythromycin-resistant strains to be sensitive to it. There is thus more extensive evidence than that cited in connexion with spiramycin to show that cross-resistance is not the rule in naturally occurring strains of staphylococci.

In trying to adjudicate on the merits of these various preparations, information seems desirable on the two following questions: (1) the activity of oleandomycin, alone and in combination with tetracycline; and (2) the closeness of the relationship between members of the whole group, from which it may be

deduced how far acquired resistance to each involves the others.

The following experiments were aimed at obtaining such information.

Materials and Methods

I am indebted to Charles Pfizer & Co. and to Hoffmann-La Roche Ltd. for supplies of pure oleandomycin. Other antibiotics were pure materials kindly supplied by their manufacturers.

Strains of staphylococci and other bacteria were recently isolated in St. Bartholomew's Hospital, except 44 strains of staphylococci the sources of which are specified later.

Medium, preparation of antibiotic solutions, methods of determining minimum inhibitory concentrations, and procedure for habituation were as described by Garrod and Waterworth (1956) except where otherwise specified.

In Vitro Activity of Oleandomycin

Of 58 strains of *Staph. pyogenes* initially tested for sensitivity to oleandomycin, 54 were inhibited by a concentration of 0.5 but not by 0.25 µg./ml. The usual minimum inhibitory concentration (M.I.C.) of erythromycin as determined by this method is 0.12 µg./ml.; oleandomycin thus has one-quarter of the activity of erythromycin against this species. Of the remaining four strains, two were inhibited by 0.25 µg./ml., and two were resistant: these strains were also resistant to erythromycin.

A few tests were done with two other species. Each of six strains of *Str. pyogenes* of group A, and four out of six strains of *Str. pneumoniae* (the remaining two being somewhat more resistant) were inhibited by an oleandomycin concentration of 0.25 µg./ml. These findings again indicate a degree of activity inferior to that of erythromycin, the difference for both species being about eightfold (cf. Garrod and Waterworth, 1956).

Combined Action of Oleandomycin and Tetracycline

The claim that a 2:1 mixture of tetracycline and oleandomycin ("P.A.755," "sigmamycin") exerts a synergic action on staphylococci is made by English, McBride, van Halsema, and Carozzi (1956). Their *in vitro* tests were made with 22 strains, and for nine of these the M.I.C. of the combination is significantly lower than that of either of its constituents separately. The differences are most striking when the organism is abnormally resistant to one of the two antibiotics.

Several series of tests were made to examine this claim, both on solid and in liquid media. They included initially the 56 strains with normal sensitivity to oleandomycin referred to in the preceding section: 45 of these were also normally tetracycline-sensitive. Fourteen further strains were tested which were abnormally resistant to one or other of these antibiotics. It is unnecessary to present the results in detail, because they are covered by the statement that not in a single instance was the M.I.C. of the combination lower than that of one of its constituents acting alone.

Through the courtesy of Dr. W. Williams, of Chas. Pfizer & Co., and of Drs. van Halsema and English, of the Pfizer Therapeutic Institute, Maywood, New Jersey, I obtained, first, a culture of the strain "Canada 1475," against which synergic action was particularly striking in the findings of English *et al.* (1956), and, later, particulars of how their tests were made. According to these authors the M.I.C. of tetracycline, oleandomycin, and P.A.775 for the strain "Canada 1475" were 8.3, 4.12, and 0.19 µg./ml. respectively. Repetition of this test in my laboratory, using a different broth and a somewhat smaller inoculum, gave M.I.C. of 0.25, 0.5, and 0.25 µg./ml. This strain appears to have lost the resistance to both antibiotics which it possessed when originally tested.

The inoculum used by English *et al.* was 0.5 ml. of a 1 in 1,000 dilution of broth culture, and their medium was Difco brain heart infusion broth, of which they state: "Final pH in our laboratory was 7.0." Some of this medium was obtained: it is labelled as having a pH of 7.4, and in fact had one of 7.6 after being dissolved and autoclaved. It was used both at its natural pH and adjusted to pH 7.0. The above inoculum was used (added to 4.5 ml. medium + 0.5 ml. antibiotic solution), and results were read as presence or absence of turbidity after overnight incubation. The M.I.C. so determined for strains sensitive to both antibiotics and resistant to each and both are stated in Table I.

TABLE I.—Sensitivity to Tetracycline, Oleandomycin, and P.A.775

Strain	Sensitivity Pattern	Minimum Inhibitory Concentration (µg./ml.)

"	"	64	2 (1)	4 (2)
"	"	8	1	2 (1)
No. 83* ..	Oleandomycin-resistant	0.12	16 (32)	0.12
" 88* ..	Erythromycin-resistant	0.25	2 (1)	0.12
" 95* ..	Tetracycline- and oleandomycin-resistant	32	32 (16)	16
"	"	64 (128)	32 (16)	32

* For source and other characters see Table III. M.I.C. are those in Difco brain heart infusion broth at pH 7.0; the figures in parentheses are those in same medium of pH 7.6, when the result differed.

As before, the M.I.C. of P.A.775 was usually the same as that of the more active of its two components, or one tube higher. In only two instances, strains 83 and 88, was it lower, and then only by one tube, a result to which no unequivocal significance can be attributed. These experiments have therefore failed to demonstrate the synergic action claimed for the tetracycline-oleandomycin combination.

Habituation to Tetracycline, Oleandomycin, and P.A.775

It is also claimed by English *et al.* (1956) that a proceeding of habituation which causes a large increase in resistance to either tetracycline or oleandomycin has little effect when the two are combined.

Six strains of *Staph. pyogenes* were habituated to each antibiotic and to the combination by 16 transfers in increasing concentrations in broth, and finally tested for sensitivity to all three. The results, which were broadly consistent among the six strains, are summarized in Table II. The increased resistance obtained to each single antibiotic, which

TABLE II.—Habituation to Tetracycline, Oleandomycin, and P.A.775 of Six Strains of *Staph. pyogenes*

Habituated to	-Fold Increase in Resistance to		
	Tetracycline	Oleandomycin	P.A.775
Tetracycline ..	16-64	0	2-4
Oleandomycin ..	0	32-256	0-2
P.A.775 ..	16-32	0-2	4-8

was somewhat larger to oleandomycin, was unaccompanied by a change in sensitivity to the other, or by much change in sensitivity to the combination, since the second retained its activity. In habituation to P.A.775 the tetracycline component seemed to play the dominant part, and resistance to it increased almost as much as to tetracycline alone: sensitivity to oleandomycin changed comparatively little, and to the combination to an intermediate degree. It seems that the smaller amount of the weaker antibiotic fails to interfere effectively in the reaction of the organism to the major component in the combination.

Relationship between Oleandomycin and Other Antibiotics of the Erythromycin Group

The evidence already cited about cross-resistance between oleandomycin and erythromycin is conflicting. To explain these discrepancies it was necessary to examine a large number of strains, and I am much indebted for cultures of erythromycin-resistant strains of *Staph. pyogenes* to the following: Dr. S. D. Elek, St. George's Hospital; Professor R. Knox, Guy's Hospital; Dr. Mary Barber, St. Thomas's Hospital; Dr. E. J. L. Lowbury, Birmingham Accident Hospital; Dr. W. A. Gillespie, Bristol Royal Hospital; Dr. J. R. B. Williams, Lister Hospital, Hitchin; Professor R. W. Fairbrother, Manchester Royal Infirmary; and Dr. E. S. Duthie, Royal South Hants Hospital, Southampton. I am also much indebted to Dr. R. E. O. Williams, of the Central Public Health Laboratory, for determining the phage types of these strains and for supplying me with other strains of ascertained phage type.

The sources and properties of these strains and of four isolated in this hospital are stated in Table III. That a strain resistant to erythromycin may or may not be resistant to oleandomycin is fully confirmed. The strains isolated in four London hospitals, in Manchester, and in only 1 out of

the 14 of those from Southampton, were resistant to both antibiotics; the remainder from Southampton and those from Birmingham, Bristol, and Hitchin were highly resistant to erythromycin only, the M.I.C. of oleandomycin and spiramycin being either normal or only slightly raised. These two types of resistance are henceforward referred to as "double" and "dissociated."

Distribution of Resistance in Staphylococcus Populations

An indication had been obtained that erythromycin resistance of the dissociated type is not uniform throughout a culture, and experiments such as that in Table IV proved that this is so. When different quantities of a broth culture are cultivated in pour-plates containing different concentrations of erythromycin, a sharp end-point is obtained with a strain of double type: either every cell grows or none. A strain of the dissociated type, on the other hand, appears to contain cells of different degrees of resistance: the higher the concentration of erythromycin, the fewer are the colonies obtained: results with a small inoculum show that the highest degree of resistance is possessed by <1% of the cells. A culture derived from one of this small minority is uniformly resistant (last line of Table IV). It was found in

further experiments that growth in broth containing erythromycin in concentrations from 32 to as low as 0.0015 $\mu\text{g./ml.}$ bred a population uniformly resistant to $>64 \mu\text{g./ml.}$ Uniformly high resistance so produced was unstable: after six transfers in antibiotic-free broth much of it was lost.

Effect of Adding Erythromycin after Growth has Begun

These findings illustrate the behaviour of a population of the dissociated type in the presence of erythromycin: they afford no clue to its composition *qua* erythromycin resistance in normal medium. It seemed at least possible that so mixed and apparently unstable a population might include fully sensitive cells in the absence of the antibiotic. This was first investigated by adding erythromycin in different amounts at intervals after incubation of a broth culture had begun. The results in Table V typify those of several such experiments, and show that this suspicion was well founded. Whereas the time of addition of antibiotic up to five hours makes no difference to the growth of a strain of the double type, addition after two, three, or four hours enables much lower concentrations to arrest visible growth of one of dissociated type. It therefore seems that this type, growing in the absence of antibiotic, consists largely of more sensitive cells.

The mechanism of this effect was further investigated in a more complex experiment, which after several ineffectual trials of less lengthy proceedings had to be begun at 7 a.m. and terminated at 10 p.m. It comprised three cultures of strain 87 (dissociated), one containing no antibiotic, one having erythromycin (2 $\mu\text{g./ml.}$) added at the start, and the third receiving the addition after four hours' incubation. Viable counts were made from each at intervals up to 15 hours on plain medium and medium containing 1 and 8 $\mu\text{g.}$ of erythromycin per ml., a picture being thus obtained not only of the rate of growth (or death) but of the proportion of resistant cells at each stage. Detailed results are omitted for the sake of brevity: they may be summarized as follows. The antibiotic-free cultures showed growth at a normal rate of cells of which only a minority were resistant. With erythromycin added at the start, growth was delayed, but consisted eventually entirely of resistant cells. The addition of erythromycin at four hours caused a progressive fall in the viable count during the ensuing nine hours, showing a 98% mortality in the predominantly sensitive population: the few almost exclusively resistant survivors ultimately resumed growth.

If so low a concentration of erythromycin has a bactericidal effect on them, it seems probable that the bulk of the

Inoculum, etc., and symbols as in Table VI.

cells in an antibiotic-free culture of the dissociated type are normally sensitive. If this is so, erythromycin resistance of the dissociated type is conditioned by the presence of the antibiotic.

The examination of many colonies from such a culture failed to yield pure cultures of organisms of normal sensitivity.

Effect of the Presence of Erythromycin on Resistance to Other Antibiotics

Since it appeared that the presence of erythromycin is necessary for organisms of the dissociated type to exhibit resistance to this antibiotic, it became of interest to determine

Fig. 1.—Nutrient agar plate containing 1 $\mu\text{g.}$ oleandomycin per ml., surface-inoculated with strain 87, with three cups containing erythromycin solutions of 100 (top right), 50 (below), and 25 (top left) $\mu\text{g./ml.}$ Growth of all but very few colonies is inhibited within a few millimetres of the cups: in a zone surrounding this the erythromycin permits growth despite the presence of oleandomycin. Elsewhere oleandomycin inhibits it.

whether in these circumstances there is any change in resistance to related antibiotics. The experiment in Table VI shows that there is: in the presence of 0.06 $\mu\text{g.}$ of erythromycin per ml. the concentration of either oleandomycin or spiramycin required to inhibit the growth of each of five strains of the dissociated type is increased fourfold to eightfold; there is no effect on a strain (70) of the double type.

In further experiments the concentration of erythromycin as well as of the other two antibiotics was varied: all the strains in Table VI were so tested with similar results and those for two of them are stated in Table VII. With fourfold increases in concentration of erythromycin from 0.003 to 0.25 $\mu\text{g./ml.}$ there is a progressive increase in resistance to both oleandomycin and spiramycin.

The presence of a low concentration of erythromycin thus confers double resistance on an organism of the dissociated type. This highly paradoxical result has no parallel that I am aware of, and is not fully explicable in the present state of knowledge about this group of antibiotics and their mode of action. On the other hand, it serves to explain further the observations of Chabbert

(1956) on "antagonism" between erythromycin and spiramycin. This can be illustrated more strikingly than in this paper by placing erythromycin solution in cups in a plate containing an inhibitory concentration of oleandomycin: a strain of dissociated type then grows only in a zone surrounding the cups (Fig. 1).

When fully erythromycin-resistant variants (see above, under the heading "Distribution of Resistance in Staphylococcus Populations") of strains 80, 87, and 103 were cultivated in medium containing different concentrations of oleandomycin or spiramycin and much higher concentrations of erythromycin than those used in the preceding tests, it was shown that all concentrations of the latter up to 64 $\mu\text{g./ml.}$ enabled growth to take place despite the presence of concentrations of oleandomycin (16–128 $\mu\text{g./ml.}$) or spiramycin (32–256 $\mu\text{g./ml.}$) which were otherwise inhibitory.

Effects of Habituating Dissociated Type

Strains 77, 80, 81, 87, and 103 were transferred repeatedly in broth containing 64 $\mu\text{g.}$ of erythromycin per ml. After six transfers they acquired partial resistance to oleandomycin but none to spiramycin: after 12 transfers in either this concentration or one of only 0.1 $\mu\text{g./ml.}$ oleandomycin resistance became more pronounced and there was some increase in resistance to spiramycin.

Strains 87, 90, 91, and 92 were habituated to oleandomycin, and all became resistant to 512 $\mu\text{g./ml.}$ in eight transfers: sensitivity to spiramycin was unaffected. The same strains were habituated to spiramycin: all became resistant to 512 $\mu\text{g./ml.}$ both of spiramycin and of oleandomycin (Fig. 2). Thus habituation of this type to oleandomycin still leaves a dissociated form of resistance: habituation to spiramycin makes the organism resistant to all three antibiotics.

Attempts to Produce Dissociated Resistance Artificially

All authors are agreed that when staphylococci are habituated to one of these antibiotics *in vitro* by the usual proceedings, resistance also develops to the others. Naturally occurring strains may either have this type of resistance ("double") or be resistant to erythromycin only. What determines this difference is unknown, but the factors operative *in vivo* can presumably be imitated *in vitro*. The following fruitless attempts were made to identify them. Six normally sensitive strains having phage patterns corresponding to those of certain strains in Table III, kindly furnished by Dr. R. E. O. Williams, were habituated to erythromycin. Two of these had the phage patterns of strains 72, 80, 82, and 85, all of which had dissociated resistance. All six developed double resistance. It seems unlikely from this and from the distribution of phage

Fig. 2.—Nutrient agar plates containing (left) 512 $\mu\text{g.}$ oleandomycin per ml. and (right) the same concentration of spiramycin. Both inoculated with strains 87, 90, 91, and 92: those on the left half of the plate had been habituated to spiramycin by eight transfers in increasing concentrations, those on the right half to oleandomycin by the same process. When a strain of this type is habituated to this extent, exposure to oleandomycin produces resistance to that antibiotic only: exposure to spiramycin produces resistance to both.

patterns among strains of the two resistant types (Table I) that phage type is a factor.

The same six sensitive strains were transferred repeatedly in or on the following media with added erythromycin: on nutrient agar aerobically; on nutrient agar anaerobically; in broth at 20° C.; in broth at pH 6.0; in Ringer's solution at 30° C.; in serum; in plasma. In so far as resistance was developed, it was of the double type. So also was that of variants appearing after six days in massively inoculated pour-plates containing up to 8 µg. of the antibiotic per ml. Thus various conditions less favourable to growth *in vitro* and corresponding to some which may exist *in vivo*, do not alter the result of artificial habituation.

Sensitivity to E 129

Antibiotic E 129 shows a minor degree of cross-resistance with erythromycin and spiramycin in artificially habituated strains (Garrod and Waterworth, 1956). The 45 strains in Table III were tested against it: 30 were inhibited by 0.25 µg./ml. (the normal concentration), 14 by 0.5, and 1 by 2 µg./ml. (this last being the double type). The inclusion of erythromycin in the medium did not alter these results. These findings suggest an even more remote relationship between E 129 and the erythromycin group than those reported earlier.

Discussion

The Problem of Cross-resistance

Relationships in this group are evidently less close and more complex than those between the tetracyclines. This would not be supposed if only the effects of habituation in the laboratory were considered: authors cited earlier are unanimous in finding that artificially produced resistance involves other members of the group, and Jones, Nichols, and Finland (1956) have amply confirmed this. By producing a high degree of resistance to erythromycin, oleandomycin, spiramycin, or carbomycin, and studying resistance to all four during the process of habituation to each, they showed that resistance to all four increased to the same extent and at approximately the same rate.

In striking contrast with this uniform behaviour, it has been shown that erythromycin-resistant staphylococci recovered as such from patients may or may not be resistant to other antibiotics of this group. An extraordinary feature of the strains is that with a single exception all the strains from each source behaved in the same way. Disregarding for this purpose sources from which only a single strain was obtained, all those from three London hospitals were fully cross-resistant, while 14 from Birmingham, 4 from Bristol, and 10 out of 11 from Southampton showed resistance of the dissociated type. Even the single exception is accounted for, since it came from a patient who had been treated with spiramycin.

Inquiries which the donors of some of these strains have kindly answered for me about the mode of therapeutic use of these antibiotics in their hospitals have revealed no differences in such use or in the types of case treated that can be held accountable for the difference in effect on the organism. That all staphylococci from one hospital should behave alike would be expected if in fact they were of a single strain spreading by cross-infection, but some diversities in phage pattern show that this was not always so. Whatever the explanation of this consistency of behaviour within one hospital, an explanation of why resistance should sometimes embrace all three antibiotics and sometimes involve only erythromycin has yet to be found. Attempts to induce the dissociated type of resistance by various manoeuvres *in vitro* have failed.

The nature of the dissociated type of resistance is peculiar. The cells forming such a culture are evidently not stable mutants: it has been shown that in erythromycin-free medium the majority are quite sensitive, whereas a colony on medium containing the antibiotic yields descendants which are uniformly resistant. The presence of erythromycin, even in very low concentration, also converts these organisms

immediately to the cross-resistant state. This observation explains the findings of Chabbert (1956), which he interprets as indicating "antagonism" between erythromycin and spiramycin. This is not antagonism in the ordinary sense, but a kind of interaction of which, so far as I am aware, no previous example has been seen.

To what extent the clinical use of oleandomycin or spiramycin may produce bacterial resistance to erythromycin remains uncertain. In so far as resistance in the strains studied was attributable to a course of treatment, erythromycin was the antibiotic which had been used in almost all the patients: systematic study of the effects of administering either of the other two has been quite inadequate to provide the necessary information. It seems probable, and it would certainly be safer to assume, that cross-resistance may sometimes follow the use of any of the three. Granting that they can be placed in an order of merit, we thus have the unusual and unsatisfactory position that the use of an inferior drug can deprive a better one of its usefulness.

Merits of Individual Members of the Group

Spiramycin has a considerably lower activity *in vitro* than erythromycin, and oleandomycin one intermediate between them. In tests reported here, the activity of oleandomycin against the three perhaps most important species of bacteria was about one-quarter of that of erythromycin: Jones and Finland (1957), in tests of which no details are given, find this proportion to vary from one-quarter to one-thirty-second. These authors also report unfavourably on the antibacterial activity of the plasma of subjects to whom oleandomycin was administered. It is well known that *in vitro* and *in vivo* activity do not always correspond, but confirmation of *in vitro* results by the method used by Jones and Finland gives them added significance.

It is notoriously difficult to assess therapeutic value with any exactitude on the basis of clinical reports unless these deal with comparative trials. The considerable literature on the clinical use of spiramycin includes, so far as I am aware, no account of any adequate comparison with another antibiotic, and in particular with erythromycin. Reports on the clinical use of oleandomycin are few: apart from that of Ross (1955-6), already quoted, there are two emanating from Switzerland. Essellier and Keith (1956) and Siegenthaler, Keiser, and Hegglin (1956) treated 412 and 216 patients respectively suffering from a wide variety of conditions and are enthusiastic about the drug. The latter report success in treating urinary-tract infections caused by demonstrably resistant coliform species, and the former in diverticulitis and inoculation hepatitis: the improbability of any specific effect in such conditions suggests that the credit awarded to the antibiotic in connexion with other patients may sometimes have been misplaced. It can reasonably be concluded that neither spiramycin nor oleandomycin has been shown to be superior in therapeutic action to erythromycin: by the only criterion susceptible to accurate measurement, which is *in vitro* activity, they are both inferior to it, and the probability is that this inferiority has at least some counterpart in their action in the body.

The claim that a 2:1 mixture of tetracycline and oleandomycin (sigmamycin) has a synergic action on staphylococci *in vitro* has been examined and not confirmed. This finding is by no means put forward as final, but only as suggesting that more searching investigations of the combined action of these two antibiotics is called for if this claim is to be sustained, and might indeed well have been undertaken before the claim was made originally. The method used by English *et al.* (1956), and followed in my repetitions of their tests, is a very simple one: more information might well be obtained by one employing serial viable counts to determine the rate of bactericidal action. These authors also report therapeutic tests in mice in which the effect of a given dose of P.A.775 was compared with that of the amounts of tetracycline and oleandomycin contained in that dose. It

would be interesting to know the results of such tests in which the total dose, whether of individual components or of the mixture, was the same.

Synergic action between antibiotics of this type has been thought not to occur, but one other example has been reported by Oskam (1956): using a very unusual *in vitro* method, he claims to have demonstrated synergy between tetracycline and erythromycin. Substantiation of this finding by other methods might raise the question whether a mixture of tetracycline and erythromycin could perhaps be therapeutically superior to one of tetracycline and oleandomycin.

Summary

The *in vitro* antibacterial activity of oleandomycin has been found to be somewhat less than that of erythromycin. The merits of these two antibiotics and of spiramycin are considered, and the conclusion reached is that neither oleandomycin nor spiramycin has been shown to be therapeutically superior to erythromycin: it is probable that the ratios of *in vitro* activity are reflected to some extent in their action in the body.

The repetition of tests showing that a mixture of tetracycline and oleandomycin exerts a synergic action *in vitro* did not confirm the claims made.

Studies of cross-resistance among antibiotics of the erythromycin group showed that, whereas complete cross-resistance develops in strains of staphylococci habituated *in vitro*, erythromycin-resistant strains isolated from patients may or may not be resistant to oleandomycin and spiramycin. Efforts to identify the factors determining which type of resistance is developed were fruitless. The behaviour of strains resistant to erythromycin only was peculiar in several ways. The presence of this antibiotic in a culture medium conferred on them resistance to each of the others.

For not only the execution of much of this work, but for the conception of many of the experiments, I am indebted to my assistant, Miss Pamela M. Waterworth, whose experience in the study of antibiotics has been extensive and continuous since she first worked with penicillin in my laboratory in 1943.

The Wellcome Trustees have made a grant of £5,000 to McGill University, Montreal, for the purchase of books related to the history of medicine needed to fill important gaps in the Osler Library. The Trustees have also agreed to provide £1,200 annually for twenty-five years to assist the further development of this library. A new extension and reading-room for the library, to be known as "The Wellcome Camera," is to be provided by McGill University.

A TRIAL OF FIVE TRANQUILLIZING DRUGS IN PSYCHONEUROSIS

Clinical Genetics Research Unit, Institute of Child Health, The Hospital for Sick Children, Great Ormond Street, London

Prolonged or disabling anxiety and tension are non-specific accompaniments of many psychiatric disorders. Conflict and frustration may be important contributory factors, and where they can be defined and resolved symptomatic relief may follow. Hence the most effective approach may often be by psychotherapy, especially if the symptoms are of recent origin. As an additional measure, where distress is severe or prolonged drugs are often prescribed. Recently there has been a striking increase of available tranquillizers, as the new preparations are termed. In this paper we report the results of a controlled trial of certain drugs claimed to reduce tension. We are not here concerned with the use of any of these drugs in the treatment of psychotic conditions, for which purpose they are given in much larger dosage to patients under strict hospital supervision.

Among clinical trials which have been reported chlorpromazine in daily dosage ranging from 75 to 300 mg. has been claimed to be of value for the relief of tension in psychoneurotics (Garmany *et al.*, 1954; Winkelman, 1954; Azima and Ogle, 1954). Selling (1955) and Borrus (1955) report favourably on the use of meprobamate in tension states. The usual dose in Selling's series was four tablets a day (each tablet = 400 mg.) and the maximum dose he used was eight tablets a day. Lasagna (1956) found its hypnotic effect equal to that of phenobarbitone, while Hollister *et al.* (1956) found that meprobamate provided effective relief of anxiety symptoms in half or more of the patients treated. Encouraging results with benactyzine in treating psychoneurosis have been reported by Jensen (1955), Munkvad (1955), Davies (1956), Raymond and Lucas (1956), and Hargreaves *et al.* (1957). Seager and Leitch (1956), however, reported unfavourably on its use on a series of 13 patients. A dosage of 2 mg. thrice daily is in line with the recommendations of most workers.

Method

The patients were selected from those attending the psychiatric out-patient department of St. George's Hospital. They comprise a heterogeneous group of psychoneurotic disorders, the criterion of selection being the presence in the symptomatology of a tension component. They were patients who, in the opinion of the referring consultant, had a definite load of symptoms, and they were comparable to those patients for whom sedation is commonly and properly prescribed in general practice. During the trial period we attempted to include all such patients who attended the department. Each patient served as his own control, and was given six medicaments (five tranquillizers and a placebo) for successive two-week periods. He was told that he was taking part in a trial to find out which of several tablets was best for him. He was asked to record his judgment of

effect of each drug day by day on a five-point scale, as set out on the form reproduced here. He was not told that one of the tablets was inert.

Form Issued: Patient's Name: _____

This trial is designed to find out which of several tablets is best for you. At the end of the day please record how you have felt, using the following signs:

No effect (you do not think the drug has had any effect on you, good or bad) = 0
 Good effect = +
 Very good effect = ++
 Poor effect = -
 Very poor effect = --

You may reduce your own tablets if you wish, but please do not stop taking them altogether, no matter how well you may feel. If you do change your dose, please record this below.

PLEASE BRING THIS FORM WITH YOU WHEN YOU KEEP YOUR APPOINTMENT

It will be noted that the patient was not asked to compare either one period with another, or his state with his concept of his own "norm." No objective rating by the interviewing psychiatrist was attempted, for the aim of the inquiry was to find out how the patient felt, and the simplest way was to ask him. Only the chief pharmacist knew the drug to which each code letter referred, and he also allotted the patients successively to the orders of treatment, which were unknown to the doctor (see below under Experimental Design).

We were particularly concerned that each drug should be made available in dosage generally considered adequate for out-patient treatment in this group of disorders, and also that the patient could reduce his dose if he thought it was too strong. We also considered it important that the number of tablets prescribed should be the same for each treatment (two tablets thrice daily).

Drug	Dosage
1. Amylobarbitone ("amytal")	Dosage two tablets three times a day. Each tablet containing: ½ gr. (50 mg.)
2. Benactyzine ("suavasil," "nutinal")	1 mg.
3. Chlorpromazine ("largactil")	25 mg.
4. Meprohamate ("equanil," "miltown," "mepavlon")	400 mg.
5. "Sedaltine" (a poly-pharmaceutical preparation)	Carbromal B.P.C., 195 mg. Bromvaletone B.P.C., 65 mg. Aluminium hydroxide, 100 mg. Rauwolfia B.P.C., 0.25 mg. (Total alkaloids 55%) Mephanein B.P.C., 100 mg. 5 gr. (320 mg.)
6. Placebo (lactose)	

Experimental Design

The order in which treatments are given may affect the result. It is therefore necessary to use a balanced design, so that each treatment can be fairly compared with each of the others. It is further desirable to partition the variation in the analysis, so that irrelevant causes can be eliminated in assessing the direct results of the treatments. Moreover, some of the other causes of variation are of interest on their own account.

There were six treatments, including the placebo, so successive sets of six patients were allotted at random to six orders of treatment, the design being a Latin square. In each set of six patients each treatment occurs once in the first, once in the second, once in the third, etc., two-week period. The variation due to the differing two-week periods might be important. For example, some patients might start off with enthusiasm and become progressively less interested towards the end of the twelve weeks. If so, the treatments given towards the end might be undervalued compared with those given earlier.

There is a further source of variation which has hitherto been little studied in drug trials, though on general grounds it might sometimes be expected to be important; it seemed particularly necessary to consider it in the present observations. This is a possible carry-over or residual effect of the preceding treatment. In the present instance any such residual effect would probably be psychological rather than pharmacological. Thus, if a patient considered that a particular drug had had a very good effect he might be inclined to undervalue the effect of the next drug. Conversely, a drug which followed one which was thought useless or was disliked might tend to be overvalued. A very useful method for studying residual effects has been elaborated by Williams (1949), though, so far as we are aware, it has not yet been used in pharmacological trials. The Latin square needed is one which has the further property that in each set of six patients each treatment follows each other treatment (or is the first treatment) once. It is then possible to assess the magnitude of residual effects of previous treatments and also to eliminate this source of variation when making the basic comparison, which is the direct effect of the treatments.

The Latin square used is one of those given by Williams, the six treatments being designated A, B, C, D, E, F.

Patients	Two-week Periods					
	1	2	3	4	5	6
1	A	B	C	D	E	F
2	B	C	D	E	F	A
3	C	D	E	F	A	B
4	D	E	F	A	B	C
5	E	F	A	B	C	D
6	F	A	B	C	D	E

As patients entered the trial they were allotted successively to the orders of treatment 1-6, the sequence starting again with the seventh patient, and so on.

Results

The total number of patients included in the trial was 79. Four had filled in at least some of the forms so badly that these could not be used, so that they were eliminated from the analysis.

Twenty-four patients defaulted. Eight did not return to the hospital after the first treatment; the numbers defaulting at the end of the five further fortnights of treatment were respectively 3, 5, 6, 2, 0. It would seem, however, that defaulting was not related to any particular order of treatment or to any particular drug. Thus the numbers defaulting on the six orders of treatment were 6, 4, 4, 4, 4, 2. It is even more important that defaulting was apparently not related to the drug taken during the fortnight after which the patient failed to attend. The numbers defaulting after the six drugs (including the placebo) were 5, 5, 4, 4, 4, 2. Both these series of numbers are as near equality as could reasonably be expected, and do not suggest that in respect of drug treatment the defaulters are other than a random loss. The number available for analysis was thus 51. The sets of six were formed by taking the first patient who completed order of treatment 1, the first completing 2, etc. In this way seven complete sets of six were formed, leaving nine patients belonging to further incomplete sets. The first part of this analysis deals with the 42 forming the completed sets.

The responses were made numerical, as follows: very good effect = +2; good effect = +1; no effect = 0; poor effect = -1; very poor effect = -2. The 14 responses for each drug were averaged to give a single figure.

The great majority of patients returned a daily response for each drug—that is, 14 responses—but there were some omissions. Patients were allowed to reduce the dose but asked to continue taking some of the drug if possible. Some, however, did omit the drug altogether on some days. With the exception to be mentioned immediately, the minimum number of responses was seven. For these incomplete schedules the average response was accepted. The exception related to one drug, chlorpromazine. Six patients discontinued treatment after three to six days, but gave definite reasons for doing so; for example: "Made me feel terrible; I did try," and "More tense and depressed." As a definite explanation had been given, the forms were included, the score being, as before, the average of the responses before treatment was abandoned.

The analysis of variance, based on the seven complete sets of six patients, is shown in Table I. The first line shows the variation due to differences between patients in pattern of response. The mean square, compared with the mean square for remainder ("error" in the technical sense) is highly significant. It is, of course, only to be expected that patients should show significant differences in their patterns of response.

The variation due to differences between patients can be subdivided into two parts—namely, the differences between the six orders of administration of drugs and the differences between patients on the same order of administration. This is shown on the second and third lines. The mean squares are almost identical, so that the responses are independent of the order of treatment selected.

The fourth line shows the variation due to differences between the six fortnightly periods. There is no indication of any secular effect during the trial period. Incidentally, the overall means for the six two-week periods do not suggest any trend. It is interesting to find that the patients' evaluation of the drugs is unaffected by the period within the 12 weeks during which they were given.

Full details of the method for calculating direct and residual effects of treatment are given by Williams (1949). Briefly, an adjusted sum of squares is calculated for direct effects corrected for residual effects, and similarly an adjusted sum of squares for residual effects corrected for direct effects. This gives alternative analyses as indicated by the double columns under sum of squares in the Table.

The result for residual effects is particularly convincing. The mean square is smaller than would be expected by chance—that is, is smaller than the residual or "error" mean square. The patients' evaluation of a drug is thus quite independent of the preceding drug. This is a point of general interest, and may also be taken as lending some support to the plan of avoiding comparisons in asking patients to record responses. Presumably the patients did what they were asked to do—namely, assess each day what they thought the effect had been: very good, good, nil, poor, or very poor—and they were uninfluenced in this by what they had thought of the preceding drug and a fortiori in all probability of still earlier treatments.

TABLE I.—Analysis of Variance. Seven Sets of Six Patients

Source of Variation	Degrees of Freedom	Sum of Squares	Mean Square	Variance Ratio	P
Patients	41	52.4028	1.278	1.94	0.005-0.001
Between orders of treatment	5	6.5634	1.313	1.03*	>0.2
Within	36	45.8394	1.273	1.26	>0.2
Two-week periods	5	4.1499	0.8300	3.88	0.005-0.001
Treatments:				0.45	>0.2
Direct effects	5	13.3804	2.552†		
Residual effects of preceding treatment	5	1.4935†	0.2987†		
Remainder	195	128.2345	0.6576		
Total	251	199.6611			
Further analysis of variation due to direct effects of treatments					
Between amylobarbitone and the other 5 treatments	1	8.6006	8.601	13.08	<0.001
Between the other 5 treatments	4	4.7798	1.194	1.82	0.2-0.1
Total	5	13.3804			

* Divisor 1.273. † Residual effects corrected for direct effects. ‡ Direct effects corrected for residual effects.

The direct effects of the treatments stand out as showing highly significant variation. There are large and real differences in the average response of the patients to the different drugs. As is shown below, the outstanding difference is that between amylobarbitone and the other five. Accordingly in the last two lines of Table I the variation due to

Distribution of score of each patient's average response. +2=Very good effect. +1=Good effect. 0=No effect. -1=Poor effect. -2=Very poor effect. Each square represents a patient. Dotted lines show the mean score for each drug.

Treatments is broken down into two parts: the difference between amylobarbitone and the others, and the differences amongst the five others. Partitioning the variation in this way, the whole of the differences due to treatments can be accounted for by the difference between amylobarbitone and the others, and when this highly significant part is removed there is no significant variation between the other five treatments.

The foregoing analysis shows that it is justifiable to make simple and direct comparisons between the treatments, and the nine additional patients can be added to the 42 previously used. The frequency distributions of the responses of the 51 patients are shown graphically.

The mean response to each treatment in order of preference is as follows:

Amylobarbitone ..	+0.392	Placebo ..	-0.018
Meprobamate ..	+0.090	Chlorpromazine ..	-0.251
Sedaltine ..	+0.025	Benactyzine ..	-0.280

The response to the placebo shows considerable variation, as shown in the Chart, but on the average at least the patients have drawn the right deduction, for the mean score is very nearly 0, no effect.

A comparison of the five drugs with the placebo is shown in Table II.

TABLE II.—Comparison of Five Drugs with the Placebo

	Mean Difference	S.E.	Diff./S.E.	Significance
Amylobarbitone—placebo ..	+0.4098	0.1352	3.03	++
Meprobamate ..	+0.1078	0.1499	0.72	—
Sedaltine ..	+0.0431	0.1492	0.29	—
Chlorpromazine ..	-0.2333	0.1546	1.51	—
Benactyzine ..	-0.2627	0.1631	1.61	—

++ = $P < 0.01$; + = $P < 0.05$; — = $P > 0.05$.

In calculating the standard errors of the differences, the fact that each patient is his own control is, of course, allowed for, account being taken of the intercorrelations.

Table III gives a comparison of amylobarbitone with the other five treatments.

TABLE III.—Comparison of Amylobarbitone with the Five Other Treatments

	Mean Difference	S.E.	Diff./S.E.	Significance
Amylobarbitone—meprobamate ..	+0.3020	0.1189	2.54	+
—sedaltine ..	+0.3667	0.1590	2.31	+
—placebo ..	+0.4098	0.1352	3.03	++
—chlorpromazine ..	+0.6431	0.1772	3.63	++
—benactyzine ..	+0.6726	0.1691	3.98	++

The results of the trial may therefore be summed up very simply. In terms of patients' judgments amylobarbitone is highly significantly superior to the placebo; the other drugs do not differ significantly from the placebo. Amylobarbitone is highly significantly superior to benactyzine and chlorpromazine and significantly superior to sedaltine and meprobamate.

One final point may be mentioned. Three patients returned 0, no effect, for every drug on every occasion. It might be argued that as they refused to discriminate at all they should be omitted. It happened that all three fell into one of the sets of six, so the calculations of Table I were repeated, omitting that particular set. The changes, however, proved to be very slight and did not affect any conclusion. Similarly, the omission of the three patients from Tables II and III made practically no difference and did not affect the significance or non-significance of any comparison.

Comment

To evaluate the effect of a drug in the treatment of the psychoneuroses must always be difficult. We considered that, for the purpose of the present trial, a simple day-by-day rating by the patient of how he felt was more likely

to give a measure of the effect of the drug than a retrospective assessment made at intervals in conjunction with an interviewing psychiatrist.

Since this was an out-patient trial, no attempt could be made to keep environmental factors uniform; indeed, it would not have been desirable to do so, since the purpose of the trial was to assess the drugs as they are used in daily practice. In any case, environmental and other variations have been randomized.

We considered that the patient would be more co-operative, and his observations more carefully made, if he knew that he was trying a series of tablets in order to find something which suited him personally. Since the patient knew the nature of the trial, standardizing the appearance of the tablets did not seem a point of great importance. All the tablets were white but different in size, and some were sugar-coated. The prescribed number of tablets was the same for each drug. It is of some interest, perhaps, that the tablets of amylobarbitone were the smallest and least impressive of the series. Incidentally they were also the cheapest, not excluding the placebo.

Summary

The five drugs included in this trial are claimed to relieve tension. They were amylobarbitone, benactyzine, chlorpromazine, meprobamate, sedaltine. A placebo was also included. The patients were psychoneurotic out-patients selected as having a tension component in the symptomatology. Each patient received each drug for two weeks, being asked to record daily his assessment of the drug on a five-point scale.

Of 79 patients included in the trial, the records of four were faulty, and 24 defaulted. Reasons are given for supposing that the loss was probably random.

Only the chief pharmacist knew which drug was being given, and a randomized design was used. The scores based on the patients' assessments did not vary according to the particular period during the 12 weeks when the drug was administered. The scores were independent of the drug previously given. In terms of the patients' judgments the average score for the placebo was close to a nil response, neither good nor bad. The average score for amylobarbitone was highly significantly superior to that for the placebo. There was no significant difference between the other four drugs and the placebo.

We are indebted to Dr. Desmond Curran for his interest and constructive criticism. We also thank him and the other consultants who referred suitable cases for the trial. We are grateful to Mr. A. Stirling, lately chief pharmacist, and to his staff at St. George's Hospital for their close co-operation throughout the trial, and to the following drug houses for supplying the drugs: Clinical Products Ltd. supplied the sedaltine; Glaxo Laboratories Ltd. supplied the benactyzine (suavatil); John Wyeth & Bro. Ltd. supplied the meprobamate (equanil). The chart was drawn by Mrs. M. G. Young.

STUDY OF THEOPHYLLINE PLASMA LEVELS AFTER ORAL ADMINISTRATION OF NEW THEOPHYLLINE COMPOUNDS

BY

M. TURNER-WARWICK, D.M., M.R.C.P.
 Formerly Medical Registrar, University College Hospital

The pharmacological action of theophylline is well known; it relaxes the bronchi, both after histamine-induced spasm and in clinical asthma (Goodman and Gilman, 1955); it decreases the venous filling pressure and increases the cardiac output in patients in cardiac failure (Howarth *et al.*, 1948); it causes a diuresis in patients in heart failure partly by its effect on the cardiac output and also by depressing tubular reabsorption (Walker *et al.*, 1937). Theophylline with ethylenediamine (aminophylline) is highly effective in controlling Cheyne-Stokes breathing, but there is evidence that this may be due to the ethylenediamine (Marais and McMichael, 1937). These properties make theophylline a useful drug in the treatment of bronchial asthma and cardiac failure.

Parenteral administration of theophylline compounds is unsatisfactory for long-term treatment; the intravenous route is impracticable and there is some evidence that it may be dangerous (Bresnick *et al.*, 1948); intramuscular injections are often extremely painful. Oral administration of theophylline is useless because it causes severe gastric irritation and its solubility is very low (1:120). Aminophylline has a much greater solubility (1:5), but it is strongly alkaline in solution and is hydrolysed by gastric juice; free theophylline is liberated and gastric irritation occurs. Theophylline derivatives have been prepared which are readily soluble in water and are stable over a wide range of pH; they are stated to cause negligible gastric irritation when given in therapeutically effective doses by mouth. It is possible that the absorption of these substances from the gastro-intestinal tract may differ both in regularity and in degree, and that their therapeutic value can be related to the theophylline plasma concentrations.

In the present investigation five theophylline preparations have been compared in a small group of patients, by studying the plasma levels over a period of five hours, after a single oral dose of equivalent theophylline content. The minimal plasma concentration for relief of bronchospasm has been estimated.

Methods

Twenty-five patients were studied; 20 suffered from chronic asthma and were continuously wheezy, and five were in congestive cardiac failure (two rheumatic and three arteriosclerotic heart disease).

TABLE I

	Group 1	Group 2	Group 3	Group 4	Group 5
	Dihydroxypropyl-Theoph.	Choline Theoph.	Theoph. Ethanoate with Piperazine	Sodium Glycinate Theoph.	Aminophylline
theophylline-content solubility in water	79%	60%	56%	49-52%	79%
Dosage given	1:6 0.6 g.	1:1 0.79 g.	1:5 0.85 g.	1:5 0.95 g.	1:5 0.6 g.

The theophylline content of each trial dose was 0.47 g. and equivalent to that contained in 0.6 g. of aminophylline.

Five groups were formed so that each contained five patients of similar age and sex distribution (four asthmatic and one cardiac failure). Each group received one of the five theophylline preparations under investigation in a single dose by mouth (Table I).

Some of the cases were studied as out-patients and therefore the test dose was given 1½ to 2 hours after breakfast (between 9.30 and 10 a.m.). Samples of venous blood were taken after one, two, three, and five hours; these were heparinized and the plasma theophylline was estimated by the method described by Schack and Waxler (1949). Plasma was used rather than whole blood because of the uneven distribution of theophylline between cells and plasma (Schack and Waxler, 1949). The double extraction process described by these authors recovers approximately 98% of the plasma theophylline.

Caffeine and barbiturates were avoided before the test because they are known to interfere with the ultra-violet spectrophotometric estimation of theophylline.

Spirographic records of each asthmatic subject were taken before the test dose and at one hour after it; for technical reasons it was not possible to repeat the test after this time. From the spiograms (drum speed 5 mm./sec.) one second vital capacities were measured. The time of onset and the duration of subjective improvement were also noted, and these were correlated with the timed vital capacities.

Results

The theophylline plasma levels of each patient are shown in Table II, in each group the mean level at one, two, three, and five hours has been calculated and these have been expressed graphically in Fig. 1.

TABLE II.—Theophylline Blood Levels (mg. per 100 ml. of Plasma) in 25 Subjects

Patient:	1	2	3	4	5	Mean	Standard Error of Mean
Group 1. Dihydroxypropyl-theophylline							
1 hour	0.765	0.946	0.915	0.927	0.901	0.891	±0.032

3 "	1.370	1.090	1.462	1.586	1.148	1.331	±0.094
5 "	1.030	0.491	1.180	1.060	0.965	0.955	±0.108

Patient 2 in each group had congestive cardiac failure. Italic figures indicate subjective relief from asthma.

The mean level at one hour in groups 2 and 5 rose to about 1 mg. per 100 ml. of plasma, and, except in one instance, remained over this level for the whole trial period. In contrast, in groups 1, 3, and 4 the mean levels (with one exception) did not rise above 1 mg. per 100 ml. of plasma, and were usually considerably lower.

Each compound was compared with each of the others (ten pairs) by a variance ratio test. Choline theophylline and aminophylline showed significantly higher plasma levels than the dihydroxypropyl, ethanoate, and glycinate derivatives ($P < 0.001$), but no difference was shown between the choline salt and aminophylline on the one hand, or between the dihydroxypropyl, ethanoate, and sodium glycinate compounds on the other.

The theophylline plasma levels of each asthmatic patient have been plotted in Fig. 2; they have been indicated by a dot if bronchospasm was relieved and by a cross if it was not. With few exceptions relief of symptoms was noticed only when the theophylline levels exceeded 1 mg. per 100 ml. of plasma. Six patients improved within the first hour of the test, and in five of these there was slight but definite improvement in the timed and total vital capacities.

Fig. 1.—Theophylline plasma levels in a trial of five compounds.

Fig. 2.—Theophylline plasma levels correlated with subjective relief from asthma. ● = Relief from bronchospasm. x = No relief.

pharmacological actions in experimental animals (Quevauviller and Morin, 1953). There are few reports upon plasma levels following equivalent theophylline dosage or upon comparatively clinical effects. Gagliani *et al.* (1954) studied the blood levels of choline theophylline and aminophylline with and without aluminium hydroxide; higher levels were found with the choline derivative. In the present study similar concentrations were found with the two drugs. Gagliani *et al.* (1954) used whole blood for their estimations, but in view of the different solubilities of the compounds it is possible that their cell-plasma partition is also different and the blood and plasma levels may not be comparable.

The results obtained from the present series of patients indicate that a theophylline level of about 1 mg. per 100 ml. of plasma is necessary to relieve bronchospasm. Truitt *et al.* (1950) correlated their studies of theophylline blood levels with a report by Segal *et al.* (1949) on the interval between theophylline administration and the relief of bronchospasm in histamine-induced asthma. They deduced indirectly that the therapeutic blood level was 0.5 mg. per 100 ml. of whole blood. Aminophylline does not appear to enter the cells (Schack and Waxler, 1949), and therefore the finding of Truitt *et al.* would correspond to a plasma level of about 1 mg. per 100 ml. and agree well with the present results.

Of the theophylline preparations studied it appears from a single-dose trial that, apart from aminophylline, choline theophylline is the drug most likely to have clinical effect. A further investigation of patients on maintenance treatment is needed to assess fully the therapeutic value of these products. In the present series only 12 subjects were studied in this way; four out of five with theophylline levels over 1 mg. per 100 ml. of plasma four hours after the morning dose were receiving choline theophylline (200 mg. q.d.s.), whereas eight out of nine patients with plasma concentrations under 1 mg. per 100 ml. were receiving one of the other preparations (dihydroxypropyl, 400 mg. q.d.s.; sodium glycinate, 640 mg. q.d.s.; ethanoate of piperazine, 500 mg. q.d.s.; these are approximately the largest recommended doses). Other workers (Truitt *et al.*, 1950) using theophylline sodium glycinate have found considerably higher blood levels ranging from 0.7 mg. at two hours to 1.2 mg. per 100 ml. of whole blood after 12 hours (dosage 650 mg. q.d.s.). In the present series two patients were treated in the first instance with theophylline ethanoate of piperazine with plasma levels of 0.4 and 0.46 mg. per 100 ml.; they were then changed to choline theophylline and the concentration was increased to 1.28 and 1.74 mg. per 100 ml. of plasma. In view of these findings the occurrence of side-effects is important. Using choline theophylline (200 mg. q.d.s.), Brown and Clancy (1955) reported gastro-intestinal symptoms in 5 out of 35 cases, and Dann *et al.* (1954) in 4 out of 18. The number of patients in the present series is too small for accuracy, but symptoms of nausea, epigastric pain, and "fullness" did occur in a few patients receiving choline theophylline but in none treated with any of the other products, although the total doses received each day were two to three times larger.

The observations reported here on theophylline plasma levels in subjects treated with theophylline compounds of dihydroxypropyl, sodium glycinate, and ethanoate of piperazine, together with those upon the absence of side-effects, suggest that the recommended dosages should be increased.

Theophylline is largely excreted in the urine. When renal flow diminishes in cardiac failure, theophylline excretion might be expected to fall and the plasma level to rise. The opportunity was taken to study five patients in cardiac failure; there was no demonstrable difference in the plasma levels in these subjects compared with asthmatics in the same group.

Summary

The theophylline plasma levels were studied in five groups of patients; each group received a single oral dose of a different theophylline compound of equivalent theophylline content (0.47 g. of theophylline).

Higher theophylline levels were found in subjects receiving choline theophylline and aminophylline (theophylline ethylenediamine) than those receiving dihydroxypropyl theophylline, theophylline ethanoate of piperazine, or theophylline sodium glycinate.

The minimal theophylline plasma level for the relief of bronchospasm appears to be about 1 mg. per 100 ml.

The importance of these findings in the maintenance treatment of patients with theophylline compounds is discussed.

Five patients with cardiac failure showed no appreciable difference in theophylline plasma levels from asthmatics receiving the same compound.

I should like to thank Dr. Kenneth Harris for his helpful criticism and for allowing me to study patients under his care. I am most grateful to Dr. Andrew Morland and to Dr. Howard Nicholson for allowing me to study their patients; to Dr. Monica McAllen for her help; and to Mrs. McNroy for assistance with spirometry. I am indebted to Allen and Hanburys (choledyl), Continental Laboratories (neutraphylline), Medo Chemicals (aminomed), and Rona Laboratories (etophyllate) for samples of their products.

SALM. THOMPSON GASTRO-ENTERITIS REPORT OF TWO OUTBREAKS

BY

HELEN A. WRIGHT, M.B., Ch.B., D.P.H.
Senior Lecturer, Edinburgh University Bacteriology Department; Honorary Consultant Bacteriologist, South-Eastern Regional Hospital Board, Scotland

JOHN NORVAL, M.R.C.V.S.
Veterinary Inspector, City of Edinburgh

AND

ALASTAIR ORR
Assistant Sanitary Inspector, City of Edinburgh

Since the end of the war *Salmonella thompson* has been one of the commoner causes of human salmonellosis in England and Wales (Wilson and Miles, 1955; Public Health Laboratory Service Reports, 1954, 1955), but until 1956 had been rarely encountered in Edinburgh. In the University Laboratory which serves the City of Edinburgh and much of the South-East of Scotland, *Salm. thompson* was not isolated from any cases in 1950-1-2, from only one in 1953, from another in 1954, and from two in 1955. In the summer of 1956, however, two apparently unrelated outbreaks of *Salm. thompson* infection came to our notice, and these seem to be of sufficient interest to be put on record.

First Outbreak

The first outbreak occurred in May, 1956, when *Salm. thompson* was isolated from faecal specimens in 10 cases of acute gastro-enteritis within a fortnight. The patients were all children (aged 10 months to 7 years); and, except for two brothers, were from different households widely distributed throughout the city. *Salm. thompson* was also isolated about this time from the faeces of three adults who frequently travelled into Edinburgh from surrounding districts; three more cases were admitted direct to the Edinburgh City Hospital for Infectious Diseases; another was found in a private nursing-home, and two more were found in the wards

of a general hospital. (One of these patients had undergone an operation for hernia two days before the onset of rhoea.) Food-poisoning was not notifiable in Edinburgh at this time, and other cases may have occurred which did not come to our notice.

The condition varied from comparatively mild diarrhoea and vomiting, which cleared clinically and bacteriologically in a few days, to a more severe type of illness which required hospital treatment (in one case for six weeks), and in two cases with *Salm. thompson* persisting in the faeces for four to eight weeks respectively.

Owing to the unexplosive character of the outbreak and the scattered distribution of the cases, there was inevitable delay in arriving at any facts to indicate a common source of infection, for often the housewife could not recall where or what foodstuffs she had bought at the relevant time. Suspicion, however, focused on a city bakery and restaurant. One patient had eaten "trifle" from this firm 24 hours before the onset of illness; two of the patients lunched daily in this restaurant; another had had tea and cream cakes there two days before symptoms appeared, and in six instances this firm supplied goods to the household. Therefore, some two weeks after the first case was diagnosed it was decided to visit this bakery.

It was found that a good standard of general cleanliness of premises and equipment was being maintained, and all meringues, cream cakes, sponges, and similar products were being made in a separate department. From our own previous observations of samples of imported whole egg and egg albumen, and from reports from other parts of the country (Newell *et al.*, 1955), imported egg was thought to be the most likely vehicle of the infection; but at this time the bakery in question was using home-produced, hen shell-eggs instead of imported liquid egg. Egg albumen, which was being used in large quantities mainly for meringues, was, however, an imported product. Two days before this inquiry Chinese albumen crystals had been in use for meringues, but this stock of albumen had been exhausted and frozen Argentine egg albumen brought into use.

The method of handling this was to defrost a 22-lb. (10-kg.) tin and to pour the contents into a "reservoir" container from which the albumen could be ladled. The favourite container used as a "reservoir" was a round three-gallon (13.6-litre) "synthetic cream" tin, which after removal of the cream was washed in warm water and then used for the egg. It was alleged that a different tin was obtained daily for this purpose or at least every second day. However, at the time of the inspection this seemed doubtful, as deposits of dried albumen were found encrusting both the inside and the outside of the rather dented tin.

Samples for bacteriological examination were taken from (1) stock tins of frozen Argentine egg albumen; (2) tins of synthetic cream; (3) the albumen encrusted on the sides of the "reservoir" tin; and (4) fluid albumen from the ladle. *Salm. thompson* was isolated both from the dried albumen on the sides and from the fluid albumen in the centre of the container, but was not isolated from the stock tins of albumen or synthetic cream.

Immediately after obtaining the samples the reservoir container and its contents were discarded, and the firm undertook to use for this purpose special containers constructed of stouter metal which could be more effectively cleansed with boiling water. Otherwise no change was made: the stocks from which the synthetic cream and egg albumen were drawn were still the same; the shell-eggs (manipulated in another part of the building) were obtained from the same source; and no change was made in personnel. Repeated samples of cream and albumen were examined during the next few days, always with negative results; and no further clinical cases came to our notice after the infected "reservoir" tin was put out of use. No cases of *Salm. thompson* infection did, in fact, come to our notice until some ten weeks later, when this organism was isolated in the second group of cases about to be described and the infection traced to an entirely different source.

Attempts were made to trace the batch of Chinese egg albumen used before the Argentine albumen. Unfortunately, owing to the sudden death of the head of the firm which had supplied it, no exact information was obtainable and none of their stock was left; but we found from information supplied by the bakery firm that the date on which this Chinese egg albumen had been put into use could be related to the incidence of the cases.

The precise source of the contamination of the albumen in the container must remain a matter for conjecture. After the inspection of the bakery the conditions were unchanged except for the use of a different "reservoir" for the albumen; but cases ceased. This would seem to rule out the Argentine albumen and the synthetic cream as the source of contamination, and also the shell-eggs, and the likelihood of contamination by a healthy carrier among the workers. It seems, therefore, that the Chinese albumen in use before the Argentine product must have been the real source of contamination; and that, owing to the continued use of the same "reservoir," the contamination continued. The danger to the consumer must have been at least lessened by the bactericidal effect of heating the meringue; and one must conclude that casual contamination of meringues and cakes after baking, by the hands of the workers or by contaminated implements, must have constituted the main danger to the consumers. The fact that in several instances the victims had eaten cream cakes and not meringues lends emphasis to this.

Second Outbreak

The second outbreak occurred two and a half months later. On August 16 a medical practitioner in an outlying district of Edinburgh notified the medical officer of health that his own 9-months-old child had acute salmonella infection and that his elder child was also ill with gastro-enteritis. He strongly suspected that the household milk supply, which came from a near-by farm and which was not heat-treated, was the vehicle of the infection. Within an hour of this notification another practitioner in the same district informed the medical officer of health that the byreman on the same farm had acute gastro-enteritis.

This farm supplied tuberculin-tested unpasteurized milk to households in the surrounding district. As a result of the notifications, the farm was immediately visited and information obtained about the byreman's illness and the health of the other farm workers. A veterinary inspection was also made and a sick cow found amongst the twenty-four dairy cows. This cow was removed from the herd, her milk was ordered to be destroyed, and arrangements were made for the milk of the herd to be pasteurized before distribution pending further investigations. The byreman's wife, whose work it was to wash the dairy utensils, was sent off duty. Faecal specimens were obtained for bacteriological examination from the farm workers and their relatives; also dung from the sick cow, a specimen of her milk taken with aseptic precautions, and the samples of the bulk milk before pasteurization. No pathogenic organisms were isolated from the bulk milk on this and numerous subsequent occasions, but *Salm. thompson* was isolated from the dung and milk of the sick cow, both on this occasion and from specimens taken on August 21. Five symptomless excretors of *Salm. thompson* were found among the farm workers and their relatives. These were the wife of the byreman, his 14-year-old daughter and 9-year-old grandson, the farm manager, and a worker employed mainly as a vanman. These were all suitably treated and excluded from the dairy until judged bacteriologically negative.

As well as the byreman, whose symptoms appeared on August 14, altogether five persons supplied with milk from this farm are known to have been acutely affected. The first became ill on August 10 and the last on August 17. Two were infants of less than a year, one was a 2-year-old child, and the others were adults. Clinically, all rapidly responded to treatment; but one man, a fishmonger who was eventually admitted to hospital, was found to be carrying the organism

eleven weeks after the onset of the illness. *Salm. thompson* was again isolated from the doctor's baby after seventeen weeks, when there was a recurrence of symptoms. Specimens of dung and milk from the infected cow were consistently negative by the end of August, but she was not returned to the dairy herd.

The sick cow had been in the herd for two years. She had produced a healthy calf at the beginning of August, but had developed "milk fever" (a calcium deficiency) on August 3. She responded to calcium injections, but remained listless and did not feed well, and when seen on August 17 seemed very ill. There were obvious signs of dehydration, the abdomen seemed tender, the dung was soft, dark, and foul-smelling. The udder was, however, normal and the milk free from clots. So far as could be ascertained, the byreman had been excluding this cow's milk from the milk for distribution, though a milking-machine unit had been used on her after the other cows had been milked; but after the byreman had fallen ill the sick cow's milk had actually been distributed with the rest on two occasions.

It seems, then, reasonable to conclude that this cow's infection was the cause of the human cases. These ceased to occur as soon as she was removed from the herd. Although her milk is thought to have been included in the milk for distribution on only two occasions since calving, there was sufficient opportunity for contamination of the whole supply from the milking-machine. The machine and other dairy utensils were sterilized after the morning milking; but, following the usual custom in dairy farms, the apparatus was merely rinsed after the afternoon milking. Thus bacterial contamination from the milk of the sick cow could readily be carried over to the milk for distribution at the subsequent milking. Although it is not known how long the byreman's wife had been a symptomless excretor of *Salm. thompson*, she too may have contaminated the dairy utensils and, in turn, the milk from the healthy cows.

The actual source of the cow's infection was not determined. The farm was within an urban area with a water-borne sewage system which made any human source of infection highly improbable. No faecal carrier of *Salm. thompson* was found among the other cattle on the farm and none of them was known to have been sick. Serological examination of the hens, which had no access to the byre but were housed in a building adjacent to it, proved negative. No other poultry were kept and the pig-sties were well removed from the byre. The cows grazed in a near-by field and drank from a stream below a housing estate, but no case of *Salm. thompson* infection was known in the district before this outbreak, although cases of *Salm. typhimurium* enteritis had occurred in Edinburgh during the summer.

Two theories might reasonably be advanced regarding the cause of the septicaemic infection in the cow. The first is that the cattle cake (a well-known brand of compound feeding-stuffs) was infected and this cow, unlike the others in the herd, was unable to combat the infection, or, secondly, that this animal was a carrier of *Salm. thompson* and the strain of calving activated the infection. An analogous human case of latent *Salm. typhimurium* infection which flared up into fatal septicaemia after childbirth is known (Riddell, 1954).

Discussion

Although enteritis due to *Salm. thompson* had been almost unknown in the Edinburgh district for years, and these two outbreaks occurred within four months, we have been unable to find any link between them. Numerically they were comparatively trivial—some nineteen cases in the first and six in the second. Probably the most important limiting factor was the low atmospheric temperatures in both May and August in 1956, which would not encourage rapid multiplication of bacteria even in such excellent media as cakes and milk. There were several other fortunate circumstances: the incriminated egg albumen was used mainly for meringues and therefore heated, and also the bakery was owned by a reputable firm who employed a good type of worker; and

in the milk-borne outbreak the ready co-operation of the general practitioners in notifying the cases made it possible to find and eliminate the source of infection with the minimum delay. Even so, it seems unnecessary to stress the personal annoyance and economic waste of an infection of this kind and its potential danger, especially to young children and to the old or debilitated; and, as apparently *Salm. thompson* readily leads to the convalescent carrier state, there is a real danger that this type of salmonella infection may become endemic if the sources of infection are not eliminated.

One such source is known to be frozen imported egg (Ministry of Health, 1956). In 1956 we ourselves examined 350 tins of this product and found that 5% were infected with salmonellae. Of this number, seven were found to contain *Salm. thompson*. Newell *et al.* (1955) found *Salm. thompson* in 20 out of 153 tins examined. It is true that, even although the constituents may have been contaminated, cakes which have been adequately heated are made safe for the consumer; but the presence of any contaminated commodity in a bakery must always constitute a risk too grave to be countenanced. The handling of infected material by workers who are largely ignorant of aseptic techniques must remain difficult to control; and sooner or later, through pressure of work or carelessness, regulations, however strict, will be disregarded. Contamination will then be conveyed from the raw ingredient to the finished article, and it only remains for conditions such as atmospheric temperature and humidity to combine to favour bacterial growth, and cakes and confections which are in effect lively cultures of pathogenic organisms will be distributed to the public.

The heat treatment of egg albumen crystals at present being carried out—that is, 127–130° F. (52.8–54.5° C.) for 10 days—seems to be satisfactory, but the evolution of an efficient pasteurizing process for whole-egg products, which at present presents great practical difficulties (Murdock, 1956), seems really essential.

The main interest of the second outbreak is that the infection was milk-borne and due to a septicaemic type of *Salm. thompson* infection in a cow. *Salm. typhimurium* and *Salm. dublin* are the types of salmonella which most commonly infect cattle in this country (Taylor *et al.*, 1953). In adult cattle the acute infection usually takes the form of an enteritis with the likelihood of faecal contamination of the milk; but the disease may also become septicaemic, with actual excretion of the infecting organism in the milk. Thus two epidemics in Dundee in 1926 and 1927 were traced to cows with *Salm. dublin* septicaemia which were excreting the organism in the milk (Tulloch, 1939); and similarly, in an outbreak in County Durham involving 252 persons, *Salm. typhimurium* was isolated from the faeces and milk of a sick cow in a herd supplying tuberculin-tested milk (Norton and Armstrong, 1954); also Henderson *et al.* (1948) described an outbreak of milk-borne infection in Aberdeenshire traced to *Salm. dublin* enteritis in a bovine animal.

On the other hand, *Salm. thompson* infection of cattle is apparently rare. *Salm. dublin* was isolated from the faeces of 8.6% of 1,000 healthy cattle in Belfast, but *Salm. thompson* was isolated from only two animals (Murdoch and Gordon, 1953); and from England and Wales only two strains of *Salm. thompson* in 1955 and one to the middle of November, 1956, had come to the notice of the Veterinary Laboratory of the Ministry of Agriculture, Weybridge (personal communication). So far as we are aware, there is no record of any previous outbreak of milk-borne *Salm. thompson* infection, or of the generalized type of the disease in cattle.

The method of disposal of infected imported egg should be carefully considered. The finding of a bovine case of generalized infection, with resultant infection of a milk supply, presents, in our opinion, a warning against the possible disposal of rejected imported egg by its inclusion in the manufacture of animal feeding-stuffs.

Summary

Two outbreaks of *Salm. thompson* gastro-enteritis are described.

The infections are attributed to (1) Chinese egg albumen used in a bakery, and (2) a septicaemic type of disease in a cow producing infected milk.

Attention is drawn to this type of bovine disease as a source of milk-borne infection.

The importance of excluding bacteriologically contaminated commodities from bakeries is stressed.

The field investigations were under the medical direction of Dr. J. L. Gilloran, deputy medical officer of health for the City of Edinburgh.

We thank Dr. H. E. Seiler, medical officer of health, and Dr. R. H. A. Swain for their interest and advice; Dr. Joan Taylor, Enteric Reference Laboratory, London, for confirming our identification of the bovine strain; and Dr. A. W. Stableforth, Veterinary Laboratory of the Ministry of Agriculture, Weybridge, for information on the recent incidence of salmonella types in cattle. We are also indebted to Mr. R. Burrows, B.Sc., M.R.C.V.S., for the examinations carried out on the dairy herd and poultry; and to Mr. J. A. Sutherland, F.I.M.L.T., and other members of the University staff for technical assistance.

Bournemouth

Houssay and Biasotti (1930, 1931) and Houssay (1936) demonstrated that hypophysectomy relieved the diabetes mellitus of depancreatized animals. The Houssay animal exhibited diminished glycosuria, negligible ketosis, increased insulin sensitivity, survival for months without insulin treatment, widely fluctuating glycaemia, and a tendency to progressive undernutrition and to hypoglycaemic episodes. The clinical counterpart due to natural disease, conveniently termed the Houssay syndrome, is apparently rare. Indeed, Balfour and Sprague (1949) found no true example in the records of a 15-year period at the Mayo Clinic. Apart from the sporadic literature prior to Houssay's observations, 17 well-documented cases (listed in the discussion) have since been recorded.

The varied clinical patterns of hypopituitary coma (Sheehan, 1955) include three standard types—namely,

pyrexial, a hypothermic, and a hypoglycaemic variety as well as a miscellaneous group, into which our patient appears to fit. The explanation of his "vanishing diabetes" was elusive until the final histological demonstration of substantial anterior pituitary ablation.

Case Report

A retired clergyman aged 76 was admitted to hospital on May 8, 1955, for the stabilization of his recently self-diagnosed diabetes mellitus. His only salient illness was an attack of malaria 20 years earlier. In six months he had noted an unexplained loss of weight of 14 lb. (6.4 kg.) and he then weighed 168 lb. (76.2 kg.). His remaining symptoms were loss of appetite and energy, an increase in thirst and in both frequency and hesitancy of micturition.

He was an intelligent witness, of good physique and colour. The main abnormalities were:—skeletal and tegumentary: Heberden's nodes; vascular arteriosclerosis, without loss of peripheral pulses, and a blood pressure of 155/100 mm. Hg; alimentary: hepatic enlargement to 1 cm. below the right costal margin; urological: phimosis with mild balanitis and a firm enlarged prostate. His haemoglobin was 15.3 g. per 100 ml., and leucocyte count 7,900 per c.mm. The chest x-ray film was normal, except for marked unfolding of the aorta. The blood urea was 37 mg. per 100 ml. The Wassermann reaction was negative. The initial glucose-tolerance test showed a frankly diabetic curve—that is, fasting value, 444 mg. per 100 ml.; three-quarters of an hour after 50 g. of glucose, 546 mg. per 100 ml.; two hours after glucose, 586 mg. per 100 ml. There was no ketonuria, but the "fasting urine" contained 3.9 g. of glucose per 100 ml. and the specimen taken two hours after the ingestion of glucose 6 g. per 100 ml. After stabilization, the blood-glucose values (May 26) were: fasting, 92 mg. per 100 ml.; pre-lunch, 137 mg. per 100 ml.; pre-tea, 87 mg. per 100 ml.

Progress

On the second day in hospital he had acute retention of urine. In view of his phimosis a Riches suprapubic catheter was inserted. The diabetes was stabilized on a diet of 20 black and 14 red Lawrence lines (200 g. of carbohydrate, 105 g. of protein, and 125 g. of fat) and an injection of 46 units of insulin zinc suspension daily. The "clintest" for glycosuria now showed regular green colours, and the "acet-test" (modified nitroprusside test) no ketonuria.

On June 17 he underwent a prostatectomy and a circumcision. That day his dose of insulin zinc suspension was reduced from 46 to 26 units, so that complementary soluble insulin could be continued post-operatively. Instead of lunch he received 50 g. of glucose orally, three hours pre-operatively. The operation, which ensued without cardiovascular or respiratory incident, lasted one hour. The immediate post-operative blood-sugar level was 87 mg. per 100 ml. On regaining consciousness about one hour after the operation he was given 50 g. of glucose orally. This dose was repeated four hours later. We tried throughout to avoid hypoglycaemia because of its danger in the presence of arteriosclerosis. Strict attention was given to glucose administration and to the use of a modified scale of dosage of soluble insulin, according to the results of four-hourly clintests—that is, when red or orange, 20 units; when yellow, 10 units; and otherwise, no insulin. Histologically, the prostate showed benign hypertrophy.

June 18.—In the early hours of the first post-operative day it was observed that he could not be fully roused. The cardiac rate was 96 a minute, the rhythm was regular, and the blood pressure was 100/75. Although he was not perspiring, hypoglycaemia was considered. However, 70 g. of glucose intravenously had no alerting effect. His blood-glucose level was determined on a specimen taken two hours later. The value was 462 mg. per 100 ml. He remained stuporous, mute, and rather inert, but obeyed simple commands. No abnormal neurological signs were elicited. The temperature was normal. There was no clinical or urinary

evidence of ketosis. As his confusional state persisted, a test dose of 10 mg. of amphetamine sulphate was given intramuscularly. It had no rousing effect. It was found that his haemoglobin level had fallen to 11.1 g. per 100 ml., so 2 pints (1,140 ml.) of blood was transfused. Although he swallowed small feeds of milk and fruit juice a dextrose-saline infusion was continued after the transfusion, using normal saline with the first pint (570 ml.) of dextrose and, thereafter, N/5-strength saline.

June 19.—Stupor persisted. His blood-sugar level was 190 mg. per 100 ml. The blood pressure was 110/80.

June 20.—In the morning there was no clinical change. By now the clintest usually showed green, and a daily dose of 10 units of soluble insulin sufficed (see Table). In the

Daily Blood-sugar Levels and Dose of Insulin Post-operatively.
Insulin was not Required after One Week

Date	Blood Sugar, 10 a.m. Values (mg./100 ml.)	Insulin (Units)

afternoon neurological signs appeared. Responses to stimuli included groaning and grimacing. He had ocular conjugate deviation to the left. The right arm was flaccid, with areflexia, but nuchal rigidity, facial paresis, grasp-reflex, and Hoffmann's and Babinski's signs were all absent. Lumbar puncture revealed normal spinal-fluid pressure. Apart from a raised glucose level (exact value undetermined), the spinal fluid was normal. The blood-urea level was 83 mg. per 100 ml. A diagnosis of cerebral thrombosis in the left hemisphere was entertained. Oral feeding with milk and solutions of vitamins was continued with the dextrose-saline infusion.

June 21.—Ocular conjugate deviation had gone. The arms were seen to move with equal facility.

June 22 and 23.—No change was detected.

June 24.—At 6.30 p.m. perspiration began. The clintest at 4 p.m. and 6 p.m. had shown a blue colour. He remained stuporous. The temperature had risen to 101° F. (38.3° C.). The haemoglobin level was 9.8 g. per 100 ml., with a leucocytosis (13,800 per c.mm.; 93% polymorphs). The pyrexia and sweating were attributed to a pyaemia from a localized cellulitis of the anterior abdominal wall. In case, however, of hypoglycaemia, 50 g. of glucose was promptly given intravenously. There was no clinical response. The 6.30 p.m. blood-sugar level was now known to have been satisfactory (102 mg. per 100 ml.). The blood urea was 131 mg. per 100 ml. The dextrose-saline drip was stopped. Further glucose was given orally, using intubation when necessary. A five-day course of oxytetracycline, 100 mg. twice daily intramuscularly, was begun.

June 25 to July 2.—Steady deterioration ensued. There were spikes of temperature to about 103° F. (39.4° C.). Oedema increased. He died quietly in the early hours of July 2. Unfortunately the blood-sugar level was not determined after June 27.

During the post-operative phase frequent blood-sugar determinations were made. All values exceeded hypoglycaemic levels. For a convenient daily comparison, the 10 a.m. values alone are set out (see Table). It is noteworthy that, after the first week of stupor, insulin was unnecessary.

Necropsy Findings

Owing to a week-end delay the necropsy was performed 48 hours after death, with, however, intervening refrigeration.

External examination showed moderate oedema of the legs and cellulitis close to the suprapubic site of cystostomy. The lungs were pale, emphysematous, and oedematous. The heart showed moderate sclerosis of the coronary arteries, which were patent. The pancreas contained an unsuspected carcinoma of the tail, with axial spread to the body of the organ. Some small metastases of this tumour were present in the liver, and also tiny infarcts and abscesses. There were a few septic infarcts in the spleen and kidneys. The bladder showed haemorrhagic cystitis. The brain and the pituitary gland were macroscopically normal.

The significant histological findings were: adenocarcinoma of the pancreas, with destruction of islet cells; extensive anterior pituitary necrosis (Figs. 1 and 2);

FIG. 1.—Pituitary gland section, passing through upper part of gland at genu of stalk into posterior lobe. Some 10 to 20% of gland has survived (black) at this level, where survival of anterior lobe is best in all instances of pituitary necrosis. In terms of total gland volume, however, about 95% has suffered necrosis. (×6.)

secondary carcinoma and numerous areas of necrosis in the liver (where the polymorph reaction around the necrotic areas was partly due to the necrosis and partly to the infection, but the "primary" condition was the necrosis, which was probably caused by tumour growth obstructing the vessels); hepatic necrosis of about one week's duration unrelated to the pituitary necrosis; and, finally, inflammation of the glomeruli in the kidneys.

The pituitary histology merits special consideration. The age of the lesion was judged to be about three to four weeks, based on evidence from cases of post-partum necrosis where the exact time of onset and the time of survival of the patient are known.

FIG. 2.—Pituitary gland as seen under high-power microscopy. Normal parenchyma (black) is seen in right-hand lower corner and advanced necrosis in the diagonally opposite corner, with an intervening broad band of repair. (×60.)

The central parts of the necrotic areas displayed the usual total loss of nuclei; the margins of the necrotic zone showed re-opening of sinuses, complete removal of necrotic debris, loose fibrous tissue or condensed stroma, and a general appearance of good healing; the remaining parenchyma was sharply outlined, and contained the three basic types of cells.

Comment

Certain aspects of our case warrant elucidation.

1. The stupor was of an unusual and ill-defined type, remotely akin to akinetic mutism (Cairns, 1953), except that limb movements were occasionally observed. Primarily, it conformed neither to the types with striking thermal changes nor at all to the hypoglycaemic variety. There was no katatonia. The demeanour was placid, and neither tremors nor convulsions were detected. At least twice he seemed anxious to speak, but was unsuccessful. Unlike the case of Feldman *et al.* (1947), our patient did not seem to recognize surrounding objects. Neither amphetamine nor intravenous dextrose had an alerting effect.

2. The lack of dependence on insulin therapy after the first week of stupor aroused speculation. His general deterioration precluded an improved production or utilization of insulin. The assumed evidence of a cerebral infarct prompted the suggestion of a simultaneous ischaemic necrosis of the anterior hypophysis. At necropsy, however, a careful search failed to disclose a cerebral infarct.

3. Anterior pituitary necrosis, although not apparent macroscopically, was gross microscopically—a reminder that pituitary histology should not be glibly overlooked.

4. The estimated duration, histologically, of the pituitary necrosis was certainly over a fortnight but less than six weeks before death. This estimation denotes a pre-operative onset of a silent type. There was no complaint of severe headache such as Harvey and de Klerk (1955) have stressed.

5. The cause of the pituitary necrosis invites comment. His undoubted arteriosclerosis may have predisposed. This view is supported by a wider analysis of the case. It may be significant that six of the nine male patients discussed below had well-marked arteriosclerosis. Perhaps in some of the inexplicable cases a silent anterior pituitary infarct, analogous to the concept of silent myocardial infarct, had ensued. Our patient showed no distress during the operation, but the accompanying anaemia and hypotension might have facilitated the extension of this lesion. The seeming paradox of the apparent absence of hypoglycaemia yet extensive anterior pituitary necrosis may be partly reconciled with the corrective dextrose therapy. The total daily carbohydrate intake was, however, not great—that is, about 200 g. during the first week of stupor and about 150 g. thereafter.

6. Appropriate therapy was hard to envisage. The later progressive toxæmia despite oxytetracycline medication, mounting azotaemia, water retention, and a presumed cerebrovascular lesion all militated against the use of cortisone, which was earlier withheld because of a seemingly inadequate rationale. Indeed, we then argued that such treatment would only aggravate the diabetes.

Discussion

The Houssay syndrome due to natural disease, excluding acromegaly and parapituitary tumours, has been reported in 17 well-documented instances (Kotte and Vonderahe, 1940; Feldman *et al.*, 1947; Vanderbroeck and Félin, 1947; Marzullo and Handelsman, 1951; Williams, 1952; Israel and Conston, 1952; Poulsen, 1953; Alexander, 1953; Martin and Pond, 1954; Levin, 1954; Rothfeld and Rodas, 1954; Brenner, 1955; Brouwer and Schopman, 1955; Harvey and de Klerk, 1955, three cases, of which Case 2 is identifiable with fuller detail in Harvey and Bordley's book (1955); Brennan *et al.*, 1956, Case 3).

Analysis, including our patient, clearly reveals:

1. *Heterogeneity of Group.*—Age and duration and severity of the antecedent diabetes have varied widely (Harvey and de Klerk, 1955). There is no evident sex predilection.

2. *Frequently Ill-explained Hypopituitarism.*—The Houssay change often synchronized with apparently irrelevant and diverse conditions. For instance, in the subgroup of nine male patients, individual mention was made of

The treatment of eclampsia, therefore, is directed to the restoration of normal functions of the maternal heart, lungs, liver, kidneys, and brain. The modern routine medical measures that are designed to restore these functions may be summed up as follows: (1) To ensure a clear airway, by direct intubation if necessary, and to maintain a 100% oxygen atmosphere; (2) sufficient glycogen replacement; (3) intravenous administration of vitamins on a body requirement basis; (4) maintenance of an adequate circulating volume of fluid under filtration pressure greater than 100 mm. Hg systolic, a wide pulse pressure, and a diastolic pressure of at least 60 mm. Hg; (5) 20% hypertonic glucose as a diuretic; (6) prompt reduction in venous return to the failing and decompensated heart which is working under the strain of excessively high systolic and diastolic pressures—this is best carried out by conduction nerve-block, which by vasodilatation produces a "bloodless phlebotomy" for as long as is necessary, and does not waste blood.

However, the all-important, all-absorbing, most disturbing symptoms which demand urgent control are the extremes of nervous excitation causing the convulsions, and the hypertension, both of which are the result of vasospasm. Every possible type of sedative and combination of sedative and hypotensive drug (anti-hypertensive) has been from time to time employed for the purpose of controlling the convulsions and reducing the hypertension.

The phenothiazine derivatives chlorpromazine and promethazine reduce tension, anxiety, and excitement (tranquillizing property), and have a potentiating effect on the activity of anaesthetics. Chlorpromazine has a place in the management of eclampsia chiefly on account of these properties. By virtue of its pharmacological effect of balancing the sympathetic and parasympathetic nervous systems it produces a "dampening" of adverse body reactions so that the metabolism of the organism is steadier, and in the event of severe stress it improves the chances of survival. Its use decreases the amount of sedative or general anaesthetic required, and it eliminates the complication of post-anaesthetic vomiting.

Chlorpromazine is a vasodepressor and vasodilator in that it reduces the pressor effect of adrenaline on the blood pressure, as a sequel to its sedative action. Large doses cause a marked fall in the blood pressure, but this action is of moderate duration. Its anticonvulsive property is fair. It is an antipyretic, and is rapidly eliminated by the body. It inhibits salivary secretion owing to its parasympatholytic effect, a property which is advantageous in the management of the unconscious eclamptic patient. Animal experiments have shown that it has no deleterious effects on the liver, heart, or kidneys. By its combination in a lytic cocktail with promethazine and pethidine (or barbiturates), a prolonged and profound sedation can be produced.

Fournel (1952) and Courvoisier *et al.* (1953) have suggested that the anti-adrenaline action of chlorpromazine and the antihistamine action of promethazine possibly afford considerable protection against the onset of traumatic shock. This protection should be of advantage in the obstetric management of the eclamptic patient.

It is well known that intra-partum eclampsia has a lower mortality than ante-partum eclampsia and that immediate delivery is associated with fewer deaths than

late delivery. The longer the convulsion-delivery interval the greater the hazard to the mother. However, the eclamptic patient is not an ideal subject for any type of operation (abdominal or vaginal) and yet the longer the condition lasts the higher is the mortality. Even if the convulsions have been controlled the patient's condition would not be improving, as only one symptom of the disease has been held in abeyance.

Present Investigation

A study of 124 consecutive unselected cases of eclampsia, treated with a lytic cocktail consisting of chlorpromazine, promethazine, and pethidine in 5% glucose, was based on the premise that chlorpromazine and promethazine reduce the hazards of traumatic shock, and that therefore termination of the pregnancy by operation (forceps or caesarean section, depending on the findings at vaginal examination) could be expedited as soon as the convulsions had been controlled. The study covered the period from November 1, 1954, to June 30, 1956 (20 months), and was conducted in the Kandang Kerbau Hospital for Women, Singapore. During the period under review, 43,206 obstetric cases were admitted into this hospital, giving an incidence of eclampsia of 1 in 348 admissions.

The eclamptic patient's urinary output, temperature, and pulse and respiratory rates are usually normal initially, and she is therefore a better risk for operation within two to three hours after the onset of convulsions than after one or more days. This question of time was thought to be an important one from the point of view of the mother's prognosis, and it was hoped that a reduction of the first convulsion-delivery interval would result in a lowering of the maternal death rate from eclampsia.

Method of Treatment.—Hudson and Siew (1956), in their preliminary report, formulated a standard of treatment using a lytic cocktail consisting of 50 mg. of chlorpromazine, 50 mg. of promethazine, and 50 mg. of pethidine in 250 ml. of 5% dextrose. The first half of this solution was allowed to flow into the vein with the drip screw wide open, and the second half was given at 200 drops a minute. When this solution had run through it was followed by a second infusion consisting of 100 mg. of chlorpromazine with 50 mg. of pethidine in 250 ml. of 5% dextrose given at a speed of 40 drops a minute. These infusions were followed by deep intramuscular injections of 100 mg. of chlorpromazine with 50 mg. of pethidine given six-hourly for three or four doses, the first intramuscular injection being initiated two hours or earlier after operation. In most of the cases reviewed in their preliminary report, this regimen of sedation alone sufficed to control the convulsions and lower the blood pressure. However, in a small number, supplementary intermittent doses of 0.1 g. of thiopentone were administered in cases where fits recurred after the infusion of the lytic cocktail. Besides adopting this regimen of sedation, the conventional modern medical measures for the treatment of eclampsia were instituted, and stress was placed on ensuring a clear airway, a high oxygen atmosphere, and the administration of 50% intravenous dextrose solution. This line of treatment was carried out in all the 124 cases studied and, so far as the procedure adopted for sedation was concerned, there was no modification.

Observations During Treatment

Within a few minutes of administration of the infusion of the lytic cocktail the patient appeared to fall into a deep sleep. This rather dramatic change was especially evident in the violently restless cases which were quickly brought under complete control. The plethoric patient assumed the pallor characteristic of chlorpromazine administration. The respiratory rate returned to normal.

The blood pressure showed an initial drop of an average of 44 mm. Hg, though in some cases this was as much as 126 mm. Hg. However, within three hours one could

expect a slight rise above the lowest level. The only precaution necessary was to nurse the patient flat in bed, instead of raising her head, should the initial fall of blood pressure reach a level lower than 100 mm. Hg.

Of the 124 cases treated, fits recurred in 43 patients (33%) after treatment had started. However, these recurrent convulsions differed materially from the usual type seen in eclampsia in that they consisted of mild twitches of the face and limbs of short duration. These atypical convulsions occurred in the oedematous patients who had been heavily sedated and whose blood pressure had dropped appreciably below the pre-treatment level. It is possible that cerebral oedema was the main cause of these manifestations of cerebral irritation, for an intravenous transfusion of 200 ml. of 50% dextrose helped considerably in the reduction of these spasms. In a few cases intermittent doses of 0.1 g. of thiopentone were introduced into the transfusion initially, until control of the spasms was effected, but this adjuvant to the sedative regimen was omitted in the later cases.

The most noteworthy point was the speed with which the patient's condition improved to a degree permitting the consideration of a method for termination of the pregnancy. In the very large majority of cases this became possible within one to four hours after starting the lytic infusion, and a vaginal examination could be carried out in order to decide whether a vaginal delivery was likely to take place in a short time, and, if this was not likely, to proceed on to caesarean section. Of the 124 cases, 34 (27.4%), or just over 1 in 4, were delivered by caesarean section. In all of them the operation was carried out within half to six hours of the beginning of treatment, except in three cases in which the caesarean section was performed after intervals of 12, 18, and 41 hours. There were three deaths among the 34 cases of caesarean section, a mortality rate of 9%, but none of the deaths could be attributed to post-operation shock or haemorrhage.

Another point, not less noteworthy, was the very small amount of general anaesthetic required for the operation and the absence of post-operation shock. In most cases nitrous oxide and oxygen with gallamine triethiodide proved very satisfactory, but in some cases, rather than risk any degree of hypoxia, minimal amounts of cyclopropane were added.

Results

Perinatal Mortality.—Thirty-three infants were lost—15 were stillborn and 18 died in the neonatal period—giving a perinatal mortality rate of 26.2% (there were two sets of twin delivery). Ten (30.3%) of these infants weighed less than 3 lb. (1,360 g.).

Maternal Mortality.—Ten patients died (see Table), giving a maternal mortality rate of 8.06%. There were four deaths from cardiac failure, four from intracranial haemorrhage, one from an improperly administered blood transfusion, and one from status epilepticus.

Summary

A study of 124 consecutive unselected cases of eclampsia treated in the Kandang Kerbau Hospital for Women, Singapore, is recorded.

A method of sedation using a combination of chlorpromazine, promethazine, and pethidine proved to be the most suitable, as patients could be quickly brought under control and prepared for delivery, thus lessening the load on the medical and nursing staff of a very busy hospital.

The results of treatment by the new method compare very favourably with those obtained prior to its introduction. In the years 1952, 1953, and 1954 (excluding November and December, 1954) a total of 188 cases of eclampsia were treated principally by the Dieckman method. The maternal mortality rate in that series was

36%, which is about 1.5% higher than the result obtained by the new method. The eclampsia perinatal mortality rate over the same period was 36%, which is about 10% higher than the figure for the new method of sedation, and this figure is statistically significant.

TREATMENT OF SCHIZOPHRENIA "PACATAL" AND CHLORPROMAZINE COMPARED

BY

J. LOMAS, M.B., D.P.M.

Late Assistant Psychiatrist, Springfield Hospital, London

Delay *et al.* (1952) first reported the use of chlorpromazine in psychiatry, and since then its value in the treatment of schizophrenia has become firmly established (Meyer, 1953; Labhardt, 1954; Lomas, 1955; Vaughan *et al.*, 1955; Boardman *et al.*, 1956).

The therapeutic success of chlorpromazine led to the trial of a host of new "tranquillizers," some of which were hailed with more enthusiasm than wisdom, and in particular to the more intensive investigation of the phenothiazine compounds. The need to find a substitute for chlorpromazine was increased by its potentially dangerous toxic effects, especially on the liver (Lomas *et al.*, 1955).

"Pacatal" (10-(N-methyl-3 piperidylmethyl)phenothiazine) is, like chlorpromazine, a phenothiazine derivative and has the graphic formula:

Nieschulz *et al.* (1954) published the first pharmacological study of the drug, and their work has since been further extended and confirmed by other workers (Nieschulz *et al.*, 1955; Kopf, 1955). In animals pacatal has similar effects to chlorpromazine in producing sedation without hypnosis and in potentiating the effects of other sedatives, hypnotics, and analgesics. It also has a similar though not so pronounced sympatholytic effect, but there is only slight antagonism to adrenaline, and, unlike chlorpromazine, pacatal has a marked depressive action on the parasympathetic nervous system. In consequence its hypotensive action is relatively weak.

Electroencephalograms in normal animals show that pacatal has a similar action to other phenothiazine derivatives, but experiments done in the Warner-Chilcott research laboratories showed that it does not block the arousal pattern, and Himwich *et al.* (1956) could demonstrate no blocking effect on the reticular formation.

Little has yet been published on the effects of pacatal in schizophrenia, but Werenberg (1955) reported improvement in 85% of 100 patients, most of them disturbed schizophrenics and nearly half of whom had been in hospital for over 20 years. Hiob and Hippus (1955) treated 65 female psychotic patients, nearly half of them diagnosed as suffering from schizophrenia: 65% were much improved and 20% were discharged. Most of them had shown no significant improvement with other physical methods of treatment including various "tranquillizers."

Bowes (1956) considered pacatal to be of most value in manic and schizo-affective psychoses. He found chlorpromazine more useful in acute schizophrenic disorders. In chronic schizophrenics he found pacatal controlled the grosser behaviour disturbances, but thought that a combination of pacatal and chlorpromazine was the treatment of choice in these cases. Jepsen (1955) thought that pacatal was effective in one out of three cases which had failed to respond to chlorpromazine and in which aggressive tendencies or paranoid symptoms prevailed.

It is the aim of this paper to compare the effects of pacatal and chlorpromazine in the treatment of the schizophrenic group of disorders.

Selection of Patients

All new admissions were included in the series when the diagnosis was schizophrenia, paraphrenia, or schizo-affective disorder and when the doctor in charge of the case considered that chlorpromazine was the treatment of choice. This excluded acute katatonic conditions where E.C.T. was indicated, schizo-affective cases where the affective disorder was predominant and consequently E.C.T. again the treatment of choice, and all those cases in which insulin was thought advisable. The results were based on 50 male and 50 female patients selected in this way. Once inclusion in the series had been decided on, patients were assigned to either the pacatal or the chlorpromazine group according to a prearranged code known only to the chief pharmacist. The order of assignment was decided by dealing out a well-shuffled pack of 25 red and 25 black cards for male and female patients.

The distribution of patients into the various diagnostic subgroups was comparable for the two groups. Over 60% of both pacatal- and chlorpromazine-treated patients were diagnosed as suffering from paraphrenia or paranoid schizophrenia, half the remainder were assigned to the katatonic subgroup, and the rest were evenly distributed between the simple schizophrenic, hebephrenic, and schizo-affective subgroups.

The age distribution for the two groups was also closely comparable. The mean age for the pacatal patients was 37.1 ± 1.5 years (males 33.8 ± 2 ; females 40.5 ± 2), while the chlorpromazine patients averaged 36.9 ± 1.5 years (males 33.4 ± 2 ; females 40.4 ± 2.1). The differences are entirely insignificant statistically.

The assessment of the duration of a mental illness is a notoriously difficult task, and is made even more so where, as in this case, the breakdown is not necessarily the first. The duration of the current attack is obviously unreliable, as it neglects the prognostic effect of previous illness. On the other hand, the duration since the first symptoms appeared may be equally unreliable. One patient in this series had a first attack 20 years ago and apparently remained perfectly well until the acute onset of her present symptoms; but if both the number of previous attacks and the duration of the illness since the first symptoms appeared are taken into account a fairly reliable guide to the comparability of the two groups can be obtained.

Table I shows the distribution of previous admissions. It will be seen that there is very little difference between the

TABLE I.—Number of Previous Admissions

No. of Previous Admissions	Chlorpromazine			Pacatal		
	Males	Females	Total	Males	Females	Total
0	13	5	18	10	4	14
1	6	12	18	7	13	20
2	3	5	8	4	5	9
3+	3	3	6	4	3	7

chlorpromazine and pacatal groups and that this difference is entirely insignificant statistically.

The mean duration of illness in the chlorpromazine group was 4.4 ± 0.6 (males 3.1 ± 0.7 ; females 5.7 ± 0.9), while for the pacatal group it was 4.4 ± 0.7 (males 4.6 ± 1 ; females 4.3 ± 0.9). Thus, while the male patients were more favoured prognostically in the chlorpromazine group, the female patients receiving pacatal were equally well placed, and in the patients as a whole there was no difference in duration of illness between the two groups. The differences in the male and female subgroups were not statistically significant.

Those patients receiving chlorpromazine could therefore be regarded as prognostically comparable to the pacatal group in respect of age, type of disease, and duration of illness.

Procedure

Dosage and Method of Administration.—Pacatal was supplied in tablets containing 50 mg. and chlorpromazine in tablets of either 25 mg. or 100 mg. Once included in the investigation, patients were prescribed "Tabs. P.L." in a dosage of a multiple of 50 mg. Whether they received pacatal or chlorpromazine depended on the chief pharmacist's code. The usual dosage of either was 300 mg. daily, but it might vary above or below this figure. Treatment was discontinued when the patient left hospital, if the doctor in charge of the case considered a different type of treatment desirable, if serious toxic effects supervened, or after treatment had lasted for three months. A full three-months course was always given if possible.

Assessment of Results.—The trial was only approximately a blind one. The ward medical officer did not initially know whether a patient was receiving chlorpromazine or pacatal, but as the two tablets are different the nursing staff who administered the drugs inevitably had this knowledge, and it would not always be kept from the ward doctor. The final assessment, however, was made by the physician-superintendent, who had no knowledge of the type of treatment received. The results were assessed when treatment was discontinued, for whatever reason, on the following scale: (1) Not improved=slight or no change either in symptoms or in behaviour. (2) Slightly improved=decrease in symptoms and disappearance of gross behaviour disturbances. (3) Moderately improved=improvement in adjustment at hospital level or to the outside world at a dependent level, as shown by taking an interest in environment and in social activities and by employability within the hospital. (4) Much improved=improvement in adjustment to the outside world at an independent level shown by increases in initiative, reliability, and responsibility. (5) Recovered=symptom-free, with insight and capacity for adjustment to the outside world at the level extant before the breakdown.

Results

The results are shown in Table II. It can be seen that chlorpromazine is much more effective than pacatal and that

TABLE II.—Results

Assessment	Chlorpromazine			Pacatal		
	Males	Females	Total	Males	Females	Total
Not improved	3	1	4	8	4	12
Slightly improved	6	3	9	6	3	9
Moderately improved	5	9	14	9	12	21
Much improved	9	9	18	2	4	6
Recovered	2	3	5	0	2	2

this difference is greater for males than for females. The difference is significant at the 1% level for the results as a whole, at the 5% level for male patients, and not statistically significant for female patients. This difference between the sexes is probably due to the variation in the duration of illness of male and female patients, and cannot therefore be regarded as reflecting any real difference of effect of the two drugs in the two sexes.

Study of Table II shows that only 8 out of the 50 patients receiving pacatal were better than moderately improved, as against 23 of those on chlorpromazine. The distribution of the pacatal patients is in fact no better than could reasonably be expected in a group of similar patients subjected to routine hospital regime without any specific treatment.

The same difference is shown if discharge rate is taken as a criterion of improvement, although this is not, of course, a very reliable guide. By the end of the investigation, defined as three months after the last patient had started treatment, 33 patients on chlorpromazine had been discharged as against 26 on pacatal. On the other hand, of those discharged the mean duration of stay in hospital was 13.2 ± 1.5 weeks for those receiving pacatal and 14.2 ± 1.5 weeks for the chlorpromazine cases. The differences are not statistically significant.

It has already been mentioned that the nursing staff invariably, and the medical staff on occasion, knew the nature of the treatment. This introduces an element of bias which might influence the results, although the final assessment was made without any knowledge of the treatment given. The staff had already accepted chlorpromazine as being a valuable method of treating schizophrenia and would therefore be inclined to suspect anything new. If treatment were therefore not immediately successful they might be inclined to abandon the newer pacatal more readily than the well-tried chlorpromazine and thus influence the results by not giving pacatal a long enough trial to produce its best effect.

The analysis of the reasons for finishing treatment shown in Table III suggests that no such bias in fact influenced the results. The two groups differ only in the numbers of patients discharged where those on chlorpromazine exceed the pacatal figure and in those patients for whom a change

TABLE III.—Reasons for Discontinuing Treatment

Reason	Chlorpromazine			Pacatal		
	Males	Females	Total	Males	Females	Total
End of course	12	14	26	13	13	26
Discharged	6	7	13	3	4	7
Discharged against advice	1	2	3	2	2	4
Change of treatment	4	1	5	4	5	9
Treatment refused	1	0	1	1	1	2
Toxic reaction	1	1	2	2	0	2

of treatment was considered necessary. Nine pacatal patients were taken off treatment for this reason, against the five in whom chlorpromazine was discontinued, but although this difference may have been due to bias it is too small to have influenced the final results.

The results of this trial therefore suggest that chlorpromazine is superior to pacatal in the treatment of a mixed group of recently admitted schizophrenic patients.

Side-effects and Toxic Reactions

The toxic reactions to chlorpromazine are now widely known and have been fully reported by Lomas *et al.* (1955). The most serious are liver damage and the much rarer agranulocytosis. Doughty (1955) from a perusal of the world's literature estimated the incidence of jaundice as 1.4% out of over 7,000 patients.

The toxicity of pacatal is less well known. Troublesome though not serious side-effects are due to the drug's parasympatholytic actions. Dryness of the mouth and difficulty in visual accommodation are frequent occurrences, and are

mentioned by most writers. Constipation, nausea, and vomiting are less common but have been mentioned in most investigations. Opinions vary about the hypotensive effects of the drug. Horatz (1954), reporting on 439 cases, thought that the danger of orthostatic collapse necessitated great caution in management, but most investigators were not seriously concerned with this complication, and the general consensus of opinion was that in this respect pacatal is safer than chlorpromazine.

Of the more serious complications following use of chlorpromazine, only Werenberg (1955) reports the incidence of epileptic fits, which occurred in 7% of 100 patients. Of these cases, four had been leucotomized, one had had fits previously, and two had had frequent electroplexy. Skin reactions and oedema are rare. Kroner (1955) reports a few cases of light sensitivity, but no mention is made of this complication anywhere else in the literature. No case of jaundice has yet been reported.

As with chlorpromazine, the blood picture varies, but a mild leucopenia is the most commonly reported finding. Three cases of agranulocytosis, however, have been recorded, two of them fatal (Wenderoth and Lennartz, 1955; Werenberg, 1955; Gore and Biezanek, 1956).

Bowes (1956) mentions one case of atonic bladder and one of paralytic ileus, while Kline and Jacob (1955) considered the drug so toxic that they abandoned it altogether. Their experience was, however, limited to seven cases.

In the present series, among the 50 patients receiving pacatal, dryness of the mouth was an almost universal complaint and in some cases was very troublesome but did not necessitate taking anyone off treatment. Cycloplegia was also common and necessitated two patients having to discontinue treatment. Physostigmine drops alleviated the complaint to some extent. Constipation was occasionally troublesome, but less so than with chlorpromazine, and neither nausea nor vomiting was noted. Twelve patients underwent extensive laboratory investigations with negative results, at periods varying from 5 to 13 weeks after treatment started. Haemoglobin levels and sedimentation rates were unchanged and the lowest recorded total white count was 4,800. Urinalyses were invariably normal, and alkaline phosphatase levels, non-protein nitrogen, and serum bilirubin were within normal limits.

In 2 of the 50 cases receiving chlorpromazine it had to be discontinued. One developed jaundice and another had an intractable dermatitis while on the drug.

Summary and Conclusions

Fifty cases falling within the schizophrenic group of disorders were treated with pacatal, while a similar number received chlorpromazine.

The method of selecting patients and the scheme of dosage are outlined. It is considered that the two groups are comparable so far as prognosis is concerned.

Assessment of results was made on a five-point scale by an independent observer who knew nothing of the type of treatment. Assessment was made either after 13 weeks or when treatment had to be discontinued for one of various reasons.

The results are significantly better in those patients receiving chlorpromazine, and there is nothing in this trial to suggest that pacatal has any value in the treatment of a mixed group of schizophrenic patients.

Both from a review of the literature and from experience in this trial pacatal would appear to be less toxic than chlorpromazine. Jaundice does not seem to be a risk in using pacatal, but agranulocytosis is a dangerous complication with both drugs.

I thank Dr. H. C. Beccle, physician-superintendent of Springfield Hospital, for his kindness in making the independent assessment of results; and Mr. Mayall, the chief pharmacist, for his

invaluable assistance in arranging the order of treatment. I am indebted to Messrs. William R. Warner and Co. Ltd. for their generous supplies of pacatal.

ADDENDUM.—Since this article was written, two reports on the use of pacatal in psychiatry have appeared in this country. J. G. Thorpe and A. A. Baker (*J. ment. Sci.*, 1956, 102, 790) agreed that pacatal was less effective but less toxic than chlorpromazine, while P. H. Mitchell, P. Sykes, and A. King (*British Medical Journal*, 1957, 1, 204) found it of some value in controlling incontinence, noisiness, and aggression in deteriorated female schizophrenics, but considered it to be much more toxic. They reported one death due to agranulocytosis and two cases of jaundice.

A considerable number of cases of arachnodactyly have been reported since Marfan's original description of a girl aged 5 years with spider fingers (*pattes d'araignée*) and poorly developed musculature (Marfan, 1896). Although the deformities described in this case were predominantly skeletal, subsequent reports of patients with this syndrome have indicated that it may be associated with other congenital abnormalities. Salle (1912) was the first to recognize the association with patent foramen ovale, and Börger (1914) reported details of a patient who had dislocation of the lens and iridodonesis with arachnodactyly. The frequency with which congenital anomalies of the heart may occur in patients with Marfan's syndrome has been stressed by Piper and Irvine-Jones (1926). Baer, Taussig, and Oppenheimer (1943) associated arachnodactyly with developmental abnormalities of the media of the aorta, and a further case with dissecting aortic aneurysm was described by Etter

and Glover (1943). High arched palate and anomalies of the lungs have also been reported (Börger, 1914).

Rados (1942), reviewing 204 previously reported patients with Marfan's syndrome, stated that no involvement of the genito-urinary system had been described. Genital and urinary tract abnormalities have, however, been recorded in association with arachnodactyly, although they appear to be rare. Börger (1914) and Delord and Viallefont (1936) described genital hypoplasia in the male, and other writers (Haridas, 1941; Stern, 1944) reported undescended testes in their patients. Olcott (1940) reported the case of a patient with arachnodactyly in whom "the left kidney was in the pelvis of the body with its hilum against one of the flat surfaces," and presumably a description of an ectopic left kidney; and Fischl and Ruthberg (1951) recorded three cases of Marfan's syndrome, in one of which the left kidney was ectopic and hydronephrotic.

No previous report has drawn attention to the association between arachnodactyly and abnormalities of the urinary tract. This paper describes the clinical features and post-mortem findings in two patients who had Marfan's syndrome, and who died with renal failure due to congenital lesions of the urinary tract.

Case 1

A brewery clerk aged 33 was referred to Hammersmith Hospital on October 14, 1954, because of extreme weakness of his arms and hands, and protuberance of his abdomen. He had always been thin, being known as the "Belsen horror" when serving in the R.A.F. in 1945, but his arms and hands had become progressively thinner and weaker during the previous five years, and his speech somewhat slurred. He was myopic and completely colour-blind. There had been no frequency of micturition, no dysuria, and no haematuria. He shaved daily, and sexual function was normal.

On examination he was 5 ft. 10 in. (177.8 cm.) tall and weighed 8 st. 7 lb. (54 kg.). His fingers were very long and thin and his palate was high and arched. There was marked wasting of the muscles of his face, neck, and shoulder girdle, with the exception of the deltoids, which gave him an emaciated appearance contrasting strikingly with his dysarthric protestations of good health. He had bilateral ptosis and frontal recession of the hair, which, with the wasting, produced a typical myopathic facies. The abdominal and thoracic muscles were unaffected, but there was slight weakness and wasting of the extensors of the feet. The biceps, brachioradialis, and ankle jerks were diminished. Sensation was normal. The grip was myotonic, and percussion myotonia, exaggerated by neostigmine, was demonstrated in both thenar eminences. Blood pressure was 180/120 mm. Hg, but the heart was not enlarged and there were no murmurs. The abdomen was distended by two large polycystic kidneys which filled both loins. The testes were soft, but of normal size, and the prostate was small.

Investigations.—The blood count showed a mild normochromic anaemia (Hb, 10.9 g. per 100 ml.; W.B.C., 6,000 per c.mm.), and the E.S.R. (Westergren) was 60 mm. in one hour. Twenty-four-hour urine output averaged two litres, with a protein content of 900 mg. a day. The blood urea was 168 mg. per 100 ml. Plasma proteins were normal (albumin 4.2 g., globulin 2.1 g.). Serum electrolytes were: Na⁺ 136, K⁺ 4.5, Cl⁻ 103.5, HCO₃⁻ 21.3 mEq per litre. Alkaline phosphatase was 17.5 King-Armstrong units per 100 ml. Radiography of the abdomen after peritoneal air insufflation confirmed the presence of two large polycystic kidneys.

The blood urea rose to 300 mg. per 100 ml. during the month after his admission to hospital. In an attempt to improve his renal function, a Rovsing operation was per-

formed on the right side, many of the cysts being punctured. Following the operation, however, his condition deteriorated rapidly and he died.

Necropsy Report.—The necropsy confirmed the clinical findings. The most striking features were the two enormous polycystic kidneys. The right kidney weighed 2,024 g. and the left 2,610 g. There was no abnormality in the cardiovascular system. The testes were normal.

Family History.—The patient had no siblings. His father was aged 56 and alive and well. His mother had died at the age of 63 from cancer of the lung. She was said to have had excessively long fingers. The mother had four brothers and four sisters, of whom only one sister was living, the remainder having died suddenly from unknown causes before the age of 40. The patient's maternal grandfather had been colour-blind. There was no history of polycystic kidneys in his family.

Case 2

G.C., a young storeman aged 16, attended hospital on August 17, 1955, complaining of shortness of breath on exertion, lethargy, and weight loss for two months. Pallor had been noted by his family for the preceding six months.

A deformity of the left knee had been present since birth. There was no history of haematuria, polyuria, or frequency of micturition.

On examination he was a tall slender youth—height 5 ft. 6 in. (169.5 cm.), weight 7 st. 6 lb. (47.2 kg.). The skin was pale but there was no oedema. The length of the forearms and legs was striking, his span measurement being 3 in. (7.5 cm.) greater than his height, and the symphysis pubis to ground measurement 5 in. (12.5 cm.) greater than from symphysis to vertex (Fig. 1). The fingers and toes were long and thin, and there was slight webbing between the fingers. There was old subluxation of the left knee, and the right thumb was hyperextensible at the metacarpo-phalangeal joint. The patella on the right side was very mobile and higher than normal, the distance from its lower border to the tibial tubercle measuring 2 in. (5 cm.). There was a moderate kyphosis and slight "pigeon-chest" deformity. The palate was normal and there was no dislocation of the lens. Blood pressure was 150/100 mm. Hg; the heart was not enlarged and there were no murmurs. Neither kidney was palpable; testes and prostate were of normal size, and pubic hair was of masculine distribution. Muscular development was poor, tendon reflexes were uniformly diminished, and abdominal reflexes were absent.

Investigations.—The blood count showed a normochromic anaemia (Hb, 8.1 g. per 100 ml.; M.C.H.C., 32.5%; W.B.C., 6,000 per c.mm.). E.S.R. (Westergren) was 72 mm. in one hour. Twenty-four-hour urine output varied from 1,200 to 3,200 ml., and there was a heavy albuminuria, ranging from 4.7 to 9.7 g. in 24 hours. Urinary deposits contained no cells or casts, and cultures were repeatedly sterile. The range of urinary specific gravity was 1004–1008. The blood urea was 104 mg. per 100 ml. Plasma proteins were: Ca⁺⁺ 4.55, Na⁺ 145, K⁺ 3.6, Cl⁻ 104.5, HCO₃⁻ 17.2 mEq per litre. Alkaline phosphatase was 55 King-Armstrong units per 100 ml.

FIG. 1.—Case 2. Illustrating the long extremities and subluxation of the left knee.

Bone x-ray films revealed a coarse trabecular pattern with subperiosteal bone erosions in the fingers and right femur suggestive of secondary hyperparathyroidism. Retrograde pyelography (Mr. R. Shackman) showed a small kidney on the right side with some dilatation of the right ureter; the left renal pelvis was slightly larger than normal and the calices were truncated.

The patient was treated with repeated blood transfusions to correct the anaemia, a low-protein diet, and a high fluid intake. Despite a progressively increasing blood urea level, he was able to remain at work for 11 months. He was admitted to hospital for the last time on July 22, 1956, and died in uraemic coma one week later.

Necropsy Report (Dr. M. Ralston).—Post-mortem examination confirmed the clinical findings and revealed the nature of the renal lesions. The dissection of the urinary tract is shown in Fig. 2. Both kidneys were much reduced in size,

FIG. 2.—Case 2. Dissection of the urinary tract.

the right weighing 16 g., the left 72 g. Both showed scarring of the capsular surfaces, the right having rather coarse scars, the left being more finely and regularly scarred. The cut surfaces of both showed cortical narrowing and loss of pattern. The right renal pelvis and ureter were greatly dilated down to a point 3 cm. above the right ureteric orifice, where the lumen narrowed abruptly. The left ureter was a little dilated throughout its length. Microscopically both kidneys showed the features of chronic pyelonephritis. Sections of the right ureter, however, revealed no explanation for the narrowing. Other post-mortem findings of note were secondary parathyroid hyperplasia (combined weight 260 mg.), with resultant effects on the bones, pulmonary oedema, and superficial haemorrhagic ulceration of the terminal ileum. The aorta showed no evidence of medial degenerative changes.

Family History.—The relevant clinical findings are summarized in the accompanying Table. No genito-urinary abnormalities were detected in the parents or siblings of this patient. The brothers and sisters were, with one exception, tall and remarkably thin. The father had aortic incompetence, but the Wassermann reaction had been negative, and there was no other cardiac lesion or any previous history of rheumatic fever. The mother was normal in all respects. Of the siblings, F.C. had unexplained exophthalmos, O.C. had a pulmonary cyst and a congenital deformity of the right middle lobe, and J.C. suffered from epilepsy. All these abnormalities may be found in association with arachnodactyly. One sister (E.C.) had arachnodactyly without any other abnormality.

Discussion

Both of these patients had arachnodactyly and congenital abnormalities of the urinary tract. The polycystic kidneys in Case 1 were clearly of congenital origin. The lesion in Case 2 is less easily defined, but the narrowing of the right ureter was presumably congenital, for microscopical examination of the wall of the ureter at this point revealed no evidence of either inflammation or fibrosis. The small right kidney is fully explicable as the end-result of pyelonephritic scarring without invoking congenital hypoplasia. Theoretically it is possible that pyelonephritis has been superimposed

Age, Height, Finger Length, Height of Patella, and Clinical Findings in Parents and Siblings of Case 2

* Length of patellar ligament is the distance from the lower border of the patella to the tibial tubercle.

on a congenitally hypoplastic kidney, but unequal involvement of the kidneys in pyelonephritis is well recognized, and the obstruction on the right side would explain the greater severity of the process in the right kidney. The radiological appearance of the bones and the raised alkaline phosphatase indicated that this patient had renal osteodystrophy, and the parathyroid glands found at necropsy were characteristically hypertrophied. These bone changes are often found in young patients with chronic pyelonephritis and uraemia.

Patients with Marfan's syndrome may have a number of associated abnormalities. Congenital defects and spider fingers may also be found in other members of their families (Rados, 1942). The coincidence of colour-blindness, illustrated by Case 1, has been recorded previously (Neresheimer, 1916). This patient also had dystrophia myotonica. Poor muscular development has been a feature of the syndrome since it was first described by Marfan (1896), and amyotonia congenita has been reported in patients with arachnodactyly (Young, 1929), but we have found no previously recorded cases with dystrophia myotonica. Our first patient had neither testicular atrophy nor cataract, and no other case of dystrophia myotonica had been recognized in his family. The myotonia and the distribution of the muscle wasting were, however, characteristic of this disease. His mother was said to have had excessively long fingers, and it is of interest that most of her family had died suddenly before the age of 40.

The associated abnormalities in the second patient involved the skeletal system. In addition to long fingers, he had long arms and legs. The subluxation of the left knee and the hyperextensible right thumb were typical findings in a patient with arachnodactyly, and the patella on the right was high. "High patella" has frequently been described in patients with Marfan's syndrome since Méry and Babonneix (1902) drew attention to this abnormality in a further report of Marfan's original case. Fischl and Ruthberg (1951) stated that the patella was 3 cm. above the normal position in one of their cases, but no report has defined the normal position of the patella. The distance of 2 in. (5 cm.) from the lower border of the patella to the tibial tubercle, which was found in the second patient and in four of his siblings, was greater than in any of 25 control subjects,

in whom the mean distance, measured by the same observer, was 1.4 in. (3.5 cm.), with a range of 1.1 to 1.8 in. (2.7 to 4.6 cm.).

Examination of the family of Case 2 revealed a number of interesting abnormalities. Only one (E.C.) had arachnodactyly, but five out of the six siblings were strikingly tall and thin, and the patella was high in four. Whittaker and Sheehan (1954) have recorded instances of aortic lesions without arachnodactyly in the families of patients with Marfan's syndrome, and although the father had no skeletal abnormality it is tempting to consider his aortic incompetence as possibly of congenital origin. Unexplained exophthalmos, illustrated by F.C., has been described in patients with arachnodactyly (Baer *et al.*, 1943), and abnormalities of the lobes of the lungs, which were present in the sister, O.C., are not uncommon (Rados, 1942). Another sister suffered from epilepsy, a finding also reported by Marfan in one of the siblings of his original case (Marfan, 1896).

The aetiology of Marfan's syndrome, like so many other congenital anomalies, remains obscure. Weve (1931) explained the skeletal and visceral abnormalities on the basis of a congenital mesodermal dystrophy, but it has been repeatedly stressed that, if this theory were true, urogenital abnormalities should also occur (Rados, 1942). In fact, genital abnormalities have been reported from time to time. The two cases reported by Olcott (1940) and by Fischl and Ruthberg (1951) illustrate that congenital lesions of the urinary tract may also be found with arachnodactyly. These findings lend some support to Weve's hypothesis, but it is interesting to speculate how a dystrophy affecting one of the germinal layers may at the same time result in excessive growth of the extremities.

Summary

A brief survey of the abnormalities which may be found in patients with Marfan's syndrome is given. The apparent rarity of the association of arachnodactyly with genito-urinary abnormalities is stressed. Two patients who had arachnodactyly and congenital lesions of the urinary tract are described. The first had bilateral polycystic kidneys, and the second had chronic pyelonephritis resulting from a congenital stricture of the lower end of the right ureter. These findings lend some support to the hypothesis that the visceral abnormalities associated with Marfan's syndrome may be due to a congenital mesodermal dystrophy.

The first patient also had dystrophia myotonica. The coincidence of arachnodactyly with this disorder has not previously been described.

We thank Dr. C. L. Cope, Dr. G. R. Fearnley, and Mr. R. Shackman for permission to report details of patients who were under their care; Dr. M. Ralston for the post-mortem report on Case 2; and Professor J. McMichael and Dr. M. D. Milne for their criticism and advice.

A SIMPLE METHOD OF BLOOD-SUGAR ESTIMATION

BY

W. M. LANCASTER, M.B., F.R.F.P.S., M.R.C.P.
 Department for Metabolic Diseases, Victoria Infirmary,
 Glasgow

Many methods of blood-sugar estimation are available at present—for example, Hagedorn and Jensen, Maclean, Folin, Harman, and Somogyi. In recent years, moreover, the "true glucose" methods have become more and more popular, Nelson's modification of the Somogyi technique, giving close approximation to the true glucose level, being widely used in hospital practice. While there can be no doubt that these methods, particularly the latter, give accurate and consistent results, all of them require laboratory facilities to a greater or less extent and are best carried out by a person experienced in the particular technique involved. Very often, however, when faced with a problem involving the need for a blood-sugar estimation, it is adequate for the clinician to know that the blood sugar lies within a certain range. The method described below requires a minimum of technical equipment and training, and can be readily performed in the consulting-room or the patient's home, the results being available within ten minutes.

Method

The outfit for this simple method is manufactured by Ames Company (London) Ltd., who supplied it for the purpose of this investigation. The test is in essence a quantitative copper reduction method, the test solution being compared with a standard colour range chart, and the blood-sugar range being read directly from this chart. The total equipment is two standard test-tubes (7.2 by 1.4 cm.—"clintest" pattern) graduated in millilitres, a metal test-tube rack, two pipettes, filter papers, and two small bottles of reagents conveniently presented as tablets (A and B). No external heating is required. The whole apparatus can be packed in a box some 3 by 3 by 1 in. (7.5 by 7.5 by 2.5 cm.), and is therefore very readily portable.

The test-tubes are set up in the rack, 2 ml. of water is put into one tube, then one tablet A is added and allowed to dissolve completely. Then 1 ml. of venous blood is placed in this solution and thoroughly mixed with a glass rod, this procedure deproteinizing the blood. A filter cone is then placed in the second test-tube and the solution from the first test-tube poured into the cone. A clear filtrate is obtained and 1 ml. is collected. (These measurements are very easily made, as the tubes are graduated in millilitres.) To this solution one tablet B is added; vigorous boiling occurs, during which time the tube should not be touched. After the boiling ceases the test-tube is shaken briskly three or four times, there is a wait for 30 seconds, and the colour is then compared with the standard scale provided. This colour scale shows three definite stages—blue, olive green, and tan—corresponding to blood-sugar levels of 100, 150, and 200 mg. per 100 ml., but with a little experience intermediate levels of 125 and 175 mg. can be judged reasonably accurately. This range—that is, 100 to 200 mg. per 100 ml.—is the standard range claimed by the manufacturers. An attempt has been made to extend this range to increase the usefulness of the method. The effective range of the scale can be readily extended to a level of 400 mg. per 100 ml. by simple dilution of the filtrate, 0.5 ml. of filtrate being collected, making up to 1 ml. with water, the actual testing being carried out as above, and the result obtained being multiplied by two. Further dilutions to an upper level of 800 mg. per 100 ml. can be readily made if desired.

Results

The method has been tried on blood specimens from 80 diabetic patients, simultaneous blood-sugar estimations using the Nelson method being carried out as a control. Five millilitres of venous blood was drawn into a fluoride tube and the specimen divided equally for testing by both methods. The results obtained are shown in Fig. 1. This

FIG. 1.—Comparison of blood-sugar determinations by the Nelson method with the new test in 80 diabetic patients. FIG. 2.—Comparison of the Nelson method and the new test at intermediate levels in 31 patients.

gives the results of the test carried out without dilution of filtrate and without any attempt at intermediate readings on the test scale. It will be seen that within the range 100 to 200 mg. per 100 ml. the test gives a reasonably accurate estimate of the blood-sugar level, in the majority of cases within ± 25 mg. of the true level. It should be noted, however, that at both the lower and the upper range of the test considerable variations in the true levels may occur without any apparent variation in the test colour. While a more accurate estimate of levels over 200 mg. per 100 ml. may be made by simple dilution, it is important to recognize that levels below 100 mg. per 100 ml. cannot be assessed, and hypoglycaemic levels may be present without any definite indication from the test results.

After the initial test, inquiry was made whether a more precise estimate of the blood sugar could be arrived at by use of the method. By judging the colour given by the test as approximately intermediate between the colours on the standard scale, a reading of 125 or 175 mg. per 100 ml. might be possible. This was tried in 31 cases and the results were compared with those obtained by Nelson's method. The findings are summarized in Fig. 2. It will be seen that in the majority of cases intermediate levels can be judged with a fair degree of accuracy and that most of the results can be determined to within ± 25 mg. of the true level. Fig. 2 also illustrates the inability of the test to distinguish between levels below 100 mg. per 100 ml.; here true levels of 100 and 35 mg. per 100 ml. appear identical.

Fig. 3 shows the results in 49 patients. The initial tests showed the rapid development of an orange colour sug-

FIG. 3.—Comparison of the Nelson method and the new test at levels between 200 mg. and 400 mg. per 100 ml. in 49 patients.

FIG. 2

had shown a blood-sugar level above 400 mg. per 100 ml. further dilution of 1 to 4 of the filtrate was carried out. The results were:

Case	Nelson method	Test
1	650	600-700 mg. per 100 ml.
2	838	700-800 " " "
3	565	500-600 " " "

When dilutions of this order are carried out the degree of precision is less, but the results do give a useful guide to the blood-sugar level.

Comments

The method described gives blood-sugar estimations of reasonable accuracy in the range 100 to 400 mg. per 100 ml. The most accurate results are obtained when the blood-sugar level is between 100 and 200 mg. per 100 ml., and the accuracy diminishes with dilution of the filtrate. The procedure is easy to carry out, and requires no elaborate equipment. It could, if necessary, be performed in the patient's home or in the consulting-room. It is a rapid test and on average can be completely carried out in 10 minutes.

A real difficulty in the technique is in deciding the colour of the tested solution when comparing it with the standard scale. When it compares exactly with the standard range then the result is obvious, but intermediate colours are frequent and may cause considerable difficulty. With experience intermediate values can be estimated with reasonable accuracy, although absolute precision is not possible.

Certain features in the method merit comment. First, occasional difficulty was encountered during the period of filtration and a cloudy filtrate was at times noted, presumably associated with defective filtration. Testing this solution gave inaccurate results, and it is therefore important to note that the filtrate is clear before completing the test. Secondly, the importance of the time interval before reading should be noted. The colour change must be read at exactly 30 seconds after shaking. If this interval is prolonged, further colour changes may occur, with resultant discrepancy in the readings. On the other hand, shortening of the interval gives readings much below the true level.

The test appears to be a simple, rapid, and reasonably accurate method of blood-sugar estimation. While it does not give a high degree of precision in many cases, it may well be of value where an approximation is adequate—for example, in a busy diabetic clinic. Two patients illustrate this: both were pregnant diabetic women showing a heavy glycosuria. The test (confirmed by Nelson's method), however, showed their blood sugar levels to be within satisfactory levels, indicating lowering of the renal threshold. The method may also be used in the management of diabetic ketosis in emergency, when full laboratory facilities are not available. The values obtained, although approximate, give adequate information for the assessment of the response to treatment and the adjustment of insulin dosage. It is important to note, however, that the test is of no help in distinguishing between normal and low blood-sugar levels, and hypoglycaemic levels may be reached without any indication from the test. This would appear to be the major disadvantage of the method.

Summary

A simple method of blood-sugar estimation has been tried in a series of 80 diabetic patients, the results obtained being compared with blood-sugar estimations by the Nelson method.

The most accurate results are obtained when the blood level lies between 100 and 200 mg. per 100 ml. In higher ranges the results are less precise, but often are adequate approximations.

The test is of no value in the diagnosis of hypoglycaemia.

Factors which may give rise to fallacies in the test are discussed, and possible practical applications are described.

I thank Dr. Ian Murray for his advice and help in the preparation of this paper; Dr. I. Anderson and the staff of the biochemistry department for their willing co-operation throughout the trial; and Ames Company (London) Ltd. for supplying the kit.

USE OF HYALURONIDASE IN
INSULIN COMA THERAPY

BY

J. C. HOLDEN, M.R.C.S., D.P.M.

Senior Registrar

AND

O. L. MCGUINNESS, M.B., B.Ch.

Registrar, Winwick Hospital, Warrington, Lancs

Hyaluronidase was first named by Chain and Duthie (1939, 1940), but it was as early as 1928 that Duran-Reynals isolated what he called a spreading factor from normal testis. Various sources of hyaluronidase have since been determined—ciliary body, cornea, skin, and spleen—and it is now recognized as a specific enzyme having the special property of depolymerizing hyaluronic acid—a mucopolysaccharide constituting the tissue cement or ground substance of the mesenchyme. The possible applications of such an enzyme, once extracted and standardized—namely, a substance which can, as it were, reversibly reduce the viscosity of the intercellular matrix—are numerous, and there is a great deal of evidence to indicate its useful application in the fields of surgery and midwifery.

It seemed feasible, therefore, that hyaluronidase could be of use in deep insulin therapy, perhaps increasing absorption rate and allowing for a smaller dosage of insulin, and indirectly minimizing the possibility of hypoglycaemic after-shock. Hyaluronidase has thus been used and reported on by various workers with conflicting results, but Gysin and Wilson (1954), investigating a series of 53 cases, found that the amount of insulin was reduced by some 40%, a smoother induction resulted, and late adverse reactions were reduced by about 73%. There is such great individual variation to the effects of injected insulin that such results should be regarded as very significant. One factor, for instance, is the undoubted possibility of injecting into fascial planes, causing variable absorption.

The object of this paper is to report on a series of 42 patients treated in the deep insulin unit over the period from January, 1956, to January, 1957, combining the use of hyaluronidase with insulin.

Method

Methods similar to those of Gysin and Wilson were used, the patients serving as their own controls. The dose of insulin was increased by daily increments until coma was produced, and then lowered until the patient was stabilized on a set dose. Once stabilized, treatment continued for approximately two weeks before hyaluronidase was introduced—the usual dose being 500 Benger units, and the quantity of insulin being reduced by a third. By comparison with overall figures for the previous year we were able to ascertain the incidence of other features, such

as smoothness of treatment and the presence of hypoglycaemic after-shocks. Also, there was always a group of patients, not on hyaluronidase at the time of the investigation, who could be likewise used for comparison.

The hyaluronidase was given with the insulin at the usual time of administration—that is, 7.30 a.m.—in the same syringe, there being no flocculation. The time of onset of coma, its depth, and the rapidity of recovery following interruption were carefully observed in all patients. Frostig's (1940) criteria of depth were used. A double check was made in the majority of cases stopping hyaluronidase after some 30 comas and restabilizing the patient, and again by reintroducing the hyaluronidase later in treatment.

Benger's "hyalase" was the preparation used for this investigation, 1,000 units being equivalent to 450 units (T.R.U.) of American products.

Results

With this treatment it was soon found that patients fell into one of three groups: (1) 26 (61.9%) responded as expected by going into coma on a much smaller dose of insulin (70% of original dose), induction was smoother, and recovery more rapid; (2) 10 (23.8%) who were for the most part on comparatively small doses (150 units or under) seemed to gain little benefit in dose reduction by the addition of hyaluronidase; (3) 6 (14.3%), even though on doses of 300 units or more, initially responded well to the hyaluronidase-insulin combination, but the coma-producing dose soon began to increase until the original level of insulin was reached or passed, even with hyaluronidase.

Over the year there was no significant reduction in the number of intravenous interruptions necessary or the incidence of hypoglycaemic after-shocks. Two important clinical features noted were: (1) the consistency of treatment—each individual patient going into coma to the same level daily without the tendency to daily fluctuation as normally occurs; and (2) a significant drop in the incidence of hangover effects—namely, headache, dizziness, malaise, and inertia.

The time of onset of coma for each individual remained unchanged and there were no toxic signs or signs of hypersensitivity to either the hyaluronidase or the insulin.

All other conditions remained unchanged in the deep insulin unit over the 12 months, there being the same medical and senior nursing staff in charge.

Summary

Hyaluronidase was found to be of most use in 61.9% of patients undergoing deep insulin therapy, these patients normally requiring high doses. Its main values lay in allowing a smaller dosage of insulin yet providing a smoother induction and a trouble-free coma. Two other advantages noted were the improvement in consistency of treatment and the elimination of hangover effects such as headache, dizziness, and inertia.

No explanation can as yet be given for the small group of patients who, in spite of hyaluronidase, became insulin-resistant. This feature had probably little to do with the introduction of hyaluronidase, and it seems reasonable to assume that these patients would have developed some degree of insulin resistance in any case.

In 23.8% the addition of hyaluronidase did not result in reduction of the dose necessary for coma, these patients being those on basically small doses initially. Smoothness of treatment and elimination of side-effects, as above, were enhanced, however.

There appeared to be no special influence upon the time of recovery or the incidence of hypoglycaemic after-shocks, though on the whole these latter were not so severe.

It is suggested, therefore, that in view of the above advantages hyaluronidase be given routinely in deep insulin therapy, even though the benefits do not appear to be as significant as was initially thought.

Medical Memorandum

Inheritance of Human Cancer: Five Cases in One Family

Several extensive surveys have been published with regard to the inheritance of cancer. Some important records of pedigrees, showing apparent transmission from mother to daughter, were published nearly a century ago. The most remarkable were those recorded by Broca (1866), in which four generations of females had cancer of the breast. It is a point of general agreement amongst recent authors that mammary cancer is familiarly transmitted—Penrose *et al.* (1948a, 1948b) and Smithers' (1948) following Wassink (1935) and Jacobsen (1946). But here uniformity ends, and a divergence of opinion appears on the issue whether cancer of other sites is increased in frequency amongst relations of patients with carcinoma of the breast. By Busck's (1948) computations on Jacobsen's (1946) results it has been demonstrated that close relatives of patients with mammary cancer show a significantly increased number of cancer cases.

In the family reported below there seems to be strong evidence that cancer of the breast is familial and does predispose to malignant tumours of other sites.

In this family of 10 children three sisters developed carcinoma of the breast proved by hospital records (Cases 1, 2, and 3). Patient No. 2 had two children—a girl (Case 4) who had fibrosarcoma of the right mandible, and a boy (Case 5) who died from hepatoblastoma of the liver. There was no history of cancer in any near relation of the father or mother, and no blood relationship between the parents.

CASE REPORTS

Case 1.—This patient was a married woman. There is one daughter, aged 16, alive and well and unmarried. The patient underwent right radical mastectomy on February 7, 1946. Pathological report: (1) solid and trabecular polygonal celled carcinoma of breast; (2) carcinoma infiltration of skin and nipple (Paget's disease and subjacent breast tissue); (3) carcinomatous infiltration of ducts and lymphatics in surrounding tissue; and (4) secondary carcinoma in four axillary lymphatic glands. Operation was followed by radiotherapy. The patient was readmitted with extensive multiple secondary deposits (spine, pelvis, femora), and died on April 23, 1947, aged 29.

Case 2.—This patient, a sister of Case 1 and the mother of Cases 4 and 5, married at the age of 23. There was no blood relationship between her and her husband. Her first child (female) was born on March 28, 1943, and her second child (male) on June 19, 1948. The mother still remained fit, and breast-fed her second child for nine months. In 1949 she developed a lump in her left breast and attended hospital. She was operated upon in November, 1949, for carcinoma of breast. The appearances at operation were typically those of a scirrhous carcinoma. Operation was followed by radiotherapy. She died on October 3, 1950.

Case 3.—The 34-year-old married sister of Cases 1 and 2 had one child, a girl aged 9. Hospital notes reveal that she had an anaplastic carcinoma of one breast removed on August 24, 1955, and an adenocarcinoma of the other breast removed on September 15, 1955. At the time of writing she was having radiotherapy.

Case 4.—The elder child of Case 2, born March 28, 1943, had had chicken-pox, measles, and tonsillitis. Her tonsils and adenoids were removed in 1952. She remained very well and was examined in July, 1955, when she was fit. On September 5, while on holiday, she developed a swelling on the right side of her face. She returned home and was treated by her own doctor. The swelling did not respond to treatment and she was admitted to hospital. Investigations showed that the lump was a spindle-cell tumour with the morphology of a fibrosarcoma of the right mandible. A course of x-ray therapy caused little diminution in the size of the tumour. When last examined (February 27, 1956) she had lost weight and had a large hard mass over her right cheek extending below the jaw, over the parotid to the ears, and causing limitation in opening of mouth.

Case 5.—The younger child of Case 2, born June 19, 1948, had had whooping-cough, measles, mumps, and chicken-pox. When examined at school on March 30, 1954, he was found to be suffering from recurrent tonsillitis and earache. There was nothing else abnormal, and he had been referred to an E.N.T. surgeon for his opinion. In July, while on holiday, he developed severe abdominal pain and was admitted to hospital, where a large mass was discovered in his abdomen. In August a very large hepatoblastoma, very malignant in type, was removed from the right lobe of his liver. He received deep x-ray therapy and recovered sufficiently well to attend school for a short period. He developed ascites in February, 1955, and died on March 26.

remains a "one-man book." Many sections have been rewritten and numerous additions have been made, so that the volume is as up to date as is possible in this time of rapid technical advances. As showing how recent advances have been incorporated there is an account of the cardiac complications (pulmonary stenosis) which sometimes accompany a carcinoid tumour (argentaffinoma) of the ileum. As evidence that it is almost impossible (owing to the necessary delay between writing and publishing) to be absolutely up to date it has not been possible to refer to the plastic substitutes now being used to replace portions of excised arteries; moreover, in discussing the treatment of aortic aneurysms it is no longer strictly accurate to write that "only arteries situated below the level of the renal arteries" are suitable for excision and grafting.

The merits of this book are many. It brings together an amazing number of facts with a reasonable and readable discussion of their meaning, and after an explanation of the pathology it gives a very judicious account of every aspect of treatment. Moreover, it points the way to the sources whence the surgeon or senior student may find fuller and more detailed information. It is safe to say that every surgeon, however experienced, will find much that is new to him in this book. The reviewer felt a little crestfallen at finding so many things of which he was ignorant, but he was a little comforted when he read in the author's preface: "I myself have found it of use in preparing clinical lectures and demonstrations, and in refreshing my own memory." A word of commendation must be added for the historical details concerning the origin of many of the conditions and techniques described. It is also gratifying to find that there is now an excellent coloured illustration which makes the technique of Wardill's operation for cleft palate quite clear. I have no reservations in recommending this book to surgeons in general and senior students in particular.

ZACHARY COPE.

CORONARY OCCLUSION

The Pathogenesis of Coronary Occlusion. By A. D. Morgan, M.A., M.D. Foreword by John B. Duguid, M.D. (Pp. 171; illustrated. 42s.) Oxford: Blackwell Scientific Publications, 1957.

This monograph, the amplification of a doctorate thesis, falls into two sharply demarcated parts. In the first the author surveys from many angles, and in 17 short chapters, the literature on the pathogenesis of atherosclerosis in general and the factors which tend to localize it with particular gravity in the coronary arteries. These chapters deal, *inter alia*, with the morphology of the atherosclerotic lesion and coronary thrombosis, the influence of age, activity, diet, and such other factors contributing to or inhibiting the condition as are capable of analysis by simple statistical treatment. One aspect of the problem, the omission of which is to be regretted, is any reference to the physiological peculiarities of the coronary circulation and the unique stresses that are imposed upon it by the fluctuations of its intra-arterial blood pressure and by the intermittency of its blood flow. Atherosclerosis of these vessels offers an opportunity for a collaborative approach by physiologists and pathologists with modern instrumental aids to an urgent medical problem that might prove highly rewarding. But within the limits that he set himself the author has produced a useful survey of what is known or suggested of the pathogenesis of atherosclerosis and coronary occlusion. The second part of the book is chiefly concerned with the author's own detailed study of the morphology of the atherosclerotic lesion—copiously illustrated with photomicrographs—and his inferences as to their origins. It may be stated at once that he leans to the view advanced persuasively by Duguid that the earliest recognized change is the deposition of films of fibrin on the endothelial lining of the vessel. From these incipient stages he traces the development of the plaques through the various phases of their evolution to their final degeneration and calcification. Morgan's book, which contains a bibliography of nearly 400 references, is the most complete account yet available of

the morbid morphology of this distressingly common disease. It is on this well-laid foundation of structural changes that future functional and biochemical studies must be based.

G. PAYLING WRIGHT.

LYMPH AND ITS CIRCULATION

Lymphatics, Lymph, and Lymphoid Tissue. By Joseph Mendel Yoffey, D.Sc., M.D., F.R.C.S., and Frederick Colin Courtice, M.A., D.Phil., D.Sc., F.R.A.C.S. (Pp. 510+vii; illustrated. 60s.) London: Edward Arnold (Publishers) Ltd. 1956.

Aselli described the existence of the lacteals in 1622, and Pecquet the circulation of chyle soon after. There has been vigorous discussion about the circulation of lymph in the body ever since, starting perhaps with the denial in 1652 by William Harvey that it occurred at all. The mass of data collected in the ensuing three centuries is enormous, and it is essential that some attempt be made from time to time to unify and review the knowledge of the subject. The authors of this present monograph have undertaken the task, and their book is a successor to the earlier works by Drinker and Field in 1933 and Drinker and Yoffey in 1941. Professor Yoffey, who is an anatomist of the new school which relates function to structure, has written the sections pertaining to the cells and the nodes, and Dr. Courtice, who is well known for his physiological studies, has dealt with the lymph and lymphatic vessels as well as with some of the practical aspects of the subject. The authors state that they "believe that the main purpose of the lymphatics is to return to the blood stream the large protein molecules which slowly, but continuously, leak through the pores of the capillaries." This is perhaps an over-emphasis on one of their functions, but it is an important one and one that is well dealt with. The section describing the pore theory of capillary permeability and its relation to the different sizes of protein molecule allowed to pass is particularly useful. We should indeed be grateful to the authors for this book. It will be of immense value to practising clinicians as well as to pure research workers.

J. B. KINMONTH.

ESSENTIALS OF PHYSIOLOGY

Bainbridge and Menzies: Essentials of Physiology. Tenth edition. Edited and revised by H. Hartridge, M.A., M.D., Sc.D., M.R.C.P., F.R.S., and J. L. D'Silva, M.B., Ph.D., D.Sc., M.R.C.P. (Pp. 506+x; illustrated. 36s.) London, New York, Toronto: Longmans, Green and Co. 1957.

This well-known textbook reappears after a lapse of 13 years since the last edition. The editors would appear to have been successful in three aims: to preserve the scope and personality of the original volume; to embrace the main, very considerable, advances; and to keep within the approximate compass of the original book. The volume has been entirely rewritten, and many new and useful illustrations have been added. A good deal of stress is laid, with success, upon the applications of physiology in the human subject. Increased readability has been achieved by omitting paragraph-entitlement and introducing a more continuous narrative. The sophisticated reader might ask for more evidence than is provided for some of the statements made, but such omissions are perhaps inevitable in a work of this limited size. Moreover, intermediary metabolism and neural physiology as providers of evidence for physiological phenomena justifying biochemistry and biophysics are treated too lightly for the preclinical student. But as the book is intended not only for the preclinical student but also for the larger population of nurses, pharmacists, and physiotherapists, perhaps this is warranted. As the editors say, it is intended as an introduction.

A. ST. G. HUGGETT.

A supplement to the *British Pharmaceutical Codex*, 1954, has been published and is obtainable from the Pharmaceutical Press, 17, Bloomsbury Square, London, W.C.1 (pp. 124+xiii; 27s. 6d.).

SATURDAY JULY 13 1957

DIETARY FAT AND CORONARY DISEASE

Figures are often quoted to show that nations with a high consumption of fat have a high incidence of coronary thrombosis. Thus the United States has the highest consumption of fat per person in the world and the highest death rate from coronary disease, whereas Japan with a low average intake of fat has a low incidence of this condition. But a correlation between two sets of figures is no proof of causal relationship. The association may be fortuitous, as is the rise in the cost of living since 1939 and the concomitant increase in deaths from coronary disease. J. Yudkin¹ has shown that in most countries there is an apparent correlation between deaths from coronary thrombosis and the fat intake of the population, but only up to the figure of 120 g. daily. Beyond this intake there is no correlation, and deaths vary from country to country. The rise in coronary disease in the better-off countries may be due to factors other than diet. There is a high standard of living and a low level of physical activity in those countries with high death rates from coronary thrombosis. Ancel Keys and his associates,² of the University of Minnesota, have collected data on diet and serum-cholesterol levels in men classified by age and physical activity and drawn from various parts of the world. They came from places as far apart as Minnesota, Sweden, Naples, and South Africa, where three ethnic groups were studied. It was concluded that within some populations there is a tendency for men doing heavy manual labour to have somewhat lower serum-cholesterol levels than those doing light work or engaged in sedentary occupations. But differences in

physical activity did not explain the large differences in serum cholesterol found when groups with different dietary habits were compared. According to Keys the habitual diet, especially its fat content, had a much greater influence than physical activity as such on the total cholesterol and beta-lipoprotein cholesterol in the blood serum.

The fact that atheromatous plaques are composed mainly of lipid has resulted in attempts to correlate the incidence of coronary artery disease with abnormal lipid metabolism. Excess dietary fat has been incriminated as a cause of atheroma.³ Patients with coronary artery disease are stated to have a higher serum cholesterol than normal subjects of the same age and sex,⁴ and according to D. W. Barritt⁵ males with this condition show a greater and more prolonged lipaemia than normal controls after ingesting large quantities (60 g.) of butter fat. However, it cannot be argued that a raised level of serum cholesterol is necessarily a cause of coronary disease, because the cholesterol determinations were made on the blood of patients already suffering from the disease. There are no figures available to show that subjects with a high level of serum cholesterol maintained over a long period succumb to coronary disease more often than those with a lower value. This is the crucial observation that needs to be made. It could in fact be postulated that a raised blood cholesterol is the result rather than the cause of coronary artery disease.

The level of serum cholesterol in man can be lowered by the substitution of carbohydrate for the common meat and dairy fats in the diet, and this effect is to some extent independent of the cholesterol intake. It is claimed that the administration of fats containing large amounts of unsaturated fatty acids or vegetable oils reduces the serum cholesterol⁶⁻⁸ and that the consumption of saturated fat is a factor in the aetiology of coronary disease. But E. H. Ahrens and colleagues point out⁹ that the effect of the non-fatty-acid constituents of fat—that is, the sterols—cannot be completely ruled out. According to Ahrens' corn (maize) oil is particularly effective in lowering serum cholesterol, and he suggests that the effects of dietary fats on this depend on the relative degree of saturation of their constituent fatty acids. H. M. Sinclair⁹ believes that hypercholesterolaemia is an expression of a deficiency of essential fatty acids in the diet, which can be corrected by the consumption of fats rich in linoleic acid, such as corn oil.

Keys urges caution on the premature conclusion that the consumption of unsaturated fatty acids might prevent atherosclerosis and coronary heart disease by lowering the blood cholesterol. With his co-workers he has investigated the effect of various fats on

the serum-cholesterol level.¹⁰ They conclude from experiments on volunteers with various test fats, which included corn oil, sunflower-seed oil, sardine oil, and butter fat (all of which are largely unsaturated), that the serum-cholesterol level is not a simple inverse function of the amount of essential fatty acids in the diet, or of the degree of unsaturation of the fatty acids. This work has been criticized by L. W. Kinsell and Sinclair¹¹ on the grounds that the composition of the fats used in the experiment was not known. They claim that the powers of vegetable oils to reduce the level of serum cholesterol are proportional to their iodine numbers—that is, to their degree of unsaturation.

The development of gas-liquid chromatography by A. T. James and A. J. P. Martin¹² has made possible the direct isolation, identification, and analysis of all the fatty acids between C₆ and C₂₀ in a few milligrams of mixed fatty acids. Using this technique James and his co-workers¹³ have compared the fatty-acid content of the blood of patients with established coronary artery disease with that of normal subjects of the same age and sex. They found no detectable differences in the two groups between the proportions of any fatty acids in the red-cell and plasma-phospholipid fractions, nor in the proportions of "essential fatty acids" or in the amount of unsaturated fatty acids.

Endocrine factors undoubtedly play a part in the aetiology of coronary artery disease. Why should women escape it up to the time of the menopause? Why should it be a disease primarily of middle-aged men? Thyroid extract causes a fall in the serum-lipoprotein and serum cholesterol,¹⁴ and triac (triiodothyroacetic acid) brings about the same changes in euthyroid hypercholesterolaemic men with coronary disease.¹⁵ The effect of thyroid and triac is only short-lived, and it is not suggested that they should be used for the long-term treatment of the disease, though in the dose used triac does not appreciably affect the basal metabolic rate.

With this welter of conflicting opinion, the picture is far from clear. Even if it were conclusively shown that a high-fat diet, or a high intake of certain fats, does produce a permanent hypercholesterolaemia, it has still to be proved that the hypercholesterolaemia causes faster blood coagulation. Evidence on this is also conflicting. According to H. W. Fullerton and colleagues,¹⁶ after a fatty meal the clotting time is accelerated. But in a recent paper C. Merskey and H. L. Nossel¹⁷ state that the amount of fat in the diet has no effect on the coagulation time of blood. They gave patients low-fat and high-fat diets, and a diet containing little animal fat, but supplemented with

salad oil. These different diets did not significantly affect blood coagulation. Tests done included the coagulation time of whole blood in silicone tubes, calcium time of plasma with varying number of platelets, thrombin generation test, blood-thromboplastin generation test, prothrombin consumption, and accelerated one-stage prothrombin time ("stypven" time). The stypven time of the blood of patients on the high-fat diet was lower than that of blood from patients on a low-fat diet. Merskey and Nossel conclude that present evidence is insufficient to indict either saturated or unsaturated fats as a cause of accelerated blood coagulation.

What advice on diet is to be given to patients who fear getting coronary disease? It should be to eat in moderation and to avoid getting overweight. Until we have more precise information on the relationship, if any, between dietary factors and coronary disease, there is no need for the middle-aged man to forgo his breakfast of eggs and bacon in favour of cereal and skim milk, followed by toast and marmalade with a scraping of butter.

PLASTIC SURGERY OF THE MIDDLE EAR

The end-organ of sound perception consists of a fibre carrying the organ of Corti. The vibration of this fibre stimulates the organ of Corti to transmit its impulses to the nerve centres, whence sound arrives in consciousness. There are a large number of these fibres, forming together the basilar membrane, and the whole apparatus is full of fluid contained by the tough membranous cochlea, which itself is suspended in fluid inside the bony cochlea. There are two openings in this bony capsule, the oval window and the round window. The footplate of the stapes fits into the oval window and is kept in contact with it by the annular ligament. Movement of the membrane of the oval window inwards causes a movement in the fluid on one side of the basilar membrane, which itself moves and transmits a further movement in the fluid on the other side of it, thus causing a movement outwards of the round window. For adequate stimulation of the end-organ it is essential that the membranes of the oval and round windows should be capable of moving in these opposite phases.

Sound waves are brought to the oval window by the ossicles constituting a system of levers in the air-filled tympanic cavity. The waves enter the external auditory meatus and set the drum membrane

vibrating. This membrane is attached to the malleus, which articulates with the incus and this in turn with the stapes. The movements of these three small bones transmit the vibrations of the large drum to the much smaller membrane of the oval window with diminished amplitude but with greater force. This conversion of amplitude to force is necessary, since the stapes has to move the fluid of the inner ear. Two small muscles in the middle ear—the tensor tympani inserted into the malleus and the stapedius inserted into the stapes—damp down excessively violent ossicular movements, such as those occurring in response to a loud sound. For normal hearing, assuming the integrity of the perceptive organ, the components of the conducting apparatus must be intact and their movements must be unimpaired.

Chronic infection in the middle ear is the most common cause of perforations of the drum membrane, partial or complete destruction of the ossicles, and adhesions. Until recently the surgical ablation of the diseased tissue has been the only principle in treatment, although for years there has been an increasing conservatism in the type of operation performed. This conservatism has taken the form of limiting the classical radical mastoidectomy to a so-called modified radical operation, and has been helped by the fewer and less severe cases of chronic suppuration now seen—a salutary effect of the lessened incidence and more effective treatment of acute otitis media. However, the incus is often removed and the head of the malleus sometimes amputated; while a perforation commonly remains in some part of the tympanic membrane. Marsupialization of the resulting cavity, either by skin flaps or skin grafts, or both, was and is the most popular method of closure. Although the construction of a skin-lined cavity is not necessary,¹ these procedures are all ablative in principle, with preservation of hearing as a secondary consideration, and therefore not in the strict sense of the word conservative.

During the past six or seven years more truly conservative operations have been devised. The pioneers in this field of plastic surgery, W. Moritz, F. Zöllner, and H. Wullstein, working in Germany, have evolved certain principles which have been summarized by F. C. Ormerod and K. McLay,² whose paper includes a bibliography of the advances made up to the end of last year. More recently P. H. Beales³ has described the results obtained in a series of 57 cases followed up for from six to eighteen months. In the simplest type of case there is a perforation in the drum membrane but an intact ossicular chain; this can be determined by the use of an acoustic probe⁴ or by other devices.⁵ Myringoplasty—that is, repair of the

perforation of the drumhead—can restore hearing almost to normal, and can be effected by swinging in flaps of meatal skin or by full-thickness skin grafts.

When the ossicles are damaged and their lever action abolished there is no possibility of restoring a normal form of hearing, for which, as already described, not only are intact oval and round window membranes necessary, but also a "baffle" mechanism of some kind to ensure that a sound wave reaches each window in a different phase. The damage done by the disease and its ablation results in several varieties of residual deformity, for each of which a different type of tympanoplasty can be performed. If the stapes is intact and its footplate mobile a skin graft draped over it and connected with the drum membrane (or this latter itself stretched to reach the head of the stapes) can move the footplate in and out in a fashion similar to the columellar mechanism in birds. When the crura of the stapes have been destroyed or removed, and if the footplate is mobile, the oval window can be left exposed, while the remains of the drum membrane, extended if necessary by a skin graft, are used to form a false drumhead over the round window. A sort of small tympanic cavity is thus formed in which the round window is included and into which the Eustachian tube opens. Sound waves thus fall directly on the oval window but reach the round window only after passing through the new drum membrane and the air space between the two. This is known as a round-window baffle. Finally, if the stapes footplate is ankylosed, the oval window can be by-passed, as in the standard fenestration operation, by making a fenestra in the external semicircular canal and combining it with a round-window baffle.

These methods are simple in conception, but demand a scrupulously careful technique and great patience. They can and probably should be combined with complete ablation of the disease in the one operation, which may take from two to four hours. As in fenestration, the protection of antibiotics and the use of magnification have made the operations possible. The results depend upon the extent of the original disease and therefore of the amount of tissue excised in removing it. It is often possible to raise hearing to a level at which the conversational voice can be heard, even when much middle ear destruction has occurred. If the organ of perception has been affected the results of these operations are poorer. By suitable tests in a well-equipped otology unit cases can be assessed and the prognosis estimated with some accuracy, and there seems no doubt that with increasing skill in these delicate manœuvres the results will continue to improve. The development of this new field

of surgical endeavour should benefit many patients. But it is still essential always to bear in mind that early treatment of acute middle-ear infection remains the best method of preventing the chronic condition.

HAZARDS OF TRANQUILLITY

Reports of ill-effects from the so-called tranquillizers are mounting. An influential editorial¹ in the U.S.A. recently condemned the widespread use of these drugs in out-patient clinics and in general practice. There was a real danger, it said, of seducing patients into a bogus health and of weakening their adaptive capacities. Similar fears have been expressed by H. A. Dickel and H. H. Dixon,² who declare the excessive use of tranquillizing drugs against anxiety is a threat to American society. They fear that these drugs may smother the incentive to change and progress that derives from fear and anxiety. Their concern becomes understandable in the light of their report about 8,200 patients in whom anxiety was the chief symptom. More than nine-tenths had taken some tranquillizing drug and more than one-third of those patients had suffered ill-effects, many of them of a serious nature. W. Sargent³ drew attention to the potential dangers of these drugs when writing in this *Journal* a year ago. He aptly compared them to alcohol and tobacco, and called for more research into their scope and limitations.

There has been some progress in this direction since. Earlier impressions that these drugs deserve a place in the treatment of certain psychotic states have been confirmed. H. Freeman,⁴ writing from the Worcester State Mental Hospital, U.S.A., is not unduly concerned about the complications that may accompany their use, for the complications are as a rule reversible provided they are recognized early. He sees the main value of the drugs in making the patients more accessible to psychotherapy. In his view their advent has caused "a mild revolution" in the mental hospital. Perhaps it would be more appropriate to speak of a counter-revolution in the therapy of the psychoses, since these drugs have in some hospitals replaced leucotomy and greatly diminished the use of electric shock and insulin. A comparative study⁵ carried out in Great Britain suggests that chlorpromazine may be a more effective form of treatment than insulin in previously untreated cases of schizophrenia, and in a paper published at p. 78 of the *Journal* this week Dr. J. Lomas concludes that chlorpromazine is superior to "pacatal" in a mixed group of schizophrenic patients. J. N. P. Moore and E. A. Martin⁶ were much impressed by the results of reserpine therapy in schizophrenia and speak highly of the

quality of the remissions. They have made it a rule that no schizophrenic should be subjected to leucotomy without having a trial on reserpine first. The views of French psychiatrists deserve special attention because they have had more experience in the use of these drugs than workers in other countries. They are as much concerned about the indiscriminate use of "neuroleptic therapy" as their colleagues elsewhere. G. Deshaies and his associates⁷ have found chlorpromazine and reserpine invaluable in the treatment of the psychoses; they do not regard them as substitutes for established physical therapies but as supplementary to them. They have been less impressed by their effects in cases of neurosis.

The indications, if any, for giving tranquillizing drugs in the treatment of the neuroses have not yet been established. A carefully controlled trial of four tranquillizers against a placebo and amylobarbitone carried out at St. George's Hospital is reported by Dr. M. J. Raymond and colleagues at p. 63 of the *Journal* this week. The patients, of whom 51 contributed data to the final analysis, were neurotic out-patients who suffered mental tension as part of their symptomatology. "They were comparable," say the authors, "to those patients for whom sedation is commonly and properly prescribed in general practice." The patients were on each form of treatment for two weeks; the drugs were given in different orders to different patients to assess any possible residual effect of one drug when followed by another. The results analysed were the patients' judgments of the effect the various drugs and the placebo had on them. The conclusion to which Raymond and his colleagues come is that there was no significant difference between the placebo and the four tranquillizers in terms of the patients' judgments, and the "average score for the placebo was close to a nil response." In contrast, the average score for amylobarbitone was statistically significant—that is, it was the only one of these drugs which, under the conditions of the trial, was found to be efficacious. Another recent trial of one of the same tranquillizers, benactyzine, on a somewhat similar group of patients, was that by G. R. Hargreaves and his associates.⁸ Their conclusions were slightly more favourable to the tranquillizer (which was compared with a placebo), though the difference between the scores did not attain the conventional level of statistical significance. In addition, they pointed out that side-effects had to be watched carefully and the dosage adjusted accordingly.

Though in general the tranquillizers appear to have little or no advantage over placebos in the treatment of neurotic out-patients, some symptoms may be more responsive than others to drugs in this group.⁹ Further research will be needed to establish this. The dangers of prescribing tranquillizers have also to be weighed against their possible benefits. Parkinsonism, severe suicidal depression, skin rashes, agranulocytosis, jaundice, and a few other side-effects are formidable complications of the use of chlorpromazine or reserpine, while the risks of later preparations are still incompletely known. Even the supposedly rather innocuous meprobamate ("miltown," "equanil") has

been found apt to cause extensive purpuric reactions.¹⁰ There is still no proof that conventional sedatives prescribed with discretion are inferior to the tranquillizers, which have been listed among the habit-forming drugs in a recent W.H.O. report.¹¹ It is true that suicides with tranquillizing drugs have not been reported so far, though they have been used in suicidal attempts,^{12 13} and this seems at first sight to recommend tranquillizers. But any such apparent advantage is outweighed by the tendency of some tranquillizing drugs to produce severe depression with suicidal tendencies. They are therefore contraindicated for depressed patients.

TUBERCULOSIS IN SCOTLAND

Until about the end of the second world war the socio-economic environment of a patient with respiratory tuberculosis was influential, and often almost exclusively so, in determining his chances of recovery. Latterly that has ceased to be true owing to the striking benefit obtainable from chemotherapy in conjunction, if necessary, with surgery. The steep decline in the death rate now characteristic of tuberculosis throughout Great Britain has not been everywhere matched by a similar decline in the rate at which new cases are notified. This lag has been most evident in Scotland; the death rate in 1955 was only one-quarter of what it was in 1948, but the notification rate was still three-quarters of the 1948 figure. No doubt one of the causes of this is the more thorough search for cases made nowadays, such as the record-breaking mass radiography campaign at Glasgow last April.¹ Another cause may be that the low mortality rate leaves more survivors intermittently infective to transmit the disease to their neighbours. Even so, a recent report² from Scotland shows how greatly things have changed for the better there. A committee under the chairmanship of Dr. C. Clayson has looked at the probable future requirements for the ascertainment and treatment of pulmonary tuberculosis in Scotland, and comes to the conclusion that by 1965 only one-third the number of beds in use to-day will be needed. This is in cheerful contrast to the prognostications of only a few years ago, when there was even talk of setting aside more beds for this disease. The apprehensions of the immediate post-war years, for which there was good cause, seem at last to be dying away. But "the gratifying trends" of the statistics have, as the report says, increased rather than lessened the work of tuberculosis clinics, for in consequence of the improved survival rate more patients are in need of treatment at any given time, with the result that the out-patient work will continue to expand. Forecasts of this nature are notoriously subject to revision as time unfolds the events, but the committee has summarized the facts clearly and has drawn conclusions that should be of much help in the planning of Scotland's attack on tuberculosis during the next ten years or so.

IODINE COMPOUNDS IN PLASMA

Thyroxine, tri-iodothyronine, and iodide probably account for all the iodine in normal human plasma, though the presence of other iodine-containing compounds in very low concentration cannot be excluded. There is, for instance, some evidence that di-iodothyronine is secreted by the rat's thyroid,¹ but it has not been found in human plasma. Thyroxine and tri-iodothyronine are found in the plasma of patients with metastatic cancer of the thyroid, even if no normal thyroid tissue is present,² showing that some metastatic tumours of the thyroid can synthesize thyroid hormone. Mono-iodotyrosine and di-iodotyrosine, though present in the thyroid, are not normally found in the blood stream.

In abnormal conditions other iodine-containing compounds may circulate in the blood. Some years ago J. Lerman showed that thyroglobulin often appears after partial thyroidectomy in the plasma of patients with Graves's disease.³ More recently, thyroglobulin has been shown to enter the circulation in patients with cancer of the thyroid treated with large doses of radio-iodine.⁴ There is also some evidence that thyroglobulin is present in the plasma of patients with Hashimoto's disease.⁵ Another abnormal form of protein-bound iodine has been reported in the blood of people given large doses of Lugol's solution.⁶ This substance differs from thyroxine in being insoluble in butanol at acid pH. Yet another abnormal iodine-containing substance has now been found in the blood of patients with cancer of the thyroid treated by radio-iodine. W. Horst and H. Rösler reported one such patient whose serum contained a radioactive substance that behaved like albumin on electrophoresis.⁷ Two years ago J. Robbins and colleagues extended this observation by showing that in some of these patients a radioactive substance appears in the plasma resembling thyroglobulin in its chromatographic behaviour, but differing from it in its electrophoretic mobility.² Whereas thyroglobulin moves in a barbiturate buffer to a position between the α_1 and α_2 fractions of the serum proteins, this new substance (compound X) moves with the albumin. They also showed that thyroxine and mono-iodotyrosine, but not di-iodotyrosine, could be released from compound X by enzymic hydrolysis.

J. R. Tata, J. E. Rall, and R. W. Rawson have now described their attempts to identify compound X.⁸ Their results at first suggested that it was either an iodinated albumin or an iodine-containing compound of small molecular weight adsorbed to albumin. It could not be separated from the serum albumin by electrophoresis or by precipitation in varying concentrations of salts, and its sedimentation constant was indistinguishable from that of albumin. However, it now seems more likely that compound X is an iodinated substance distinct from albumin, though resembling it in several physical

properties, since it is not precipitated by an antiserum that precipitates both albumin and iodinated albumin. Since it contains large amounts of mono-iodotyrosine, with little or no di-iodotyrosine, compound X is probably not a fragment of the thyroglobulin molecule. This raises the possibility that it results from a disturbance of the normal synthesis of thyroid hormone, and, since it has been found in the blood of patients with no normal thyroid tissue, its synthesis may occur in the cells of the tumour tissue. Its entry into the blood stream can hardly be due to radiation damage to the cells in which it is synthesized, because it is found in patients who have been given doses of radio-iodine too small to cause radiation damage to the tumour by the time the substance has begun to enter the blood. Its small molecular size, compared with that of thyroglobulin, may explain why it leaks out of the cells in which it is formed. It is too early to say yet whether the more detailed analysis of compound X will throw any new light on the way in which thyroid hormone is synthesized in the normal thyroid.

INHERITANCE OF ALBINISM

Albinism confined to the globe of the eye without any obvious albinotic changes elsewhere in the body—the ocular albinism of Nettleship—is held to be inherited in a recessive sex-linked manner. As nystagmus is frequently present, many of these families have been recorded as cases of congenital sex-linked nystagmus. The different modes of inheritance recorded for nystagmus itself have constituted a puzzling problem, and it is likely that sex-linkage is the underlying pattern, with suppression of manifestation in some women who possess a gene dominant for the affection and with location on the X-chromosome. The difficulties in inheritance of albinism are also real. It is likely that the affection is conditioned by more than one pair of recessive genes, for the rate of consanguinity—some 20 to 30%—is too high for a fairly common affection, and there is at least one sibship of normal children born to albino parents,¹ who presumably carried different genes for albinism. Furthermore, there is also the possibility of dominant inheritance,² while intermediate autosomal inheritance was suggested many years ago by P. J. Waardenburg on his finding that the irises of heterozygotes showed abnormal translucency on transillumination of the sclera—a suggestion supported by the fact that various partial aspects of albinism, such as excessively light-coloured hair and skin, may often be seen in apparently normal members of albino families. Evidence that ocular albinism, as distinct from generalized albinism, shows intermediate sex-linkage was first advanced by H. F. Falls, who in 1952 drew attention to the unusual appearance of the fundus of women carrying the gene: in them the central area is normal, though perhaps slightly stippled, but within a disk diameter or two from the macula the

pigment assumes a coarse granular appearance, cocoa-brown in colour, and becomes arranged in little groups of islets; the choroidal vessels can be seen with unusual clarity. In general these female carriers therefore show but little retinal pigmentation, especially at the equator and the periphery; visual functions are normal. Similar findings have been given by J. François and J. P. Deweer³ for a large Belgian family, and now Vagn Ohrt⁴ has reported equally definite findings in a large Danish family. It appears that—as in choroideremia⁵ and sex-linked retinitis pigmentosa⁶—expression of this intermediate gene varies considerably in different carriers. It is also likely that ocular albinism is not strictly ocular, for mild manifestations of generalized albinism are by no means exceptional. The recent studies on ocular albinism have been of interest not only in enlarging our knowledge of the carrier state but also as emphasizing that strictly local manifestations of gene action are probably uncommon clinically.

CEMENT DUST

The production of cement in England and Wales in 1956 rose to 12½ million tons, twice the amount produced ten years previously. And anyone who has seen a cement works in action—a sight difficult to avoid nowadays—will not be surprised to learn from a Ministry of Housing report¹ that “complaint is widespread.” In fact the Ministry finds that the problem of dealing with the emission of dust from cement works is “perhaps the most difficult” facing it. The Romans were the first people to make cement more or less as we know it to-day, but Portland cement, the modern product, was invented by one Joseph Aspdin in 1824,² and so called because of the resemblance of the concrete made from it to Portland stone, a variety of limestone. It is now made all over the world.

In manufacture, a slurry of water with chalk and clay, or limestone and shale, slides into a kiln, where it is dried and calcined into a clinker; this is then mixed with 5% gypsum and ground up. The main problem of laying dust is in the treatment of the kiln gases. Electrical precipitation of the dust is thought to be the most efficient method, but unfortunately it is very expensive and requires skilled supervision. Much commoner in use are various forms of mechanical precipitation, and high chimneys, up to about 400 feet (120 m.), help to diminish the nuisance. Even so, amenities can be much impaired, and are notably so along the Thames between Dartford and Gravesend, Kent, where some 4½ million tons a year are being produced, and in the Medway area of Kent. In contrast, the danger to health seems to be only slight, and is mainly due to irritation of skin, cornea, and nasal mucous membrane among cement workers, builders, and others who handle the material. An inquiry carried out by the Dartford Division of the B.M.A.³ suggested that in the populace living near cement works health was chiefly affected by mental and physical irritation, though there was some evidence that the dust aggravated asthma.

ACTION STATIONS IN AUSTRIA

BY

N. H. MOYNIHAN, M.A., M.B., B.Chir.
Clinical Assistant, Chest Department, St. Thomas's Hospital, London

Six months ago, when the magnitude of the refugee problems in Austria was realized in this country, many doctors offered their aid to the British Red Cross in the hope of being able to assist the overburdened Austrian Medical Services in the task of caring for the thousands of refugees who poured over the Austro-Hungarian frontier. Owing to the somewhat confused state of affairs in Austria in those early days and to the slow communication of accurate news to us here, many of these volunteers were not then accepted by the British Red Cross, although some were able to render valuable service to the refugees in this country at a later date.

A few doctors who were, however, directly in touch with voluntary workers in Austria in the middle of November were able to go out there on their own initiative and take part in casualty work on the border. The experience of one of these who has just completed six months' work in South-east Austria and Yugoslavia might be of some general interest.

Arrival of a Medical Team

Like many others, the members of a small team offered their services to the British Red Cross in London, having heard from a worker in Austria that medical aid was urgently needed. A most sympathetic reception was accorded to them by the Red Cross medical adviser, but his information indicated that no medical aid was needed in Austria at that time. The strength of the appeal from Vienna, however, was so great that the team decided to proceed there by road with stores of food, clothes, and medical supplies. On arrival three days later it was met by the correspondent in question with a rasping indictment of the time it had taken to travel out from England. It appeared that, in the south-east corner of Austria, where refugees were crossing the frontier at the rate of 800 to 1,000 nightly, medical assistance was indeed urgently required. It was decided that the services of the team should first be placed at the disposal of the Red Cross in Vienna, but the British Headquarters there did not feel that these could be utilized within its framework.

The team then proceeded with all haste to Gussing, in South Burgenland, some 150 kilometres from Vienna. There, in a Franciscan monastery, a loose formation of voluntary workers, consisting of five men and four girls, all British, two Swiss girls, and a Dutchman, had come together and were caring for some 500 to 800 refugees every night. The bulk of these refugees were receiving no medical attention: the serious and urgent cases were taken to the small local hospital, where the two local doctors were assisting the two hospital consultants in working around the clock with magnificent devotion. The limited number of beds in the hospital had long since been filled and the services overflowed into the corridors and other rooms. Surgeons and physicians alike were tired and overworked, and they welcomed the British team with enthusiasm and kindness. No word of praise can be too high for the Primarius and his staff, who co-operated in every possible way at all times.

Working Round the Clock

In the monastery itself the volunteer team of men and girls were also working around the clock, with the five Franciscan monks, to feed, house, and clothe the hundreds of Hungarian refugees who were constantly being brought

in from the border by Austrian post-buses. These people crossed the border, mainly by night, in the villages some 10 to 20 kilometres distant, and were then brought to the staging post in the monastery. To the south-east of Gussing there is a small salient of land shaped like the head of a spear, and from there the border lies on three sides of you. It is clearly marked with flags, but later it was not wise to rely on the flags, since the Russians and Hungarian Secret Police put up false Austrian flags to trap the refugees trying to cross the border. In this salient the organization later set up field kitchens in the border villages with housing accommodation and feeding facilities. There are now in the salient some half-dozen such kitchens supplied from Gussing, and the organization has been formed into a company known as “Aid to Hungary from Britain,” which subsidizes and supplies the needs of the workers and refugees.

The monastery refectory seated at capacity only 60 refugees, and each meal required about 10 sittings. Preparation of food, cutting of bread and *Wurst*, and washing-up became a monotonous and wearisome task after several days of 20 working hours per person. A constant night shift was essential, as the arrival of cold, wet, and hungry refugees was absolutely unscheduled and the workers were not sufficient in numbers to work in regular shifts. The refugees lived and slept in the classrooms of the monastery, packed on straw pallets on the floor, and often they overflowed into the corridors when the flow was heavy, making the transit of new arrivals very difficult among the sleeping forms. The first sight of these men, women, and children lying in the sleep of utter exhaustion was a moving one, and soon became commonplace. Some of them had spent days hiding in frozen fields and in haystacks or had walked scores of miles in open country at night. Some were old people, some were children; but most of them were young men in their early twenties, some with wounds still unhealed after the fighting in Budapest.

Precautionary Measures

The epidemic potential of such a situation was obviously very high, and the first action of the team was to organize the sanitary arrangements of the camp in conjunction with the local and very friendly medical officer of health. Disinfectant precautions were enforced, any suspicious cases being immediately isolated, and scrupulous cleanliness was ensured, especially with eating and drinking utensils. In this connexion it was soon quite apparent that the Hungarians themselves were extremely co-operative, and their enthusiasm for personal and communal cleanliness was of a high order.

Surgeries were then set up by the team—after the morning meal at 8 a.m. and after the midday meal, during which an announcement was made by the interpreter. For the first week these surgeries averaged some 80 patients per session and seemed to form a reasonable parallel to a National Health practitioner's surgery in any large English town. However, with the increase in the number of urgent night calls to the border villages once the facilities became known, it soon became clear that a system of medical night rounds to these villages must be organized, and thereafter a round between four and five o'clock in the morning was carried out to give succour to refugees who had just crossed the frontier. The weather at that time was cold and damp, and many of the fugitives had to swim across the rivers and canals which parallel the border in this region. Later the weather became extremely cold, with temperatures under 20 degrees below zero, and this was followed by a period of deep snow, which probably accounted to some extent for a falling off in the numbers of refugees, since walking was extremely difficult and all the roads were blocked for some days.

Medical Problems

The medical problems encountered both in the surgeries and in the field were remarkably varied and most interesting, and the experience was extremely valuable not only to

the student contingent but also to the doctors themselves. Language difficulties at first seemed to loom large, but it was soon found that each contingent usually contained a small number of interpreters who spoke either English or German, and, as an added help, often these were themselves doctors. There was at one time a trio of consultants to a Budapest teaching hospital, all unfortunately in specialist branches which could not be readily utilized in a surgery set-up. As interpreters, however, they formed an amusing choir which made all things clear. When all other help failed, moreover, the list of medical phrases in Hungarian and English, compiled and distributed by the Women's Voluntary Services in England, proved moderately useful. Such phrases as, "The lavatory is next door" did not seem to find full use and an agitated pantomime might fail to register, whereas the patient's pointing to the Hungarian phrase, "I am constipated," often made things clear.

The backbone of every practitioner's surgery was more prominent than ever in the Kloster: coughs, colds, sore throats, backaches, bunions—all these were legion. A rectal surgeon could have run a respectable clinic on the haemorrhoidal cases: the team concluded that these were caused mainly by the great distances which the refugees had often walked—40–60 kilometres was a good average—and to the fact that constipation was frequent owing to the practical difficulties of maintaining daily regular bowel habits over the period of perhaps a week or more. At one time suppositories were at a premium and made an urgent demand on the supply list to England. The bronchitic cases in the surgeries not infrequently developed into cases of pneumonia and had to be removed to hospital, but when acute shortage of beds arose these patients had to be nursed in the monastery, and this necessitated a twice-daily sick-round in an improvised sick-bay, the beds of which consisted of double-thickness straw mattresses laid on the floor.

Obstetrics and gynaecology were not neglected. Eighteen miscarriages occurred, often brought about by extreme hardship on the long journey from Budapest to the border. Some of these women had to be hospitalized: others refused to be separated from their families and required constant watching in the monastery. Four emergency births took place, one almost at term, the remainder some weeks prematurely; and one unfortunate child owes his name of Kloster to the stone walls among which he first saw the light of day. The gynaecological cases were again mainly due to aggravation of semi-permanent conditions by the long walking, often made more onerous by the need to carry small children or luggage. There was a sprinkling of vaginal infections, and, quite unfathomably under the circumstances, an occasional shy request for contraceptive facilities, which, needless to say, were not, and could not have been, granted.

A number of fresh gunshot wounds were seen at the border, and the majority of these casualties were taken to the hospital in the team's transport. Twenty-three cases with old gunshot wounds, mostly received in the fighting in Budapest and treated a few weeks before, were dressed, and the recipients, some of them women, treated with antibiotics. These included a man who had had a bullet extracted from his skull—he was put on a Swiss Red Cross train—and a boy of 15 who had been shot in the chest. The bullet had entered just lateral to the sternum at about the level of the second right costal cartilage and had emerged in the right axilla. He was getting severe pain in the right forearm and hand; fibrosis around the medial cord of the brachial plexus was diagnosed, and he was sent to the professor of neurology in Vienna. Two cases of tetanus were encountered, one patient dying later. Most of those wounded had received antitetanus serum and three had had serum reactions, one fairly severe. Eight diabetics applied for insulin and one diabetic coma was encountered.

Undoubtedly the prize exhibits of the surgeries were the blisters. It is difficult to imagine to what extent human beings can misuse their feet and still continue to walk. Some of the blisters which the members of the team saw resolved that particular difficulty for them. Blisters involv-

ing the whole of the heel and reaching down to the bone, often infected, were a commonplace in those early days: in the latter months, when the urgent necessity to flee from their homeland had died, the refugees' blisters became less severe. Frostbite of the toes was also extremely common, and some cases required surgical interference and amputation. Most, however, responded to long-term treatment, and calls upon the clothing expert for suitable footwear for these patients sorely tried his ingenuity. In March there were still eight of these patients in the hospital; they had been there for many weeks, but all were walking again.

Hospital Cases

On the surgical side, five cases of acute appendicitis were admitted to hospital, all making a good recovery. There were two cases of acute cholecystitis, and one of gall-stone colic which caused many people a very restless night. Eighteen persons were treated for post-operative complications of laparotomies carried out some weeks before, four requiring hospital admission, two of them being treated surgically.

Medical cases included chronic gastric and duodenal ulcers, numerous cases of valvular heart disease—some on digitalis—three severe cases of hypertension, and an interesting case of multiple sclerosis—a crippled woman. There were a number of medical emergencies, including four "coronaries," one severe asthmatic, and one patient with miliary tuberculosis, who later died. There were also a number of cases which were thought to require radiography because of a history of haemoptysis, cough, loss of weight, or physical signs. Of these 18 were found to have tuberculous lesions. One case of carcinoma of the bronchus was diagnosed and later confirmed. As Posner (1957) suggested, the response of these refugees to a suggestion of a chest radiograph was excellent; no objections were ever raised. A mobile x-ray unit would have been invaluable, and Aid to Hungary from Britain has sent two such units to Yugoslavia for use in the Hungarian refugee camps there.

The history of tuberculosis found in 10% of the refugees examined in England (Eldon, 1957) was confirmed by our investigations, and the pleas put forward by Smith and Mann for follow-up mass x-ray examinations of all the refugees in this country is stressed (Smith, 1957; Mann, 1957). Incidentally, a man seen at one of the border field kitchens by Dr. Mary Howson had large tuberculous glands of the neck which he had himself opened with a penknife on the way to the border. There seemed to have been a marked lack of sterile precautions in that operative procedure.

Conclusion

On the whole, the findings of Broad (1956), that the health of the refugees seen on the journey to England seemed generally to be very good, were borne out by our findings, although it should be remembered that many cases of illness had been weeded out before he saw them. The children were bonny and well nourished, and were extremely lovable and friendly. Physique was excellent in the young adults examined, and, seen at that stage when spirits were high in spite of exhaustion, morale was very good. At a later stage, when the channels of refugee-flow became clogged in the back-area camps and refugees stayed longer in the monastery, depression became more marked. This was accentuated when, in bitterly cold weather, refugees had to stay for periods of up to a week at the border kitchens, where conditions were of necessity very primitive and where it was very difficult to keep the refugees occupied.

Nearly 25,000 refugees passed through Gussing, and for the four doctors and three medical students who assisted the organization at Gussing over the period the experience of attending and helping the Hungarian people was undoubtedly valuable and exhilarating, although for those who came out as replacements in the later period the work was less exciting and more humdrum than during the chaos of the first few weeks.

It is desired to thank sincerely those medical firms and organizations in England who supplied dressings and drugs and all manner of appliances, from surgical instruments to Elsan lavatories, and did so spontaneously and generously. Their help will long be remembered by the medical workers, the Austrians, and, it is hoped, by the Hungarians themselves.

BRITISH EMPIRE CANCER CAMPAIGN THIRTY-FOURTH ANNUAL REPORT

For any but the cancer research worker the British Empire Cancer Campaign's latest report is stiff reading. Even the introductory summary assumes much specialized knowledge, and the arrangement of the main text, by place of work or under the name of the individual worker rather than by subject, makes it hard to get a clear picture of what is happening in this most important field. The lack of a subject index intensifies the difficulty. But what does emerge quite clearly from the Campaign's report is the remarkable breadth of the present attack on cancer. The assault troops include among their number chemists, physicists, virologists, immunologists, radiobiologists, crystallographers, microscopists, and cytochemists, as well as clinicians, radiotherapists, and those concerned with environmental hygiene. And there are many others. Their approaches are as varied as their trainings. There can be no doubt of the formidable array of talent now being deployed in research on cancer, or of the Campaign's key rôle in sponsoring, co-ordinating, and financing this work.

The Report and Finances

The thirty-fourth annual report covers the year 1956. It is a massive volume of 31 introductory pages and 559 pages of text. It opens with the membership of the Campaign's standing committees and subcommittees and a summary of the work reported; then come research reports from 18 British centres and five area councils or branches in Britain, an account by Professor G. F. Marrian, F.R.S., of the Campaign's conference on "Oestrogen Methodology" last year, reports of research in Uganda, Canada, New Zealand, and Australia, and individual reports from the Campaign's 45 grantees and 17 fellows. This forms the bulk of the volume (pp. 1–532); and each report, besides recording research findings, lists the staff concerned and their publications and gives a bibliography of other work cited. The annual report concludes with a statement of the Campaign's financial position and a name index of the research workers. The Campaign's income last year was £563,953 and its expenditure £558,694. A particularly heartening feature is that the income from donations, collections, and legacies showed another large rise during the year to reach the figure of £529,102. Over the last two years income from these sources has increased by some 40%. Of the expenditure, £492,388—88% of the total expenditure—was spent on the "main objects of the Campaign."

Summary of Research

Necessarily, states the report, the Campaign's research programme is still in a phase of expansion, and this will continue until greater knowledge permits a more selective approach or a key discovery revolutionizes the situation. In the meantime much work is proceeding on the mechanism of carcinogenesis and on such basic problems as protein synthesis and the enzymatic regulation of normal growth. One feature of recent cancer research stressed in the report is the great revival of interest in tumour immunology. Studies in carcinogenesis include work at the Middlesex Hospital on two of the simplest chemical carcinogens at

present known, β -propiolactone ($\text{OCH}_2\text{CH}_2\text{CO}$) and ethyleneimine ($(\text{CH}_2)_2\text{NH}$), in the hope that they may throw light on the action of the complex polycyclic carcinogens. At the Strangeways Laboratory, Cambridge, tissue cultures are being used to investigate the effect of carcinogens on the synthesis of deoxyribonucleic acid. The carcinogenic properties of mineral oils—"a matter of some concern"—are being further investigated by workers in Birmingham and Exeter. Another investigation at Birmingham has shown that large doses of oral copper give some protection against chemically induced hepatomas in rats; copper has also been found by a histochemical technique in the livers of three human cases of hepatolenticular degeneration.

Cancer of the Lung

Naturally there has been much research on cancer of the lung, atmospheric pollution, and smoking. Work at St. Bartholomew's Hospital on the cyclic hydrocarbons in tobacco suggests that these are almost entirely absent from the fresh leaf and that the most probable source of such compounds as anthracene, pyrene, and 3:4-benzpyrene is in the drying and curing. When a cigarette is smoked two processes appear to occur simultaneously—combustion of the contaminating hydrocarbons and their production *de novo* from the tobacco. The amount of these hydrocarbons in the tobacco before smoking is greatest in the case of cigars; in the products of smoking it is greatest in the case of pipes. But "probably the most important factor here," states the report, is the temperature of combustion, which is lowest in pipes, higher in cigars, and highest in cigarettes. Arsenic has also been studied. The arsenic content of the lungs of 23 persons without obvious signs of pulmonary disease at necropsy averaged 48 μg . (As_2O_3) per 100 g., but the amount of arsenic in the lungs of men and women respectively was in the ratio of 64:28. Tobacco grown in the East ("Turkish") contains very little arsenic, but new analyses of "one of the most popular brands (of cigarette) smoked in Britain" show a fall in arsenic content from 25 and 100 μg . in 1948–9 to between 1 and 2 μg . last year. The change is thought to be due to the "gradual abandonment of arsenical insecticidal sprays by the growers in the U.S.A." Most of the attempts to produce tumours in animals with tobacco tars have failed, but the intrapulmonary inoculation of eight rats with tars from a cartridge-type filter was followed in two cases by the development of tumours (a sarcoma and an oat-cell cancer). This lead is being followed up. Cigarette smoke contains large amounts of carbon monoxide (about 4–5 cu. cm. per cigarette), and this gas is being studied at the Institute of Cancer Research (London) in view of the possible role of anoxia in tumour induction. Other work on lung cancer has of course included much chemical and epidemiological research on atmospheric pollution.

Therapy

The principal lines of investigation here have been on the hormonal control of cancer, the chemotherapy of cancer, radiotherapy, and the role of chemicals and oxygen as "radio-sensitizers." At Mount Vernon Hospital the adjuvant effect of oxygen on radiotherapy is being studied both experimentally and clinically. Selected patients are receiving x-ray treatment while breathing oxygen at a pressure of one atmosphere. This follows encouraging reports by I. Churchill Davidson on patients treated at an oxygen pressure of three atmospheres. It is now firmly established experimentally, states the report from Mount Vernon, that "radiosensitivity is strongly dependent upon the availability of oxygen at the time of irradiation." At Cambridge, Professor J. S. Mitchell, F.R.S., is reaching, after 10 years, the end of the first stage of his clinical trial of chemical radiosensitizers. "Synkavit," a synthetic water-soluble vitamin K analogue, given intravenously, has been found to have a "definite small but practically useful effect" as a radiosensitizer in inoperable cancer of the bronchus. It is now being tried in combination with oxygen.

Among other therapeutic investigations is one at the Middlesex Hospital on the effectiveness of simply cutting the pituitary stalk as an alternative to hypophysectomy. It appears that this succeeds in producing "gross pituitary dysfunction." A relatively simple surgical technique has been devised for this operation. At Great Ormond Street the series of cases of neuroblastoma treated with massive doses of cyanocobalamin (vitamin B₁₂) has now reached 28. Regression occurred in 50%, a figure greatly in excess of the natural 1-3%, but what is even more striking is that regression occurred in every case with a clinical onset in infancy.

Other Studies

The report describes many other investigations, too numerous to mention individually. The metabolism and immunological properties of the cancer cell are being examined. Studies are reported on hormone excretion, the chemical and genetic effects of radiation, cytological diagnosis, and work with radioactive isotopes. There were crystallographic and histochemical investigations. Linear accelerators and caesium bomb units were tested. To end with, two investigations only recently started may be mentioned—a systematic study of the incidence of bone tumours in animals fed on strontium-90 and other "bone-seeking" radioisotopes, and two experiments on radiation-induced ageing.

The registered office of the British Empire Cancer Campaign is at 11, Grosvenor Crescent, Hyde Park Corner, London, S.W.1.

Reports of Societies

STUDIES ON FERTILITY

[FROM A SPECIAL CORRESPONDENT]

At the seventh annual conference of the Society for the Study of Fertility, held at Exeter on July 5 and 6, the first day was devoted mainly to clinical subjects. The second day was given over to basic scientific and veterinarian matters which are not reported here.

Correction of Retroversion

Mr. P. RUSSELL (Exeter) discussed the various operations for retroversion and their place in the treatment of infertility. He reported a series of 26 patients in whom, after full investigation, retroversion appeared to be the only significant factor. The average duration of infertility was 4½ years (range 2½ to 7½ years). After operation 21 had had an adequate chance for conception, and of these 12 became pregnant, producing 11 live births and 1 abortion. The interval between operation and pregnancy was 2 months to 10 years, but excluding this last case the average interval was 10 months. In the subsequent discussion adverse comments were made by various speakers on most of the current operative techniques for the correction of retroversion; the opinion was expressed that relief of venous congestion might be the main cause for the successful outcome regarding pregnancy; and serious doubts were raised as to whether retroversion *per se* was a cause of infertility.

Mr. D. H. YOUNG (Warrington) discussed testicular mal-descent and described his experience in a 32-year-old man with bilateral ectopic testes on whom first the left and then, two years later, the right testis was brought into the scrotum. Bilateral biopsies at the time of the second operation showed, on the right, small tubercles with Sertoli cells only, but on the left some traces of spermatogenesis. Three and a half years after the first operation, the seminal specimen showed a few active spermatozoa. Bilateral biopsy was repeated and showed spermatogenesis, albeit of a low order, in both tubules. However, the seminal fluid continued to contain only small numbers of spermatozoa and it was thought doubtful if the man would ever be fertile.

Therapeutic Value of Tubal Patency Tests

Mr. H. H. FOURACRE BARNS and Dr. G. I. M. SWYER (London) have extended the results of an investigation into the therapeutic efficacy of tubal patency tests, as judged by the incidence of conception within six months of their performance in apparently normal women with apparently fertile husbands, so as now to include a total of 304 subjects. The overall comparison gave a pregnancy rate of 37.5% after tubal patency tests as against 39.8% after endometrial biopsies. The pregnancy rates after tubal insufflation and after hysterosalpingography with water-soluble and with oily media were 35.2, 36.5, and 42% respectively, there being no statistical significance in these differences. These speakers expressed their continued doubts on the therapeutic value of tubal patency tests.

Dr. E. SOLOMONS (New York) gave a preliminary report of extensive studies being made by his group on thyroid function in pregnancy, with a view to establishing what part thyroid dysfunction might play in abortion and other forms of pregnancy wastage. The elevation of serum protein-bound iodine (P.B.I.) in pregnancy was confirmed, and administration of triiodothyronine was found to depress the P.B.I. slightly, as in normal women. Whereas triiodothyronine causes less than 20% decrease in the ¹³¹I uptake of hyperthyroid patients, a depression of more than 30% is the rule in euthyroid women. In pregnancy the ¹³¹I was found to lie in the upper level of the normal range, but triiodothyronine depressed it in the same way as in normal euthyroid women. The evidence suggests that the apparently increased thyroid activity in pregnancy is not comparable with hyperthyroidism in non-pregnant women.

Tests of Spermicidal Activity

One session of the meeting consisted of a symposium on methods of testing for spermicidal activity. This was opened by Dr. T. MANN, F.R.S. (Cambridge), who pointed out that no single biochemical mechanism was affected by all spermicides, and that there were at least three groups of these: enzyme and competitive inhibitors, sulphydryl-binding substances, and surface-active agents. Dr. CLARE HARVEY (Exeter) discussed the dichotomy of opinion on whether the end-points for tests should be the concentration required to kill within a fixed time, or the time required to kill at a fixed concentration. She preferred the former (modified Baker test of total spermicidal activity). Dr. B. CARRUTHERS (London) said that at the Family Planning Association laboratories satisfactory results had been obtained with the modified Baker test. He also mentioned his studies with the Davidson contact test and how the results could be affected by various factors, especially ingredients in the vehicle themselves not regarded as spermicides.

Dr. P. E. LINDAHL (Sweden) described how he has replaced the glass upper and lower surfaces of the cell used in the Davidson test by semipermeable membranes so as to allow of the access of oxygen, since he believes conditions within the vagina to be aerobic, not anaerobic. Dr. J. MACLEOD (New York) said that a special laboratory had been set up at the Sanger Bureau of the International Planned Parenthood Federation, with the express purpose of reinvestigating all the existing methods of spermicide testing. He himself believed that fundamental studies on "spermigration" were urgently needed.

The issue of the *Deutsche Medizinische Wochenschrift* of June 28, 1957, celebrates the 500th anniversary of the University of Freiburg im Breisgau, which was founded in the autumn of 1457. The staff of the medical faculty of the university have contributed all the signed articles published in this special number, which opens with a short historical account of the medical school. The other papers are an indication of the extensive clinical research now being carried out at the university.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Gamma Globulin for Generalized Vaccinia

SIR,—Occasional accounts of generalized vaccinia following vaccination have appeared in the literature over the past few years, and the most recent I have seen was in your columns last year by Galloway and McBean.¹ As others have done, they stress its danger to life. An infant who suffered from this condition was recently under my care. She had been born prematurely with a birth weight of 3 lb. (1.4 kg.). At the age of 7 months she was vaccinated in the left upper arm. Ten days later she started to come out in secondary vesicles which appeared in successive crops and eventually were present on the ears, the face, both arms, and both legs. The original vaccination site was examined at this time and the ulcer was found to be the size of a five-shilling piece. At this time also the child's pallor was observed and the haemoglobin was found to be only 44% with a colour index of 0.7. Under observation, further lesions continued to appear, and there seemed no reason why they should not continue to do so. The clinical picture was as described by Jubb,² and fulfilled all the criteria except that we could not definitely exclude auto-inoculation. It seemed to us, however, that it was much more likely to be due to blood spread and we also thought that the child's resistance was low because of the low haemoglobin level, although the possibility of hypogammaglobulinaemia was borne in mind.

I therefore asked Dr. E. H. Gillespie, director of the Public Health Laboratory Service regional laboratory situated in the City General Hospital, if he could provide some ordinary gamma globulin. He informed me that there was a special variety for infants with this condition derived from the serum of recently vaccinated subjects. He very kindly obtained a supply of this for me, and after the second injection no further lesions appeared; eventually all the lesions were healed at the end of six weeks. The anaemia was then treated by means of intramuscular iron and the child is now perfectly normal in every way. We ascertained, six months after the incident, that this child's gamma globulin level was perfectly normal.

Whether one believes or not that the special gamma globulin arrested the progress of the child's vaccinia, it is useful to know that such gamma globulin exists, and clearly if one encounters generalized vaccinia nowadays its administration is urgently called for. It is in order to draw attention to the existence of such gamma globulin (which is, I believe, available from any of the laboratories of the Public Health Laboratory Service) that I write this letter.—I am, etc.,

Sheffield, 5.

Evaporated Milk in Infant Feeding

SIR,—I should like to congratulate Dr. P. D. Moss on his paper advocating the use of evaporated milk in infant feeding (*Journal*, June 22, p. 1453), and also on his success in obtaining the co-operation of clinic doctors and health visitors on the use of this milk. I fully endorse Dr. Moss's claims for the value of this milk for premature and mature babies, and it is, in my opinion, the most satisfactory food for most babies when breast milk cannot be used. Evaporated milk can be reconstituted—20 calories per fluid oz. (28 ml.)—and in this form a full-cream mixture is acceptable to premature babies when full-cream dried milk is not well tolerated.

The use of evaporated milk in maternity and children's hospitals must unfortunately be restricted until its value is appreciated by the family and clinic doctors and by health visitors. There must be continuity in the advice given to mothers on infant feeding, and babies must not be switched from evaporated to dried milk after leaving hospital, either because the clinic do not supply evaporated milk, or because the doctors or health visitors disapprove of its use. Practical experience with evaporated milk in infant feeding will convince the most prejudiced antagonist of its advantages, and I hope in the near future it will be used very much more frequently.—I am, etc.,

London, W.1.

URSULA JAMES.

SIR,—Dr. P. D. Moss (*Journal*, June 22, p. 1453) argues that evaporated milk or National dried milk makes little difference to a family budget. As it depends entirely on the size of the family budget, I must wholeheartedly disagree with his generalization, working in a rehoused semi-industrial area as I do.

What has the National dried milk done to be black-listed after seventeen years? The recorded outbreaks of food-poisoning (which are in the nature of accidents) are chalked up against it. However, general practitioners and the makers of evaporated milk alike know that the half-emptied tin of evaporated milk, with its congealed pouring holes, standing on the shelf, and used a few days later after the cat has had a go at it, may well produce food-poisoning. For a large number of mothers, inadequately housed or insufficiently endowed with method or organization, dried milk has the infinite advantage that it stores within the dates printed on the tin. No doubt all milk feeds, including breast feeds, can be made ineffective and useless by the mother's lack of understanding and observance of even the simplest instructions. Yet with evaporated milk, as with dried milk, the feed has to be reconstituted.

The misleading quotations in Dr. Moss's paper are, however, related to costs. These claim that it makes very little difference to a family budget whether evaporated or National dried milk is used. The unreality of this claim has been discovered by my more unfortunate patients since the local maternity hospital has deserted the National dried for a brand of evaporated milk. It is only cheaper to feed a baby on evaporated milk so long as the baby takes less than a total of 6 oz. (170 ml.) per feed, and while the family buys at least 1 pint (0.6 l.) of milk per day for the baby. As most babies require more than 6 oz. (170 ml.) per feed for more than two-thirds of their bottle-feeding span, it is clear that the evaporated milk, even when balanced by a cheap pint of milk, is more expensive; 1s. 9d. per week makes quite a difference to some mothers whom I have to look after.

However, there is another fallacy. If the family is in strained circumstances and the first-born is fed on evaporated milk, the mother and father may not use more than ½ pint (0.3 l.) of milk per day, or even less, using a few drops of the baby's milk for their tea, with the result that they do not buy the extra daily cheap pint of milk upon which the cheapness of evaporated milk depends. If, on the other hand, it is their second or third child, the cheap milk of the other children is probably the only milk that is taken up by such a family, and no milk is bought on account of the new baby. So, in fact, the evaporated milk feed would cost the parents twice as much as the National dried milk.

Mothers come from the hospital with instructions for the evaporated milk, and, of course, think "hospital" knows best what is right for their baby. It is no use ignoring the fact that a hospital recommendation, or even use of evaporated milk, is a "must" to most mothers, even though no pressure on the mother as regards the type of food is claimed by the hospital. I would plead for the "uncritical prejudice," which has been quoted as being one of the reasons why evaporated milk is not being used more, to be turned into a critical analysis of the full social factors.

I hold no brief for National dried milk, having found in many cases evaporated milk particularly useful throughout

the past seventeen years, particularly in the premature babies, but I am anxious that the difficulties, which are many for a mother in straitened circumstances, should not be unnecessarily increased, and the confidence undermined in the National dried milk. Cheapness has a snowballing effect to the good on the general economy of the family.—I am, etc.,

Edinburgh.

E. V. KUENSSBERG.

Dangers of Cigarette-smoking

SIR,—It is not my wish to detract in any way from the report of the Medical Research Council (*Journal*, June 29, p. 1523) or the efforts of the Government to reduce the undoubted excessive and harmful smoking of a large part of the population; but having experienced nearly 30 years of mixed general practice, it seems to me that several questions require careful thought and even more careful answer.

In the last year I have had four patients die of "carcinoma of the lung," two males and two females. The two males both smoked, the one who died in his 80th year to excess, the other only moderately. One of the females had never smoked; the other had smoked to excess, and, although she was diagnosed in hospital as a primary lung cancer, at necropsy less than six months later she had a carcinoma of the stomach involving the whole of the posterior wall of the organ which must have existed for at least 18 months before her first chest symptoms, and was the undoubted cause of the thoracic secondaries. We are living in an x-ray age, but do let us be quite sure of our facts. Primary and secondary thoracic growths frequently look much the same on x-ray, and not all carcinomata of the body of the stomach are spotted on x-ray if the state of this organ is in fact questioned. I feel very strongly that statistics of the seriousness of those in mind can only be of real value when upheld by competent necropsy findings. Deaths from carcinoma of the lung and carcinoma of the stomach have many similarities. It is my belief that many of the diagnoses were not and still are not quite as accurate as we would wish to have them.—I am, etc.,

Wokingham.

RALPH ROSE.

Cigarette Advertisements

SIR,—In its leading article of June 30 the *Observer* states: "Many young people start smoking because it strikes them as a normal adult habit: we should do all we can to make it appear to them a bad and unnecessary habit." Whatever one thinks about action regarding adult smoking, most people who have read the recent reports will agree with the *Observer*.

In this connexion might I as an advertising man—and one who owes a great debt to medical skill—make a suggestion? One of the factors persuading young people to smoke is of course advertising; and any publicity by the Ministry of Health on the findings of the Medical Research Council is likely to be more muted than its commercial counterpart, and will probably reach only the more thoughtful section of the community. For some years press and advertising alike have accepted a voluntary "code of standards" and have refused all advertising for many formerly accepted patent medicines, now thought to be harmful or to make dubious claims. Similarly, advertising for any type of treatment for a number of diseases is excluded from the press. There would seem to be an even stronger case for refusing publicity to products which cause avoidable disease, and I suggest that the medical profession uses its great influence to have the "code of standards" extended to include tobacco among the list of unacceptable advertising.

We in this country rightly dislike all limitation of freedom, but if in fact there is a choice between the freedom of the cigarette manufacturer to persuade and of a young man or woman to be healthy, I believe the press (and commercial television) will recognize its responsibilities—even if a little tardily in some quarters.—I am, etc.,

Metch End, Middx.

HAROLD SUMPTION.

Giving Up Smoking?

SIR,—Some of my colleagues might be interested in a method of giving up cigarette-smoking which has proved successful and more or less painless both personally and to quite a large number of patients.

It should be borne in mind that there are three problems to be overcome, the drug addiction, the habit, and the psychological factor. The approach to the first problem is as follows. The addiction must be reduced, and so the smoker must be switched at once to a good filter-tip cigarette. At the commencement, this will cause some discomfort because so much of his drug is strained off by the filter-tip, and he must be warned not to increase his usual daily number of cigarettes. After 8 to 10 weeks' smoking of filter tips, he will already have lost a good deal of his craving and then it is much easier to reduce the number smoked until about five a day has been reached. This number can be kept up for another two to three weeks, and by the end of this time he has so little addiction left that it will be easy to cease the five at one "go." The next problem is, of course, the habit, and this is just as difficult, but I have found that eating a sweet at the normal time that one would smoke works well; holding a cigarette-holder empty in the mouth; and, finally, that great solace to mankind—chewing gum. The psychological or emotional aspect was very tricky with several people until I had an inspiration and told people to call them "cancerettes." When your moral courage is failing and you surreptitiously creep through the house to find that packet, the thought that they are cancerettes produces the same effect as the letters V.D. used to do to another and older vice. Try the system and see it work.—I am, etc.,

Staines, Middx.

HENRY BERGH.

Polyneuritis and Illness in Cats

SIR,—Dr. A. M. G. Campbell has written to you about three cases of acute polyneuritis with raised protein in the cerebrospinal fluid associated with an acute illness of a cat in the house of a patient (*Journal*, May 18, p. 1183).

In March I had a patient under my care suffering from the Landry-Guillain-Barré syndrome. Three months before the illness started she had a kitten suffering from "cat influenza," of which there was an epidemic in the district in which the patient lives. Both the patient and the kitten have since completely recovered. The association here may also be coincidental, but I agree with Dr. Campbell that further investigations may be helpful in elucidating the aetiology of some of the forms of polyneuritis.—I am, etc.,

Harrogate.

T. G. REAH.

Diabetes Mellitus with Acute Polyneuritis

SIR,—The communication of Dr. J. Wedgwood (*Journal*, June 8, p. 1346) prompts me to report a case seen at the Central Middlesex Hospital.

The patient, a woman of 62, developed a sore throat, nasal catarrh, and a slight cough. Five days later she noticed difficulty in walking and two days later weakness of her hands, so that by the tenth day she was unable to get out of bed or feed herself. She also noticed "pins and needles" in her feet and hands when they were touched—this coincided with the onset of weakness in each limb. Previous medical history showed nothing of note. She had had three children, each weighing less than 10 lb. (4.5 kg.) at birth. There was no family history of diabetes mellitus.

Physical examination on admission revealed no abnormality in the cranial nerves. There was gross weakness of the limbs and trunk, in the legs maximal in the proximal muscles, and in the arms in the distal. The tendon jerks and abdominals were absent, plantar responses flexor. There was no objective sensory loss. Cardiovascular and respiratory systems were normal. Blood pressure was 150/90. The significant lumbar puncture findings were:—On admission: protein—75 mg.%, globulin—slight excess, cells—6 R.B.C. per cu.mm.; one week later: protein—70 mg.%, globulin—

very slight excess, cells—3 W.B.C., 1 R.B.C. per cu.mm.; three weeks later: protein—55 mg.%, globulin—no excess, cells—none. Other findings were: haemoglobin—15.1 g.%, total W.B.C.—7,000 per cu.mm., E.S.R. 4 mm. in one hour, both red and white cells appeared normal; the urine contained no albumin, sugar, red cells, casts, porphyrins, or porphobilinogen; x-ray of chest showed no abnormality in heart or lungs; blood and C.S.F. W.R. were negative; Paul-Bunnell test was negative. The only significant finding was a glucose tolerance test, which showed values (capillary blood) of 150 mg.% fasting and 230, 260, 220, and 130 mg.% at half-hourly intervals after 50 g. glucose by mouth. The test was repeated two weeks later and the results were 120, 197, 235, 240, 165. In each case glycosuria occurred only in the last hour of the test. The condition of the patient improved slowly from the time of her admission. No new symptoms or signs appeared, though at times she had a persistent fever of 99° F. (37.2° C.). When discharged six weeks later she was able to walk alone and use her arms but still had considerable residual weakness.

The features in this case atypical of the Guillain-Barré syndrome are the absence of cranial nerve involvement and only a slight rise in the C.S.F. protein. The respiratory illness at the onset, the distribution of the weakness, and the predominance of motor signs are more characteristic of it. Reitman and Rothschild¹ state that the Guillain-Barré syndrome has been seen in diabetics, but do not say whether it is seen more than in non-diabetics. In that the patient showed no objective sensory loss she resembled the cases of Garland² and Garland and Taverner.³ She differed, however, because of the sudden onset, rapid progression, and symmetry of the weakness, spontaneous recovery, and the complete absence of pain.

The finding of Haymaker and Kernohan⁴ of C.S.F. blood sugar of over 80 mg.% in 7 out of 15 fatal cases of Landry-Guillain-Barré syndrome (with a maximum figure of 182 mg.%) may be of significance. None of these cases was stated to have diabetes. The conclusion which may perhaps be shown from these findings is that in cases of acute polyneuritis the investigation of glucose metabolism may be of value.

I thank Dr. R. J. Porter for permission to publish this case.—I am, etc.,

London, N.W.10.

R. S. KOCEN.

First Aid

SIR,—I submit that Sir Zachary Cope's review of Dr. R. A. Mustard's *Fundamentals of First Aid* (*Journal*, June 8, p. 1348) was far more merciful than the book deserved. Most will agree that the tourniquet is best forgotten and that antiseptics are best left out of wounds; many will be surprised that pressure points are not to be taught, though the arguments for the omission have some superficial logic. Yet I have known at least three lives saved by the use of pressure points, where other means of haemorrhage control would probably have failed. Dr. Mustard's book does not explain how his local pressure technique is to be used where severe bleeding comes from a fracture site.

Some frightening items to be noted in the book are:—p. 59: a firm bandage round the popliteal fossa; pp. 59, 62, 65, 67: clear-cut advice to use traction on a fractured limb, by pulling firmly to straighten the broken bone; p. 79: after (correctly) advising copious water washing to the chemical burn the author then advises applying baking soda or vinegar (amounts or strength not detailed) as neutralizing agent. It is commendable to try to teach first aid by simplification, but this attempt has failed. One paragraph from it headed "How to Give Fluid to a Child" must be quoted in full (p. 96):

If the child refuses to drink copiously, wrap him in a blanket to pin down his arms or legs, pinch his nostrils, and pour the

diluting fluid down his throat when he opens his mouth to breathe.

This terrible manoeuvre, which would efficiently flood the trachea, is accompanied by a picture as clear incredible as the text itself.—I am, etc.,

Cambridge.

The Forgotten Thomas Splint

SIR,—I am disturbed to find that practically all the ambulance authorities—i.e., county ambulance services, St. John, and also, I understand, the National Hospital Reserve first-aid teams—are advising the use of long Liston splints for first-aid treatment of fractured femurs.

As long ago as 1916, during the first world war, Sir Robert Jones introduced the Thomas splint in the military services and showed convincingly that by its use mortality from fractured femurs could be dramatically lowered. In the second world war the Thomas splint was again widely used by all military services. In peacetime, however, these lessons appear to be forgotten and we have gone back to the long Liston splint which does little to immobilize the fracture, nothing to ease the pain, and cannot hope to prevent the onset of shock. Admittedly such casualties usually reach hospital within a very short time, but if they arrive with a well-applied Thomas splint on it makes examination in the casualty department much easier, transport to the x-ray department much easier, and the final transport to the ward less shocking to the patient.

I hope that by bringing this matter to your notice those responsible for the ambulance services may again provide Thomas splints and have their efficient application taught.—I am, etc.,

Windsor.

G. P. ARDEN.

Post-maturity

SIR,—Professor F. J. Browne's paper (*Journal*, April 13, p. 851) has been commented upon critically by two different authors, Professor D. Baird and Mr. W. G. Mills (*Journal*, May 4, p. 1061). A biochemical study of newborn infants which we are doing¹ supports Professor Browne's opinion that prolongation of pregnancy *per se* is not so dangerous and does not call for induction of labour.

The opinion, advocated by Walker² and supported by MacKay,³ that the oxygen saturation falls with increasing gestation time is certainly not always valid. MacKinney *et al.*⁴ in a study of 594 infants in Buffalo found no support of Walker's thesis. In 202 cases with spontaneous uncomplicated delivery studied by us the following results were obtained (Table I).

TABLE I.—Umbilical Oxygen Saturation (Per Cent.) After Varying Periods of Gestation

Gestation Time in Weeks	38	39	40	41	42	43
Vein	61.8	62.9	61.3	62.6	60.4	64.5
No. of observations	20	28	39	52	33	30
Artery	30.6	39.7	36.4	34.6	33.0	30.4
No. of observations	16	21	26	42	27	25

TABLE II.—Umbilical Oxygen Saturation (Per Cent.) at Varying Degrees of Dysmaturity

Stage of Dysmaturity	0-1	1	2	Normal
Vein	58.6	56.9	51.1	63.7
No. of observations	35	59	12	104
Artery	34.7	34.6	24.3	38.7
No. of observations	29	47	10	79

If, however, the infants, not the duration of pregnancy, are studied a different picture will be seen (Table II). The infants have been classified as normal or dysmature as described by Ballantyne,⁵ Bossi,⁶ Bäcker,⁷ and Runge.⁸ The dysmature infants have then been grouped according to the stages described by Clifford.⁹ As the word post-maturity is

used sometimes to describe the time of gestation and sometimes the state of the infant, we prefer to use the name dysmaturity for the description of the infants with signs of placental insufficiency.

Thus some infants are hypoxic not because they have been too long in utero but because of a placental insufficiency. It seems from our study of 1,171 live-born infants, classified as above, that even the dysmature infants have no higher mortality than the other infants.—We are, etc.,

Hypogammaglobulinaemia, Splenomegaly, and Hypersplenism

SIR,—Since the report of Bruton¹ many cases of agammaglobulinaemia or hypogammaglobulinaemia have been reported in the literature. Prasad and Koza² described the first instance of this disorder complicated by hypersplenism and haemolytic anaemia in an adult female. Unfortunately, the article entitled "Agammaglobulinaemia with Splenomegaly," by Dr. K. M. Citron (*Journal*, May 18, p. 1148), contains no reference to the aforesaid article. Because of its unusual features the first reported case³ was included in the groups reported by Good,⁴ Good and Mazzitello,⁴ and by Zinneman *et al.*⁵ (with the permission of the original authors). At the time of the first report³ a distinct relationship between hypogammaglobulinaemia, splenomegaly, hypersplenism, and reticulum cell hyperplasia was not as obvious as it is now. However, it was postulated³ that the reticulum cell hyperplasia was secondary to hypogammaglobulinaemia and resultant repeated infections.

Further observations and a review of the literature⁶ indicates that seventeen such cases (excluding the two reported by Citron) of acquired idiopathic hypogammaglobulinaemia with splenomegaly have been reported in the literature. I agree with Dr. Citron's conclusion that acquired idiopathic hypogammaglobulinaemia should be considered in the diagnosis, in obscure cases of splenomegaly, reticulo-endothelial hyperplasia associated with recurrent infection, and hypersplenism. It is quite conceivable that in such cases the primary fault lies in a disturbance in formation of plasma cells and that their absence and consequent hypogammaglobulinaemia then serve as stimuli to reticuloendothelial cell hyperplasia.

The persistently low E.S.R. readings during infection in these cases are rather an interesting observation, as mentioned by Citron. This was also first observed by Prasad and Koza.²—I am, etc.,

Minneapolis, Minnesota, U.S.A.

Women's Footwear

SIR,—If Mr. Reginald T. Payne (*Journal*, May 18, p. 1180) expects the Government to emancipate women from fashion, he will remain a lone voice crying in the wilderness. But why not start on the men? Could he not persuade Lord Nuffield to pause in founding orthopaedic hospitals and turn his attention to the boot and shoe trade? The immense capital required to advertise and flood the market with properly shaped shoes (at a price which people could afford) would be required only temporarily, as, once the new shoe

got going, manufacturers would have to scrap all their present lasts and follow suit, or else go out of business. This has been proved in the case of children. It is now almost impossible to get a badly shaped child's shoe, because directly the first enlightened manufacturer got ahead all the others saw the red light, and we got nature-form shoes, which do not look in the least incongruous or unsightly, because the public nowadays never sees anything else. But directly the teenager passes from children's to ladies', the manufacturers have nothing to offer. Even the best of them fail to carry a sufficient range for all occasions (including the dance hall or ballroom), and the unhappy girl, with hitherto perfect feet, is compelled to ruin them for ever in the present rubbish, including the "peep" for the great toe in line with the third metatarsal.

But if only our greatest benefactor would come to our rescue he would kill three birds with one stone. Englishmen would be properly shod; thousands of recruits, at present rejected by regulations, would be available for the Forces; and, best of all, his valuable beds, instead of being cluttered up with disabilities which need never have occurred, would be available for varicose veins, which at present cry aloud, in vain, for expert surgical treatment.

Dr. B. J. Bouché (*Journal*, June 1, p. 1306) is, of course, beside the point. It is common knowledge that anything is obtainable in this life, "if the price can be met."—I am, etc.,

London, E.4.

FREDERIC SANDERS.

SIR,—The correspondence regarding women's footwear has been most interesting, and personal experience enables me to endorse all that has been said about the difficulty of obtaining a really comfortable pair of shoes. The fashions in women's footwear have recently become so extreme and unphysiological that for the last year I have been searching the shoe shops in many towns in different parts of England for a comfortable pair of shoes for summer wear, so far without success. The irony of the situation is that the styles of men's shoes during the same period have become much more pleasing in appearance and lighter and more comfortable in wear, so much so that some women are now buying men's shoes for their own use. One firm told me that so popular was one of their men's styles that they now make a woman's shoe based on the same design.

A small investigation into the posture of schoolchildren, which I carried out some years ago in collaboration with the physical training organizers in some of the schools in Lincolnshire, showed evidence of widespread postural deformity and we found that foot deformities were exceedingly common. I am told that they are now even more prevalent, and that to find a girl with perfect feet is a rarity, especially among the grammar school age groups. Dr. W. G. Booth, of Ealing, has begun a scheme for helping parents to provide proper shoes for children with a view to the prevention of foot deformities, and it seems to me that a similar sort of campaign is urgently needed for educating the women of this country to insist on proper shoes, and by their insistence to compel manufacturers to produce a shoe which shall be comfortable, of pleasing appearance, and physiologically designed. It should not be impossible to make a shoe satisfying these requirements.—I am, etc.,

Spalding.

IRIS M. CULLUM.

SIR,—The question of women's footwear urgently needs all the publicity the medical profession can give. Therefore it is good to see so many doctors writing to the *Journal* about it. However, as a school medical officer, I do protest against the statement made by Mr. C. A. Pratt (*Journal*, June 22, p. 1472) "that the school medical service shows little awareness of the position."

We who see the growth of children's feet are only too well aware of the crippling effects of ill-fitting, too small, and poorly shaped shoes, and of socks several sizes too small. In this division the schoolchildren's feet are regularly inspected and measured, their shoes are measured, and the parents are informed of the correct type and size of

shoe required. But what are we up against? First, there is this question of fashion set by the shoe trade and slavishly followed by teen-age girls and their mothers. Then there is the difficulty of obtaining the right shoes for teen-age girls, even when asked for. The shoes are shown in the makers' catalogues, but the would-be buyers are told they will have to be ordered specially and it will be several months before probable delivery. The only type of shoe in stock is the long, narrow, pointed-toe type, and when a protest is made that the teen-age girl's foot is not this shape the "sales patter" is that "the girl's feet have been allowed to spread and so spoiled by school shoes." How much damage must be done before the shoe trade and the public will adopt shoes the shape of feet?—I am, etc.,

Kidderminster.

C. STARKIE.

Cause of Cancer

SIR,—May I voice appreciation of the letter by Dr. L. Llewellyn Davey (*Journal*, May 25, p. 1245), and suggest just one alteration in a sentence as follows? "There seem to be some criteria [instead of no criteria] by which it can be stated that, if a certain set of circumstances in or around a cell is created, then a mutation will sometimes take place in that cell from normality to malignancy."

I refer to the frequency with which cancer supervenes in an area subject to chronic lymphatic obstruction due to either chronic inflammation or mechanical change—for example, chronic post-nasal catarrh or sinus infection, adenitis, cancer in the region of the pharynx; chronic mastitis, axillary adenitis, lymph obstruction, cancer; chronic bronchitis, infective or due to smoking, or healed tubercle, cancer of lung or bronchi; chronic adenitis round the coeliac axis artery, lymph obstruction, oedema massaged to the pylorus by peristalsis, cancer; chronic adenitis in the glands near the portal fissure, lymph obstruction, and cancer of liver or head of pancreas; chronic lymph obstruction due to filaria, cancer of the skin of the limb, later when abdominal glands involved cancer of the stomach and intestinal canal; chronic lymph obstruction following serpiginous ulcer or ulcer tropicum, cancer in the area involved by the chronic adenitis; lymphatic obstruction due to burns or lupus, cancer.

One could elaborate such examples recognizable with the eye alone, but the above is sufficient to show that pre-cancerous states do exist and may readily be recognized. Prevention seems to be the elimination of any chronic inflammatory focus before adenitis blocks lymph drainage, a point that we may all keep in mind, and so mitigate the scourge until the experts find the physico-chemical cause.—I am, etc.,

Seaton, Devon.

A. INNES COX.

Reticulohistiocytosis

SIR,—The interesting article by Drs. R. P. Warin, C. D. Evans, M. Hewitt, A. L. Taylor, C. H. G. Price, and J. H. Middlemiss (*June 15, p. 1387*) will doubtless serve to establish the definite entity of the striking disease described. I would like to emphasize the terrifying appearance of the patient at periods. In the man described by Freudenthal and myself,¹ the nurses suspected at first that I had introduced a case of leprosy. Myxomatosis even might be thought of, could that disease attack human beings. The almost confluent eruptions of swellings at the back of the neck and shoulders where the skin was warmed by the pillows was especially striking. My latest remarks on the subject were published under the heading, "A Rare Disease with Features Resembling both Rheumatoid Arthritis and a Lipoid Accumulation,"² and in *Interesting Cases and Pathological Considerations*,³ which contains one additional reference to the literature—namely, the paper by Cave, Kopf, and Vegas.⁴

Evidently in regard to this remarkable disease ("lipoid dermato-arthritis"—the second of the two titles suggested by Dr. Warin and his colleagues—is the one that I prefer) there is still much to be investigated. For instance, though it is certain that at least in some cases the symptoms may be greatly aggravated by the local or general application of

heat, nobody, so far as I know, has suggested a trial of local or general application of cold as a therapeutic measure. This could be carefully tried out at any modern general hospital. A visit to a Swiss high-altitude winter resort might even be thought of, though care would have to be taken to shield the patient from the glaring sunlight. If in some unexpected way the disease should become really common, the establishment of an international sanatorium camp on the way to Mount Everest might even be considered, though the patients might possibly be regarded by the natives as "abominable snowmen."—I am, etc.,

F. PARKES WEBER.

Medical Use of Hypnotism

SIR,—May I congratulate you on giving so much publicity in the *Journal* of June 8 to a most valuable therapeutic agent, which has for some long time been relegated to the "medical dust heap," but which has in recent years been rescued and placed on a scientific basis? It is also gratifying to learn that such an eminent physician as Professor Alexander Kennedy (p. 1317) uses hypnosis as a method of treatment.

I must, however, disagree with Professor Kennedy on his remarks concerning hypnosis and smoking. In my experience, provided the patient sincerely wishes to relinquish the habit, and has a very good reason for so doing—e.g., a persistent cough, a dyspeptic ulcer, fear of lung cancer, or perhaps pecuniary difficulties—success in the majority of cases is assured. I have found that from four to six sessions of re-enforcement are necessary. I would add that the majority of these cases had tried hard to give up the habit of their own accord.

One remark of Professor Kennedy surprised me. This concerned his reference to "the use of a lay hypnotist to continue under . . . supervision." Surely the treatment by hypnosis is essentially a personal matter, and the personality and prestige of the hypnotherapist play a most important role in the results obtained. Through sheer pertinacity medical experimentalists have succeeded at long last in placing hypnosis on a respectable footing, and the employment of a lay hypnotist would tend to defeat this object.

The time has now come for all hospitals to employ hypnotherapists on their staff. In particular, results in the allergic conditions and skin diseases are so successful that the employment of medical hypnotists in these departments would not only help to deplete the waiting-lists but would alleviate much pain and suffering in a very short time.—I am, etc.,

London, W.1.

J. R. ROBSON.

Scapulo-thoracic Crackling in Youth

SIR,—Mr. W. D. Coltart (*Journal*, June 29, p. 1532) does good service in pointing out the undesirability of manipulative treatment in hypermobility, but where hypermobility is dependent on stasis or limited mobility in adjacent segments of the spinal column the only cure for that hypermobility, which is a compensatory mechanism, is by restoring mobility in the affected segments. Many conditions of faulty posture and mechanical imperfection may be helped by manipulation; one has always laid down the principle that manipulation makes available the patient's own resources for recovery, and one should not hesitate to use it for this purpose.

Manipulation of postural difficulties has and always will be practised for conditions of kyphosis and scoliosis, whether they are inevitable, permanent, and by radiographic evidence apparently impossible to help, for, while agreeing that one cannot affect a bone that is bent, one can affect the resultant state of imbalance and stiffness.—I am, etc.,

London, W.1

GUY BEAUCHAMP.

Intestinal Lipodystrophy

SIR,—Dr. S. F. Cahalane's comment (*Journal*, June 15, p. 1421) on your annotation (*Journal*, April 27, p. 998) on the diagnosis of Whipple's disease is very apt to a case with which I am concerned at the present time. In this patient, a young woman, a muscle-cell tumour had caused blockage of lacteals in the jejunal mesentery, and had produced an appearance in the jejunal mucosa and in lymph nodes which bears a striking resemblance to Whipple's lesions. In this case, biopsy of an abdominal node might have been misleading.—I am, etc.,

Workson, Notts.

G. A. DUNLOP.

Pseudomonas pyocyanea in Cetrimide

SIR,—Not only cetrimide but soap and chloroxylenol solutions and calamine lotion are liable to contamination with *Ps. pyocyanea* in bottles covered with corks. Mr. P. J. Keen (*Journal*, June 8, p. 1363) is undoubtedly right in thinking that the use of alternative forms of cover on bottles will reduce or eliminate the risk. It is well known that bacterial growth-promoting substances are present in cork.¹ Experimental evidence reported by us in 1951² suggested that *Ps. pyocyanea*, probably deposited by contaminated fingers, received protection and perhaps nourishment from cork stoppers; after the introduction of screw-cap bottles for storage and dispensing of the fluids mentioned above, *Ps. pyocyanea* was no longer found in any of them on repeated samplings, and *Ps. pyocyanea* infection of wounds became less frequent. Since that time (in 1953) an improved cetrimide which is more active against *Ps. pyocyanea* has been made available by the makers. In view of this, it is interesting that Dr. G. L. Robinson (*Journal*, May 25, p. 1242) should recently have found *Ps. pyocyanea* in cetrimide solutions as we did in solutions of the earlier product.—I am, etc.,

Birmingham, 15.

E. J. L. LOWBURY.

REFERENCES

- Nelson, J. H., *J. Path. Bact.*, 1942, 54, 449.

Rheumatoid Arthritis of Crico-arytenoid Joints

SIR,—The articles on rheumatoid arthritis of the crico-arytenoid joints by Dr. J. E. G. Pearson (*Journal*, May 4, p. 1047) and Dr. W. S. C. Copeman (*Journal*, May 15, p. 1398) and Drs. O. A. Baker and E. G. L. Bywaters (p. 1400) were of great interest to me. A further case is at present under treatment in the Royal Southern Hospital, Liverpool.

The patient, a tram driver aged 61, has suffered from rheumatoid arthritis for 18 years and is now severely crippled. His two brothers also suffer from rheumatoid arthritis, but neither has had any laryngeal involvement. The patient's left knee, left wrist, and right elbow are ankylosed and there is very little movement in the other knee or in the small joints of the hands and feet. The shoulders and the temporo-mandibular joints are affected to a lesser extent, while the hip-joints have largely escaped. There are several rheumatoid nodules over the elbows and sacrum. Successive courses of treatment with sodium aurothiomalate, phenylbutazone, salicylates, oral cortisone, and intra-articular hydrocortisone had all failed to halt the progress of the disease. During the twelve months prior to admission the only forms of treatment used were physiotherapy and calcium aspirin 10 gr. (0.65 g.) six-hourly. E.S.R. records are available for 1954 and 1955 and varied between 18 and 33 mm. (Wintrobe) until December, 1955, when the reading fell to 8 mm. At that time the Rose test was positive 1:128. Since then mild exacerbations of joint pain have recurred up to the present time and suggest that the disease is still active. At the time of writing the E.S.R. is 25 mm. and the Rose test is positive 1:256.

The patient had always been fond of singing and possessed a good voice. Three years ago his voice became croaky and made singing impossible. Three months before admission he experienced increasing difficulty in swallowing fibrous foods, such as grape skins, and towards the end of the period noticed a dry, slightly sore feeling in his throat and all swallowing became uncomfortable. On March 14 this year he developed a dry cough and slight dyspnoea which suddenly increased three days

later with the onset of inspiratory crowing. He was admitted to hospital and within a few hours the stridor became severe and he was cyanosed. Examination of the chest and pharynx at this time did not reveal any abnormality. The patient was transferred to the Liverpool Ear, Nose, and Throat Hospital and an emergency tracheotomy was performed under local analgesia. Next day a direct inspection of the larynx under general anaesthesia showed that the vocal cords were apparently normal but were in a paramedian position with very little abduction. Since then there has been persistent bronchitis and a course of penicillin was required to control an acute exacerbation. Purulent discharge from the trachea and wound edges became excessive at one stage, but cleared up with a course of sulphadiazine. The outer tube is changed monthly and the inner tube is cleaned several times daily. There is no suggestion of stridor when the tube is corked, and the patient is able to converse freely although the croak persists. The symptomatology of this case corresponds with the majority of the previously reported cases. A period of minor alteration in the voice is followed successively by dysphagia, dyspnoea, and stridor.

It is notable that three out of the four cases reported in the *Journal* of June 15 had serious involvement of only one crico-arytenoid joint. One might expect that if only one joint is affected the chances of symptoms developing will be much reduced, and it may be that many cases remain undiscovered because of this. I suggest that sufferers from rheumatoid arthritis developing voice changes should have a laryngoscopy. It is possible that if a diagnosis could be made at an early stage and intensive treatment pursued tracheotomy might be avoided.

I am indebted to Dr. R. W. Brookfield for permission to describe this case.—I am, etc.,

Liverpool, 8.

D. P. MANNING.

Prevention of Recurrences of Rheumatic Fever

SIR,—The fact mentioned by three of us (*Journal*, May 25, p. 1234) that penicillin V is a costlier oral prophylactic than penicillin G is mildly criticized by Mr. R. Levin (*Journal*, June 22, p. 1474) on the grounds that its higher cost is offset by the smaller doses necessary to achieve a given blood level. This is too ingenuous an argument. The virtue claimed for penicillin V lies in its superior efficiency, dose for dose, in the maintenance of an effective prophylactic level; to reduce the dose is to reduce the advantage. At present for rheumatic fever prophylaxis it is still cheaper to use penicillin G than to use penicillin V in a dose which retains comparative benefit.—We are, etc.,

E. G. L. BYWATERS.

G. T. THOMAS.
E. J. HOLBOROW.

Gardening Hazard

SIR,—The gardening gloves mentioned in Dr. E. M. Town-Jones's letter (*Journal*, June 29, p. 1532) had no doubt been impregnated with sodium chlorate used as a weed-killer. Being relatively non-poisonous it is commonly regarded as harmless. It is, however, so inflammatory that a solution splashed on gardening gloves, shoes, or the legs of one's Saturday afternoon trousers can become dangerous, and Dr. Town-Jones's letter is a useful reminder of this fact. Sodium chlorate is much used in the manufacture of fireworks.—I am, etc.,

London, S.E.18.

T. C. SCOTT WEBB.

SIR,—The accident reported by Dr. E. M. Town-Jones (*Journal*, June 29, p. 1532) under this heading is probably more purely a gardening hazard than his letter suggests. Had the gloves worn by his patient been used previously when handling sodium chlorate as a weed-killer? This substance is usually used in solution, but when allowed to dry in contact with an organic material (such as leather or cloth) it becomes highly inflammable—even explosive.—I am, etc.,

Ballanard, I.O.M.

B. B. HARRISON.

Obituary

G. ROCHE LYNCH, O.B.E., M.B., F.R.I.C., D.P.H.

Dr. Roche Lynch, who died suddenly on July 3 at the age of 68, was the latest in a remarkable succession of medico-legal experts attached to St. Mary's Hospital. First came the well-remembered Augustus Pepper, then Arthur Luff, followed by Sir Bernard Spilsbury and Sir William Willcox. All were men of distinction. From the nature of the case and through no seeking of their own, the light of publicity beat upon them. The anonymity which enfolds most doctors could not cover those who were called upon to give expert evidence in sensational criminal trials. Roche Lynch became senior official analyst to the Home Office in 1928, having held the junior post for eight years previously. In the same year he became director of the department of chemical pathology at St. Mary's, and in 1936 succeeded the late Sir William Willcox as lecturer in forensic medicine. He held all these positions until his retirement in the autumn of 1954.

By permission of the Society of Apothecaries of London.

Gerald Roche Lynch was born at Notting Hill on January 12, 1889, the son of a doctor. He was educated at St. Paul's School, and entered St. Mary's Hospital Medical School as a scholar in natural science in 1906, when he was bracketed first in the entrance scholarship examination. He became research student in physiology in the University of London in 1909. At this time his interest was mainly in the physiology of the nervous system. Quite early he distinguished himself in chemistry, and before he became medically qualified in 1913 he acted as demonstrator in that subject. After graduation he served for a time as house-physician at St. Mary's, and in the first world war, from 1914 to 1918, as a temporary surgeon lieutenant in the Royal Navy. During his wartime service he published two papers on carriers of the meningococcus. In 1922 he was appointed demonstrator in chemical pathology at St. Mary's, and in 1926 he became lecturer in that subject. He was appointed O.B.E. in 1919.

His official position soon made Roche Lynch's name known to the public at large. Like his predecessors, in addition to many routine duties he was called upon to give expert advice in criminal trials, and in doing so he inherited their manner and attitude. It could be said of him that in the witness-box he was Sir William Willcox over again—deliberate, scrupulously careful, not ruffled by cross-examining counsel, seeking to make no impression of brilliance, but merely being thorough and having regard to the truth down to the smallest detail. As time went on he was called to many important positions. In 1933 he became a member of the Poisons Board. In 1943 he was made Privy Council visitor to the examinations of the Pharmaceutical Society. He was examiner for the D.P.H. to the Royal College of Physicians, the Royal Institute of Chemistry, and the University of London. From 1939 to 1942 he was president of the Medico-Legal Society. In the world of chemistry he achieved an unusual distinction for a medical man, being elected president of the Royal Institute of Chemistry for 1946-9. An honour which pleased

Ovarian and Endometrial Grafting

SIR,—I have just had an interesting experience, for I have received a letter from a patient upon whom I operated in 1934.¹ She was physically and psychologically disturbed because she had never menstruated. All drugs had failed, and so I grafted a piece of ovary from another patient into the rectus sheath; this was unsuccessful in producing menstruation. Later I grafted a piece of endometrium from another woman upon whom I had done a hysterectomy for fibroids. I opened the uterus and stitched it into the uterus. The patient writes now that "the operation was successful and I menstruated and put on weight. I shall always be grateful for what you did." Her reason for writing was that she was having irregular periods and that her doctor wished for details of her previous operations.—I am, etc.,

Dun Laoghaire, Eire.

Medical Directory, 1958

SIR,—The annual schedule, upon the return of which the accuracy of the *Medical Directory* depends, has recently been posted to all traceable members of the medical profession. The speedy return of the schedule would be appreciated. Should it have been mislaid, I will gladly forward a duplicate upon request. The full name and year of qualification of the doctor should be sent for identification. Communications should be addressed to the Editor, *The Medical Directory*, 104, Gloucester Place, London, W.1.—I am, etc.,

London, W.1.

B. STANTON,
Editor, *Medical Directory*.

St. Luke's Tide Services

SIR,—Since the National Health Service came into operation the old and well-established practice of observing Hospital Sunday as a day when Christian congregations might be kept in touch with the work of hospitals up and down the country has tended to fall into abeyance. There is, however, a growing practice of holding special services at St. Luke's Tide, when local Divisions of the British Medical Association or representatives of the profession in the locality are invited to take part in services either on the Sunday afternoon nearest to St. Luke's Day, on the eve of St. Luke, or at one of the regular morning or evening services, when a medical man is invited to address the congregation.

The Churches' Council of Healing, which comprises representatives from the churches associated with the British Council of Churches, from the British Medical Association, as well as from the Guilds of Healing and a number of medical fellowships, was initiated by Archbishop William Temple to promote greater co-operation between medicine and the Church and to unite informed and convinced Christians in common action in the field of health and healing. From time to time the Council receives invitations from churches to provide medical speakers for special services, and to meet this demand it is setting up a panel of doctors willing to preach the sermon, read the lesson, or otherwise assist in such services. As chairman of the Council I shall be glad to hear from doctors willing to participate in this enterprise, and shall be grateful if any who are interested will communicate with me at the Churches' Council of Healing, 10, Eaton Gate, London, S.W.1.

It is hoped that in the course of the next few years the practice of holding such services in connexion with the work of hospitals and of the medical profession may develop and thereby serve to promote a revival of an excellent custom, and focus interest on the spiritual factor in health and recovery.—I am, etc.,

Bishop's House,
Lichfield, Staffs.

STRETTON LICHFIELD.

him greatly was his election for 1950-1 as master of the Society of Apothecaries, the Society of which he had become a licentiate nearly 40 years earlier. He was president of the Society of Public Analysts in 1936-7. He wrote many authoritative articles in the medical encyclopaedias and journals, but he published no textbook, nor did he yield to what must be a considerable temptation to any man concerned with criminal detection—to write a book of reminiscences. But his enduring work will be his teaching to successive generations of students at St. Mary's, where he was lecturer in forensic medicine for 18 years, and also at Westminster Hospital Medical School, where he was lecturer in forensic medicine and toxicology from 1924 to 1945. For his recreations he turned from the sinister quest after poisons to the innocent fields of horology and photography. Dr. Roche Lynch was a widower and leaves one daughter.

We are indebted to Professor D. M. PRYCE and Dr. E. KAWERAU for the following appreciation: The death of Gerald Roche Lynch deprives legal medicine of an outstanding personality—the last of a great succession at St. Mary's Hospital. It also deprives many of a great friend. Those who worked with him hold him in high regard, not for originality of thought but for his scrupulous care in analysis, ability as a teacher, and his wide range of knowledge. It should not be forgotten that he was an authority on toxicology, forensic medicine, and public health, as well as on chemical pathology. Unfortunately he regarded the use of the routine laboratory for research as an imposition to be resisted, and, with the increasing importance of chemical pathology, this led to stubborn differences and estrangements which are now perhaps best forgotten. Those who can think back will remember a lively personality with likable little oddities whom everyone was pleased to know. Each day he would make a sprightly entrance and stick his carnation in a test-tube. Outside the laboratory he was a gardener, photographer, collector of clocks, and, in his younger days, a keen sailor. But he could not be a passive spectator in anything, and thus it was inevitable that his daily journeys by train from Slough should make him an expert on railways and their history (especially the G.W.R.). He had a good knowledge of wines and was an excellent host in the Savage Club and the Apothecaries' Hall. He was also a good raconteur, and his choice in literature (e.g., Anatole France) was largely determined by its utility in this respect. Curiously his love of music was similarly restricted—to Wagner. In the age of extra specialization we may not often see men of such varied interests, and their passing is to be regretted.

Sir LOUIS KNUTHSEN, K.C.V.O., O.B.E., M.D.

Sir Louis Knuthsen, for many years Physician-in-Ordinary to the Princess Royal, died at his home in London on July 7. He was 86 years of age.

Louis Francis Roebuck Knuthsen was born at Santa Cruz in the West Indies in 1871. Educated at Edinburgh Academy and at Edinburgh University, he graduated M.B., C.M. in 1893 and proceeded to the M.D. in 1901. After graduation he was in general practice for a short time at Truro, in Cornwall, and later at Falmouth, where he became consulting surgeon to the hospital and lecturer on ambulance work under the Cornwall County Council. He was also local secretary of the British Medical Association, in the days before the formation of the present Divisions. In 1901 he moved to Shifnal, in Shropshire, where he remained until he finally settled in London in 1903. During these early years he travelled extensively and attended postgraduate courses at several Continental medical schools.

Knuthsen's early London appointments included those of clinical assistant at the Hospital for Diseases of the Throat, Golden Square, and at the Hospital for Sick Children, Great Ormond Street, and he continued as a lecturer and examiner on ambulance work under the London Council. But he had determined to specialize in dermatology, and in 1904 he was appointed clinical assistant at St. John's Hospital for

Diseases of the Skin. Later he became casualty medical officer to the hospital, and, in 1908, assistant physician. From 1915 onwards, except for the period of his service in the first world war, he was physician to the London Skin Hospital, to which he was appointed consulting physician on his retirement from active practice. During the whole of the war he was officer commanding No. 5 British Red Cross Society's hospital at Wimereux, with the rank of honorary major in the R.A.M.C. He was twice mentioned in dispatches, and in 1919 was appointed O.B.E. In 1924 the President of the French Republic conferred on him the Médaille de la Reconnaissance and the Médaille des Epidémies for his distinguished services during the war.

Knuthsen was appointed C.V.O. in 1934, and in the following year he became Physician-in-Ordinary to the Princess Royal. In 1936 he was promoted K.C.V.O. In 1951 he became an Extra Physician to the Princess Royal. He was a Knight of Grace of the Venerable Order of St. John of Jerusalem and a vice-president of the British Hospitals Association. He was also a warden of the Queen's Chapel of the Savoy.

In 1901 he married Miss Mildred H. Howell. Lady Knuthsen died in 1946. There were no children of the marriage.

I. W. H. MANSFIELD, M.R.C.S., L.R.C.P.

Dr. I. W. H. Mansfield, who was well known in the northern parts of New Zealand, died suddenly on April 15 at the age of 54.

Ivan William Harold Mansfield, who was born in India on August 10, 1902, studied medicine at the Middlesex Hospital, qualifying L.M.S.S.A. in 1930. After holding a number of house appointments he joined the staff of Whipps Cross Hospital in 1932, where he remained for a period of twenty years, a period interrupted only by his service as a captain in the R.A.M.C. during the second world war. He took the London Conjoint diploma in 1946. He had endeared himself to a large number of people in the Leytonstone district, and, although he did not specialize in any particular subject, had considerable ability in many branches of medicine, especially as an anaesthetist. For some years he assisted in the treatment of the staff at Whipps Cross Hospital. In February, 1952, he left England to settle in New Zealand, having received an appointment at Rawene, and at the time of his death was medical superintendent and director of medical services at the Hokianga Hospital and for the Hokianga district. In this capacity he had many opportunities of making contact with the Maori people, whose history and culture he studied, and they appreciated his deep sympathy and profound understanding: in this way he established himself as their particular friend. Dr. Mansfield is survived by his widow, to whom we extend our sympathy.—A. N. J.

D. M. CONNAN, M.D., D.P.H.

Dr. D. M. Connan, who was medical officer of health for Bermondsey for nearly thirty years, died suddenly at Oban on May 16, a few months after he had retired. He was 67 years of age.

A son of the manse, Donald Murray Connan was born in London on January 23, 1890. He attended University College School in London and studied medicine at King's College and also at Westminster Hospital. Qualifying M.R.C.S., L.R.C.P. in 1913, he served in the Navy during the first world war. In 1919 he took the London degrees of M.B., B.S., with honours in forensic medicine and hygiene.

After a short time in general practice in Derby he was appointed in 1920 as medical officer to the tuberculosis clinic in Bermondsey. When that clinic was taken over by the Bermondsey Borough Council in 1921 he became tuberculosis officer and assistant medical officer of health. In 1922 he took the D.P.H., and in 1928 was appointed medical officer of health for Bermondsey. He took up this post with

great zeal and the determination to improve living standards and to encourage the people to take a pride in the public health services which were provided. His interest in people made him deeply concerned with health education, and he was convinced that there was a great need for propaganda to educate the public in health and hygiene. In this field he did some brilliant pioneer work. Few suitable films on health subjects were available at that time, and he began his educational campaign by making films to illustrate the important aspects of health and hygiene. Lectures were given from a van at street corners and many talks were given to children in the schools. He later published a book on health propaganda. He also wrote a history of public health in Bermondsey and used this subject as a thesis for the M.D., which he obtained in 1935.

Soon after his appointment as M.O.H. the public health services were completely reorganized, and during the years which followed people came from all over the country to see the borough where so much pioneer work had been done and so much success achieved. In 1937 one of the first health centres in the country was opened in Bermondsey. Specialist clinics and pathological and x-ray facilities were provided for general practitioners, and the patients were all seen by appointment, thus avoiding long hours of waiting in hospital out-patient departments. During the war years, when Bermondsey was one of the most bombed areas in the country, Dr. Connan stayed in the borough day and night. Although his health was not good at that time, he did not spare himself and was always available to give help and guidance in the many difficult situations which arose.

With his retirement Bermondsey lost a vivid and colourful personality. He was a well-known figure in the streets, and was always ready to see and to help anyone who had a problem. A man of high purpose and of the utmost integrity, he was humble and unassuming and always gave credit to others rather than to himself for the work done. His many acts of kindness were done quietly and often anonymously. His death so soon after his retirement has saddened his many friends in Bermondsey, but his influence will be felt for many years to come. Bermondsey is a very different place to-day from the Bermondsey of thirty years ago, and much of the improvement can be attributed to the energy and enthusiasm which he devoted to it. He leaves a widow and two daughters, Dr. Jean Landsborough and Dr. Elizabeth Connan.—F. L. T.

W. B. P. writes: It was mainly through Dr. Connan's efforts that in the twenties Bermondsey led the country in public health matters. Posters, propaganda vans, and health exhibitions brought the elements of hygiene to the multitudes. Straight as a die, trustworthy, a loyal friend, he was admired and respected by all sorts of people in Bermondsey. Outspoken, he never shrank from defending what he believed was right, inside or out of council, at whatever cost to himself. His relations with his fellow practitioners were of the happiest nature. His death was a great shock to his friends and fellow workers, who only a few months ago gathered around him and his wife in his beloved health centre to pay parting tribute and wish him God-speed. His usual quizzical humour enlivened his farewell speech. He had scarcely reached his native Scotland, where he had hoped to spend his retirement, when the end came suddenly, but not as a surprise, for he had bravely struggled against ill-health for some time.

B. G. M. writes: The sudden death of Dr. Connan has brought a sense of loss to his many friends in the Bermondsey neighbourhood. Others more qualified than I am have written of his part over many years in organizing the medical services which have made the borough of Bermondsey second to none. To those of us who worked in the medical missions and settlements in the area he showed great kindness and a willingness to assist at any time with his wise advice in many matters. For many years he served on the committee of the Bermondsey Medical Mission, and until his health made the journey from Wimbledon impossible he helped us at the Sunday services, where his sincere

faith encouraged all who worshipped there. For about twenty years he was a superintendent of the London City Mission, and many missionaries benefited by his advice and encouragement in their work in visiting in the neighbourhood. His favourite text when preaching, "What doth the Lord require of thee, but to do justly, and to love mercy, and to walk humbly with thy God," forms a fitting epitaph to his life of service.

I. H. BEATTIE, L.M.S.S.A.

Dr. I. H. Beattie, who had made his home in Fiji for over 30 years, died at Levuka, Fiji, on June 8 at the age of 71.

Ivor Hamilton Beattie was born on November 23, 1885, at Edinburgh, where his father, an architect, designed the North British Station Hotel and other buildings in the city. From Rugby School he entered Corpus Christi College, Oxford, as a scholar and took first-class honours in the physics finals. For a time he worked as an assistant demonstrator in the Clarendon Laboratory, and then took the physiology finals in 1908. At that time he was interested in experimental psychology and worked with Dr. W. McDougall, chiefly on hypnotism and teleesthesia. In 1911 he turned to archaeology, joining the staff of Liverpool University and assisting at excavations in Syria and the Sudan. He volunteered for the Royal Navy in 1914 and was told he should qualify as a doctor. He therefore went to St. George's Hospital as a medical student, and qualified L.M.S.S.A. in 1916. After holding the post of house-physician at St. George's he joined the Navy as a surgeon lieutenant, serving first as an anaesthetist at the Royal Naval Hospital at Plymouth. In 1917 he went to sea and was relieved of medical duties for a time so that he could serve as a wireless officer. He was mentioned in dispatches.

After the war he returned to St. George's as resident obstetric assistant and then resident anaesthetist. Deciding to specialize in anaesthetics, he was appointed anaesthetist at the Royal Northern Hospital. However, he did not stay in England long, for in 1924 he went out to Fiji, and was in general practice at Suva until 1937. At Suva he was lecturer in anaesthetics at the medical school and physician to out-patients at the War Memorial Hospital. He was also a district surgeon to the St. John Ambulance Brigade, and was appointed an Officer of the Order of St. John in 1946. He became a member of the Fiji Branch Council of the B.M.A. in 1935, was president of the Branch in 1938-9, and honorary secretary during the war years. Apart from his medical work he took an active part in the life of the British community in Suva: he was a municipal councillor for some years; he edited a vernacular monthly journal in Hindi and English; and he was secretary of the cathedral chapter.

GRACE H. STEWART BILLINGS, M.B.

Dr. Grace Stewart Billings, who practised at Cheltenham for many years, died there on June 13 at the age of 84.

Grace Harwood Stewart was trained in medicine at the Royal Free Hospital and at Newcastle upon Tyne, graduating M.B., B.S. from Durham University in 1898. After her marriage in the following year to Mr. F. W. Billings, she set up in practice at Cheltenham, where she continued in active work until her retirement in 1936. Besides general practice, Dr. Stewart Billings did part-time medical inspections at various schools for a number of years, lectured to members of the St. John Ambulance Brigade, and was for a time lady superintendent of the Cheltenham nursing division. She was one of the first medical officers of the Cheltenham Infant Welfare Association and held a clinic from 1917 until her retirement. She pioneered in family planning, and saw at her surgery women who needed contraceptive advice for medical reasons and who were sent to her from the infant welfare clinics. From small beginnings this developed into

¹With honours. ²Distinguished in pathology. ³Distinguished in medicine. ⁴Distinguished in applied pharmacology and therapeutics. ⁵Distinguished in surgery. ⁶Distinguished in obstetrics and gynaecology.

The following candidates at the University College of the West Indies have been approved at the examination indicated: THURD M.B., B.S.—A. St. J. P. Jones, S. E. H. Brooks, G. S. McLeod.

The following degrees were awarded by the Senate on May 22: M.D.—Eunice Lockey, J. Newsome. M.S.—K. Owen.

Dr. A. P. Waterson has been elected into an official Fellowship of Emmanuel College, with tenure from October 1, 1957, on appointment as an Assistant Tutor and as Director of Studies in Medicine.

UNIVERSITY OF BIRMINGHAM

Professor A. P. Thomson's term of office as Dean of the Faculty of Medicine has been extended to September 30, 1959. He will then be succeeded by Mr. A. L. d'Abreu, part-time Reader in Thoracic Surgery and consultant surgeon to the United Birmingham Hospitals. Professor Thomson's tenure of the Chair of Therapeutics has also been extended to September 30, 1959.

The following have been given the title of University Clinical Lecturer in the subjects indicated in parentheses: Dr. H. Roberts (Obstetrics and Gynaecology); Drs. Ann A. Guest, J. M. Inglis, R. E. Lee, and W. L. Price (Anaesthetics); Drs. P. Jacobs and C. P. Moxon (Radiology); and Dr. A. H. Cameron (Pathology).

The title of University Research Fellow has been given to Dr. S. C. Shrivastava during the tenure of his present appointment in the Department of Experimental Psychiatry.

Dr. E. A. Brown resigned his appointment as Lecturer in Physiology on April 30, 1957.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on June 13 with Sir Harry Platt, President, in the chair, the Hallett Prize was awarded to Dr. R. Y. Calne, of Guy's Hospital Medical School.

The Council agreed to submit evidence to a committee of the Central Health Services Council on the arrangements made in hospitals for the welfare of ill children—as distinct from their medical and nursing treatment—and to make suggestions which could be passed on to hospital authorities.

A report from the Museum and Research Committee disclosed the need for skeletons and individual human bones for museum and examination use.

A Diploma of Membership was granted to M. B. Rees-Jones.

Vital Statistics

Smallpox in England

The outbreak of smallpox at Tottenham, London, which resulted in three confirmed cases including one death, is believed to have been started by a Wembley business man who returned from Lagos, Nigeria, on March 29. He fell ill early in April with a disease believed in retrospect to have been smallpox, and at a time when he could have been infectious was visited by his half-brother. The half-brother was taken ill and died of a disease diagnosed as leukaemia, but now thought to have been smallpox. His body was taken to the Prince of Wales Hospital, Tottenham, for necropsy, and a hospital cleaner there, a woman aged 61, fell ill on June 8. On June 23 her 6-year-old grandson, who was unvaccinated, became ill, and on June 27 he was diagnosed as having smallpox.¹ He died of it on July 5. Meanwhile the boy's aunt had contracted the disease, and at the time of going to press was the only remaining confirmed case, the grandmother having recovered.

A suspected case of smallpox in a woman aged 76 was also reported from Walthamstow, London. She died on July 5 of a disease diagnosed by experienced clinicians as haemorrhagic smallpox, but laboratory tests have proved negative. No route of infection is known for certain connecting this case with those at Tottenham. A 2-year-old girl from Oldham, Lancs, was also under observation at Bury, but at the time of going to press was thought not to be a case of smallpox.

Distribution of Poliomyelitis

The Table below shows the districts with populations of 15,000 or more in which the notification rate per 100,000 in the year to date exceeds 30:

District	Incidence per 100,000 of Population	Total Cases in 26 Weeks	
		Paralytic	Non-paralytic
Barnet U.D. (Herts)	66.33	14	3
Colchester M.B. (Essex)	72.72	26	19
Tendring R.D. (Essex)	52.91	3	10
Harpenden U.D. (Herts)	38.37	3	3
Stevenage U.D. (Herts)	49.91	4	7
St. Thomas R.D. (Devon)	42.28	5	32
Brighton C.B. (Sussex)	31.51	18	12
Maidstone M.B. (Kent)	30.63	5	9
Redditch U.D. (Worcs)	35.04	8	3

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in May was 95, compared with 141 (revised figure) in the previous month and 115 (revised figure) in May, 1956.

The numbers of cases of industrial diseases in the United Kingdom reported during May, 1957, were as follows: lead poisoning 10, mercurial poisoning 6, aniline poisoning 3, epitheliomatous ulceration 18, chrome ulceration 20; total 57. There were no deaths.—*Ministry of Labour Gazette*, June, 1957.

Eire in First Quarter

The birth rate for the March quarter of 1957 was 20.4 per 1,000 population and the rate was 1.1 above the rate for the preceding first quarter. The infant mortality rate was 38 per 1,000 registered births and was 7 below the rate for the March quarter of 1956. The death rate was 13.4 per 1,000 population and was the lowest rate for recent first quarters, being 0.9 below the rate for 1956.

Deaths from tuberculosis included 155 from respiratory tuberculosis and 33 from other forms of tuberculosis; these were 12 and 5, respectively, fewer than in the preceding first quarter. Deaths from infectious diseases included 85 from

¹ *British Medical Journal*, July 6, p. 51.

influenza, 26 from gastro-enteritis (under 2 years), 9 from measles, 9 from whooping-cough, 6 from acute poliomyelitis, and 3 from diphtheria. Deaths attributed to cancer numbered 1,240 and were 54 more than in the first quarter of 1956. 584, or 47%, of these deaths were due to malignant neoplasms of the digestive system.

Infant Death Rates

Of towns in England and Wales with a population over 200,000, Manchester had the highest infant mortality rate in 1956 with 30.0 deaths per 1,000 related live births. Kingston-upon-Hull was next, with 29.0, and then Bradford with 28.4. The large town with the lowest rate was Plymouth, with 17.7, which was followed by Croydon, with 18.7, and Bristol, with 19.4. In 1954 Cardiff had held the highest place, with a rate of 34.0; in 1956 the rate fell to 27.9.—*Registrar-General's Quarterly Return for England and Wales*, first quarter, 1957.

Week Ending June 29

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 436, whooping-cough 1,554, diphtheria 4, measles 17,417, acute pneumonia 252, acute poliomyelitis 119, dysentery 464, paratyphoid fever 2, typhoid fever 3.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1948-56 (influenza, 1952-6) are shown thus — — — — —, the figures for 1957 thus —. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest increases in the number of notifications of infectious diseases in England and Wales during the week ending June 22 were 351 for measles, from 21,793 to 22,144, 221 for whooping-cough, from 1,371 to 1,592, 100 for food-poisoning, from 125 to 225, and 32 for dysentery, from 457 to 489, and the only large fall was 190 for scarlet fever, from 547 to 357.

105 cases of acute poliomyelitis were notified, and these were 20 more for paralytic and 2 more for non-paralytic cases than in the preceding week. The largest returns were Essex 13 (Chigwell U.D. 3, Harlow U.D. 3), Lancashire 9 (Liverpool C.B. 4, St. Helens C.B. 2), Devonshire 8 (Bristol C.B. 4), London 7, Hertfordshire 7 (Welwyn Garden City U.D. 4), Lincolnshire 7 (Lincoln C.B. 2, Scunthorpe M.B. 2), Glamorganshire 7 (Barry M.B. 2, Rhondda M.B. 2).

In 7 counties the number of notifications of measles rose by 100 or more and in 5 counties the number fell by 100 or more. Areas with a large increase in incidence included Nuneaton M.B. 163, from 80 to 243, Huddersfield C.B. 162, from 135 to 297; Castleford M.B. 74, from 44 to 118; Sheffield C.B. 65, from 738 to 803; Plymouth C.B. 87, from 180 to 267; Mifflord and Launditch R.D. 58, from 52 to 110; Bristol C.B. 142, from 376 to 518; Kidderminster M.B. 69, from 17 to 86; Redditch U.D. 42, from 99 to 141; Leicester C.B. 45, from 88 to 133. The largest falls in the incidence of scarlet fever were 35 in Yorkshire West Riding, from 66 to 31, and 30 in Lancashire, from 66 to 36. The only large rise in the number of notifications of whooping-cough was 65 in Yorkshire West Riding, from 66 to 122. 4 cases of diphtheria were notified, being 4 fewer than in the preceding week; 3 of the 4 cases were notified in Birmingham C.B.

The largest centres of dysentery were Lancashire 113 (Liverpool C.B. 20, Swinton and Pendlebury M.B. 19, Denton U.D. 10), Yorkshire West Riding 62 (Leeds C.B. 25), London 38 (Islington 12), Surrey 34 (Croydon C.B. 32), Warwickshire 29 (Birmingham C.B. 16), Durham 29, Northumberland 29, and Cheshire 21.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending June 22 (No. 25) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
§ Includes puerperal pyrexia.

Medical News

Alternative Edition of "British National Formulary."—The *British National Formulary*, 1957, which comes into operation on October 1, is due to appear on August 1. But in addition, as a new venture, an "alternative edition" is also being published. This will group the medicaments listed in the main edition by their pharmacological actions instead of alphabetically under descriptive headings such as mixtures and tablets. In the alternative edition the "Notes for Prescribers" has been expanded and a separate note will appear at the head of each group of preparations; the titles of preparations will be the English subtitles used in the main edition instead of the Latin ones; and wherever possible the approximate metric equivalents of imperial doses will be used. The alternative edition, which will cost a little more than the main edition (7s. 6d. as against 6s. 6d., or 10s. 6d. as against 10s. for interleaved copies), is not being purchased by the Ministry of Health for distribution to general practitioners and hospitals, but is being published by the B.M.A. and the Pharmaceutical Society for private sale. Copies are expected to be available about the middle of September. The change in name of the formulary from simply *National Formulary* to *British National Formulary* is to avoid confusion with the *National Formulary, U.S.A.*, a book of pharmacopoeial standards.

Naval Diving Vessel at B.M.A. Meeting.—H.M.S. *Reclaim*, the naval diving vessel, will be visiting Newcastle upon Tyne from July 13 to 17 as part of the Royal Naval Physiological Laboratory's demonstration for the Scientific Exhibition. Visitors will be welcome on board on the mornings of Monday, Tuesday, and Wednesday (July 15-17), when modern diving techniques will be demonstrated. Further details, and boarding permits, will be available at the Laboratory's stand at the Scientific Exhibition.

"Emergencies in General Practice."—A new Refresher Course volume, *Emergencies in General Practice*, is now available. It contains 57 selected articles from the invited series under this title which appeared in the *British Medical Journal* during 1955 and 1956. Each article has been specially revised by its author, and the articles are grouped in the book under the following broad subject headings: Haemorrhage and thrombosis; cardio-respiratory crises; anaesthesia and hazards of therapy; acute abdominal cases; obstetrics; fits and coma; electrocution, burns, and gassing; poisoning; acute psychiatric states; special and minor surgery. Copies of *Emergencies in General Practice* (price 25s.; postage 1s. 6d. inland, 1s. overseas) may be obtained from the publishing manager, B.M.A. House, Tavistock Square, London, W.C.1; from booksellers; or, during the remainder of the Association's annual meeting at Newcastle upon Tyne, from Stand No. 12 at the trade exhibition in the Stephenson Building, King's College. Other books in the same series also available include volumes 2 and 3 of *Refresher Course for General Practitioners* (price each, including postage, 26s. 6d. inland, 26s. overseas), and *Clinical Pathology in General Practice* (price, including postage, 22s. 3d. inland, 21s. 9d. overseas).

Ciba Foundation.—The Ciba Foundation for the Promotion of International Co-operation in Medical Research has recently issued its report for 1956. During the year nearly 900 scientists from thirty-one countries were accommodated at the Foundation's House, 41, Portland Place, London, W.1. Five international conferences were held, four meetings to discuss clinical problems, and six sessions of scientific films, and the proceedings of seven conferences in the international series were published in book form. The five international conferences last year dealt respectively with the influence of ionizing radiations on cell metabolism, the biophysics and biochemistry of viruses, the chemistry and biology of purines, the regulation and mode of action of thyroid hormones, and the methodology of the study of ageing. At

each conference the audience was invited, international in character, and limited to a maximum of 30 people. The Foundation also undertook a special programme to encourage research in relation to ageing, and in this connexion made twelve awards for research reports in this field; a section on gerontology was also added to the library, which otherwise specializes in endocrinology. Under the exchange scheme with the Institut National d'Hygiène, Paris, seven British medical graduates visited France, and six French graduates came to Britain. Sir RAYMOND NEEDHAM, Q.C., became chairman of the Foundation's executive council in succession to the late Lord Horder, and Sir RUSSELL BRAIN became a trustee. The other trustees are Lord ADRIAN, O.M., F.R.S., Lord BEVERIDGE, the hon. Sir GEORGE LLOYD-JACOB, and Sir RAYMOND NEEDHAM.

R.C.S.: Election to Council.—After a postal ballot in which 2,379 fellows returned valid papers, the following were elected to the council of the Royal College of Surgeons on July 4: Mr. A. DICKSON WRIGHT, St. Mary's Hospital, Paddington (1,179 votes, re-elected); Sir STANFORD CADE, Westminster Hospital (1,144 votes, re-elected); Professor F. A. R. STAMMERS, Birmingham United Hospitals (1,056 votes, elected); Professor D. CHAMBERLAIN, General Infirmary, Leeds (947 votes, re-elected); and Mr. T. HOLMES SELLORS, Middlesex Hospital (860 votes, elected). Those unsuccessful in the ballot, in vote order, were Mr. R. H. Maingot (830), Mr. J. C. Barrett (714), Mr. N. L. Capener (689), Mr. F. W. Holdsworth (585), Mr. D. W. C. Northfield (563), Mr. S. H. Wass (522), Mr. R. Marnham (416), Mr. A. J. Gardham (415), and Mr. R. W. Raven (413). The number voting represented a little over half the total electorate (about 4,700).

British Association of Urological Surgeons.—The 13th annual meeting was held in London from June 27 to 29, under the presidency of Mr. R. H. O. B. ROBINSON. The meeting was attended by about 160 members. There was a full scientific programme, the main discussion being on "Hypertension as a Urological Problem." The papers will be published in the *British Journal of Urology*. The following were elected officers and members of council for 1957-8: President, Mr. Arthur Jacobs; immediate past president, Mr. R. H. O. B. Robinson; vice-president, Mr. Hugh Donovan; hon. treasurer, Professor Victor W. Dix; hon. secretary, Mr. J. D. Fergusson; hon. editorial secretary, Mr. David Band; members of council, Mr. F. R. Kilpatrick, Mr. W. S. Mack, Mr. T. J. Millin, Mr. T. W. Mimpriss, Mr. R. A. Mogg, Mr. D. S. Poole-Wilson, Mr. E. W. Riches, and Mr. J. Swinney.

Second World Congress of Anaesthesiologists.—The dates of the second World Congress of Anaesthesiologists in Toronto in 1960 have now been finally fixed for September 4-10. The congress is sponsored by the World Federation of Societies of Anaesthesiologists, and inquiries about it should be made to Dr. R. A. GORDON, chairman of the organizing committee, 516, Medical Arts Building, Toronto, 5, Ontario.

British Empire Cancer Campaign.—The Campaign's annual meeting was held at St. James's Palace on July 11, under the presidency of the DUKE OF GLOUCESTER. Professor D. W. SMITHERS proposed the adoption of the annual report and balance sheet (see p. 97), Sir CHARLES LIDBURY seconding. The following honorary officers were re-elected on the proposal of Sir SAMUEL BEDSON, F.R.S.: Chairman of grand council, the DUKE OF DEVONSHIRE; vice-chairmen of grand council, Lord NATHAN and Sir CHARLES DODDS, F.R.S.; hon. secretary, Professor R. W. SCARFF; hon. treasurer, Sir CHARLES LIDBURY; and hon. secretary of the scientific advisory committee, Professor T. CRAWFORD.

Royal Society of Health.—New members recently elected to the Society's council include Sir JOHN CHARLES, Chief Medical Officer, Ministry of Health; Professor F. GRUNDY, professor of preventive medicine, Welsh National School of Medicine, Cardiff; and Dr. J. V. WALKER, M.O.H. of Darlington.

Honorary Degrees Conferred.—On June 26 Oxford University conferred the honorary degree of Doctor of Letters on Professor JOHN FULTON, of Yale; on July 4 Dublin University conferred the honorary degree of Doctor of Medicine on Professor J. H. BIGGART, dean of the faculty of Medicine, Queen's University, Belfast; on July 5 Aberdeen University conferred the honorary degree of Doctor of Laws on Professor A. W. DOWNIE, F.R.S., professor of bacteriology at Liverpool; on July 5 Edinburgh University conferred the honorary degree of Doctor of Laws on Sir HOWARD FLOREY, F.R.S., professor of pathology at Oxford; and on July 6 Durham University conferred the honorary degree of Doctor of Civil Law on Sir JOHN STOPFORD, F.R.S., formerly vice-chancellor of Manchester University.

Sheffield University.—The title of reader in child health has been conferred on Dr. J. LORBER, the present senior lecturer in child health. Dr. Lorber is also a consultant paediatrician at the Children's Hospital, Sheffield. Dr. D. VEREL, first assistant at the medical professorial unit at the London Hospital, has been appointed senior lecturer in medicine. Dr. Verel graduated in medicine at Cambridge in 1943, later obtaining the M.D. and M.R.C.P. He has been a Beit memorial research fellow, a Raymond Horton-Smith prizeman, and a Copeman medallist for medical research. Dr. J. D. ACLAND has been appointed lecturer in pharmacology and Dr. A. BRADLEY lecturer in forensic medicine. Dr. Bradley has graduated in both law and medicine.

Birmingham University.—Dr. P. C. HARRIS, formerly a Nuffield medical fellow at Bellevue Hospital, New York, has been appointed lecturer in medicine from July 1. Dr. Harris graduated in medicine from King's College Hospital, London, in 1946, later obtaining the M.R.C.P. and proceeding M.D., with university medal, and Ph.D. (London). Dr. K. BROWN-GRANT has been appointed lecturer in physiology from August 1. He graduated in medicine at Cambridge in 1951, later proceeding M.D.

St. Andrews University.—Dr. E. W. WALTON, demonstrator in pathology at King's College, Durham, has been appointed lecturer in pathology at Queen's College, Dundee. He graduated in medicine at Durham University in 1949, later proceeding M.D.

COMING EVENTS

British National Conference on Social Work.—Edinburgh, August 11-14, under the chairmanship of Professor ALAN MONCRIEFF. Details from the National Council of Social Service, 26, Bedford Square, London, W.C.1.

Central Council for Health Education.—Summer school will be held at Reichell Hall, University of North Wales, Bangor, August 20-30. The subject will be "The Promotion of Health." Details from the medical director of the council, Tavistock House North, Tavistock Square, London, W.C.1.

Medical Association of South Africa.—The Scientific meeting and congress will be held in Durban, September 16-21. There will be plenary sessions on "Parasitic Diseases of Man in Africa" and "The Surgery of Repair." Details from the organizing secretaries, 112, Medical Centre, Field Street, Durban.

"Influence of Living and Working Conditions on Health."—International conference, arranged by the World Congress of Doctors for the Study of Present-day living Conditions, September 27-29, Cannes, France. Official languages: English, French, German, Russian, and Spanish. Details from the organizing secretary, 1, rue Le Nôtre, Paris 16.

Asian Paediatric Congress.—The first Asian regional paediatric congress will be held in Singapore from May 26 to 30, 1958. Doctors from the following regions are invited: Indian sub-continent, Far East, South-east Asia, and Australasia. Details from the organizing secretary, paediatric unit, General Hospital, Singapore, 3.

NEW ISSUES

Journal of Neurology, Neurosurgery and Psychiatry.—The new issue (Vol. 20, No. 2) is now available. The contents include:

THE ENTRY OF RADIOSODIUM AND OF BROMIDE INTO HUMAN CEREBROSPINAL FLUID. R. B. Bourdillon, M. Fischer-Williams, Honor V. Smith, and K. B. Taylor.
PROGRESSIVE FAMILIAL CHOREOATHETOSIS WITH CUTANEOUS TELANGIECTASIA. Charles E. Wells and G. Milton Shy.
THE OCCURRENCE OF EPILEPTIC FITS IN LEUCOTOMIZED PATIENTS RECEIVING CHLORPROMAZINE THERAPY. D. W. Liddell and N. Retterstöl.
THE EFFECT OF INSULIN COMA AND E.C.T. ON THE THREE-YEAR PROGNOSIS OF SCHIZOPHRENIA. D. M. Lieberman, J. Hocnig, and I. Auerbach.
THE URINARY EXCRETION OF HISTAMINE IN SCHIZOPHRENIA. J. Adam and R. G. Mitchell.
INFANTILE CEREBRAL GLIOSIS WITH GIANT NERVE CELLS. L. Crome.
A CONTRIBUTION TO THE DIAGNOSIS OF TUBEROUS SCLEROSIS. V. L. Hudolin and F. Petrovich.
SUBDURAL HAEMATOMA IN AN ADULT AFTER AIR ENCEPHALOGRAPHY. R. G. Robinson.
A CASE OF BRAIN GUMMA. M. Bianchi and C. Frera.
IRREGULARITIES IN THE CONTOUR OF THE ANTERIOR PART OF THE LATERAL VENTRICLE AS SHOWN IN AIR ENCEPHALOGRAMS. V. L. Hudolin and F. Petrovich.
DISORDERS OF OCULOMOTOR FUNCTION IN LESIONS OF THE OCCIPITAL LOBE. Morris B. Bender, Donald M. Postel, and Howard P. Krieger.
"THE LIMP CHILD." John N. Walton.
BOOK REVIEWS.

Issued quarterly; annual subscription, £2 2s.; single copy, 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Preventive and Social Medicine.—The new issue (Vol. 11, No. 2) is now available. The contents include:

THE STATURE AND WEIGHT OF MEN FROM ENGLAND AND WALES IN 1941. E. M. B. Clements and Kathleen G. Pickett.
RANDOM SELECTION IN THE THERAPEUTIC TRIAL. R. F. Wrighton.
A NOTE ON THE PRACTICAL INTERPRETATION OF 2x2 TABLES. J. H. Edwards.
A CRITICAL EXAMINATION OF THE REPUTED PRIMARY INFLUENCE OF ABO PHENOTYPE ON FERTILITY AND SEX RATIO. J. H. Edwards.
RECENT TRENDS OF MORTALITY FROM VIOLENCE. W. J. Martin.
AN EXAMINATION OF FERTILITY OF WOMEN FOLLOWING PREGNANCY ACCORDING TO HEIGHT AND WEIGHT. Thomas McKewen and R. G. Record.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Pharmacology and Chemotherapy.—The new issue (Vol. 12, No. 2) is now available. The contents include:

THE ACTIVITY OF DIFFERENT STEROIDS IN PRODUCING THYMIC INVOLUTION. Jennifer Shewell.
EFFECT OF CHAIN LENGTH OF ALIPHATIC AMINES ON HISTAMINE POTENTIATION AND RELEASE. J. L. Monrar.
A COMPARATIVE STUDY OF KININ, KALLIDIN, AND BRADYKININ. D. J. Holdstock, A. P. Mathias, and M. Schachter.
THE RELATIONSHIP BETWEEN INHIBITION OF PHOSPHOFRUCTOKINASE ACTIVITY AND THE MODE OF ACTION OF TRIVALENT ORGANIC ANTIMONYALS ON SCHISTOSOMA MANSONI. E. Bueding and Joan M. Mansour.
HYPOTHALAMO-NEUROHYPOPHYSIAL INVOLVEMENT IN THE CORTICOTROPHIC ACTION OF ACETYLCHOLINE. S. Casentini, A. De Poli, and L. Martini.
ANTIMALARIAL ACTIVITY OF HYDROXY-SUBSTITUTED NAPHTHALENE COMPOUNDS. W. M. Duffin and I. M. Rollo.
THE PHARMACOLOGICAL ACTIONS OF MUREXINE (UROCANYLCHOLINE). V. Erspamer and A. Glässer.
THE TREATMENT OF EXPERIMENTAL TOXOPLASMOSES IN RABBITS. J. K. A. Beverley and B. A. Fry.
SULPHADIMIDINE, PYRIMETHAMINE, AND DAPSONE IN THE TREATMENT OF TOXOPLASMOSES IN MICE. J. K. A. Beverley and B. A. Fry.
OXYTOXIC ACTIVITY OF BASIC (AMINOMETHYL) DERIVATIVES OF PHENOLS AND RELATED COMPOUNDS. A. Cohen, R. A. Hall, B. Heath-Brown, M. W. Parkes, and A. H. Rees.
SOME PHARMACOLOGICAL ACTIONS OF FOUR SYNTHETIC ANALOGUES OF OXYTOCIN. B. Berde, W. Doeppner, and H. Konzett.
VENTRICULAR FIBRILLATION IN THE ISOLATED RABBIT HEART. A. K. Armitage, J. H. Burt, and A. J. Gunning.
LEAD IONS AND SYNAPTIC TRANSMISSION IN THE SUPERIOR CERVICAL GANGLION OF THE CAT. Krista Kostial and V. B. Vouk.
OXYTOXIC POLYPEPTIDES IN HUMAN URINE. E. J. Walaszek.
ANTICONSULVANT COMPOUNDS AND 5-HYDROXYTRYPTAMINE IN RAT BRAIN. D. D. Bonnycastle, N. J. Giarman, and M. K. Paasonen.
THE ACTION OF EROOTAMINE ON THE INTRACRANIAL VENOUS PRESSURE AND ON THE CEREBRAL VENOUS OUTFLOW OF THE DOG. A. Carpi and M. Virno.
THE EFFECT OF CORTISONE ON THE MULTIPLICATION OF M. TUBERCULOSIS IN NORMAL AND IMMUNE MICE. J. M. Robson and F. M. Sullivan.
THE RELATION BETWEEN SEDATION AND BODY TEMPERATURE IN THE MOUSE. A. W. Lessin and M. W. Parkes.
PROLONGATION OF CHLORAL HYDRATE SLEEPING TIME BY 5-HYDROXYTRYPTAMINE AND BY CERTAIN OTHER DRUGS. F. N. Fastier, R. N. Speden, and Hendricka Waal.
THE EFFECT OF PHENYLBUTAZONE UPON DIHYDROTACHYSTEROL OVERDOSEAGE IN THE RAT. H. Selye.
THE INTERACTION BETWEEN EDROPHONIUM (TENSILON) AND ACETYLCHOLINE AT THE MOTOR END-PLATE. B. Katz and S. Thesleff.

Issued quarterly; annual subscription £4 4s.; single copy 25s.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked *. Application should be made first to the institution concerned.

Tuesday, July 16

*CHARTERHOUSE RHEUMATISM CLINIC.—6 p.m., Gilbert Scott Memorial Lecture by Mr. W. Alexander Law: Role of Surgery in the Treatment of the Rheumatic Diseases.
SOUTH-WEST LONDON MEDICAL SOCIETY.—At Bolingbroke Hospital, Wandsworth Common, S.W., 8.30 p.m., annual general meeting.

Wednesday, July 17

INSTITUTE OF NEUROLOGY.—5.30 p.m., Dr. M. B. Bender (New York): Oculomotor System Based on Experimental Studies in Monkeys.
ROYAL SOCIETY OF HEALTH.—At 90, Buckingham Palace Road, S.W., 6 p.m., symposium: Development of Integrated Schemes of Training for Nursing and Health Visiting. Papers by Miss P. E. O'Connell, S.R.N., and Miss Augusta Black, S.R.N., S.C.M.

Thursday, July 18

INSTITUTE OF NEUROLOGY.—5.30 p.m., Professor H. W. Magoun (Los Angeles): The Waking Brain.

Friday, July 19

BIOCHEMICAL SOCIETY.—At Washington Singer Laboratories, Exeter University, 11.15 a.m., 364th meeting.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. G. Scadding: clinical demonstration.
INSTITUTE OF NEUROLOGY.—5.30 p.m., Dr. H. G. Wolff (New York): Headache Mechanisms.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—4 p.m., Charles Tomes Lecture by Professor A. E. W. Miles: Sebaceous Glands in the Lip and Cheek Mucosa in Man.

APPOINTMENTS

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, London, W.C.—J. E. S. Scott, F.R.C.S., Surgical Registrar; S. K. Guha, M.B., B.S., Resident Registrar to Ear, Nose, and Throat Department; D. C. Gardner, M.B., B.S., House-surgeon to Orthopaedic and Plastic Departments; E. P. Wilson, M.B., B.S., D.C.H., Katharine R. Garrett, M.B., B.S., and M. H. Lees, M.B., B.S., M.R.C.P., House-physicians; E. Aberdeen, M.B., B.S., F.R.C.S., D.C.H., Senior Surgical Registrar to Thoracic Unit; Mavis Buck, M.B., B.S., D.A., Junior Resident Anaesthetist; W. J. Glover, M.B., B.Ch., F.F.A.R.C.S., D.Obst.R.C.O.G., Resident Anaesthetic Registrar; E. I. Kohorn, M.B., B.Chir., D.Obst.R.C.O.G., and A. G. Da S. Martins, L.Med. e Cir. (Lisbon), House-surgeons.
MANCHESTER REGIONAL HOSPITAL BOARD.—H. B. Marsden, M.B., Ch.B., D.C.H., D.Path., Whole-time Consultant Pathologist to Royal Manchester Children's Hospital, Pendlebury; S. Panikkar, M.B., Ch.B., F.R.C.S., D.L.O., Consultant Ear, Nose, and Throat Surgeon, Blackburn and District Hospital Centre; D. W. Dawson, M.B., Ch.B., M.R.C.P.Ed., Whole-time Consultant Pathologist, North Manchester Group of Hospitals; D. Macaulay, M.D., M.R.C.P., D.C.H., Consultant Paediatrician, South Manchester Hospitals; D. B. Murray, L.R.C.P.&S.Ed., D.A., Whole-time Assistant Anaesthetist (S.H.M.O.), Blackburn and District Hospitals; D. J. Ryan, M.B., B.Ch., D.A., Whole-time Assistant Anaesthetist (S.H.M.O.), Wigan and Leigh and Warrington Hospital Centres; J. Cowen, M.B., Ch.B., D.M.R.D., Maximum Part-time Consultant Radiologist, North Manchester and Booth Hall and Monsall Groups of Hospitals, tenable mainly at Manchester Victoria Memorial Jewish Hospital and Crumpsall Hospital; Z. S. Lech-Lachowicz, Med.Dip.(Lwow), D.M.R.D., Whole-time Consultant Radiologist, South Manchester Group of Hospitals, tenable mainly at Withington Hospital; R. L. McCorry, M.B., B.Ch., M.R.C.P.I., Whole-time Assistant Pathologist, Preston and Chorley Hospitals.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Thomas.—On June 16, 1957, at Cardiff Maternity Hospital, to Anne (formerly Tighe), M.B., B.Ch., wife of Lewis P. Thomas, F.R.C.S., a son.

MARRIAGES

Priddle—Davies.—On June 14, 1957, Glyn Priddle, M.B., B.S., of 49, Highdown Road, Hove, Sussex, to Diane Mary Davies, of 41, Abbotsford Gardens, Woodford Green, Essex.

DEATHS

Duguid.—On June 27, 1957, at 2, Castle View Road, Strood Kent, Nigel Duguid, M.B., Ch.B., aged 56.
Duncan.—On July 1, 1957, in a nursing-home, Edinburgh, John Adamson Honey Duncan, M.D., F.R.C.S.Ed., of 4, Cluny Drive, Edinburgh.
Edmondson.—On June 25, 1957, at Cringleford, Norfolk, Charles Reginald Edmondson, M.B., C.M., late of Scarborough, Yorks, aged 89.
Harbord.—On June 28, 1957, in London, the result of an accident, Katharine May Harbord, M.R.C.S., L.R.C.P., of Englefield Green, Surrey, formerly of India, aged 67.
Killingback.—On June 19, 1957, at his home, Ashford Hill, near Newbury, Berks, Harry Cyril Killingback, M.R.C.S., L.R.C.P.
Macnab.—On June 21, 1957, at Kirkcaldy, Fife, William Johnston Macnab, M.B., Ch.B., of 2, James Grove, Kirkcaldy, late of Leslie, Fife.
Russell.—On June 18, 1957, at "Midholm," Clarkston, Glasgow, Alexander Cappie Russell, M.B., Ch.B., D.P.H.
Ryder.—On June 18, 1957, at 36, Hookstone Drive, Harrogate, Yorks, Norman Agar Ryder, M.B., Ch.B., late of 1, Bricknell Avenue, Hull, Yorks, aged 60.
Stewart.—On June 19, 1957, in a nursing-home, Glasgow, John Stewart, M.D., D.P.H., of "Duchally," West Kilbride, Ayrshire.
Thomas.—On June 26, 1957, at his home, Bournemouth, Hants, Arnold Newall Thomas, D.S.O., M.B., B.S., Lieutenant-Colonel, I.M.S., retired.
Tibbs.—On June 15, 1957, Francis Christopher Tibbs, M.R.C.S., L.R.C.P., D.P.H., D.T.M.&H., Lieutenant-Colonel, R.A.M.C., retired, of 52, Beach Road, Emsworth, Hants.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Mongolism

Q.—What is the usual age of survival in mongols now that antibiotics cure intercurrent infections? Is there any society for the parents of mongols, and have any books been written to help them in bringing up their children?

A.—Children with mongolism have shared in the general increase in life expectation, although it is by no means certain that this increase is due principally to antibiotics. Children with mongolism are prone, like other handicapped babies, to develop chronic pneumonitis often following inhalation of food. This is singularly unresponsive to antibiotics. The death of children with mongolism is most commonly due to this condition, although a certain number die on account of heart lesions. The majority of children with mongolism now attain adult life and some reach old age.

The National Society for Mentally Handicapped Children (162A, Strand, London, W.C.2) is a useful organization to which parents of mongols can belong.

The National Association for Mental Health (39, Queen Anne Street, London, W.1) has recently issued a pamphlet on the problems of mongolism, entitled "For the Parents of the Mongol Child" (price 1s. 6d. net). There is also the same association's booklet "Mentally Handicapped Children" (price 6s. net).

Guillain-Barré Syndrome

Q.—What is the Guillain-Barré syndrome? What is known of its aetiology, treatment, and prognosis?

A.—The term Guillain-Barré syndrome is used to describe an acute form of peripheral neuropathy which is accompanied by an increase in the cerebrospinal fluid protein. There is no associated pleocytosis, and the increase in the cerebrospinal fluid protein is not invariable.¹ The clinical picture is one of rapidly progressive weakness of the limbs and is one of rapidly progressive weakness of the limbs and onset varies. Generally the lower limbs are affected first, but the paralysis may begin in the bulbar muscles. Dysaesthesiae and muscular pains are often prominent, but sensory loss is less marked than motor weakness. The syndrome varies in severity. Mild cases are encountered. Personal experience suggests that severe forms have become more frequent in recent years. Death may result from respiratory or bulbar paralysis, or both. The heart muscle may be affected, and cardiac failure is an occasional cause of death. Optic neuritis is sometimes present. Severe forms with a rising paralysis from the lower limbs are also termed Landry's paralysis. The pathological changes in fatal cases dying in the first few days consist in oedema of the nerve roots. The cause is not necessarily the same in all cases: the aetiology is unknown, but American workers have recently succeeded in producing a similar condition in rabbits after the injection of homologous or heterologous extracts of sciatic nerve.² It is suggested that the cause may be allergic, at least in some cases.

At the moment treatment will usually consist in the exhibition of cortisone, 300 mg. daily initially.³ In fulminant cases intravenous infusions of corticotrophin might be tried. The results of treatment with cortisone are encouraging, but a satisfactory response is not invariably achieved. The cause of death is commonly bulbar and respiratory paralysis, so assisted methods of respiration are invaluable. As bulbar paralysis usually accompanies weakness of the respiratory muscles, tracheotomy and a positive-pressure

breathing apparatus are generally required, and it is therefore advisable for these cases to be admitted to a neurological centre or other hospital where facilities for this form of treatment are available. If the patient can be tided over the acute stage, recovery is the rule, though it is not always complete. Elderly patients are rather bad risks. Relapses may occur after a period of months or even years.

Drug Prophylaxis after Rupture of Membranes

Q.—If a patient is not in labour 24 hours after artificial rupture of the membranes, it is agreed that antibacterial measures should be taken. What is the best drug to use? I have been in the habit of using the sulphonamides in such cases, but I am told that these are not now considered the best treatment.

A.—When the interval between artificial rupture of the membranes and the onset of labour is so protracted as to raise fears of intrauterine infection, prophylactic treatment with antibacterial agents is certainly justified—in the interests of the foetus as well as of the mother. Infection of the foetal respiratory tract directly from the liquor amnii is a special risk. In this respect there is evidence to show that, whereas most antibiotics and sulphonamide preparations enter both the maternal and foetal blood stream, only penicillin is excreted in significant amounts into the amniotic sac itself.¹ A common practice, therefore, is to give penicillin in full dosage supplemented with either streptomycin or a mixed sulphonamide preparation. Before these are given, however, a high vaginal swab should be taken for bacteriological study. The result will not be available for 48 hours or more, but may be helpful in determining a change in the type of antibiotic in those cases where infection becomes established despite prophylactic measures. It should be added that when delivery is complete both the baby and the mother should continue with treatment until they have received a full course of whatever agent is used.

There is not general agreement about which drugs should be used, and some authorities argue that sulphonamides (which are bacteriostatic) should not be combined with penicillin (which is bactericidal)—although in practice they seem to work well together. Finally, it should be mentioned that some bacteriologists would argue that sulphonamides alone should be used for prophylactic purposes, the more powerful antibiotics being kept in reserve for specific use in established infections.

Root Pains in Osteoarthritis of Spine

Q.—(1) What is the mechanism of the root pains that often complicate osteoarthritis of the spine? How should the pain be treated, and what is the prognosis? (2) To what extent is trauma an aetiological factor in osteoarthritis of the spine?

A.—To answer the question it is necessary to define osteoarthritis of the spine, and for this reason the second question will be dealt with first. It is a condition of mechanical origin affecting the posterior articulations. The joints become mal-aligned as a result of injury to, or senescence of, the intervertebral disk and consequent narrowing of the interval between the bodies. A "wear and tear," or osteo-, arthritis develops in the posterior joints as a result. The condition may arise locally from a single incident of some severity rupturing a disk, or may result from repeated trauma. It is thus encountered at the junction of fixed and mobile curves in the spine where wear is most marked—namely, in the lumbo-sacral, cervico-dorsal, and dorso-lumbar regions. Evidence of origin is most obvious in the spines

of workers engaged in heavy industry such as coal mining and dock labouring, and in patients in whom a single accident, such as a fall in the sitting position, has caused rupture of disks.

Root pain is due to direct mechanical pressure at a foramen, from reactionary change or from sleeve fibrosis. The pain may be treated by rest—for example, in the form of splinting—redevelopment of supporting musculature, fracture-board-hair-mattress bed, corset, back brace, or felt collar; traction, or occasionally, in desperate circumstances, by operation. The prognosis, in general, is good. Nerve tissue has the capacity to adapt to mechanical difficulties if it is given sufficient time. Nature is assisted by the methods of treatment outlined.

Dosage of Sulphonamides in Children

Q.—When using drugs which are well tolerated by children—e.g., sulphonamides—is it advisable to use full adult dosage as routine? If so, does this mean that the drug is of less value in adults, because on a weight basis adults will receive a lower dosage? Are similar blood levels obtained in adults and children because of differences in the amounts absorbed and excreted?

A.—If a satisfactory therapeutic effect is to be obtained by the use of sulphonamides in children full dosage for the child would certainly be employed, but this does not imply the administration of the adult dose. In general the dose of a drug may be calculated by taking not only the weight into consideration but also the patient's age. Thus, the initial dose of sulphonamides for adults may be 1.5 g. by mouth, and the equivalent dose for children is 0.5 g. up to 3 years, 0.75 g. from 4 to 10 years, and 1 g. from 11 to 15 years. This does not imply that the drug is of less value in adults in comparison to children, as the dosage calculated in this way will produce approximately similar blood levels at all ages.

Weight-reducing in Bed

Q.—Is it a fact that keeping a patient who is on a reducing diet in bed causes him to lose weight more quickly than if he is up and about? What is the reason for this?

A.—There is no doubt that if an obese individual is put to bed he tends to lose weight rapidly during the first week owing to a loss of body water. A similar diuresis is seen in oedematous patients and, to a lesser extent, in normal subjects. In the recumbent posture there is a shift of blood from venous reservoirs in the legs to the thorax. The diuresis is believed to be related to a stimulation of stretch receptors in the walls of the atria and pulmonary veins.

NOTES AND COMMENTS

Effect of Artificial Menopause on Sexual Life.—Professor H. C. McLaren (Birmingham, 15) writes: I found the answer given by your correspondent on the subject of the artificial menopause ("Any Questions?" June 8, p. 1373) rather confusing. If I am allowed to presume that the question arose because a patient had asked her doctor to give his opinion on a surgical or irradiation menopause (50 mg. of radium for 24 or 48 hours) then my chief objection to the answer lies in the general gloom which might be summed up thus: Sexual anaesthesia and loss of libido will descend on you sooner or later, so give up the struggle, accept old age. I take the view that the cure of bleeding in a woman of 40 or 50 should be achieved without producing a trail of symptoms such as hot flushes and sweats, obesity, and, worst of all, the sudden onset of numbness in the genital tract. This numbness or anaesthesia quickly leads to distaste for coitus and quite quickly to disappearance of libido. Not all radiation-castrated women are so affected, but it is very common.¹ Many women who in their middle years achieve orgasm only occasionally are by no means sexually anaesthetic, and they are often content, and indeed consider it very important, to provide satisfaction for their husbands. But this gentle waning in sexual response is an entirely different state from the anaesthesia of the genital tract which often follows irradiation. It is, moreover, easy to see how distaste for coitus might produce considerable strain, even to the point of breaking up the marriage.

After a personal study of two large series of women who had been treated for menorrhagia by irradiation castration, it became obvious that, in contrast to those who had been subjected to hysterectomy with ovarian conservation, serious after-effects were so common that I concluded that radium or x-ray castration had only a small place in the therapy of bleeding—that is, for the patient with, for instance, cardiac disease, who, despite careful preparation, is rejected as a poor anaesthetic risk. Nowadays with our modern anaesthetics and expert anaesthetists this is a rare event. That is not to say that hysterectomy with retention of ovarian tissue never disturbs married life, but simply that the disturbance is minimal and only for a few months. Both physical and psychological preparation is important before hysterectomy. The patient is made as fit as possible before hysterectomy, and this can usually be achieved by a few days' rest in hospital and on occasions blood transfusion. I give the patient a simple talk on the reason for operation, emphasizing (perhaps with more dogmatism than I should) that ovarian tissue will be preserved, and that her "femaleness"—figure, complexion, hair colour, etc.—will also be preserved. Most important, I state clearly before operation that normal and satisfactory marital life can be anticipated within a few months. In the Midlands this last announcement is usually received with a look of astonishment, even incredulity, for it is common gossip that a woman must retire from her normal sex habits after hysterectomy ("But, doctor, you're going to take everything away, aren't you?").

At first follow-up examination there may be need to explain the significance of the operation afresh, and, after examination and reassurance, that recovery from the operation is complete. The patient is then told that marital relations may be resumed if and when she chooses. At final examination there may be an anxious inquiry about post-coital "spotting"—usually due to vault granulations—and once again reassurance is necessary. With the hysterectomy, then, as an incident in the planned care of the patient, a target far above mere removal of the uterus may be aimed at—that is, the restoration of the patient's health, her sense of well-being, and finally the restoration to her place as mother of the household and wife and companion to her husband.

In brief, surgery with proper preparation and follow-up can achieve more than irradiation castration, but your expert is right on occasions. Libido may fail after hysterectomy, and sometimes the cause is not clear until the husband is sent for. One glance, and gloom may descend on the scene, and one may have to agree with the somewhat Delphic pronouncement in your columns: "If she expects the menopause to decrease libido, her expectation is likely to be realized; if she does not, however, libido will probably be retained" (my italics). *Cherchez l'homme.*

REFERENCE

¹ McLaren, H. C., *British Medical Journal*, 1950, 2, 76.

OUR EXPERT replies: Interesting and valuable though Professor McLaren's observations may be, they are mainly outside the scope of the original question and answer. As was made clear in the printed question, the problem was concerned only with the actual incidence and coital difficulties following radiation as compared with their incidence following the natural menopause. The surgical menopause was not under consideration nor was the matter of preventing frigidity as a sequel to the menopause. The reply therefore consisted almost entirely of such factual information as could be extracted from the literature, and included reference to Professor McLaren's article which he now quotes. If the brevity of the abstract led to confusion, I am sorry.

British Medical Association

ONE HUNDRED AND TWENTY-FIFTH ANNUAL MEETING, NEWCASTLE UPON TYNE, 1957

President's Address

PROGRESS OF MEDICINE AND SURGERY IN NEWCASTLE UPON TYNE

BY

WELDON WATTS, M.S., F.R.C.S.Ed.

Surgeon, Royal Victoria Infirmary and Hospital for Sick Children, Newcastle upon Tyne

I must first express my grateful thanks to my colleagues of the Newcastle Division for proposing my name as President for this year, and to my colleagues in the Association for electing me to this high office. When I recall the great names of those who have held this office with such distinction I realize how poor are my qualifications for this important position. This is the first time it has been held by a surgeon in Newcastle. When previously the British Medical Association has honoured Newcastle by holding its meetings here, the honour has always fallen on a medical colleague.

I must also take the opportunity to thank the individuals and organizations who have contributed so much to assure the success of this Meeting. First, I must thank the University through the Rector, Dr. Bosanquet, and Mr. Hanson, the Registrar of King's College, for going to such great trouble to meet our difficulties. They have gone even further, and have invited you all to a reception. I must also thank the Lord Mayor and the Corporation of this city for granting us the use of the City Hall, and for inviting us to meet them at a reception and dance.

Our grateful thanks are due to the members of the Arrangements Committee and the subcommittees, and to others, for the immense amount of thought, time, and energy they have put into their efforts to make a success of all the different functions that have been arranged to make this Meeting worthy of the traditions of Tyneside.

It is my privilege and pleasure also to welcome every one of you to Newcastle upon Tyne. We feel honoured that the British Medical Association has chosen this town as a suitable place for its Meeting, and that you have taken the opportunity to attend. I hope you will learn something from the Scientific Meetings and Exhibitions, and have some time off at least to enjoy the social events and the excursions which have been arranged.

Newcastle has had the pleasure of entertaining the Association on three previous occasions, in 1870, 1893, and 1921, and the growth of the Association in member-

ship, in its activities, and in its importance has progressed out of all recognition in the interval.

The last time the Association met in Newcastle was under the Presidency of Sir David Drummond, who gave his address in the King's Hall, Armstrong College. Mr. (later Professor) R. S. Willan was the honorary local secretary of the Meeting, during which a well-known present feature of medical life in Newcastle—the Medical Institute—was opened. This, much altered, is now the British Medical Association regional office, the centre of many official and social events. At the time of the 1921 Meeting I was a senior student, and did my first work for the Association by arranging two dances. I still treasure the letter of thanks I received from the then Council of the Association signed by Sir Robert Bolam, the local physician, so well known, who did so much for the Association that our present Headquarters are sometimes called his monument.

Now comes the most difficult part of my task, that of giving an address to such a distinguished audience. After the thrill of being made President-elect had subsided, I started to think of the various subjects which had not been used in the ninety-odd addresses delivered since the British Medical Association was founded under that name. I had decided to talk about the main milestones in the history of surgery, when it was suggested to me that this had been done before, though not recently. The same adviser suggested that a subject of local interest would be more popular, and that, as the history of medicine in Newcastle had never been extracted from the numerous books, pamphlets, and minutes, this would make an interesting and possibly useful contribution.

I therefore propose to talk about the progress of medicine and surgery in this area, illustrated so far as possible by examples of institutions, societies, and some of the men who, in company with their colleagues in other parts of the world, were slowly advancing the knowledge of medicine for the benefit of the sick. This is too big a subject to deal with adequately in a short address, and therefore you must excuse me if I dismiss some parts with only a brief reference.

Roman Times

The first medical man of whom we have records was a Roman, not unexpected when we recall that this area is noted for the number of Roman and mediaeval remains, of which the most important in Northumberland is part of the Roman Wall and its related works, one of the mightiest antiquities remaining in England. In many parts the Wall stands five feet high, having for nineteen hundred years withstood the ravages of time and weather, and, more severely, the ravages perpetrated by the hand of man. It stands for something more than a dividing barrier between North and South; it remains a sign of the desire for peace expressed by the famous Roman emperor who conquered the area, and, though the Wall and its works were not erected until some years after his withdrawal from the country, they helped to give the greater part of England a peaceful period lasting nearly three hundred years, during which a civilized standard of living was attained which was not equalled again for centuries. Romans may have conquered, but they brought civilization and in many cases freedom to those they overcame.

The earliest mention of a medical man comes from these times. In a fort, Housesteads, about 25 miles west of Newcastle, was found the tombstone of a medical orderly, and it can now be seen in the Blackgate Museum. The inscription gives his name, the name of the unit in which he served, and his age at death—a young man only 25 years of age.

Might we not picture this medical man stationed on the cold and windy heights of the Whinsill, giving some of his spare time and skill to those wives, children, and dependants who were always found in the neighbourhood—a village settlement attached to a fort—in fact, acting as their general practitioner-specialist, in a place then comparatively populous, though now so sparsely inhabited that no doctor resides within six miles of it?

The Roman Army had a complete medical service, the trained doctors coming from the eastern part of the Roman world. Of the training of the lower medical ranks in the army we know very little; there was probably nothing systematic in it, and it was gained largely through apprenticeship. These medical orderlies performed surgical operations, removed foreign bodies and arrowheads, and did amputations by methods of which the descriptions are on record. In the Black Gate Museum you can see their instruments—knives, probes, hooks, forceps, saws—not so very different from those we use to-day.

Early Newcastle Records

Following Roman times there was a long period during which no written records were kept, and certainly nothing about medical men or the treatment they gave. After this the first record I can find of a Newcastle medical man comes from Mr. Sidney Gibson's *History of the Priory and Convent of Tynemouth*. In this it is stated that King Edward II was at Tynemouth on April 26, 1312, and from his wardrobe account emerges the fact that a payment of 14s. 4d. was made to Mr. Wm. de Barntort, who was called down from Newcastle for attendance on Lord Peter de Caveston, Earl of Cornwall, a favourite of the King, and that the same fee was paid to a monk of Tynemouth, Brother Robert de Bermingham, for his care in the same case. This seems to be the first report of a specialist being called to a consultation—and a general practitioner—that is, the monk—carrying out the treatment advised. We are not told of the nature of the illness or of the treatment given, but the complaint

cannot have been serious, as the Earl was able to sail away with the King on May 5. William de Barntort seems to have had a brother who was also a medical man in the district, because the King in 1346 granted him certain lands in Tynemouth.

Another local record of a medical man of this period occurs in Eyre's *History of St. Cuthbert*. A surgeon, Galfrid de Saleby, was granted a room and food on the Inner Farne Island, and in return for this he undertook to treat the monks and their servants in the area, even travelling as far as Durham. This medical man was almost certainly trained in Newcastle or Durham.

The Guilds

After this, most early information about medicine in Newcastle comes from the records of the Barber Surgeons and Chandlers Guild of Newcastle. Some of the Minute Books of that society still survive. The earliest one, in 1616-80, mentions the date of the municipal licensing of the Guild in Newcastle, on October 10, 1442, and gives the following extract of their duties:

"That they should go together in procession on Corpus Christi Day in a livery, and afterwards give a play 'The Baptizing of Christ' at their own expense.

"Every man to be at the procession at Newgate when his hour is assigned to him on pain of forfeiting a pound of wax; to go with their pageant when it shall be a play in a livery under similar conditions.

"That no alien shall be taken apprentice or allowed to work within the town or without, under penalty of twenty shillings.

"That the Society should 'uphold the light' of the St. John baptist in St. Nicholas Church as long as they were of ability."

There is no doubt that guilds of this nature were in existence long before this time, as an Act of 1363 compelled every surgeon to belong to one. Another Act in 1387 enforced a regular return of the Guilds' Rules and Property, while a third Act fixed the length of the apprenticeship at seven years.

The guilds had not only monopoly of practice but also the power of regulating the work of their members by insisting on consultations with their colleagues in important cases and on the general efficiency of their members.

A further step in State regulation took place in 1436, when a Statute enacted that the "ordinances" of surgical and other guilds must be submitted for the approbation of the magistrates of each city, and accordingly we find municipal licensing of the Barber Surgeons Guilds in London, York, Bristol, Newcastle, Salisbury, and Exeter.

The Common Council of the Municipal Authority, besides licensing the guilds through their magistrates, also acted as an appeal tribunal to which disputes could be referred. The type of appeal usually heard was against non-members practising in the city and applications for permission to seek apprenticeship elsewhere from apprentices who had committed a misdemeanour. The "closed-shop" principle seems to have been very successfully applied among members of the Barber Surgeons Guild. After the inspection and ratification the rules were enforced by the city authorities by fines and imprisonment.

The Barber Surgeons Company in Newcastle still has legal existence. Of course, under the present Act it would have no licensing powers, even if it had kept up its old lectures and examinations.

At the height of the activity of the guilds the students were not only apprenticed to licensed surgeons but went through a regular course of anatomy, with dissection, surgical lectures, and examinations, and in many instances post-graduate work and lectures. Many guilds of barber surgeons acquired libraries, and in Newcastle the Guild was proud of having received a copy of Bartholin's *Anatomy*.

The type of medicine practised at this time is well described by Guy Patin, who reduced all cases to either bleeding or purging. Age made no difference—he bled old and young; he bled 32 times for a single illness, and up to seven times for a cold; he bled his mother-in-law, who was 80, up to four times; he bled a 3-day-old child; he bled his wife eight times in the arms and then in the feet. He describes the case of a patient who was purged 32 times in two consecutive days; then there is another who was bled 24 times and purged 40 times. Finally, he states, "We cure many more patients with a good lancet and a pound of senna, than the Arabs could with all their syrups and opiates."

There is no record of where the Guild met until the Minute Book of 1616, which states that the members usually met in Pandon Gate, one of the town wall gates, or in their own houses.

In 1646 a house was taken in Silver Street (now demolished); but this cannot have been very satisfactory, as the Guild soon petitioned the Corporation for a site, and this was granted in 1648 on a sixty-one-year lease; it was just to the east of the Holy Jesus Hospital. The new Hall, with a herb garden, was in use by 1652, and a description is available in the Diary of Celia Fiennes, a lady who toured the country on horseback in the late seventeenth century. This hall, with alterations, continued in use until 1830, and it became the home of the newly formed Newcastle Medical School in 1834. It was demolished to make way for railway extensions in 1851, when a new hall in Victoria Street, Westmorland Road, was built for the Guild by the railway company. Teaching was carried on there till 1857, when it was sold to St. Paul's Church as a parish hall, which it still is.

Minutes of the Newcastle Guild

The Minutes of the Guild make amusing and interesting reading, but unfortunately do not give many details of the practice of medicine. They are mostly concerned with sums of money spent on dinners, and the upkeep of the house and garden, and money given for such charitable objects as "distressed brethren" or a "shipwrecked surgeon" (Dispensary, October, 1777). An unusual subscription is recorded on May 21, 1722, when £2 2s. was given towards "The Plate," probably the well-known local horse race which is still run in the summer.

Fines for various offences occur regularly and must have proved a fruitful source of income—for example, for not attending meetings and funerals, for swearing and using abusive language at meetings.

Apprentices appear to have given considerable trouble and were rather harshly supervised. They had to serve for seven years, during which time they might not marry or serve in the "shop" unsupervised (in London they were not allowed to wear a beard of more than fifteen days' growth). An apprentice discharged for a misdemeanour could not be employed by any other freeman of the Guild in the city.

The teaching of anatomy seems to have begun in 1692, when £4 10s. 2d. was disbursed on "dissection," possibly the price of a body, but no names of dissectors are given. It is recorded that in 1711 a skeleton was bought.

In 1753 Mr. Hellowell, a surgeon at the infirmary, was given the body of a woman who had murdered her child, and he and three other surgeons lectured on it and dissected it. In 1691 a surgeon who was not a member of the Guild was prosecuted for practising in the town, and another surgeon was similarly prosecuted in 1720. The Guild kept in a case a set of instruments which could be borrowed at a certain charge; note is made that "they must be made good if lost, and that a surgeon must deliver them back in such condition as he receives them." Sums disbursed for cleaning the instruments are mentioned. These instruments, twenty-six in number, were contained in a handsome case with the arms of the Barber Surgeons carved on the lid, and consisted of knives, cauteries, probes, hooks, needles, saws,

bullet-removing forceps, and dental instruments. On one occasion they were pawned by the borrower (whose name is not given) and had to be redeemed for forty-five shillings. The case of instruments used to hang in the lecture room of the first medical school, and is now in the Black Gate Museum.

From the Minutes, members of the Guild practised not only in Newcastle but in North Shields, and they certainly did in Berwick, where a member was surgeon to the regiment stationed there and was allowed to have an apprentice.

In 1733 repairs to the door of the hospital are mentioned, but there is no record of this Guild running a hospital.

On May 20, 1773, a petition was sent to the governors of the infirmary asking that all practising surgeons be allowed to attend the meetings of the physicians and surgeons. There is no note saying whether this was granted.

In the latter part of the eighteenth century the importance of the Barber Surgeons Company declined owing to the growth of hospitals and medical schools in Newcastle, and as it no longer engaged apprentices it finally ended as an active practising and teaching organization. As a historical relic it still exists; for example, in 1928 the membership was eight members and two stewards (indicating the original division into barbers and surgeons). The yearly meeting still took place on Trinity Monday in the Nag's Head Hotel, but there was no dinner, only a small sum being spent on liquid refreshment and tobacco. At the present time there are fifteen members with two stewards, and two new members are to be elected soon. As no apprentices are now taken, only sons of members can become Freemen.

Treatment of the Sick Poor in Early Times

Before considering the various institutions which figure so largely in the medical history of Newcastle, we must look at the methods of treatment of the sick poor before their foundation. From early times the town provided and paid for treatment of some types of case, but it was not until 1592 that records were available in the Minutes of the Common Council of Newcastle Corporation. From that time irregular payments were made to medical men for treatment in individual cases when called in by the mayor.

In 1599 a town physician was added to the corporation staff at a salary of £40 a year, soon being reduced to £20. This post seems to have come to an end soon after 1700; but Mr. John Fife, a surgeon to the Royal Victoria Infirmary, is mentioned as receiving a payment for attending a case in the city gaol in the nineteenth century.

The town physician had to be careful, diligent, and observant, and was not allowed to leave the town without the permission of the mayor. He had to visit the inmates of the Holy Jesus Hospital when required, and latterly the gaol and places of correction.

Another way in which the public in the eighteenth and early nineteenth centuries, and before, obtained treatment was by itinerant qualified and non-qualified practitioners who in part followed the various markets and fairs, and in part attended certain towns on dates following advertisements in the local press. Many of these specialized in the treatment of certain conditions—for example, manipulation for deformities such as wryneck, and certain other organs, especially diseases of the eye. Others sold medicines, frequently from public houses, which were claimed to cure a wide range of diseases.

I now depend on the history of the institutions, medical societies, and the press for the ensuing period.

The Royal Victoria Infirmary

The history of the infirmary is probably the greatest single source of knowledge of medicine and surgery, and of those who practised these arts, in this area. We are fortunate in having had the late Mr. G. H. Hume, and his son, Sir William Hume, consultants to the infirmary, as its able historians up to the bicentenary of the institution celebrated in 1951.

In the middle years of the eighteenth century the industrial revolution was advancing with great strides. The population was increasing rapidly; great wealth was accumulating; and alongside of this there was an extension of philanthropy, especially that associated with personal donors. This was a time when hospitals were being built in all the large industrial centres, Bristol being the first in 1735.

The idea of founding the infirmary has been credited to a small social club that was to be dissolved owing to lack of support. The project was brought to the notice of the public in a letter to the *Newcastle Courant* signed with the initials B. K.; the author remained anonymous, but is supposed to have been Mr. Richard Lambert, one of the first surgeons appointed to the infirmary. A subscription list was opened and a site obtained from the Newcastle corporation on the Forth Banks, west of the present railway station. So great was the enthusiasm that the subscribers were unable to wait for a suitable building, and a house was taken in Gallowgate which could hold 23 patients. The beds filled so rapidly that a house next door was rented, the accommodation thus being increased to 35. Four surgeons and two physicians were appointed to attend on a two-monthly rota. An apothecary was also appointed on October 6, 1751, as house officer.

The hospital was governed by a committee, twelve members each from Durham, Newcastle, and Northumberland, and admission was by letter from a contributor. There is a Minute of 1751 recording the removal of a stone weighing 2 oz. from a patient, the operation being performed by either Mr. Hellowell or Mr. Lambert. In the first year 167 in-patients and 178 out-patients were treated. The building on the Forth Banks was ready for occupation on October 8, 1753; there was no opening ceremony. In the early days the total number of beds was 90, with a resident apothecary. A matron was appointed who employed the nurses at £4 a year; however, for the most part, the patients nursed each other. The staff attended on a Thursday to examine patients who had letters, and as there was only one consulting-room some inconvenience must have been experienced when more than one member of the staff attended.

Relations between the staff and patients seem to have been good, but there are Minutes relating to the drunken habits of the patients, the poor quality of the beer brewed by the hospital, and an altercation between physicians and surgeons on whose right it was to prescribe medicines: the surgeons won their case. No records of diseases of patients were kept.

By the end of the century overcrowding was excessive owing to the growth of the population. As a result of constant pressure on the governors by the medical staff, it was decided to alter the rules and to increase the accommodation. One of the new rules enjoined strict temperance on the medical staff. New beds were added, of which 12 were set aside for fevers. This last provision caused a split among the medical staff—that is, between those for and those against admitting fever patients.

Call for Reconstruction

A special meeting of the subscribing governors finally decided that the beds should be used for fever cases unless other accommodation was provided. The opponents immediately procured a site and built a separate fever hospital. The new infirmary wards were small (seven beds each) and were built on to the west side of the hospital. The ground-floor wards of the old building were converted into consulting-rooms, library, and museum: so the net increase in beds was only 30. This addition was opened in 1803.

In spite of the reconstruction and the later, 1830, addition of the third story to the old east wing, the position was still unsatisfactory. It is probable that one of the factors which influenced the medical staff to press again for further alterations at this time was the severe cholera epidemic of 1831–2, when deaths rose to over one hundred a day during the peak period in September. The City Council

at that time took action by clearing out the worst overcrowding in the slums, people being accommodated in church halls and tents on the Town Moor. The only records of the activities of the medical profession during this epidemic are a meeting in 1831 called to ensure efficient attendance on the sick poor and a vote of thanks to the profession recorded in the Common Council Minutes.

Overcrowding, leading to infection and hospital gangrene, still remained a problem, and the governors were again pressed by the medical staff to increase the number of beds and to modernize the existing accommodation. Mr. Greenhow, Mr. C. J. Gibb (brother of the better-known surgeon and physician, Dr. J. Gibb, of Blaydon Races fame), and Mr. Dobson, after a tour of investigation of London and provincial hospitals, were the chief of those applying the pressure, which was finally successful. In 1851 a new block was added to the east wing; this increased the accommodation by about one hundred beds, and at the same time part of the east wing was converted into offices, consulting-rooms, etc. It is fortunate that some increase in accommodation had been provided, for soon after the new beds became available an explosion and fire in Gateshead sent 123 victims into the infirmary in twenty-four hours.

Severe wound and other infections, and hospital gangrene, remained the principal problems, but the time was soon to come when Listerian principles were introduced, partly due to the initiative of a house-surgeon, Dr. Beatson, who had been house-surgeon to Lister. This changed the scene completely; and incidentally saved the hospital money in linseed poultices but cost it more in antiseptic dressings. During the next few years alterations and improvements came not only in accommodation (though 50 beds were added in a separate wooden block) but also in personnel. In 1868 there were only 13 nurses to look after 175 patients, and this was soon remedied. Also, additional staff was appointed—four assistant surgeons and two house-physicians and four house-surgeons, the latter superseding the unqualified clinical assistants who had acted as residents up to that time. About this period the system of admission by letter was abolished, and any sick poor became eligible. The development of workmen's contributions also improved the financial state of the hospital.

It must be realized that before this time the infirmary was outside the city walls in a rural setting; indeed, a house committee minute records a house-surgeon being rebuked for firing a gun at partridges and rabbits near the hospital.

The Present Building

The time was fast approaching when industry, and especially the railway, were to encroach too closely on the privacy of the hospital, and it became increasingly obvious that a new and larger hospital was needed. In 1896 the Diamond Jubilee of Queen Victoria's reign was approaching, and it was suggested to the then lord mayor, Sir Riley Lord, that a new and larger hospital on a site away from noise and pollution would be a fitting local memorial of her reign. This suggestion was received with enthusiasm. By 1901 £250,000 had been raised largely owing to munificent gifts from the second Lord Armstrong and Mr. John Hall.

The new infirmary on the Leazes site was opened by King Edward VII in July, 1906, and when it was occupied in September of the same year it was as up to date as possible in the terms of hospital architecture of fifty years ago. I do not propose to describe it, as it can be seen by all essentially as it was built.

During the war of 1914–18 two wooden wards and the Ministry of Pensions Hospital on the north side were added, the Pensions Hospital subsequently being converted into the Leazes Hospital for paying patients, and later partly into general surgical and ophthalmic wards.

Between the wars knowledge of disease and its treatment grew rapidly, with consequent increase in specialization. Unfortunately, the Royal Victoria Infirmary could not provide accommodation for all surgical special units, but a new

orthopaedic block was built in 1933, the only contribution of the infirmary to those rapidly advancing specialties separated off from general surgery. Demand for more accommodation led to appeals for money on two occasions after 1918, the second appeal being cut short by the outbreak of the war of 1939–45. However, some improvements were made: two extra wards on top of the west wards, a new wing to the nurses' home, and new resident quarters.

Owing to the intervention of the war a plan to amalgamate the Maternity Hospital, the Eye Hospital, the Children's Hospital, and the Ear, Nose and Throat Hospital in new buildings on the Leazes site had to be abandoned, but this did not prevent accommodation being provided for the professor of child health when the chair was created by the University in 1942. After the war accommodation was provided for other full-time chairs in psychological medicine, anaesthesia, and industrial health; since 1945 there have been built new pathological and bacteriological departments and a new x-ray diagnostic department, with extensive modernization of wards, operating theatres, and ancillary departments.

Many plans have been laid for the time when the financial position will allow their development, but I fear few present members of the staff will benefit, though I hope we may live to see them accomplished.

Newcastle General Hospital

We must now consider some of the other hospitals, and I am afraid that in dealing with these I can only be brief. The Union Workhouse Hospital, later called the Newcastle General Hospital, was built in 1838, and remained for many years a Poor Law hospital with inadequate accommodation, despite the fact that many acute cases received treatment there. Early in this century a special block was built to accommodate acute mental cases.

After the war of 1914–18 the medical superintendent induced the guardians to appoint a consultant physician and consultant surgeon. An operating theatre was built and surgical and medical beds for acute cases were allocated. Since then there has been a rapid increase in all departments of active medicine and surgery, culminating in the great hospital of to-day, with its modernized old buildings and palatial new departments.

After the passing of the Local Government Act of 1929 the Health Committee of the Newcastle Corporation took charge: under the then medical officer of health the general medical and surgical staff and beds were increased in number, and the first neurosurgical department in the North of England was formed and in time a separate department built; departments of genito-urinary surgery, thoracic surgery, and gynaecology were also successively developed.

Since the introduction of the National Health Service many structural improvements have been made, and the medical staff has increased in strength. Among the modern new departments built I would mention the combined blood transfusion and pathological department to serve the whole of the Newcastle region, also the department of radiotherapy, housing one of the four linear accelerator machines in England.

The hospital at present carries out most of the post-graduate and some undergraduate teaching, and no doubt in the future will be, and should be, fully integrated with the teaching hospital.

Princess Mary Maternity Hospital

Another hospital catering for special types of case needs special mention. The Newcastle upon Tyne Lying-in Hospital, now called the Princess Mary Maternity Hospital, was started in Rosemary Lane in 1760, under the charge of a member of the staff of the infirmary. It remained at that address for sixty-five years, and admitted about 50 patients a year into its 12 beds. About the same time a charity for the relief of poor women lying-in at their own homes was also started, and the two amalgamated in 1858.

Prior to that, as the result of a fund started by a Dr. Elliott, and known by his name, a new and larger maternity hospital was opened in 1826 in New Bridge Street. This hospital catered for the teaching of pupil midwives and medical students, and remained as the principal maternity hospital until 1923, when it was transferred to an industrial school which had been reconstructed in Jubilee Road. This building was opened by the Princess Royal, who graciously conferred her own name upon the hospital. In 1939, owing to the risk of bombing, the hospital was transferred to the Northern Counties Orphanage on the Great North Road, which had been bought by King's College for use as a hostel. After the war this building was completely reconstructed to produce a thoroughly modern maternity hospital with isolation wing and fully equipped operating theatres.

The hospital has had a long association with the University of Durham as the centre of obstetric teaching, and in 1944 it was linked with the Royal Victoria Infirmary, becoming, on the implementation of the Health Act, part of the Royal Victoria Infirmary, and is very closely associated with the department of child health.

The Eye Hospital

The Eye Hospital was first opened in 1822 in Brunswick Place, off Northumberland Street, but was soon transferred to Prudhoe Street. In 1884 a new hospital in St. Mary's Place was opened by the then Duke of Northumberland. It had 25 beds and was at that time equipped for all the most modern methods of investigation and treatment. Since then, advances in ophthalmology have been accompanied by necessary adaptations of the hospital, which was taken over by the Regional Hospital Board in 1948, and continued to function until 1956, when it was closed, as it stood on the route of a new by-pass road.

Accommodation for the patients has been provided in the Newcastle General Hospital and Walkergate Hospital until such time as a new ophthalmic unit is built, probably in association with the teaching hospital, on the Leazes site.

Fleming Memorial Hospital for Sick Children

The Fleming Memorial Hospital for Sick Children was built by Mr. John Fleming in memory of his wife, and replaced an older hospital started in Hanover Square in 1862. The new site, facing the Town Moor near the Orphan Asylum, was opened by Lady Armstrong in September, 1896. A then modern hospital of 130 beds with quite extensive grounds, it was associated in the teaching of diseases of children with the College of Medicine from 1906 until the opening of the child health department in 1946. A move has now been made to renew this association. The hospital has always attracted young surgeons interested in the surgical diseases of babies and children, before and during their early days on the staff of the teaching hospital. At least four men who became professors of surgery in the University spent part of their time on the staff of the Children's Hospital—Messrs. Page, Hume, Pybus, and Barclay. It has recently undergone extensive alterations, providing a burns unit and modern cubicles for the treatment of sick and premature babies.

Walkergate Hospital for Infectious Diseases

Separate accommodation for infectious diseases had been in the minds of many since the great cholera epidemic of 1831, when patients were housed in temporary buildings outside the walls of the city at Spital Tongues and on the Town Moor; also, cases were transferred from slums to Church Halls, Trinity House, etc., and treated and isolated there. In 1793 it was suggested that fever wards be opened in connexion with the infirmary, but a separate hospital was decided on, with the result that the old Fever Hospital in Bath Lane was opened in 1784, and continued to occupy that site until 1888, when, as Newcastle was expanding rapidly and the old site was considered unsafe in these

overcrowded conditions, Walkergate was chosen as the new site and the hospital of 105 beds was built on the pavilion system. Special arrangements were made for the disposal of sewage. The hospital was under the control of the medical officer of health in Newcastle, and soon became the major institution for the treatment of infectious diseases in the North, taking cases from outside its boundaries and becoming associated with the College of Medicine for the instruction of medical students in fevers and the qualified practitioners taking the D.P.H. or B.Hy. course. After the war of 1914-18 further pavilions, and an operating theatre for infectious surgical emergencies, were added. Later, wards were set aside for the treatment of cases of open tuberculosis.

With the diminishing incidence of infectious cases the Walkergate Hospital for Infectious Diseases has since the end of the recent war been developed as a general hospital connected with the Newcastle upon Tyne General Hospital. A new operating theatre has been built for ear, nose, and throat work; part of the Eye Hospital has been transferred here; and the wards are largely used for the treatment of acute medical cases of all types.

Newcastle upon Tyne Dispensary

The Newcastle upon Tyne Dispensary was started in 1777 by the efforts of members of the infirmary staff of that period, with the object that all, especially out-patients, who needed medical care should be able to receive it. Casuals were attended on application, but any who seemed likely to remain on the list for any length of time had to obtain a letter from a contributor. Starting in Pilgrim Street in cramped quarters and with financial problems, it migrated to Low Friar Street, Nelson Street, and finally to New Bridge Street. It fairly soon lost its association with the infirmary, and in the end was staffed with a full-time house-physician helped by general practitioners in the city. Under the National Health Service its old function has ended, and after some reconstruction it remains in service as an out-patient chest clinic.

Of the other hospitals in the city, only the Ear, Nose and Throat Hospital, which started in 1878, retains its old function under the Regional Hospital Board, in premises at the lower end of Rye Hill which have been partly reconstructed.

Other hospitals such as those for women, diseases of the skin and chest, have failed to survive.

The Medical School

Many of you will have graduated at the Medical School in this town, and its origin and subsequent development should be of interest and certainly throw some light on the history of medicine in this area.

The position of medical men in the early nineteenth century must be appreciated. They were divided into two groups: first, the physicians who had studied medicine at one of the recognized universities in England, Scotland, or Europe, and obtained a degree; and second, and by far the larger group, the apothecaries and surgeons who had obtained their medical knowledge and licence to practise by apprenticeship for five to seven years, and paid sums of about one hundred guineas or more. Some of these did go on and spend a period at a university at home or abroad and obtain a degree. Also licences could be obtained by attending a hospital, where the house-surgeon was usually entitled to have so many students as apprentices.

This position continued until the passing of the Medical Act of 1858.

There is no doubt that lectures had been given at various places, such as the Barber Surgeons' Hall and the Literary and Philosophical Society Building since 1786.

The originator of the idea of a centre of medical education was a Dr. T. M. Greenhow, who read a paper on this subject at the Literary and Philosophical Society in 1831.

After this a committee was formed on which were Dr. Greenhow and Mr. John Fife, both members of the infirmary staff. This committee drew up plans and a prospectus for a medical school. The necessary public support, however, was not forthcoming, and the plan fell through. Following this, a group of medical practitioners in the town, of which Mr. Fife was the leader, started in a more modest way, taking rooms in Bell's Court, in Pilgrim Street, and gave the first course of instruction during the winter session of 1832. The names of the eight students who took that course are known.

This starting of the school in a small way by a band of practical men instead of by the more ambitious scheme was a success, and larger and more convenient premises were soon an urgent necessity. These were obtained in 1833 by renting for a year the vacant Barber Surgeons' Hall in the Manors. This was extensively altered, a lecture room and dissecting-room were added, and in 1834 the first properly advertised course of lectures and demonstrations was given. There is no doubt that this is the real date of the beginning of the school. All certificates are headed with this date, and the book for registration of students starts then.

In spite of all difficulties, financial, jealousy of the older members of the profession, and the prejudice of the public against dissection, the school flourished, and regular courses of lectures and demonstrations on chemistry and botany and all the divisions of medicine were given. The school was recognized by the Royal College of Surgeons as a licensing body, and the number of students increased.

Names later famous in this area appear among the lecturers. Dr. D. Embleton, Dr. G. Y. Heath, and Dr. J. Gibb were all on the staff before the year 1851. The lecturers, who paid £40 for the privilege of giving lectures, had to make their living outside, and no doubt hoped that their position in the school would give them added prestige. There seems to have been no controlling body and no accounts were published, and there is little doubt that this lack of control contributed to the dissolution of the school in 1851. The occasion was due to Dr. Embleton, who was a Poor Law guardian, giving a vote to an old friend and colleague whereby he obtained the post of a Poor Law surgeon. This was resented by his assistant in the department of anatomy, and after several stormy meetings it was decided that the only solution was to dissolve the school. This took place in June of 1851, and as a result two schools rapidly came into being which carried on in opposition.

The news of the disruption spread rapidly and caused considerable excitement among the profession, students, and public. With the support of the students, the majority party, retaining such doctors as Embleton, Heath, Charlton, and Gibb, all ex-lecturers in the old school, formed a committee to establish a College of Medicine of Newcastle upon Tyne. The museum specimens which had been collected by the old school were housed temporarily in auction rooms in Nun Street, and many of these specimens were stolen on two separate occasions by the minority party.

The majority party, having decided to form a school, found great difficulty in obtaining accommodation, and finally had to occupy the gardener's cottage of the old Barber Surgeons' Hall and a temporary brick building beside it. In spite of these difficulties the 1851-2 course of lectures, etc., was held with twenty-four students.

It had long been the desire of the old school to become associated with the University of Durham, founded in 1832, and in spite of opposition from the minority party this objective was obtained in December of the same year, and in 1852 the newly established College of Medicine of the majority party was recognized by the Royal College of Surgeons of England.

The minority group, led by Sir John Fife, formed the opposition school called the Newcastle upon Tyne College of Medicine and Practical Science, with Sir John as the first president. They also started a course of lectures in 1851,

and were recognized by the Royal College of Surgeons of England. They were more fortunate in obtaining accommodation, as they were allowed to occupy the new Barber Surgeons' Hall in Victoria Street, Westmorland Road, which had been built by the railway company. The minority group always remained the smaller and resisted various efforts at reconciliation, in spite of their far from flourishing condition and inadequate discipline and academic supervision, but in 1858 a subcommittee of the two parties, largely influenced by Dr. T. M. Greenhow, resolved their differences, and a single strong and more efficient College of Medicine arose from the union.

The College of Medicine

It was obvious that the existing accommodation was unsuitable for a growing college, and an attempt was made to obtain a site near the infirmary, but this failed. An old mansion, Westmorland House, near the present Central Station, was bought, and temporary buildings were erected near it, the house being used as a hostel. As this was not satisfactory a new building was erected in the gardens of the house, facing Orchard Street, which remained as the home of the college for thirty years.

The succeeding period of the college was one of peaceful progress with gradual rearrangement of the regulations of licences and degrees to bring them into line with those obtaining in other universities, resulting in the recognition of these licences by all bodies in the country who employed members of the medical profession. It also saw a closer association with the University of Durham, the lecturer on medicine becoming the first professor and all lecturers teachers in the university. The first professor of medicine was Dr. Denis Embleton, whose picture hangs in the staff room of the Royal Victoria Infirmary.

Most of the lecturers of the college were also associated with the infirmary, and their work in the college was unremunerated for the greater part of this time.

One of the stumbling-blocks to students wishing to take a university degree was the regulation that an arts degree, entailing one year's study in Durham, had to be taken first. Even though the regulation was altered so that it could be taken in Newcastle, it still remained a difficulty and was abolished only in 1906.

During the later years of the century several changes took place. One was the institution of the degree of M.D. by examination for practitioners over 40, and of fifteen years' standing. This aroused a good deal of controversy, as the degree had nothing to distinguish it from the ordinary M.D., but it became a fairly popular degree, and was abolished only in 1932.

Continued increase in the number of students resulted in the building of new accommodation in 1882: a new dissecting-room, a physics laboratory, and a museum were added, with some alteration of the existing accommodation. Soon after new chairs were established by the university in surgery, physics, chemistry, anatomy, and comparative pathology.

Professor R. Howden, who was appointed to the chair of anatomy, still occupied that position when I was a student, and was noted for his accurate blackboard drawings; he had a reputation, too, for being the chief disciplinarian among the more rowdy students. Many other lecturers of this period (Professor Oliver, Professor Drummond, Professor Beattie, Professor Rutherford Morison, and Professor Hume, to mention a few) were still associated with the college after the 1914-18 war, when many of us were students.

The days of the rebuilt College School in Orchard Street were numbered, the railway company desiring the land to extend the Central Station. After considerable difficulty a new site was obtained in Northumberland Road, the eastern part of which at that time was largely undeveloped. The new college (named by those of us who trained there "the old college") was opened in 1889. This coincided with an

increase in the number of medical students, making the Newcastle College the largest provincial school in England at that time.

The chief developments following the occupation of this new building until after the 1914-18 war were the closer association with the Royal Victoria Infirmary on its new site at the Leazes, and the utilization of its staff as clinical teachers. Lecturers in the minor specialties such as eye and ear, nose, and throat were appointed, and the numerous and valuable pathological specimens in the College Museum were renovated and catalogued. After the war the college was working under great difficulties, the chief of which were the familiar lack of finance and overcrowding. A combined appeal to the public produced only enough money to purchase the site so long desired near the infirmary. The only new building possible was the department of bacteriology, which was built by the Armstrong College in their grounds and rented by the college for ten years. More or less minor improvements in staffing were all that could be attempted in the succeeding years. Difficulties of opinion on organization, staffing, and finance led to the appointment of a Royal Commission of inquiry into the organization of the university and its constituent colleges. As a result of the report of this Commission the College of Medicine was joined with Armstrong College to form the King's College, a Newcastle Division of the University of Durham with its own rector and internal administration. In 1938 a new medical school was built opposite the infirmary in Queen Victoria Road. This was opened by King George VI in 1939, and is already requiring increased accommodation.

A Flourishing Medical Society

We have a Northumberland and Durham Medical Society flourishing to-day, and it attracts quite large audiences to its meetings, now normally held in the Royal Victoria Infirmary. The precursor of the society, called the Medical and Philosophical Society, was formed in 1786 with an original membership of 22, which probably represented the majority of the medical practitioners in Newcastle at that time. Dr. Rotherham, a physician at the infirmary, was their first president. The rules of the society were drawn up at a meeting in 1786 by which meetings were to be held once a month and to last no longer than three and a half hours. If a paper was read lasting more than half an hour discussion on it was postponed until the next meeting. Various places were used for the meetings—St. Nicholas Church library, Katy and Bella's Coffee and Punch Room in the Sandhill, and later a room at the dispensary. The Minutes, as recorded by Dr. Embleton, give the names of some of the subjects discussed, such as angina, emetics, treatment of phthisis. The society also held a dinner once a year, usually held at Turner's House, in Pilgrim Street. This was later the Queen's Head Hotel, and is now the Liberal Club.

The Medical and Philosophical Society came to an end quite suddenly in 1805, the only indication in the Minutes being the decision to divide up the library among the members. The periodicals were given to a small society which was then in being called the Medical Book Club, whose chief concern seems to have been in dining and in buying books. The dinners were held in members' houses, the type of food provided being standardized. On March 25, 1834, a general meeting of practitioners was held in the library of the Literary and Philosophical Society, and a new society was formed consisting largely of members of the staff of the infirmary, and was called the Society of Physicians and Surgeons of Newcastle. Their Minutes up to 1846 record interesting discussions on various scientific subjects, but after that date interest waned and the society became defunct. It was followed by the Newcastle and Gateshead Pathological Society, covering much the same ground as the present society, but taking a definite part in advising the City Council on various health problems of the town. In 1860 this society changed its name to the present title, and, though times and type of meeting have altered, it has fulfilled its essential purpose to the present

time—that of presenting occasional interesting and instructive papers and cases to any practitioners in the North of England who have time to attend their meetings.

Conclusion

The history of surgery in Newcastle upon Tyne is probably similar to that of other cities, a rather slow progression until the two major discoveries of the nineteenth century. The first was the introduction of anaesthesia, which must have gone a long way to allay the patient's fear of an operation and make the surgeon's task immeasurably easier. The second was Lord Lister's discovery of the cause of sepsis, the application of his principles lowering the morbidity and mortality and enabling the surgeon to explore with safety all the body cavities.

Surgery progressed along these lines until the last war, when major improvements in anaesthesia and resuscitation, helped by the discovery of antibiotics and sulphonamides, made possible the spectacular advances in surgical operations as performed to-day. What will be the future I hesitate to forecast, but successful temporary or permanent replacement of vital organs seems to be an attainment which would give maximum benefit to mankind.

SAFETY AND ANTIGENIC POTENCY TESTING OF POLIOMYELITIS VACCINE

A REPORT FROM THE BIOLOGICAL STANDARDS CONTROL LABORATORY,* MEDICAL RESEARCH COUNCIL LABORATORIES, LONDON, N.W.3

The British poliomyelitis vaccine is prepared by the formalin-inactivation method introduced by Salk (1953) but differs in its type I component from that produced in North America. The Mahoney strain has been replaced by the partially attenuated variant of the Brunhilde strain (Enders *et al.*, 1952; Sabin, 1955a), which Gear (1956) has called "Brunenders." As in America, strains MEF-1 and Saukett are used in preparing the type II and III components of the British vaccine. Free formaldehyde is neutralized by sodium metabisulphite after virus has been inactivated, and merthiolate and versene are then added as preservatives.

The general regulations for the testing of the British vaccine have been laid down in the T.S. Amendment Regulations No. 1131 (1956), and are based on the present American ones, which are fully described in the Minimum Requirements for Poliomyelitis Vaccine issued by the U.S. Public Health Service (1956). As the British regulations are only a guide to the procedures to be adopted, those used by the Biological Standards Control Laboratory are described. The introduction of an attenuated strain in this country has necessitated some modification of the American methods of testing.

*Scientific staff engaged in the testing of poliomyelitis vaccine: Dr. D. G. Evans (Head of Control Laboratory), Dr. T. S. L. Beswick, Dr. C. R. Coid, Miss A. J. Ferguson, Dr. F. T. Perkins, Miss A. Petts, Mrs. K. Russell, Dr. J. O'H. Tobin, and Miss R. Yetts.

In Britain concurrent tests are made on each batch of trivalent vaccine by the control laboratory and the manufacturer, after the latter has shown that the tests for safety and potency on the individual type components are satisfactory. In the final tests the vaccine is examined for the presence of live virus by the inoculation of cell cultures and monkeys, and for its antigenic activity in monkeys.

Safety Test in Cell Cultures

Vaccine Sample.—Three and a half litres of each batch of formalized vaccine, neutralized by sodium metabisulphite, but without preservatives, are obtained from the manufacturer in half-litre "pyrex" blood-transfusion bottles. The vaccine is dialysed in 500-ml. quantities, first against 5 litres of Hanks solution for 24 hours and then against 5 litres of Parker 199 solution for a similar period; both stages are carried out at +4° C. (Fig. 1). Bovine albumin (Armour Fraction V) is added to the dialysed vaccine to a concentration of 0.14% immediately before it is tested in cell cultures.

Cell Cultures

Trypsinized monkey-kidney-cell cultures are used. Kidneys are removed aseptically from rhesus monkeys and, after mincing with scissors and washing in Hanks solution, are agitated in a 0.2% solution of "difco" trypsin in buffered saline. The supernatant fluid

containing the released cells is removed at intervals of 10 to 20 minutes and replaced by an equal volume of fresh trypsin solution. The cell suspension is washed twice with Hanks solution by centrifugation and the deposit diluted to a concentration of from 300,000 to 400,000 cells per ml. in 199 solution containing antibiotics, 0.09% sodium bicarbonate, and 5% horse serum free from polio-virus inhibitors. This suspension is then distributed in 10-ml. quantities into hexagonal pyrex feeding-bottles which are sealed with "esco" white rubber bungs. The bottles are incubated horizontally at 37° C., until confluent cell sheets are formed. The cell sheet in each bottle covers an area of approximately 30 sq. cm. and is usually complete five to seven days after seeding; bottles with incomplete sheets after this time are not used. Approximately 100 bottles are prepared from the kidneys of one monkey. In preparing these cell cultures the kidneys of each animal are treated separately and not pooled with those from other monkeys.

The Test

A minimum of 2 litres of dialysed vaccine is tested for the presence of live polio virus, using three or four different batches of cell cultures. The old medium is first removed from each bottle culture, which is then washed with 10 ml. of Hanks solution. The bottles are inoculated with 10 ml. of undiluted freshly dialysed vaccine to which 0.14% bovine albumin has been added. They are incubated at 37° C. for a total period of 21 days, during which time the cultures are examined microscopically twice weekly for cytopathic changes. Three days after the addition of vaccine, 10 ml.

FIG. 1.—Dialysis of vaccine. Vaccine is passed into the dialysis bag through tube A, and after dialysis is siphoned out through B. Dialysing fluids changed through C.

of 199 solution containing 0.14% bovine albumin and 0.2% sodium bicarbonate is added to each bottle, and at 7, 14, and 21 days the fluid is replaced by 20 ml. of this solution. At least 2% of the fluid removed at the end of each seven-day period is subcultured on to new cell cultures, which are examined microscopically twice weekly for 14 days, the medium being replaced after seven days. If any of these subcultures show cytopathic changes of doubtful significance, further subcultures are made.

FIG. 2.—Safety testing of vaccine in cell cultures.

At 21 days the cell cultures originally inoculated with vaccine are challenged in groups of four or five with 10 and 1 TCID₅₀ of each type, in order to confirm their sensitivity to polio virus. They have, so far, always been as sensitive as freshly prepared tube cultures.

A diagrammatic representation of the cell-culture safety test is given in Fig. 2.

Safety Test in Monkeys

Vaccine Sample.—At least 400 ml. of each batch of vaccine in final containers, selected from all filling lots, is supplied by the manufacturer.

The Test

The vaccine is tested for the presence of live polio virus by injecting it intracerebrally, intraspinally, and intramuscularly into 15 rhesus (*Macaca mulatta*) and 15 cynomolgus (*Macacus irus*) monkeys. Only those animals are used which have no inhibitors in their sera to any of the three types of polio virus. They are given cortisone intramuscularly two days before vaccine is injected, on the day of vaccine injection, and every other day until the 22nd day. They are observed for 24 to 28 days after inoculation of vaccine and signs of dysfunction recorded. On the day vaccine is given each animal receives, intramuscularly, 300,000 units of long-acting penicillin and 0.4 g. of chloramphenicol.

Rhesus monkeys, usually weighing between 4 and 6 lb. (1.8 and 2.7 kg.), receive 125 mg. of cortisone for the first two injections and at least 50 mg. for each subsequent dose. They are injected with 0.5 ml. of vaccine into each thalamus, 0.2 ml. into each of three lumbar segments of the spinal cord, and 1 ml. intramuscularly into the right arm.

Cynomolgus monkeys, usually weighing between 3 and 4 lb. (1.4 and 1.8 kg.), receive the same dosage of cortisone as the rhesus monkeys. They are injected with 0.3 ml. of vaccine into each thalamus, 0.1 ml. into each of three lumbar segments of the spinal cord, and 2.5 ml. intramuscularly into the right arm. Blood is taken from each animal at 3- to 4-day intervals during the first two weeks and the serum examined by cell culture for the presence of polio virus.

At the end of the observation period, or at death, each monkey is bled from the heart and then perfused with normal saline followed by 1 to 2 litres of 10% formalin in physiological saline (4% HCHO) to which has been added 3% of glacial acetic acid (v/v). Before perfusion all cynomolgus and those rhesus monkeys failing to survive for the full observation period have samples of lumbar cord removed for any special investigations that may be indicated.

The brain and spinal cord are removed and sections prepared from the pre- and post-central convolutions of the

cerebral cortex, from the medulla between the lateral recess of the fourth ventricle and the first cervical segment, and from the cervical and lumbar enlargements of the spinal cord; at least six cord levels and seven brain levels are examined from each monkey. The sections are cut 15 μ thick and stained by Einarson's galloxyanin lake technique (Einarson, 1932, 1951). In cases of doubt, serial sections of the original blocks are cut and other parts of the central nervous system examined.

Antigenic Potency Test in Monkeys

Each batch of vaccine is tested for antigenic activity in a group of 12 rhesus monkeys weighing between 4 and 8 lb. (1.8 and 3.6 kg.). Only those animals are used whose sera contain no inhibitors to any of the three types of polio virus. At weekly intervals each monkey is injected intramuscularly with 1 ml. of undiluted vaccine from final containers and bled seven days after the third dose. The individual sera are titrated for neutralizing antibodies to each of the three types of polio virus.

Titration of Sera

Serial dilutions of serum in Hanks balanced salt solution are mixed with an equal volume of virus suspension in Parker 199 solution containing approximately 50 to 100 TCID₅₀ per 0.25 ml. of the appropriate type of virus; Brunenders, MEF-1, and Saukett are used as the test viruses. The mixtures are held at 37° C. for three hours and then added to monkey-kidney-cell cultures, two tubes being used for each serum dilution. Each culture tube, which contains 1 ml. of medium, receives 0.5 ml. of serum-virus mixture. The inoculated tubes are incubated at 37° C. in roller drums for six days, when the final readings of the cytopathic effect of virus are made and the titre (PD₅₀) of the serum determined. Titres are given as the dilution of serum in the serum-virus mixtures before they are added to the cultures, as recommended by the Committee on Laboratory Investigations of Poliomyelitis of the Medical Research Council. The geometric mean of the titres is calculated for each of the three types of antibody.

As controls the three British Standard Poliomyelitis Antisera, each of which has been assigned a potency of 10 units per ml. (to be published), are always titrated in parallel in each set of tests and have given consistent results throughout. By this method of titration they have given modal titres of 1/480, 1/806, and 1/960 for types I, II, and III respectively.

Discussion

The methods employed by the Biological Standards Control Laboratory for safety and potency testing of poliomyelitis vaccine are in general similar to those currently used in North America.

Some modifications in the monkey safety test have, however, been necessary on account of the introduction of the attenuated Brunenders strain. It has been shown that cynomolgus tend to be more sensitive than rhesus monkeys to attenuated strains of polio virus and that concurrent injection of cortisone increases their susceptibility (Sabin and Fieldsteel, 1952; Sabin, 1955b; Bodian, 1956). In the case of the Brunenders strain we have shown that the administration of cortisone is necessary for the infection of monkeys with small doses of virus and that cynomolgus are more sensitive to this strain than rhesus monkeys. Infection of 75% of cortisone-treated cynomolgus monkeys regularly follows the injection of 20 TCID₅₀ of virus by the subcutaneous route, with or without inoculation of the central nervous system. With 25 to 50 mg. of cortisone every other day, paralysis with small doses of the Brunenders strain is exceptional, although the central nervous system may show poliomyelitis lesions, usually most severe in the lumbar cord. Increasing the dose of cortisone to 150 mg. enhances the severity of the clinical picture, palsies becoming common. So far we have been unable to demonstrate a difference between the enhancing effect of cortisone combined with x rays and that of cortisone alone.

A combination of histological examination of the central nervous system and attempted virus isolation from the blood has been shown to detect a greater number of infections by the Brunenders strain than either method used separately. Viraemia is the rule rather than the exception in infected cynomolgus monkeys, whereas virus has been isolated from the blood of rhesus monkeys only when the larger cortisone doses have been used, and in these animals the viraemia has been of shorter duration than with cynomolgus monkeys.

The cortisone schedule is different from that employed in America, divided doses being used and continued until the 22nd day of the observation period. This seems to prolong viraemia in cynomolgus monkeys and so makes virus isolation from the blood more probable.

Some doubts have been expressed on whether the monkey safety test is necessary in addition to the tissue-culture test. The American experience, however, would indicate that the monkey test is an essential part of the safety-testing procedures, since it was in monkeys conditioned with cortisone, or cortisone combined with x-radiation (Eklund *et al.*, 1956; Syverton *et al.*, 1956), that virus was isolated from vaccine suspected of causing infection, whereas in unconditioned monkeys and in tissue culture isolations were made only with difficulty.

Slight modifications of the American method have been made in the tissue-culture safety test. Ten ml. of vaccine is inoculated initially on to each bottle cell culture without further dilution, the freshly dialysed vaccine itself acting as the nutrient medium. We have found no evidence that undiluted vaccine inhibits virus infectivity. Youngner (1956) has shown that the absorption of polio virus on to cells is related to the volume of fluid in which the virus is suspended, and we have found that the number of virus particles that can be detected in a given volume of fluid is decreased by increasing the depth of medium over the cell cultures. Three to four days are allowed for absorption of virus into cells before a further 10 ml. of 199 solution is added in order to ensure good cell maintenance until the replacement of medium after the first week's incubation. Initial cell cultures are always kept for 21 days after inoculation with vaccine and the weekly subcultures for 14 days, whereas in America only 14 and 7 days respectively are required for these procedures. It has been found in titrations of virus suspensions that the type III virus may take more than two weeks to produce a cytopathic change in monkey-kidney cultures. This has not yet been noted with either the Brunenders or MEF-1 strains, these viruses having produced a cytopathic change within 14 days.

So far "foamy agent" (Rustigian *et al.*, 1955) has been the only real problem with the cell cultures. This agent has been more prevalent in the early months of 1956 and 1957 than during the summer and autumn of 1956. As it does not manifest itself until the third week of incubation of cell cultures, 2,500 ml. of vaccine has been inoculated initially during these months in order to ensure that at least 1,500 ml. is tested on good cells without the loss of time involved in repeating the tests. Other wild viruses have not given any trouble. In only one instance has a simian virus other than "foamy agent" been encountered. Monkeys used for tissue culture are housed two to a cage from the time of arrival and are not used until they have been in the laboratory for at least seven days, and are usually kept much longer. This treatment may reduce the continuous sub-clinical passage of viral agents that must take place when many animals are housed together in large cages, as is the practice in most laboratories dealing with large numbers of monkeys.

The test for antigenic potency in rhesus monkeys is similar to that used in the United States except that the British Standard Sera are employed as controls instead of those issued by the National Institutes of Health. The antigenic activity of some of the batches of vaccine have also been studied in children, and the antibody responses obtained have shown good agreement with those obtained in monkeys (M.R.C., 1957). An investigation of the value

of guinea-pigs and cotton-rats as an alternative to monkeys is also being made.

Fuller accounts of our observations on the behaviour of the Brunenders strain in monkeys, on the histopathological aspects of vaccine control, and on the antigenicity tests will be published later.

Summary

The safety and potency tests carried out by the Biological Standards Control Laboratory on formalinized trivalent poliomyelitis vaccine are similar to those in use in the United States, but the introduction of the attenuated Brunenders strain into the British vaccine in place of the more virulent Mahoney strain has necessitated some modifications of the American practice.

"POLIOENCEPHALITIS": A CLINICAL AND LABORATORY STUDY

BY

B. SNELL, M.B., M.R.C.P.Ed., D.P.H.
Deputy Medical Superintendent, Lodge Moor Hospital, Sheffield

D. BALDUCCI, M.D.
Research Assistant

AND

D. A. J. TYRRELL, M.D., M.R.C.P.
Member, External Scientific Staff of the Medical Research Council, Virus Research Laboratory of the University of Sheffield

For many years it has been believed that poliomyelitis might be manifested by an encephalitis either with or without the usual signs of paralytic poliomyelitis. In nearly all the earlier reports there was only epidemiological or clinical evidence to show that the cases were due to the same agent as paralytic poliomyelitis. Altogether five cases of encephalitis have been reported in which isolation of the virus of poliomyelitis was made (Kelleher *et al.*, 1949; Jennings *et al.*, 1949; Barrett *et al.*, 1952; Adler *et al.*, 1955). The clinical manifestations of encephalitis included somnolence or coma, tremors and incoordination, nystagmus, loss of conjugate eye movements, muscle rigidity, and hemiparesis.

An epidemic of poliomyelitis occurred in 1955, and 121 cases of paralytic poliomyelitis were admitted to this hospital. During the epidemic period nine cases initially classified as encephalitis were seen (eight at Lodge Moor Hospital), and these were studied by clinical and laboratory means. In seven of the nine there was definite evidence of simultaneous infection by polio virus. The eighth case was thought to be disseminated sclerosis, and the last had polyarteritis nodosa with brain involvement.

Laboratory Methods

The laboratory methods were based on those used in Melnick's laboratory (Kraft and Melnick, 1950; Black and Melnick, 1954; Melnick, 1955). Virus isolation was attempted by inoculating suspensions of faeces into monkey-kidney-tissue cultures. Complement fixation was carried out on paired sera against all three types of polio virus with serum dilutions from 1/4 upwards (Balducci *et al.*, 1956). In Cases 1-5 and 8 complement-fixation tests were done against herpes simplex, adenoviruses, and Coxsackie virus types A1-A8, A10, B1, B3, and B4. The results were negative except where indicated in the Table.

The frequency of positive results for polio virus and the type of serological response obtained were very similar to those obtained in a control series of cases of typical paralytic poliomyelitis (Tyrrell *et al.*, 1957). Polio virus infection was indicated when virus was isolated from the faeces or when a rise in neutralizing antibody titre occurred. In some cases the diagnosis was supported by the presence of complement-fixing antibodies.

Results

The laboratory tests as presented in the Table indicate that Cases 1-7 were associated with polio virus infection. This evidence was based on virus isolation in five, and on a rise in antibody titre in two.

In Cases 1-3 there was no disturbance of consciousness, but after a brief feverish illness with some upper respiratory symptoms and headache the patient was admitted with meningism, nystagmus, and signs of a slight upper or lower motor neurone paralysis. In Cases 4-7 there was a similar but more severe illness, with marked disturbances of consciousness and in Case 7 a fatal result.

The C.S.F. was abnormal in all these cases, the protein ranging from 30 to 85 mg. per 100 ml., and the cell count from normal to 50 per c.mm. Protein and/or cells were raised and the cells were either mainly or entirely lymphocytes.

In Case 6 an E.E.G. was done which showed an abnormal tracing (see Fig.). On regaining consciousness this child showed pica and attacked other patients, but finally made a complete recovery. The cases were followed up for from two to eight months, and residual signs seen included conjugate deviation of the eyes (Case 7), facial paralysis (Case 5), persistent nystagmus (Cases 2, 3, and 4), and wasting of

pectoral muscles (Case 3). The ataxia, hypertonia, and increased reflexes disappeared in one to two months.

Case 8 was thought clinically to be a case of disseminated sclerosis with an acute onset. Specimens were not collected till six weeks after admission and showed evidence

Electroencephalogram recorded from Case 6. Patient stuporous six days after onset. Frequent bouts of generalized high amplitude, 2-3 c/s waves occurring simultaneously in all areas.

of a recent polio virus infection which may have been acquired in hospital. Case 9 was found at necropsy to have periarthritis nodosa with gross lesions in the pons, as well as in the kidney, liver, and lungs. Cases 8 and 9 show no evidence of concurrent polio virus infection.

Discussion

Our first three cases resemble the syndrome of acute cerebellar ataxia, which in a few other cases has been shown to be associated with polio virus infection (Berglund *et al.*, 1955; Huston *et al.*, 1956). The loss of consciousness in Cases 4 to 7 may be due to lesions in the brain stem, which may also account for the involvement of the pyramidal tract (Bodian, 1952). There was no clinical evidence of respiratory embarrassment to account for the loss of consciousness in these cases (Minnesota Poliomyelitis Research Commission, 1947). The fact that seven of these cases showed evidence of polio virus infection is not proof that the illnesses were caused by that virus. However, the laboratory results obtained were similar to those found in typical paralytic poliomyelitis. The clinical manifestations were very like those found in the five other cases mentioned in the literature.

We do not know whether cases of this clinical type are always associated with polio virus infection. It would be

 † Also showed rising titres against Coxsackie A 1, A 4, A 6

necessary to study cases occurring in other seasons and at other places in order to settle this point.

Summary

During the 1955 poliomyelitis epidemic 121 cases of clinically typical poliomyelitis were admitted to hospital. In the same period nine cases of encephalitis-like illness were seen. These were investigated by standard virological techniques, and seven were shown to be infected with poliomyelitis virus. The infected cases fell into two groups—those which resembled acute cerebellar ataxia, and those which resembled acute encephalitis. Probably poliomyelitis infection can occasionally manifest itself by symptoms exclusively related to cerebellar or "encephalitic" lesions.

We are grateful to Drs. J. M. Kennedy and T. Colver for permission to publish these cases. We thank Drs. A. J. M. Warrack and L. Wolman for the pathology reports, Dr. J. M. Warboys for the E.E.G. reports, Dr. A. B. Sabin for his valuable discussion, and Professor C. H. Stuart-Harris for criticism of the manuscript.

HABITUAL ABORTION DUE TO INSUFFICIENCY OF THE INTERNAL CERVICAL OS

A PRELIMINARY REPORT OF SEVEN CASES TREATED BY A MODIFIED SHIRODKAR TECHNIQUE

BY

V. B. GREEN-ARMYTAGE, M.D., F.R.C.P.
F.R.C.S., F.R.C.O.G.

AND

J. C. McCLURE BROWNE, F.R.C.S.Ed.
F.R.C.O.G.

From the Institute of Obstetrics and Gynaecology,
Hammersmith Hospital, London

The problem of habitual abortion is fortunately relatively rare. To the woman who suffers from this condition, however, it is a most serious and depressing one. Despite every line of investigation and management, there is still a hard core of patients who habitually abort in the early months of pregnancy.

Aschoff (1906) demonstrated the intimate anatomy of the uterus and cervix, showing that the upper part of the cervical canal and the anatomical internal os were incorporated into the lower segment of the uterus at an early stage of pregnancy (Fig. 1). This was confirmed by F. J. Browne (1950). Danforth (1947), of Chicago, showed that as a result of congenital defect or of trauma by dilators, forceps extraction, or the passage of a large infant, the fibromuscular junction between the anatomi-

cal internal os and the lower uterine segment might be rendered inefficient for its purpose of retaining the growing conceptus *in utero* (Fig. 2). Clinically such a condition may be suspected in patients who, following

FIG. 1.—Showing formation of the lower uterine segment by inclusion of the upper part of the cervical canal in the uterine cavity.

surgical dilatation or amputation of the cervix, or trauma during delivery, subsequently abort repeatedly at a stage in pregnancy which will vary according to the degree of cervical impairment present.

Lash and Lash (1950) drew attention to the incompetent internal os as a factor in habitual abortion, but particularly in relation to anterior defects resulting from obstetrical or gynaecological trauma. They described a method of repair of the anterior defect. Subsequently Rubovits, Cooperman, and Lash (1953) described a means of diagnosis in the non-pregnant state by means of x-ray examination. The symptoms are, of course, present only during pregnancy, and consist of a sudden rupture of the membranes followed by a rapid and relatively painless extrusion of the products of conception. It seems curious, however, that Lash and Lash should describe only an anterior defect, for most gynaecologists would agree that lateral defects in the cervix are far more common. Shirodkar (1955), however, realizing that the defect in the internal os could be, and

FIG. 2.—To show how bag of membranes may descend or herniate if fibromuscular junction is weak or insufficient, with rupture of membranes and/or abortion.

most frequently was, in a situation other than anterior, described a method of encirclement by means of a fascial strip, forming a "purse-string" around the internal os.

Incompetence of the internal os may be suspected if there is a history of repeated early rupture of the membranes resulting in abortion. The incompetence can be demonstrated in two ways when the patient is not pregnant. First, a special hystrogram can be carried out, using a cannula tipped with an inflatable bulb. This is inserted into the uterine cavity and lipiodol or other radio-opaque substance injected so as to distend the bulb. Then, with gentle traction on the cannula, an x-ray plate is taken in the lateral and antero-posterior positions. This will demonstrate an abnormally patulous internal os (Fig. 3). On the other hand, it may be possible, with the non-pregnant patient anaesthetized and in the lithotomy position, to pass a Hegar dilator of size 4 or larger into the uterine cavity without any difficulty whatsoever. This we regard as demonstrating that the internal os is indeed deficient.

FIG. 3.—Ballooning of the cervical canal, with a patulous internal os (Case 7).

In a patient already pregnant, however, with a history of repeated abortions, inspection of the cervix through a speculum may show bulging membranes and a gaping cervix, and obviously a clinical diagnosis of threatened abortion is indicated. If there has been no bleeding it is reasonable to suppose that it is the cervix which is at fault.

We have now had seven patients suffering from repeated abortion in whom we have been able to demonstrate by these methods a deficiency in the internal os. They were all treated by a modification of the Shirodkar technique, for one of us had the privilege of watching Mr. Shirodkar perform his operation in Bombay on a patient five months pregnant who had had four abortions and in whom the bulging membranes could be clearly seen high in the dilated cervical canal. Five have now been delivered (three by caesarean section and two *per vias naturales*): two of these are now pregnant again, and the operation has again been performed. The sixth and seventh are not yet pregnant so far as we know. One is living in Ghana, and the other has only recently undergone operation.

The following are details of the seven cases.

Case 1

The patient, a para 0+4, aged 26 and married eight years, was first seen in the infertility clinic on March 18, 1955. There was no clear history of cervical trauma. There had been three miscarriages, the first in September, 1952, at 12 weeks; the second in July, 1953, at 22 weeks; and the third in August, 1954, at 24 weeks.

Clinical examination was essentially negative. A tubal insufflation test was positive and a hystrogram showed that there was a deficiency in the internal cervical os (Fig. 4). On December 16, 1955, she was found to be approximately 10

FIG. 4.—Hystrogram showing a defective internal os. (Case 1.)

weeks pregnant (L.M.P., October 10), and she was admitted immediately for a modified Shirodkar operation. This was carried out, but she aborted the same day. Following her period on March 26, 1956, she again became pregnant, and on May 18 a progesterone implant of 100 mg. (4×25 mg.) was performed. The pregnancy continued until 38 weeks, when, because of her history and a first degree of disproportion, surgical induction of labour was carried out. On introducing the finger through the cervix the nylon suture could be felt as a rigid band lying just deep to the endocervical mucous membrane. It had presumably migrated to that position from the outer aspect of the cervix. The suture was divided with long curved scissors, and immediately the cervix opened widely enough to admit three fingers. The forewaters were ruptured and clear liquor was obtained. Labour pains, however, did not follow, and 27 hours later lower segment caesarean section was carried out. A living male child weighing 5 lb. 7 oz. (2,465 g.) was delivered, and has survived. She is now pregnant again (L.M.P., April 30, 1957) and the operation has been repeated. The pregnancy continues.

Case 2

A para 0+3, aged 34 and married two years, had no history of cervical trauma. In 1954 she had a spontaneous miscarriage at 8 weeks, and in the same year one at 12 weeks. In 1955 another miscarriage occurred, again at 8 weeks. She was first seen at the infertility clinic on October 28, 1955. Clinical examination revealed a small fundal fibroid which was thought to be of no significance. There was no other clinical abnormality. A tubal insufflation test was positive. Examination of the husband's sperms showed no abnormality. The total count was 175,000,000. On November 18 a hysterosalpingogram (Fig. 5) showed incompetence of the internal cervical os, and a temperature chart

FIG. 5.—Hystrogram showing a defective internal os. (Case 2.)

showed that ovulation was indeed occurring. Her last period began on November 4, and on December 16 the Hogben test was positive. There was a slight brown discharge. She was admitted to hospital on January 2, 1956, and a modified Shirodkar operation was performed.

Pregnancy progressed uneventfully until on August 1, when 39 weeks pregnant, the blood pressure had risen from an average level of about 120/80 to 140/90. She was admitted and went into labour at 10 o'clock that night. At 1.30 p.m. the next day she was having fairly good contractions. No dilatation of the cervix could be felt on vaginal examination. The nylon suture was divided posteriorly and the membranes were ruptured. As soon as the stitch was divided the cervix dilated readily to two fingerbreadths. Labour progressed normally and at 2 p.m. on August 3, after a second stage lasting 50 minutes, a living female child weighing 6 lb. 11 oz. (3,030 g.) was delivered with the aid of an episiotomy. The puerperium was normal and the child survived.

On February 11, 1957, the patient was seen again. The last period had begun on December 16, 1956, and a Hogben test on January 8 was positive. She was admitted for the insertion of another pericervical suture. The pregnancy is continuing.

Case 3

This woman, a para 1+4, aged 32, had been married three years. Early in 1953 she underwent an operation in Hong Kong involving amputation of the cervix. In December, 1953, June, 1954, April, 1956, and December, 1955, she had miscarriages at 11 or 12 weeks' gestation. On examination in May, 1956, she was not pregnant. The cervical canal was almost non-existent; its length was approximately 4 mm.

In early May, 1956, a modified Shirodkar operation was performed, using three monofilament nylons, so as to make some real length of cervical canal. Each stitch was placed 0.5 cm. above its predecessor. The patient became pregnant immediately after operation, and went to Indonesia. On March 12, 1957, letters were received from her doctor, P. Rot, and her husband, stating that she had a breech presentation and was going to have a caesarean operation. We later heard that she had been successfully delivered of a living infant by caesarean section.

In this case the repeated abortions were clearly due to a too radical amputation of the cervix.

Case 4

A para 3, aged 31, had been married nine years. Normal deliveries occurred in April, 1949, March, 1951, and May, 1953. Her last menstrual period was August 4, 1956. On December 10 she noticed that her uterus suddenly reduced in size, and on the 14th she suddenly lost 4 to 5 oz. (114 to 142 ml.) of liquor amnii. She was put to bed, and had labour pains for 1½ hours. On December 16, in consultation with Dr. Murray, she was seen in her home. When a speculum was introduced into the vagina a watery discharge could be seen emerging from a cervix which was dilated sufficiently to admit a finger. She was taken to Hammer-smith Hospital, and a modified Shirodkar operation was performed that day. Since then she has proceeded normally. The nylon filament was removed at 39 weeks. She delivered normally at term.

Case 5

One of us (V. B. G.-A.) was asked to see this patient in Cairo in September, 1956. She was aged 25, had been married six years, and had had five abortions but no living child. On examination the cervix admitted a No. 5 Hegar dilator with ease. The operation was performed at the Coptic Hospital, but so far she has not become pregnant.

Case 6

This patient, a para 0+4, aged 25 and married three years, was referred because of repeated miscarriages. Investigation showed that she was ovulating and that her tubes were patent. There was no detectable abnormality in the uterus, except that the cervix was slightly patulous. The

husband's semen was normal. It was possible to pass a No. 4 dilator straight into the uterine cavity without any obstruction by the cervix, although there was no evidence of laceration or other trauma.

On January 3, 1957, a modified Shirodkar operation was carried out. Recovery was entirely normal, and the patient has returned to her home in Ghana. So far there has been no intimation that she is pregnant.

Case 7

A para 0+2, aged 31, had been married four years. There was no clear history of cervical trauma. In 1954 and in May, 1956, she had had miscarriages at 8 weeks, curettage being necessary in both cases. On February 8, 1957, a hystrogram (Fig. 3) showed considerable ballooning of the cervical canal, with widening of the internal os. The last period began on January 20, 1957. On February 13, at operation, a No. 4 Hegar dilator passed with ease into the uterine cavity and a modified Shirodkar operation was performed. A hystrogram (Fig. 6) showed satisfactory reduction in calibre. She is not yet pregnant.

Technique

The technique employed was as follows:

Under thiopentone and gas and oxygen, with the patient in the Trendelenburg position, whether pregnant or not, after passing a catheter the anterior lip of the cervix is grasped by a sponge-holder or single-toothed tenaculum. Then 30–50 ml. of 1% procaine with adrenaline, 1 in 200,000, is first injected sub-mucosally upwards and completely around the cervix. After a few minutes a 1-in. (2.5-cm.) transverse

incision is made at the vagino-cervical junction, and then, with blunt scissors, the submucosa and bladder are pushed upwards to expose the region of the histological internal os, which lies about 1½ in. (3.5 cm.) above the external os.

The sponge-holder or tenaculum is now transferred to the posterior lip and a small vertical incision is made at the same site on the posterior surface of the cervix. The submucosa is then deviated to the right and left with blunt scissors so that now the anterior and posterior surfaces of the cervix proper can be clearly seen smooth and white.

With size 7N or 8N nylon threaded on a needle, a bite is taken of the anterior visible cervical surface, and then, using a Moseley hook or a right-angled blunt needle (such as the right and left Macewen hernia needle), this is passed from the posterior incision next to and around the right side of the cervix to emerge at the anterior incision and pick up one free end of nylon and bring it out posteriorly. The procedure is repeated on the left side and the other free end brought out. The ends are then tied together tightly enough to approximate the walls of the endocervical canal at the level of the anatomical internal os. If need be, a second, or even a third, nylon ligature can be passed and secured. The knots are always placed *behind* the cervix to avoid irritation of the bladder. Shirodkar at present prefers to use ¼-in. (3-mm.) nylon tape. In future, possibly kangaroo tendon would be even better.

Judging the degree of tautness of approximation of the canal walls is easy in the non-pregnant, for all one need do is to pass a No. 4 Hegar dilator into the cervix and then tighten the nylon sufficiently to prevent the dilator falling out spontaneously, or, if need be, squeezing it out before

FIG. 6.—Narrowing of cervical canal after modified Shirodkar operation (Case 7). (Compare with Fig. 3, before operation.)

knotting. But in the pregnant woman it is another matter; one must use one's own judgment; the suture should be tied with very little tension. The two incisions are then closed with catgut in the ordinary way and the patient is sent back to bed. The foot of the bed should be raised for 48 hours or more if the patient is pregnant.

Mode of Delivery

With a history of repeated abortion and with a pregnancy which has reached term after this operative procedure it is tempting to deliver the child by means of caesarean section. Where there is no other obstetric indication, however, it seems reasonable to allow the patient to go into labour and divide the suture, which by this time may be found to lie just deep to the endocervical mucosa. Then, if labour proceeds normally within 48 hours, operative intervention is not indicated. If, however, after division of the suture delivery is not imminent after 48 hours, it seems to us desirable to deliver the patient by caesarean section.

Discussion

Without detailing the underlying causes, Malpas (1938) suggested that after three abortions the chance of spontaneous cure was 27%. Swyer and Daley (1953), however, found that this pessimistic assessment was far too low; that approximately 50% of such women had a chance of producing a live baby without treatment.

It is, of course, not difficult, in cases where there is a history of habitual abortion, to perform a Lash or Shirodkar type of operation, either before or during pregnancy, and if subsequently the patient carries to term there would be a natural tendency to claim that any successful result was due to the operation itself. In our opinion, success can be attributed to the operation only if a history of repeated early rupture of the membranes is obtained, or if actual incompetence of the internal os can be demonstrated.

It is quite obvious that to amass a series of cases sufficient to produce statistically significant results will take a long time owing to the relative rarity of this cause of habitual abortion. This preliminary communication is published in the hope that it may stimulate other workers in this field to carry out investigation and treatment along similar lines.

Summary

Deficiency of the internal cervical os is an occasional cause of habitual abortion. Such insufficiency may be either congenital or the result of trauma at gynaecological operation or during childbirth or miscarriage. The deficiency may be suspected from the history of repeated early rupture of the membranes followed by abortion, and may be demonstrated in the non-pregnant woman by a special x-ray technique or by the passage of a No. 4 cervical dilator freely into the uterine cavity. During pregnancy it may be confirmed by the observation that the membranes are bulging and that the cervix is partially dilated in the absence of bleeding or obvious uterine contractions.

A method of reinforcement of the inefficient internal os, based on Shirodkar's original technique, is described, and seven cases so treated are listed in detail. Five have now been delivered, and two are not yet pregnant.

ADDENDUM.—Since submitting this paper for publication we have operated on five more patients between the 15th and 20th weeks of pregnancy: none of these have aborted and all have proceeded to term normally.

PHARYNGO-CONJUNCTIVAL FEVER SCHOOL OUTBREAKS IN ENGLAND DURING THE SUMMER OF 1955 ASSOCIATED WITH ADENOVIRUS TYPES 3, 7, AND 14

BY

AND

J. C. McDONALD, M.D., D.P.H.

Virus Reference and Epidemiological Research Laboratories,
London

In 1954 Parrott and his colleagues reported a small outbreak of eight cases of febrile illness associated with type 3 adenovirus infection among patients and staff of a children's hospital in Washington. The main clinical features were pharyngitis, rhinitis, enlarged cervical lymph nodes, and conjunctival inflammation. Further outbreaks of an apparently identical illness occurring in the general population in the vicinity of Washington in the same year were described in detail by Bell *et al.* (1955). Once again type 3 adenovirus was apparently responsible, and the authors suggested that the disease be named pharyngo-conjunctival fever. Outbreaks of illness with clinical similarities occurred in Toronto in 1955 (Ormsby and Aitchison, 1955). Others had been described earlier by Guthrie and Pessel (1925) in a residential boys' school in New Jersey; by Derrick (1943) in association with a swimming-bath in Brisbane, Australia; and by Cockburn (1953) in Greeley, Colorado. Subsequent tests on paired sera from patients in the Greeley epidemic showed rising titres of neutralizing antibody to type 3 adenovirus (Cockburn *et al.*, 1956).

An epidemic of febrile pharyngitis and conjunctivitis associated with adenovirus type 4 infection occurred in Helsinki in the summer of 1955 (Forssell *et al.*, 1956). In this epidemic, however, some differences in the symptomatology were observed; severe headache, gastrointestinal symptoms, and stiffness of the neck or back were found in many patients, and sinusitis was a common complication. Meningismus and other unusual signs were also noted by Sobel *et al.* (1956) in an outbreak of pharyngo-conjunctival fever in New Hampshire in 1955, in which there was evidence of type 3 infection. A school outbreak of acute respiratory illness associated with adenovirus type 7 infection occurred in the North of England in 1955 (Tyrrell *et al.*, 1956). Conjunctivitis was seen in a small proportion of the cases.

During the summer of 1955 epidemics of an illness closely resembling that described by Bell *et al.* (1955) occurred in Lancing College and Epsom College, two residential boys' schools in southern England. This report is mainly concerned with an account of observations made in these schools. Later in the summer two of us (B. E. A. and J. C. McD.) assisted in the investigation of five other similar epidemics: four in residential

boys' schools—Queen's College, Taunton; Wrekin College, Salop; Wellingborough School, Northants; and Roysse's School, Abingdon—and one in a Royal Naval training school for boys in Portsmouth. For permission to include information on these outbreaks we are indebted to Dr. C. G. M. Donaldson, Dr. J. Prentice, Dr. W. D. Arthur, and Dr. J. H. Fisher, the medical officers of the four schools, and to Surgeon Commander P. K. Fraser and the medical department of the Admiralty. In all, over 400 boys in the seven schools were sufficiently ill to require treatment in bed. Sickness rates in the individual schools ranged from 4 to 41%. The duration and intensity of the epidemics varied greatly, as may be seen in Fig. 1, in which cases are shown by dates of onset. In three of the schools—Wrekin, Wellingborough, and Roysse's—more cases would probably have been recorded if the summer holiday had not intervened. Serological evidence of adenovirus infection was obtained from representative cases in all seven schools, and adenovirus strains were isolated from patients in five of them.

OUTBREAKS OF PHARYNGO-CONJUNCTIVAL FEVER

DATES OF ONSET OF ILLNESS IN BOYS ADMITTED TO SCHOOL SANATORIA OR KEPT HOME FROM SCHOOL

FIG. 1.—Outbreaks of pharyngo-conjunctival fever. Dates of onset of illness in boys admitted to school sanatoria or kept home from school.

Clinical Records

Symptoms and signs and their severity were recorded for 116 patients at Lancing College and 53 patients at Epsom College who were considered on clinical grounds to be suffering from the epidemic disease, and who were admitted to the sanatorium. An effort was made to record the observations in as standard a manner as possible. At Epsom a further 8 boys who were treated for part of their illnesses at home are not included in the clinical analysis. In addition, 18 boys at Lancing and 8 boys at Epsom were admitted to the sanatorium with some other respiratory illness during the summer term; at Lancing six boys were admitted with rubella and one with glandular fever, and at Epsom one boy was admitted with glandular fever. The six cases of rubella were all in the same House, were clinically typical, and occurred in two groups, the first separated from the second by 16 to 21 days. The proportion of illnesses not classified as "pharyngo-conjunctival fever" was therefore small. In the other five schools a general description of the illnesses was obtained from discussion with the school doctors, and cases were seen and examined. As one of us (J.C.McD.) visited six of the seven outbreaks, some comparison of the clinical findings in each was possible.

Specimens

Blood counts and bacteriological examinations of throat and eye swabs were made on a proportion of the Lancing and Epsom cases throughout the epidemic. Virological investigations were begun in early June. At Lancing College an attempt was then made to obtain blood specimens during the convalescent stage from as many as possible of those who had been ill, and paired acute and convalescent blood specimens from other boys who became ill subsequently. In addition, late convalescent specimens were taken from a small number of boys, most of whom had been bled at least once previously, on their return to school after the summer holiday. In all, one or more blood specimens were obtained from 71 of the 116 cases of pharyngo-conjunctival fever, from 7 of the 18 cases of other respiratory illness, and from all 7 cases with rubella or glandular fever. At Epsom College blood samples, single or paired, were obtained from a sample of the patients throughout the epidemic, 17 of the 53 patients being tested. In the remaining five schools paired sera were available from 30 typical cases. The number of pairs from individual schools ranged from 3 to 10. Specimens of serum were stored at -30°C . until tested.

Specimens for virus isolation were obtained from the conjunctival sac or throat of a small number of acutely ill patients in five of the schools, but not in Queen's College, Taunton, or in the naval training school, where all cases were convalescent when visited. Conjunctival specimens were taken by means of a cotton-wool swab on a wooden stick. Immediately after collection the swab was transferred to a 5-ml. screw-capped bottle containing 2 to 3 ml. of nutrient broth. The wooden stick was broken off and the cap screwed on tightly. Throat washings were taken in 10 ml. of saline, to which 2 to 3 ml. of nutrient broth was immediately added. Specimens were transported to the laboratory on solid carbon dioxide and subsequently stored in an electric refrigerator at -70°C .

Laboratory Methods

Sera were examined by the complement-fixation test performed in plastic plates of the type used for haemagglutination tests (World Health Organization, 1953). Serum, complement ($2\frac{1}{2}$ M.H.D.), and antigen were mixed in 0.1-ml. volumes and incubated at 37°C . for 75 minutes, when 0.2 ml. of a 1% suspension of sensitized sheep red cells was added. After 30 minutes at 37°C . the plates were stored overnight at 4°C . and the results read the next morning. Titres recorded as positive were the highest initial serum dilution showing approximately 75% of red cells unlysed. The antigen was used at the optimum dilution and was prepared from cultures of HeLa cells infected with R1-67 virus (adenovirus type 4). The medium and culture in bottles showing advanced degeneration were frozen at -30°C . and overnight. After thawing, the contents were centrifuged, and the supernatant fluid was heated at 58°C . for 30 minutes and then stored at -30°C . until required for use as antigen.

Virus isolation tests were performed by inoculation of 0.2 ml. of throat washings, or of the broth in which eye swabs had been stored, into each of two tubes of HeLa cell cultures. The cultures were left for at least 10 days and when necessary further passages were made. When characteristic degeneration occurred the cultures were frozen and thawed and the fluid was tested for the presence of adenovirus group antigen by complement-fixation with positive human convalescent serum. The HeLa cultures were grown in a medium containing 20% of human serum; before inoculation this was removed and the cultures were washed twice with a saline solution. The maintenance medium contained approximately 2% of chicken serum. Viruses were typed in HeLa tube cultures containing 1 ml. of medium to which was added 0.2 ml. of a virus-serum mixture prepared one hour previously and held at room temperature in the interval. Type-specific sera were prepared in rabbits which had received a series of intravenous injections of supernatant fluid from HeLa cultures infected with adenovirus prototype strains. The dose of the virus under test

was adjusted to give complete degeneration in two to four days, and results were read 24 hours after the control tubes had shown complete degeneration. The specific sera used had titres between 1/300 and 1/3,000 (original dilution in virus-serum mixture) to homologous virus, but did not neutralize heterologous viruses at a 1/30 dilution. Viruses to be typed were screened against 1/30 dilutions of type-specific sera. Later, as a check, some of these strains were tested in parallel with viruses of known type against a full range of dilutions of the neutralizing serum.

Clinical Features

In all seven outbreaks the clinical features were very similar, though individual illnesses varied in severity and in the prominence of particular symptoms or signs. The illnesses were characterized by three to five days' fever, sore throat, blocked nose, enlarged cervical glands, painless conjunctivitis, and the absence of any involvement of the respiratory tract below the pharynx. Diarrhoea, vomiting, and abdominal pain were not generally complained of, but about a quarter of the patients at Epsom College and about a third at Queen's College, Taunton, had gastro-intestinal symptoms. These symptoms did not appear to be due to drug treatment. The frequency with which various symptoms and signs were recorded at Epsom and Lancing Colleges is shown in Table I. Percentage figures were usually lower at Lancing than at Epsom; particularly for the less prominent symptoms. We cannot be certain whether this was the result of differences in the illnesses or in the observers, but no essential difference was apparent to those of us who saw patients in both schools. For this reason it seemed permissible to give also in Table I an analysis of symptoms in a group of 29 cases, 20 from Lancing and 9 from Epsom, in whom a fourfold or greater rise in complement-fixing antibody was found in paired sera. The detailed clinical description that follows is based upon records of patients from both schools.

Prodromal symptoms of malaise and frontal headache were experienced by some patients, but in the majority the onset was sudden and accompanied by moderately sore throat, shivering, nausea, and mild aches in the legs or back. Occasionally nasal blockage, dizziness, faintness, vomiting, and diarrhoea were present at this stage and sometimes a

TABLE I.—Clinical Findings in Outbreaks of Pharyngo-conjunctival Fever at Lancing and Epsom Colleges

Clinical Findings	Percentage of Boys in whom Observed

little itching or aching in or behind the eyes. On examination the temperature was 101 to 102° F. (38.3 to 38.9° C.), with a pulse rate of 80 to 110. The patient appeared moderately ill, with a flushed face and an erythematous haze over the bulbar conjunctivae. The soft palate and anterior fauces were erythematous, and a few enlarged vessels or petechiae were sometimes seen in these areas. The lymphatic tissue of the posterior pharyngeal wall was red and hypertrophied. A scanty follicular exudate was seen on the tonsils or in the pharynx in about one-quarter of the patients. Purulent exudate was uncommon, and ulceration was not observed. A few translucent vesicles less than 1 mm. in diameter were observed on the soft palate and faucial pillars in some cases; they were transient and were not associated with erythema or ulceration. Small discrete glands up to about 1.5 cm. in diameter were usually palpable in the posterior and anterior cervical groups, less often in the axillae, and occasionally in the inguinal regions. They were not tender. Preauricular adenopathy was not observed. The glandular enlargement was symmetrical and did not appear to be related to local inflammation. In nine cases—one at Lancing and eight at Epsom—the spleen was palpable, its size ranging from a palpable tip to three fingerbreadths of enlargement. It was smooth and not tender.

During the next two or three days the patients remained moderately ill and slightly drowsy, the temperature being sustained or remittent, with a maximum of 102 to 104° F. (38.9 to 40° C.). The throat continued inflamed, the nose became blocked, and a posterior nasal discharge often developed, though the anterior nares remained dry and normal in appearance. Hoarseness and cough were never prominent symptoms and sputum was scanty. Abnormal signs in the chest were very uncommon and consisted of scattered rhonchi only. The conjunctival inflammation frequently increased at this stage. It was accompanied by very little discomfort. The lower palpebral conjunctivae became red and oedematous and moderate-sized vessels appeared over the bulbar conjunctivae. With more severe inflammation, the lower conjunctival sacs became oedematous and granular, and follicles were formed. A false membrane was seen in one case. The discharge was usually watery: the eyelids rarely became sticky or matted. In the most severely inflamed eyes the palpebral and bulbar conjunctivae were intensely red. At any particular time one eye often appeared worse than the other, but by the end of the illness both eyes had usually been affected to some degree. In a few cases the conjunctivitis preceded or followed the main illness by three days or more. By the third or fourth day of illness the patients felt much better, the temperature falling by lysis over 24 to 48 hours, and the pulse rate returning to normal.

During the convalescent phase abnormal signs gradually resolved. A moderate degree of lassitude and shakiness was experienced, but within 14 days from onset most patients felt well and could undertake a full day's activity. By this time eyes, throat, glands, and upper respiratory tract had all become almost or quite normal. Relapses were not encountered and complications were uncommon. Two cases of moderately severe otitis media were observed; both resolved rapidly without otorrhoea. Routine chest x-ray films were not taken during the acute phase of the illness, but basal shadows were found in two cases examined about three weeks after onset. A mass x-ray survey carried out at Lancing in early July revealed no further abnormalities that could be attributed to the infection. Albuminuria, jaundice, skin rashes, hepatic enlargement or tenderness, and abnormalities of the central nervous system were absent.

The clinical features described above are those of the fully developed case, which constituted about a third of the total. In about a fifth of the patients whose illnesses were otherwise similar the conjunctivae were unaffected. The remaining cases were less severe, and in about a quarter of them moderate or severe eye involvement occurred alone, with little or no fever or constitutional disturbance. In all

these clinical varieties serological evidence of infection was found.

Slit-lamp Examination.—Mr. A. J. Cameron kindly examined seven of the Epsom cases during the convalescent stage (11th to 18th day of illness). All these cases had had moderate or severe involvement of the eyes during the acute stage of the illness, but at the time of examination few abnormalities were apparent to the naked eye. In five of these cases, many groups of small lesions, staining with 1% rose Bengal, were seen at the limbus on the nasal conjunctival side. In one case small diffuse nebulae which did not stain were found over the cornea. The staining lesions were similar to those found in superficial punctate keratitis. In the remaining case no lesions were seen.

Treatment.—Either penicillin (500,000 or 250,000 units by intramuscular injection twice daily), chlortetracycline (250 mg. four times a day), or sulphadimidine 1 g. four times a day was given in representative cases, early in the illness. No effect on the patient's general condition was apparent. The course of the signs and of the fever appeared to be unaffected when compared with cases in which symptomatic treatment was given alone.

Laboratory Findings

Paired specimens of serum were available from 91 boys in the seven outbreaks investigated, and a fourfold or greater rise in complement-fixation titres was found in 52 cases (57%). Material for the isolation of viruses had been taken from 42 patients in five of the schools and adenovirus strains were isolated from 25 (60%) of them. The samples consisted of 33 throat washings from which 22 strains were isolated and 17 eye swabs which yielded 5 strains. These results are shown for each school in Table II. It will be

seen that serological evidence of infection was obtained in a number of boys at each school, and that where material had been taken for culture a number of strains were isolated from eye or throat swabs. There was satisfactory agreement between virus isolation and serological tests in the 35 cases where both types of specimen were available. A comparison of the two tests is shown in Table III.

At Lancing College only 20 out of 50 cases tested showed a rising titre of antibody—a lower proportion than in other schools. In 21 of the 50 the first serum specimen had been taken between 8 and 23 days from the onset of illness and only one of these showed a rise in titre in the second specimen. Most of these sera, however, showed a level of antibody consistent with the stage of illness. In the remaining 29 cases the first specimen of serum had been taken before the eighth day from onset of illness and 19 (66%) showed a rise in titre. This proportion is similar to that

obtained in the other schools, where almost all first specimens of serum had been taken within a week of onset of illness. At Lancing College serum was obtained three to four months after the illness from 47 boys who had shown an antibody titre of 1/8 or more in an early convalescent specimen taken 10 to 30 days from onset of illness. The antibody titre had not altered more than twofold in 54%; it had fallen fourfold in 21% and eightfold or more in 15%. The distribution of titres obtained in the early and late convalescent specimens from these cases is shown in Fig. 2.

Fig. 2.—Distribution of complement-fixation titres in 47 cases tested 10 to 30 days and three to four months from onset of illness.

results were as follows: Lancing College, 2 strains negative to types 1 to 8 inclusive; Epsom College, 6 strains type 7; Wrekin College, 3 strains type 3; Wellingborough College, 4 strains type 3; Royse's School, 3 strains type 3. Two strains from Lancing College were subsequently tested against serum specific for an adenovirus strain isolated from a case of respiratory illness in a Dutch military recruit. This serum neutralized the Lancing strain to the dilution obtained against the homologous virus. Professor van der Veen, who isolated the Dutch strain (deWit), has informed us that Dr. W. P. Rowe has classified it as the adenovirus type 14 prototype strain.* It was found that the Lancing virus strains took longer to cause degeneration of the HeLa cultures on primary isolation than did strains from the other schools. They were also found to lose titre on storage at -30° C. considerably more rapidly than is the case with other adenovirus types of which we have experience. These points may explain the relatively low isolation rates shown for Lancing College recorded in Table II.

At Lancing and Epsom Colleges throat and eye swabs from a proportion of cases were examined bacteriologically, total and differential white blood cell counts were made, and serum was tested for heterophil antibody and a rising titre of complement-fixing antibody to influenza viruses A, B, and C. Bacteriological results generally showed a normal flora even in those cases where the throat appeared most inflamed, but in a few the growth consisted predominantly of haemolytic streptococci, pneumococci, *Staphylococcus aureus*, or *Haemophilus influenzae*. At Lancing College white-cell counts were normal or slightly low with a relative lymphocytosis; in most cases a few atypical mononuclear cells resembling those of glandular fever were present. These never exceeded 7% of the differential count. Such cells have been described in infectious hepatitis (Barker *et al.*, 1945) and other virus infections, and in some allergic conditions (Randolph and Gibson, 1944). In a few cases there was an increase in eosinophils of up to 10%. Similar results were found at Epsom College. The Paul-Bunnell test was negative in all

*A virus strain from the Lancing College outbreak has since been examined by Dr. W. P. Rowe, who confirms that it belongs to type 14.

cases examined with the exception of one case of typical glandular fever in each school. Complement-fixation tests for influenza were negative in each of the 24 cases tested.

Epidemiological Observations

All seven outbreaks occurred during the early months of the exceptionally warm dry summer of 1955. Sports and other fixture lists were examined, but no connexion was discovered between the schools. Directors of public health and other laboratories throughout England and Wales and many school medical officers were informed in June that we were anxious to learn of any similar occurrences, but, apart from an outbreak in a school in the North of England during the autumn (Tyrrell *et al.*, 1956) and one or two sporadic cases, we know of no other evidence of pharyngo-conjunctival fever in Britain during 1955. In 1956 the laboratory assisted in the investigation of what was probably the same syndrome in a residential girls' school and found evidence of adenovirus type 7 infection in a sample of patients tested. A few scattered sporadic cases were again found in 1956.

It seemed improbable that if an illness with so striking a clinical picture had occurred in this country in epidemic form prior to 1955 it would not have been recorded. Accordingly we looked for any evidence of immunity in older age groups that might have resulted from past infection with the same virus. In Lancing, Epsom, and Wrekin Colleges illness attack rates were calculated by year of birth; these are shown in Table IV. It may be seen that

TABLE IV.—Illness Attack Rate by Year of Birth in Three Schools

School	Attack Rate (%) for Those Born in:				
	1936	1937	1938	1939	1940
Lancing College	14	16	22	27	38
Epsom	0	7	10	6	36
Wrekin	12	8	17	19	23

* Only 1 boy in this age group at risk.

attack rates fell with rising age in all three schools. Further evidence of immunity associated with age was the almost complete absence of illness among adult members of the staff in any of the schools. In the four outbreaks not shown in Table IV either the number of cases was too small or insufficient information was collected for age-specific attack rates to be calculated. However, it should be mentioned that there appeared to be little difference between the attack rates in senior and junior schoolboys at either Wellingborough School or Queen's College, Taunton.

The sequence of cases was studied in detail at Epsom and Lancing, but no pattern of spread of infection was apparent. However, boys in residential schools have so many different contacts with one another that the pattern of spread of infection by personal contact might well be obscured. Attack rates in houses, dormitories, and classes showed no difference greater than could be accounted for by age or chance. The onset of the outbreak at Queen's College, Taunton (see Fig. 1), had the explosive character often associated with food-borne infection, but this possibility was not investigated. It is interesting that it was in this school that gastro-intestinal symptoms were most prominent.

Swimming-baths have in some reports been suspected of spreading pharyngo-conjunctival fever. The seven outbreaks mentioned here took place during a hot summer, and all the schools had either a swimming-bath of their own or the use of one, so bathing may have played a part in spreading infection. At Lancing College, however, where the swimming-bath was closed on May 28, the subsequent course of the epidemic was not apparently affected.

No conclusive evidence was found on the length of the incubation period. Bell and his colleagues (1955), after study of the intervals between the onset of the first and subsequent cases in households, concluded that the incubation period was probably five to seven days. The distribution of intervals between first and later cases in dormitories at

Lancing College and Epsom College, shown in Fig. 3, resembles that presented by Bell *et al.* and supports their conclusion.

Fig. 3.—Distribution of intervals from onset of first case in dormitory to onset of subsequent cases (15 intervals of more than 30 days are not shown).

Discussion

Strong evidence has been given by Bell *et al.* (1955) that the syndrome called by them pharyngo-conjunctival fever was due to adenovirus infection. The clinical features of the seven school outbreaks reported here closely resembled this American description. In the five schools where virus isolation was attempted adenovirus strains were isolated and the presence of virus was found to be followed by an increase in complement-fixing antibody in 22 out of 23 cases tested. At Lancing College results were available which indicated that a rise in antibody titre could be shown only in cases from which the first specimen of serum had been taken within a week of onset of illness. It therefore seems probable that adenovirus infection was also the cause of the outbreaks in this country.

The differentiation of individual cases of pharyngo-conjunctival fever from other acute respiratory infections, in particular influenza, streptococcal sore throat, and glandular fever, might well be difficult without laboratory evidence. In epidemic form, however, the characteristics of the syndrome seem quite unlike those of any other. The rarity of cough, tracheitis, and bronchitis should distinguish pharyngo-conjunctival fever from influenza; the nasal symptoms, general non-tender enlargement of cervical glands, and relative absence of follicular or exudative pharyngitis should distinguish it from streptococcal infection. The character, severity, and frequency of the conjunctivitis is unlike that seen in these infections. The short non-relapsing course of the illness and the occurrence of an outbreak would make glandular fever an improbable diagnosis.

Too little is yet known of the full range of clinical manifestations of adenovirus infection to be sure that pharyngo-conjunctival fever could easily be distinguished from them all. It seems quite different from the febrile catarrh seen in military recruits in whom conjunctivitis is usually absent but in whom cough and bronchitis are usually present and pneumonic complications are not uncommon. Epidemic kerato-conjunctivitis, which may be due to adenovirus infection and which is seldom accompanied by nasopharyngeal or febrile symptoms, is far more painful and the corneal damage is often much greater and lasts longer. Difficulties are more likely to arise if it should prove that the adenoviruses can cause other similar but not identical syndromes such as febrile pharyngitis unaccompanied by prominent conjunctivitis (Ginsberg *et al.*, 1955) and outbreaks such as that in Helsinki (Forsell *et al.*, 1956), where in addition to pharyngitis and conjunctivitis there were meningeal symptoms.

Type 3 adenovirus was isolated from the cases described by Bell and his colleagues. The same group of workers

subsequently reported similar illnesses following conjunctival inoculation with viruses of types 1, 3, 4, and 5 (Bell *et al.*, 1956). Types 1, 4, and 5 have not, however, been reported in natural infections causing pharyngo-conjunctival fever. On the other hand, type 3 virus has been isolated from cases of febrile catarrh in military recruits (Berge *et al.*, 1955) as well as from pharyngo-conjunctival fever. In the school outbreaks of pharyngo-conjunctival fever described here type 3 virus was found in three schools, type 7 in one school, and type 14 in another school. We have not encountered type 3 virus in association with any other clinical syndrome, but type 7 was isolated from cases of febrile catarrh in extensive outbreaks in R.A.F. recruits and from sporadic civilian and military cases. The Lancing virus appeared similar to type 14 strains found by Dr. van der Veen in cases of respiratory illness in Dutch recruits and by us in a patient with febrile catarrh in an R.A.F. unit. Virus type does not therefore seem to be the only factor in determining the clinical syndrome. Trauma to the conjunctiva, either chemical or mechanical, and route of infection may be other important factors (Bell *et al.*, 1956).

Summary

Clinical, laboratory, and epidemiological features are described of outbreaks of pharyngo-conjunctival fever associated with adenovirus infection in seven residential schools for boys.

The illnesses were characterized by three to five days' fever, sore throat, blocked nose, enlarged cervical glands, and painless conjunctivitis. A detailed clinical description based on the study of patients in two of the outbreaks is given.

Serological evidence of adenovirus infection was obtained in all seven outbreaks, and virus strains were isolated from throat washings or eye swabs from patients in five schools where this was attempted. Three of the outbreaks appeared to be due to type 3 virus, one to type 7, and one to type 14.

In three schools where the influence of age on susceptibility was studied, illness attack rates fell with rising age.

We are indebted to Mr. A. J. Cameron, consulting ophthalmic surgeon to Epsom College, for slit-lamp examinations; to Dr. D. M. Stone and Dr. N. E. G. Richardson for haematological and bacteriological work; to Dr. R. A. Cocks for help in collecting blood specimens; and to the school matrons—especially Miss N. M. J. Morris, S.R.N., of Epsom College, and Miss B. Clarke, S.R.N., of Lancing College—for considerable help and forbearance during our investigations. We are grateful to Professor J. van der Veen, of the University of Nijmegen, for kindly supplying the type 14 adenovirus strain (deWit) and a quantity of homologous antiserum. Finally, we thank Drs. J. A. Boycott, L. Hoyle, K. E. Hughes, A. C. Jones, and R. L. Vollum, of the Public Health Laboratory Service, for telling us of outbreaks and for allowing us to assist in the investigations.

ANKYLOSING SPONDYLITIS TREATED WITH CORTISONE AND ALLIED SUBSTANCES

BY

C. R. CROFT, T.D., D.M., M.R.C.P.

Physician, South Devon and East Cornwall Hospital, Plymouth

The use of cortisone and allied substances in the treatment of ankylosing spondylitis has received little attention. A recent leading article on prednisone and prednisolone (*British Medical Journal*, 1957) makes no reference to it. In this country, West and Newns (1954) report symptomatic benefit in six cases treated with corticotrophin for 18 to 30 months, but regard it as justified only in the most severe cases. Hart (1952, 1955) showed rapid symptomatic improvement in three out of six cases, but regarded it as suitable only for acute painful episodes. In America, ankylosing spondylitis is regarded as part and parcel of rheumatoid arthritis, and very little specific information on spondylitis is available. Copeman (1953) records Boland as writing that cortisone is highly effective in suppressing rheumatoid spondylitis and that most cases can be kept under control with cortisone maintenance dosage, although he regards it as second choice to x-ray therapy. Forestier *et al.* (1956) record the use of cortisone in doses of 100–150 mg. for periods of 20 to 40 days over six to eight months. They suggest that its use should be reserved for very severe cases and for patients with persistent peripheral involvement.

The general argument for and against long-term treatment with cortisone and its allies in rheumatic diseases is still inconclusive. Whatever may be one's opinion of their therapeutic value, it seems that, on grounds of safety, their use for relief of persistent pain is justified, provided certain types of patient are excluded, simple precautions are taken, and the patients are kept under occasional observation.

A long period usually elapses between the onset of symptoms and firm diagnosis and treatment. The most satisfactory figures are secured in the Services, where Baird (1955) and Morrison (1955) record that half their cases were diagnosed within two years. In the present series of 14 cases only five were diagnosed in four years or less. The patient has had little to lose from this in the past, but earlier diagnosis will be desirable if rapid and sustained relief can be provided.

I am therefore encouraged to record the symptomatic effect of treating with these substances 14 consecutive cases of ankylosing spondylitis in which the diagnosis had long been established and in which orthodox treatment, including radiotherapy, sometimes given to the limit of safety, had been abandoned. A few patients were in hospital in the early stages of treatment, but most were dealt with as out-patients and were seen first at intervals of two to four weeks, and later of three months.

Corticotrophin (long-acting, when available) was employed in earlier cases in doses of 10–25 units, once or twice daily according to supply and symptomatic response. Later, cortisone was used in doses of 50–100 mg. daily, but recently this has been replaced by prednisolone up to 15 mg. daily. The last appears to be the most effective and least liable to cause moon-face.

Estimation of the response rests almost entirely on the patient's observations.

The least that can be said is that some relief has been given when other forms of treatment have been abandoned. In the early stages the disease may show long periods of spontaneous remission, and further experience is needed to decide whether corticotrophin or cortisone compounds should be employed to tide patients over the acute phases, without resort to other treatment.

Case Reports

Case 1.—An accountant aged 47 had had symptoms for 12 years. In October, 1953, gross kyphosis was present with fusion of the whole spine and both hip-joints and very limited shoulder movement. He was no longer able to see a client sitting in front of him. He was in great pain, very thin, and had been unable to work for some months. His E.S.R. was 54 mm. in 1 hour. Previous treatment had consisted of a spinal jacket in the early years and occasional physiotherapy later. Corticotrophin was given continuously from November, 1953, until his death from cor pulmonale in December, 1955. Within a week of starting treatment he experienced almost complete relief of pain and substantial improvement in shoulder movement, which enabled him to brush his hair once more. His sleep and appetite improved and his weight increased. He resumed work, and in February, 1954, felt well enough to wish to join a sailing club, and indeed this was arranged. He remained reasonably free of pain and worked at home almost continuously until his death. All concerned—the patient, his wife, and his doctor—considered the treatment was well worth while despite the difficulties associated with it.

Case 2.—A man aged 34 had had symptoms for 11 years. In May, 1955, he was admitted to hospital and lay flat in bed with severe pains in the back, the sacro-iliac joints being mainly affected. His E.S.R. was 30 mm. in 1 hour. Previous treatment included four courses of x-ray therapy between 1949 and 1954, without much benefit. Within four days of starting corticotrophin gel he was up and about the ward and was discharged after one week, having been taught to give his own injections. He varied the dosage, between 15 and 25 units twice daily, to secure adequate relief of symptoms. Corticotrophin was continued until October, 1956, and since then he has taken prednisolone, 10–15 mg. daily. Since August, 1955, he has worked continuously as a maintenance engineer. He gets some pain when digging in his garden. With an effort he can touch his toes without discomfort. In February, 1957, his E.S.R. was 15 mm. in 1 hour.

Case 3.—A man aged 29, who had had symptoms for one year, was seen in July, 1955, with fusion of sacro-iliac joints, some kyphosis, painful dorsal spine, general weakness, and inability to work for the previous month. His E.S.R. was 43 mm. in 1 hour. No previous treatment had been given. Corticotrophin was started in July, with relief of pain and some increased mobility within one week. He returned home after two weeks, having been taught to give his own injections, and he resumed light work. He was readmitted in December with melaena from duodenal ulcer. Corticotrophin was stopped, with some recurrence of pain. He resumed work in February, 1956, with slight pain, which gradually abated, and until December he worked 10 hours a day as a market gardener. He could touch his toes, but extension of the lumbar spine was defective. In September, 1956, his E.S.R. was 17 mm. in 1 hour. Since January, 1957, pain has recurred, and further treatment with cortisone is at present precluded by the peptic ulcer, which is causing symptoms.

Case 4.—A woman aged 59, who had had symptoms for 11 years, was seen in 1955 with a straight rigid back and fixed hips, slight shoulder movement, poor general condition, mental depression, much pain, especially at night, and serious disturbance of sleep; also a large leg ulcer and oedema of legs. Corticotrophin gel, 20 units daily, was given from

July, 1955, to September, 1956; cortisone, 25 mg. twice daily, from then onwards. She reported that as soon as treatment began her pain was relieved and she slept well, her appetite and general health improved, and movement in the neck and shoulders increased. She is now a contented person, free of pain and able to take a lively interest in her household, and in recent months treatment of her leg ulcer has resulted in healing. She is very satisfied. She has been treated entirely at home.

Case 5.—A man aged 35, who had had symptoms for six years, was seen in 1955 with a rigid lumbar and dorsal spine, complaining of considerable pain in his back and buttocks, particularly for the previous seven months. He was also suffering from chronic non-specific colitis. His E.S.R. was 58 mm. in 1 hour. Previous treatment had consisted of physiotherapy. Corticotrophin gel, 10 units twice daily, was started on August 4, with immediate relief of all pain attributable to spondylitis and considerable improvement in the colitis and in general nutrition. After instruction in giving his own injections he was discharged from hospital on August 10 and resumed work shortly afterwards. Corticotrophin was maintained until September, 1956, with freedom from pain except when he ran short of the drug. It was replaced by prednisolone in September, 1956, and he was free of pain and at work when last seen in October, 1956, shortly before leaving the district, although colitis continued to cause disability. He developed some degree of moon-face, but preferred this to the pain.

Case 6.—A man aged 54, who had had symptoms for 10 years, was seen in November, 1955, with a rigid spine, slight deformity, chest expansion of 1 in. (2.5 cm.), and considerable pain in the back and chest, especially at night. In March, 1955, the E.S.R. was 9 mm. in 1 hour. He was receiving 100% disability pension. X-ray therapy had been given in 1951, and supplementary treatment in 1952, with improvement. In 1953 further x-ray therapy was considered inadvisable. Cortisone was started in November, 1955, and one month later he reported that pain was less and mobility had increased. He has continued under the care of his doctor, who tells me that he applies regularly for further supplies of cortisone, which he finds very effective in relieving his pain.

Case 7.—A man aged 65 had had symptoms for 40 years, but had received no previous treatment. His spine was kyphotic and rigid from sacrum to occiput, and he complained of pain in his shoulders and down his back. His E.S.R. was 64 mm. in 1 hour. Cortisone was started on December 1, 1955. Three weeks later he reported that the feeling of stiffness was much reduced and that he had more freedom of movement. In May, 1956, the pain was slight and activity was greatly improved; this was confirmed by his wife. In October, he reported no pain. His E.S.R. was then 60 mm. in 1 hour. In February, 1957, freedom from pain and increased activity were maintained.

Case 8.—A woman aged 45 had had symptoms for 15 years. The whole spine below the neck was completely rigid with long thoracic kyphosis. Severe pain was present in shoulders and neck, and she wore a brace. Her E.S.R. in October, 1955, was 23 mm. in 1 hour. Cortisone was given from December, 1955, to March, 1956. She said she was free of pain within 10 days of starting this and that her neck moved more freely. Improvement was maintained after stopping cortisone. In January, 1956, she said, "I feel better than I have done for years." Her E.S.R. was 12 mm. in 1 hour. In October she reported that she felt well and had no pain, and she considered that her neck movement had greatly improved. In February, 1957, improvement was maintained. Her E.S.R. was then 26 mm. in 1 hour.

Case 9.—A man aged 25, who had had symptoms for four years, was seen in April, 1956, complaining of pain, mainly in the buttocks and down the backs of both legs. There was limited movement of the lumbar and thoracic spine, with x-ray changes of ankylosing spondylitis in the sacro-iliac joints. His E.S.R. was 20 mm. in 1 hour. X-ray

therapy from October, 1955, to January, 1956, had provided some relief. Cortisone was started in April, 1956, and in May he said that the pain was less and in June that it was negligible. The dose of cortisone was reduced and the drug was stopped in September. In November he said, "I am one hundred per cent.," and examination showed a good range of painless flexion and extension of his spine. In February, 1957, the improvement was maintained. His E.S.R. was then 16 mm. in 1 hour.

Case 10.—A man aged 28, who had had symptoms for 14 years, was seen in June, 1956, with dorsal kyphosis and very restricted spinal movements, including the neck, which was very painful. Fair shoulder movement was present, but with much pain; elbows were painful and stiff; hips showed a fair range of painful movement; chest expansion was 1½ in. (3.8 cm.); E.S.R. was 36 mm. in 1 hour. X-ray therapy had been given in 1949 and 1952, on both occasions with considerable benefit; also in 1954 and 1956, after which further exposure was thought to be inadvisable. Prednisolone, 5 mg. three times a day, was started on June 30, 1956. On July 4 he reported freedom from pain and improved neck movement, and his chest expansion was 2½ in. (5.7 cm.). He was discharged from hospital. On July 10 he was fit to resume work and the dose of prednisolone was reduced to 5 mg. daily. In November he reported that the improved mobility was maintained but that he had slight pain, and the dose of prednisolone was restored to 5 mg. three times a day. In February, 1957, he reported that "by and large, the tablets keep me free of pain." His E.S.R. was then 5 mm. in 1 hour.

Case 11.—A woman aged 43, who had had symptoms for nine years, was seen in June, 1956, complaining of pain and stiffness in the lumbar region and in the neck and shoulders. She was kyphotic, with rigid lumbar and dorsal spine but with some cervical movement. Chest expansion was greatly restricted. Her hips showed a full range of painless movement. Her general nutrition was poor. Her E.S.R. was 25 mm. in 1 hour. She had received x-ray therapy for her sacro-iliac joints in 1950 and for her cervical spine in 1954, with improvement, and again in January and February, 1956. Cortisone was given in June for one month, during which she said she "felt really well" and that her pain was greatly eased; she thought her mobility had increased. She relapsed after ceasing cortisone, but improvement again occurred when prednisolone was started in September. In February, 1957, she said she felt well, had been almost entirely free of pain, and her neck was more freely movable. She was going out to work as well as looking after her own household. Her E.S.R. was 12 mm. in 1 hour.

Case 12.—A man aged 35, who had had symptoms for 14 years, was seen in July, 1956, with a rigid spine and upper dorsal kyphosis. His shoulders allowed his arms to be raised to the horizontal line and were painless; his hips showed a good range of movement but with much stiffness and pain, especially in the morning. His E.S.R. was 30 mm. in 1 hour. Previous treatment consisted of x-ray therapy in 1946 and in 1950-1, with supplementary treatment 1954 and 1955. Prednisolone was started in July, 1956. In August he reported almost complete freedom from pain, no stiffness on waking, and good hip movement. In October he was free of pain, and reported greatly improved general capacity for movement. In February, 1957, he reported continued freedom from pain and from the feeling of stiffness. His E.S.R. was 7 mm. in 1 hour. He had worked continuously as a clerk.

Case 13.—A man aged 27 had had symptoms for five years. In June, 1956, he had a well-developed dorsal kyphosis and wore a brace; he complained of considerable pain in the back, buttocks, and neck. His E.S.R. was 15 mm. in 1 hour. X-ray therapy (900 r) had been given in 1953 without effect on his pain. Prednisolone was started in July, 1956. One month later he reported that he was "much better but has slight neck pain." It was then possible to tighten his brace. In October his chest expansion was 2 in. (5 cm.) against 1 in. (2.5 cm.) in June. In February,

1957, he said he was much better since taking the tablets, and that he was reminded by discomfort if he did not take them. He has worked regularly during treatment.

Case 14.—A man aged 53 had had symptoms for 30 years. In October, 1956, he had a straight rigid dorsal and lumbar spine and slight movement of his neck, which was projected forward. His ribs showed no appreciable movement during respiration. Lumbar spine and sacro-iliac joints were completely ankylosed. His E.S.R. was 25 mm. in 1 hour. He complained of considerable pain in his shoulders and neck. Prednisolone was started in October, and one month later he reported that he was "practically free of pain—more so than for six or seven years"; also that movement of his neck had improved and he felt fully active. His chest expansion was then 1 in. (2.5 cm.). In February, 1957, he reported that pain was negligible, and he thought that movement of his neck had further improved. His chest expansion was 1½ in. (3.8 cm.). He had worked continuously as a schoolmaster. His E.S.R. was 5 mm. in 1 hour.

Summary

The response of 14 consecutive patients with advanced and painful ankylosing spondylitis to treatment with corticotrophin, cortisone, and prednisolone is recorded. There has been an appreciable degree of relief of symptoms, which had not been obtained by other means. The relief of pain was rapid, and was accompanied by some increased freedom of movement. In some cases treatment was stopped, with continuing relief.

I am indebted to Mr. G. J. Lillie, Mr. M. Salz, and Mr. F. T. Wheeldon, orthopaedic surgeons at Mount Gold Hospital, and to Dr. J. Morton, radiotherapist at the South Devon and East Cornwall Hospital, for referring patients to me and for much advice and support; also to Drs. G. F. Bigwood, C. L. Crawford, D. J. Macmillan, and F. A. Trowbridge for their collaboration.

ADRENOCORTICAL HYPERACTIVITY IN A PATIENT WITH BRONCHIAL CARCINOMA AND DIABETES MELLITUS

BY

F. D. ROSENTHAL, M.D., M.R.C.P.

Senior Medical Registrar, Royal Infirmary, Sheffield

Adrenal hyperplasia has been reported to be present at necropsy in about 6% of all patients dying with malignant disease, and appears to be associated most commonly with carcinoma of the bladder, endometrium, kidney, and respiratory tract (Parker and Sommers, 1956). Dobriner (1952) showed that in cases of cancer the mean urinary corticosteroid excretion was higher than normal, and Voigt and Kny (1954) recorded a case of bronchial carcinoma with increased insulin tolerance. The interest in the present case lies in the occurrence of marked adrenocortical hyperactivity in association with bronchial carcinoma.

Case Report

A 48-year-old furnaceman was admitted to hospital on May 17, 1955. For many years he had suffered from a cough with some mucoid sputum which he attributed to smoking about 15 cigarettes a day. In March, 1955, he had a short

febrile illness, following which he failed to regain his strength. His mouth and tongue felt dry; he drank a great deal of fluid and passed large quantities of urine at frequent intervals. His appetite decreased, he lost weight, and for one week prior to admission took no solid food. Progressive pigmentation appeared on the face and arms. For two weeks his ankles had been swollen, and he noticed tingling in his fingers and toes. Throughout this period he was troubled by an unproductive cough.

Examination showed him to be a well-built muscular individual with evidence of recent weight loss. A bluish-brown pigmentation affecting the skin and buccal mucous membranes was most pronounced on the face and extensor surfaces of the arms. The skin and tongue were dry; the sputum was mucoid. At the right lung base the percussion note was decreased and air entry diminished. The liver was enlarged to 8 cm. below the right costal margin; it was firm and its surface irregular. The urine gave an orange colour with Benedict's solution, and Rothera's test for acetone was strongly positive. His blood pressure was 130/75 mm. Hg; temperature 99° F. (37.2° C.).

A radiograph of the chest showed an opacity in the right cardiophrenic angle due to collapse of the right lower lobe; the right paratracheal lymph nodes were enlarged. Tomography of the chest revealed a mass 4 cm. in diameter in the right cardiophrenic angle with narrowing of the right lower lobe bronchus. At bronchoscopy rigidity of the right main bronchus with narrowing of the right lower lobe bronchus was demonstrated, but no neoplasm was identified; biopsy showed normal bronchial mucosa. Liver needle biopsy contained metastatic carcinoma, and the bone marrow also contained carcinoma cells.

Liver-function tests showed serum bilirubin 0.4 mg. per 100 ml., thymol turbidity less than 1 unit, serum alkaline phosphatase 28 King-Armstrong units, serum proteins 5.4 g. per 100 ml. (albumin 3.7 g., globulin 1.7 g.), bromsulphthalein excretion normal, serum iron 115 µg. per 100 ml., and prothrombin efficiency 100%. The urine was free from bile and contained only traces of urobilinogen.

Other investigations performed were: fasting blood sugar 441 mg. per 100 ml. (following 50 g. of glucose by mouth the blood sugar rose to 483 mg. after 1½ hours, and was 378 mg. after 2½ hours); 24-hour urinary excretion of 17-ketosteroids 50.4 mg., of 17-ketogenic steroids 138 mg., and of pregnanediol 8.7 mg.; serum sodium 152 mEq/l., serum potassium 4.4 mEq/l., serum chloride 99 mEq/l., and plasma alkali reserve (four days after admission) 28 mEq/l.; blood urea 40 mg. per 100 ml.

The haemoglobin was 10 g. per 100 ml., W.B.C.s 4,000 per c.mm. (polymorphs 68%, lymphocytes 28%, monocytes 4%). The Wassermann reaction was negative and an electrocardiogram showed no abnormality.

Skin biopsy revealed atrophy of the Malpighian layer and some hyperkeratinization of the epidermis. The deeper layers of the epidermal cells were heavily pigmented with melanin.

Progress.—On a diet containing 160 g. of carbohydrate a day it was possible to control his diabetes with 88 units of insulin zinc suspension. The patient slowly deteriorated, however; he continued to lose flesh, his oedema increased, he developed ascites, and the liver became larger and more irregular. There was increasing evidence of peripheral neuritis with weakness of the arms and legs, loss of deep reflexes, and absence of sensation over the hands and feet. On June 16 he was noticed to be jaundiced and to have a petechial rash. He died on June 23.

Special Investigations.—The daily urinary 17-ketosteroid and 17-ketogenic steroid urinary excretion from June 10 until his death on June 23 is shown in the Chart. Cortisone, 50 mg. six-hourly by mouth, was administered for 48 hours on June 14 and 15, and corticotrophin of known potency, 25 mg., was given six-hourly intramuscularly for 48 hours on June 21 and 22. It will be seen that the 17-ketosteroid excretion showed no great variation, and that the 17-ketogenic steroid excretion remained between 106 and 159 mg.

Urinary excretion of 17-ketosteroids and 17-ketogenic steroids.

with the exception of the two days on cortisone, when the excretion was 163 and 176 mg. The raised pregnanediol excretion was confirmed on two occasions (6.7 and 8.2 mg.). Dehydroisoandrosterone was present in the urine in increased quantities, but considerably less in amount than has been found in cases of adrenocortical carcinoma.

Post-mortem Examination

Naked Eye.—There was deep brown pigmentation of the skin as described in life, and patches of brown pigmentation were present in the buccal mucous membranes. There were petechial haemorrhages in the skin of the trunk and legs; the legs were oedematous. A carcinoma of the right lower lobe bronchus with bronchopneumonia in the lung beyond the growth was found; the mediastinal lymph nodes were grossly enlarged, metastatic tumour was present in the right cardiophrenic angle, and the remaining lung tissue was oedematous. A small right pleural effusion and the ascites were blood-stained. The liver contained multiple secondary deposits and weighed 3,090 g. Tumour deposits were found in the retroperitoneal lymph nodes and the vertebral bodies. The adrenals both contained whitish growth; together they weighed 30 g.

Microscopy.—The tumour was a poorly differentiated adenocarcinoma of the bronchus showing extensive intra-alveolar spread; the deposits in the liver and lymph nodes had a similar histological appearance. The pituitary, thyroid, and pancreas showed no abnormality. There was marked adrenocortical hyperplasia with focal lipid depletion; both adrenals contained secondary growth in the cortex and medulla.

Discussion

The sustained hyperexcretion of adrenocortical hormones is the outstanding feature of the present case. Increased adrenocortical secretion has only occasionally been observed in cases of cancer. Hardy (1955), studying steroid excretion in advanced malignant disease, reported three cases in which corticoid excretion was raised. Moore *et al.* (1955) reported the case of a woman with cancer of the breast whose urinary hydroxycorticoids remained raised for 15 days following mastectomy. Jepson *et al.* (1956) described an unusually high 17-ketogenic steroid excretion following laparotomy in a patient with inoperable gastric cancer. These findings suggest that some cancer patients respond to their disease with adrenocortical overactivity, and that in such patients the adrenocortical response to trauma as measured by urinary corticoid excretion is greater than is usually found.

In view of the normal liver-function tests and the absence of reports of high urinary excretion of adrenocortical hormones in even advanced liver disease, it must be assumed that the high 17-ketogenic steroid and 17-ketosteroid ex-

cretion in the above case was due to adrenocortical overactivity. Norymberski *et al.* (1953) have shown that the normal daily urinary excretion of 15 mg. of 17-ketogenic steroid corresponds approximately to the production of 30 mg. of 17- α -hydroxycorticosterone by the adrenals. In the present case the daily output of between 106 and 159 mg. of 17-ketogenic steroids indicated a 17- α -hydroxycorticosterone production of between 215 and 320 mg. a day. This rate of production was unaffected by the administration of 200 mg. of cortisone a day, the administered cortisone accounting for a rise of about 60 mg. in daily 17-ketogenic steroid excretion (Jepson *et al.*, 1956) and the 17-ketosteroid excretion remaining essentially unchanged. Similar failure to suppress adrenocortical steroid production by means of cortisone has been reported in severe Cushing's syndrome due to adrenocortical hyperplasia resulting from increased production of corticotrophin (Segaloff *et al.*, 1955; Laidlaw *et al.*, 1955).

To hypersecretion of adrenocortical hormones must be attributed the diabetes, hypernatraemia, and oedema, but, although symptoms suggesting diabetes had been present for three months, most of the features of Cushing's syndrome such as obesity, cervical fat pad, moon-face, red striae, hypertension, polycythaemia, and osteoporosis were absent, and in spite of the high pregnanediol excretion there was no disturbance of sexual function. In Cushing's syndrome and in adrenal virilism due to adrenocortical hyperplasia the administration of corticotrophin leads to an increase in steroid excretion (Laidlaw *et al.*, 1955), but in the present case no such increase was obtained. In the absence of such features the possibility that the bronchial carcinoma arose in a patient with primary hypercorticism must be regarded as remote.

With hypersecretion of adrenocortical hormones in response to trauma or other forms of stress a decreased glucose tolerance and sodium retention are common findings, but other features of hypercorticism are absent (Ingle, 1952); this increased secretion is thought to be caused by increased production of corticotrophin by the pituitary (Munson and Briggs, 1955). In the present case the failure of the adrenal cortices to respond to exogenous corticotrophin suggests that the cortices were already maximally stimulated by the pituitary. The increased excretion of 17-ketogenic steroids and 17-ketosteroids may have been related to the presence of the bronchial carcinoma, being produced in a manner similar to that following trauma or other stress. The findings, however, differ from those following surgery, when commonly there is only a small rise in 17-ketosteroid excretion (Hardy, 1955).

The inability of exogenous corticotrophin or cortisone to influence steroid excretion might have been interpreted as suggesting the presence of a steroid-producing tumour, but this was excluded at necropsy and in life by the only moderately raised dehydroisoandrosterone excretion (Gardner and Migeon, 1952). The pigmentation of the skin and buccal mucous membranes, similar in distribution to that seen in Addison's disease, suggested excess production of corticotrophin by the apparently normal pituitary (Mellgren, 1945; Lerner, 1955).

In Cushing's syndrome and during the administration of corticotrophin or 11-17-oxysteroids decreased glucose tolerance is a common finding. Frank diabetes is, however, unusual, and when it occurs is insulin-resistant though mild (Conn, 1953; Frawley, 1955). Slight impairment of glucose tolerance due to increased secretion of adrenocortical hormones may be seen during the response to trauma and other forms of stress (Conn and Fajans, 1956). Acidosis in Cushing's syndrome is rare, and Plotz *et al.* (1952) were able to find only one published case (Petresco *et al.*, 1937). It might therefore be considered that the severe diabetes with ketonuria in the present case was only an incidental finding. This, however, would fail to account for the simultaneous onset of chest complaints, pigmentation, and symptoms suggesting diabetes, and the high 17-ketogenic steroid production would well explain the severity and insulin resistance of the diabetes.

TOXOPLASMOSIS SIMULATING GLANDULAR FEVER IN THE ADULT

BY

MARY BATEMAN, M.D., M.R.C.P.

High and prolonged steroid excretion in association with cancer has not previously been described, and it has been shown that their association is unlikely to have been coincidental. While the findings suggested that this was due to stimulation of the adrenals by pituitary corticotrophin, the present phenomenon differed from that seen following trauma or other stress in the degree and duration of the increased 17-ketogenic steroid and 17-ketosteroid excretion.

Summary

Marked hyperexcretion of adrenocortical hormones is reported in a patient with bronchial carcinoma and diabetes mellitus.

In spite of severe steroid diabetes only few of the features of Cushing's syndrome were observed.

The possibility that marked adrenocortical hyperactivity was due to stimulation of the pituitary in response to the presence of the bronchial carcinoma is discussed.

The present phenomenon differs from that observed following trauma and other forms of stress.

My thanks are due to Dr. H. P. Brody for permission and encouragement to study the above patient, who was under his care; to Mr. M. J. Levell for the steroid estimations; to Dr. J. Dodge and D. Evans for the post-mortem and histological reports; to Mr. B. Dhillon for the bronchoscopy report; and to Professor R. P. Jepson for his kind help in the preparation of the manuscript.

A memorandum entitled "In-patient Accommodation for Child and Adolescent Psychiatric Patients" has been prepared by the Child Psychiatry Section of the Royal Medico-Psychological Association. The recommendations are as follows: (1) That in-patient units for child psychiatric patients should be established in association with local child psychiatric or child guidance clinics. These units should be linked with mental hospitals, children's hospitals, or general hospitals. It is estimated that not less than 20 beds can serve a total population of 500,000. In addition to these local units, one unit of not less than 25 beds per regional hospital board area is necessary for a residual group of patients needing prolonged care. (2) That units for adolescent patients should be established in association with adult units. It is estimated that not less than 20 beds can serve a total population of 500,000. (3) That there should be increased provision of long-term substitute home care for disturbed children in the form of hostels or special boarding schools. (4) That there should be better provision of after-care hostels for adolescent patients.

Case 1

On December 14, 1955, a 16-year-old Irish spot welder, who had been in England for three weeks, was admitted to hospital with a history of sore throat for three weeks, and cough for five days. He had been sweating profusely and had had pain in the left wrist, knee, and ankle, and in the left side of the chest. He complained of frontal headache and had noticed a rash on his abdomen on the day of admission. He had a temperature of 102° F. (38.9° C.). The only abnormal signs were reddening of the throat, enlargement of the submental and anterior cervical glands and of the spleen, and a petechial rash on the abdomen.

The initial blood count suggested glandular fever. The white cells numbered 6,200 per c.mm., with 50% polymorphonuclears, 0.5% eosinophils, 21.5% lymphocytes, and 28% monocytes, many of which were atypical. The percentage of monocytes was reduced in subsequent counts. The Paul-Bunnell test was negative.

On January 14, 1956, the toxoplasmosis dye test showed a prozone to 1:64 and was then positive to 1:1024. The C.F.T. was positive in a titre of 1:8. A second specimen of blood examined three months later, on April 4, showed a dye test titre of 1:128 and a C.F.T. of 1:16. He was discharged from hospital symptom-free after three weeks and has remained well.

Case 2

On December 10, 1955, a 31-year-old housewife who was 16 weeks pregnant was admitted ten days after the onset of fever and backache. A week before admission she had had a sore throat and a rash, with blisters on her hands and feet and red blotches on her face, which faded after a few days. For five days her trunk and limbs felt sore, and her neck had been stiff for four days, during which she had vomited frequently.

On examination there was no rash, the cervical glands were enlarged, and neck stiffness was minimal. An apical systolic murmur was heard. The uterus was enlarged to a size consistent with a 16-week pregnancy. Her temperature was 100.4° F. (38° C.) and fell to normal after 24 hours. The haemoglobin was 84%, the E.S.R. 62 mm. in one hour (Westergren), and the total white-cell count 7,909, with 66% polymorphonuclears, 1.5% basophils, 22% lymphocytes, 10% monocytes, and 0.5% Türk cells. The Paul-Bunnell test was negative.

She was discharged home after a week, but when seen three weeks later she was tired and had pain in the back and legs. She had had a further attack of sore throat and the cervical glands were still enlarged. Lassitude persisted for a further four weeks.

On March 24, 1956, the toxoplasmosis dye test was positive 1:256 and the C.F.T. 1:32. Repeat examination on April 3 gave positive results of 1:64 for the dye test and 1:32 for the C.F.T. Tests on her husband were negative.

Case 3

On March 16, 1956, a 36-year-old woman who worked as an assembler was seen in the out-patient department. She had noticed enlarged axillary glands since November, 1955, but had otherwise felt well. She was found to have enlarged axillary lymph nodes and a palpable spleen. Later, cervical and inguinal glands were also felt.

The blood count was normal. The E.S.R. in one hour was 9 mm. (Westergren) and the Paul-Bunnell test was negative. A lymph-node biopsy was performed and the histological report (Dr. D. Brewer) was: "An enlarged lymph node measuring 1.6 and 2.5 cm. It shows marked follicular lymphoid hyperplasia. It appears to be a reactive process. A prolonged search revealed no organisms."

On April 13 the toxoplasmosis dye test was positive to a titre of 1:64 and the C.F.T. to 1:8. Tests on this patient's daughter were negative.

Discussion

No history of contact with sick animals was obtained from any of these patients, though a cat was kept in two of the households. No specific treatment was given, as in each case the diagnosis was not made until the acute stage of the disease was over. *Toxoplasma gondii* is sensitive to sulphonamides, particularly sulphadiazine and sulphadimidine, and to pyrimethamine ("daraprim"), which appears to act synergistically with sulphonamides (Eyles, 1953).

There have now been numerous case reports of congenital toxoplasmosis and also of an increasing number of cases in adults. The three cases described here varied in acuteness and severity: the first two patients were ill, whereas the third complained only of lymph-node enlargement. None of these patients completely fulfils the serological requirements for diagnosis (Sabin *et al.*, 1952). However, the high titres in Cases 1 and 2, with the characteristic clinical picture, make the diagnosis of acute toxoplasmosis almost certain. In Case 3 the serological tests were done so long after the onset of lymphadenopathy that high values would not be expected.

The occurrence of the acute illness during the fourth month of pregnancy in Case 2 made foetal infection likely, but on May 11, 1956, she was delivered of a normal baby, which has since shown no signs of congenital toxoplasmosis. After birth the dye-test titre was 1:8 in the mother and 1:16 in the baby, and the C.F.T. in each was anti-complementary. On November 11 the dye test was positive to a titre of 1:8 in the mother and 1:4 in the baby and the C.F.T. was negative for each. These results probably indicate passive transference of immunity from mother to child and exclude active disease in the child.

Gard and Magnusson (1951) reported a case of acute illness in the first month of pregnancy associated with a dye-test titre rising to 1:4000. The child was normal, and the dye-test titre at 3 months was lower than at birth, indicating a passive immunity. Stanton and Pinkerton (1953) described the case of a woman who had cervical-gland enlargement in early pregnancy. Biopsy was performed and two pseudocysts were seen on histological examination of the material. The dye test for toxoplasmosis was positive in a titre of 1:1024 14 weeks after the onset of cervical-gland enlargement, falling to 1:64 after 43 weeks. Animal inoculation failed to reproduce the disease. The infant's dye test at birth was positive to a titre of 1:256. The child was normal and remained so. The authors suggested that the original toxoplasma infection of the mother might have occurred five years earlier when she had weakness, fever, lymphocytosis, and lymphadenopathy, and that the illness in pregnancy was an exacerbation of this.

Paulley *et al.* (1956) reported a normal pregnancy in a woman probably suffering from toxoplasmic myocarditis, but foetal infection would not be expected during the chronic stage of the disease in the mother. Sabin *et al.* stated that none of the 67 subsequent pregnancies in 45 mothers of congenitally affected children had shown evidence of toxoplasmosis. It has been assumed that transmission of disease to the foetus occurs during asymptomatic or unrecognized maternal infection in the early months of pregnancy. The cases reported here, and those of Gard and Magnusson and of Stanton and Pinkerton, show that infection of the child is not inevitable.

Summary

Three cases of illness with lymphadenopathy probably due to acute toxoplasmosis are described. In one the disease occurred in the fourth month of pregnancy and there has been no evidence of its transfer to the child. It is probable that acute toxoplasmosis is not so rare as is suggested by the comparatively small number of reported cases.

I thank Dr. Clifford Parsons and Dr. W. T. Cooke for permission to publish their cases and Dr. W. T. Cooke for advice and criticism. The serological tests were performed by Dr. I. A. B. Cathie, at the Hospital for Sick Children, Great Ormond Street, London.

HAEMOGLOBIN L: A NEW HAEMOGLOBIN FOUND IN A PUNJABI HINDU

BY

J. A. M. AGER, M.B., B.S.

Lecturer in Clinical Pathology, St. Thomas's Hospital,
London

AND

H. LEHMANN, M.D., Ph.D., F.R.I.C.

Senior Lecturer in Chemical Pathology, St. Bartholomew's
Hospital, London

On examining the blood of an East Indian patient admitted to hospital for investigation of erythema nodosum it was seen that his haemoglobin consisted of two fractions. One of them was normal adult haemoglobin (haemoglobin A), and the other a minor component moving on paper electrophoresis at pH 8.6 more slowly than haemoglobin A. Six haemoglobins are known to move more slowly than haemoglobin A under these conditions; they are in order of increasing mobility C, E, S and D, G, F. The minor component of the patient's haemoglobin moved differently from all these. On paper electrophoresis in barbiturate buffer of pH 8.6 using a hanging-strip technique (for details see Lehmann and Smith, 1954) or horizontal paper electrophoresis between glass plates (for details see Smith and Conley, 1953), and on zone electrophoresis using starch blocks (Kunkel and Wallenius, 1955; for details see Kunkel, 1954), the abnormal component moved between haemoglobin S (or D) and haemoglobin G (See Figure).

Following paper electrophoresis the separated fractions were dried on the paper, stained with light green (Danger-

field and Smith, 1955), and eluted. Following starch electrophoresis the haemoglobin fractions themselves were eluted. On measuring the colour of the eluates it was found that the abnormal component formed 28% of the total haemoglobin. The proportion of haemoglobin A₂ (Kunkel and Wallenius, 1955) was within normal limits.

On paper electrophoresis in phosphate buffer of pH 6.5 no separation occurred. The difference in appearance from haemoglobins A+G mixtures was insignificant, but a difference could always be discerned between the patient's haemoglobin and haemoglobin A or mixtures of haemoglobins

Comparison of patient's haemoglobin (1 and 3) with haemoglobin mixtures AG (2) and AS (4) respectively. The cells were washed in isotonic saline solution, packed, lysed with water and toluene, and centrifuged to separate the haemoglobin from the stroma. Paper electrophoresis was carried out by the hanging-strip method: Whatman filter paper No. 3 "for chromatography," barbiturate buffer pH 8.6. At the end of the electrophoretic run the strips were dried and the haemoglobin bands were stained with light green. It will be seen that the abnormal component in the patient's haemoglobin (haemoglobin L) migrates faster than haemoglobin S and more slowly than haemoglobin G.

A+S, A+E, and A+C. On paper electrophoresis in cacodylate buffer of pH 6.5 again no separation occurred, but with this buffer a difference could be seen in the appearance of the patient's haemoglobin and haemoglobin A+G mixtures.

The patient's haemoglobin mixture was rapidly denatured by alkali (Singer, Chernoff, and Singer, 1951), and it was resistant to cold denaturation (Rigas, Koler, and Osgood, 1956). The absorption spectra of his carboxyhaemoglobin and of a normal control showed identical peaks of extinction in the visible and ultra-violet ranges.

The solubility of his haemoglobin was within normal limits (Itano, 1953). We repeatedly found a slightly lower solubility of the ferrohaemoglobin than 5 g./l. when using a 2.24 M phosphate buffer. In Itano's solubility test all haemoglobin mixtures other than those containing haemoglobin S have a solubility of at least 5 g./l. at this buffer concentration. We thank Dr. H. A. Itano for measuring the solubility of our patient's haemoglobin. He found a normal solubility in 2.58 M phosphate buffer (1.8; 1.9 g./l.) and a slightly lowered solubility in 2.24 phosphate buffer (4.6; 4.7 g./l.). Dr. Itano informs us that he does not place much confidence in such a small reduction in solubility approaching 5 g./l. in 2.24 M phosphate buffer, since that figure represents all the haemoglobin added in his test. A small amount of precipitation might occur before the concentrated buffer (2.8 M) is completely mixed. Dr. T. H. J. Huisman obliged us by testing the solubility of our patient's haemoglobin by a salting-out technique; he also found it to be normal. We are grateful to Dr. Huisman for his permission to quote that the abnormal component of this haemoglobin moves on chromatography (Huisman and Prins, 1955) between haemoglobins S and C, whereas haemoglobin G moves between haemoglobins A and S, and to Dr. Itano for informing us of differences seen on open boundary electrophoresis between the haemoglobin of our patient and mixtures of haemoglobins A+S and A+G respectively.

Our patient was born a Hindu of the Khashtri caste in the Mianwali District, Pakistan. He is 27 years old and is now a citizen of India temporarily resident in London. He is not anaemic and there is nothing remarkable in his blood picture, excepting a slight eosinophilia. The osmotic fragility of his red cells is within normal limits. By the kindness of Dr. Ishwar Chandar we have examined the blood of our patient's parents and of one brother and one sister. The mother's haemoglobin consisted of haemoglobin A and of a component moving more slowly than haemoglobin A, but faster than haemoglobin S or D. The other three bloods contained haemoglobin A only.

New haemoglobins are allotted letters which are in general in alphabetical order of discovery (Statement on Hemoglobin Nomenclature, 1953). The accepted symbols for the haemoglobins so far identified are A, C, D, E, F, G, H, I, J, K, and S. The abnormal component in our patient's haemoglobin should therefore be called haemoglobin L.

RELATIONSHIP BETWEEN HAEMOGLOBINS C AND S AND MALARIA IN GHANA

BY

G. M. EDINGTON, M.D., D.C.P., D.T.M.&H.
Specialist Pathologist in charge of Medical Research
Institute and Laboratory Services, Ghana

AND

W. N. LAING, M.B., Ch.B., D.T.M.&H.
Medical Officer attached to Laboratory Services, Ghana

Haemoglobin C was first described in a North American negro by Itano and Neel (1950) and was later found in high incidence in Ghana by Edington and Lehmann (1954). Allison (1956) and Edington and Lehmann (1956) discussed its incidence and distribution in West Africa. It would appear that the gene responsible for haemoglobin C occurs in high frequency in the tribes of Northern Ghana and declines in frequency from this focus to Nigeria and Sierra Leone, where low frequencies are recorded. Haemoglobin S is also found in Ghana, the incidence of the trait being high (19%) in the Southern regions, where the incidence of the C trait is low (10%), and low in the Northern regions (7%), where the incidence of C is high (21%). There are thus present in the country in high frequency two genes which in their homozygous and combined heterozygous expression are disadvantageous to their bearers. Other abnormal haemoglobins have been detected in Ghana, but their incidence is low. The common genotypes seen are listed in Table I.

The S gene is thus being eliminated from the population at large by individuals suffering from sickle-cell anaemia, sickle-cell haemoglobin C disease, microdrepanocytic-like disease (Edington and Lehmann, 1955), and perhaps in certain unspecified instances by bearers of the sickle-cell trait. It is difficult under these circum-

TABLE I.—*Abnormal Haemoglobin Genotypes Commonly Seen in Ghana*

Condition	Genotype	Clinical Effects
Sickle-cell trait	AS	Nil*

Pure haemoglobin C disease	CC	Disadvantageous ±

* Although the sickle-cell trait is said to be innocuous, a characteristic pathology has been described at post-mortem examination in which the red blood cells sickle and the electrophoretic pattern of the haemoglobin is AS (Edington, 1957).

stances to explain the high incidence of this gene in Ghana and elsewhere in Africa, and there is evidence to show that this high incidence is due to the protection it affords the bearer against the lethal effects of *P. falciparum* malaria in holoendemic areas. The gene responsible for haemoglobin C is similarly being eliminated, to a much lesser extent, by individuals suffering from pure haemoglobin C disease and sickle-cell haemoglobin C disease. If the A, C, and S genes are in stable equilibrium it must be postulated that bearers of the haemoglobin C trait (AC) have a positive survival value, to account for its presence in high incidence in certain Northern tribes.

In a previous publication the relationship between sickling and malaria in Ghana was discussed (Colbourne and Edington, 1956). It was found that, in Southern Ghana, the sickle-cell trait appeared to protect the bearer partially against *P. falciparum* malaria in all age groups, whereas no protection over the age of 1 year was noted in sicklers in the north. The lack of protection exhibited by the trait in older children and adults in the north was thought to be due to the intense malarial transmission occurring in that district, the immunity thus rapidly acquired in the surviving non-sickler balancing the protection afforded by the trait plus the acquired immunity in the sickler.

The possibility of haemoglobin C being present in high incidence in the northern survey and interfering with the results had, however, to be considered. With the information available, no definite conclusions could be reached, although it was felt that the varying intensity of malarial transmission was probably responsible for the differing findings.

A second investigation has therefore been made in order to discover (1) if the presence of haemoglobin C in the north interfered with the findings in the original investigation, and (2) if the haemoglobin C trait protected the bearer against the effects of *P. falciparum* malaria.

Method of Investigation

The inhabitants of three villages in the Yendi (north-eastern) district of Ghana have been examined. The villagers were mainly of the Dagomba tribe, but a few Konkomba

had intermarried and settled permanently in the communities. The majority of the technical procedures employed have already been described (Colbourne and Edington, 1956). Sickling tests were repeated and electrophoretic analysis of the haemoglobin was performed on finger-prick blood in citrate saline sent by air to Accra. Four 90-volt dry batteries in series, with an output of 10 mA for five hours in barbitone buffer pH 8.6, gave satisfactory patterns on Whatman's filter paper No. 1 when utilized in an air-conditioned room.

In addition, as one of us (G. M. E.) has always considered that the protection afforded by the sickle-cell trait against *P. falciparum* malaria could be explained on physico-chemical grounds, particular attention was paid to the gametocyte count in thick films. It is known that in bearers of the sickle-cell trait the red blood cell sickles when deprived of oxygen. As the malarial parasite utilizes oxygen for growth it was thought that this reduction in oxygen within the cell would induce sickling and thus the destruction of both the parasite and the red cell by the reticulo-endothelial system. Advanced developmental forms (gametocytes) therefore should not be found in high rates in the peripheral blood of sicklers if this theory is correct.

Results

The blood of 1,055 villagers was examined. In nine the transmitted specimens were unsuitable for electrophoresis, in three the ages had been omitted from the record cards (genotype in all instances AA), and three haemoglobins on electrophoresis showed a second component moving faster than normal haemoglobin. These three specimens were sent to Dr. H. Lehmann, St. Bartholomew's Hospital, London, for identification, and the results will be published separately. Table II illustrates the genotypes seen in the remaining 1,040 villagers. It should be noted that the genotypes shown are based on the paper electrophoretic pattern of the haemoglobins and not on genetical studies. It has

* In thousands per c.mm. † Heavily weighted by one child with a density of 132,000 parasites per c.mm.

been assumed in this study that the haemoglobin pattern gives a direct expression of the genotype.

From the observed genotype frequencies in the group under 1 year the expected genotype frequencies have been calculated and the results are shown in Table III. We are indebted to Mr. M. J. Hollingsworth, Zoology Department, University College of Ghana, for his help in compiling these frequencies and for the statistical analysis shown in Table IV.

Although there were greater numbers of the genotypes AC, AS, CC, and SC observed in those aged 1 year or more than would have been expected and fewer AA and SS, none of these differences reach an accepted level of statistical significance and no conclusions can be drawn from Table III.

The observed parasite rates and densities in individuals with normal C and S haemoglobins are shown in Table IV. The malarial parasite rates and densities in individuals suffering from pure haemoglobin C disease and sickle-cell haemoglobin C disease were compared in their respective age groups with those in normal, C, and S trait individuals. No significant differences were noted. These figures are not shown separately in Table IV, and AC and CC are considered together in the haemoglobin C column and AS and SC in the haemoglobin S.

A comparison of the parasite rates and densities in those with normal haemoglobin and haemoglobin C as shown in Table IV indicates that there is no evidence that haemoglobin C protects the bearer against *P. falciparum* malaria ($t=0.1071$; $P>0.5$).

The figures for haemoglobin S, although not definitely significant, are suggestive that S may partially protect the bearer against *P. falciparum* malaria ($t=1.475$; $P<0.2>0.1$). The findings are similar to those already recorded (Colbourne and Edington, 1956), the most marked differences being in the younger age groups. It can be concluded that the differing type of protection afforded by haemoglobin S against malaria in Northern and Southern Ghana is due to the variation in intensity of malarial infection and that the presence of haemoglobin C did not interfere with the results recorded in the paper quoted above.

It was disappointing to note that the incidence of gametocytes was similar in sicklers and non-sicklers, suggesting that the protection afforded by sickle-cell haemoglobin against malaria is not explicable by the physico-chemical mechanism mentioned above.

Discussion

We have been unable to show any protective relationship between haemoglobin C and malaria in this survey, and from our results we consider it most unlikely that any protection exists. It must be remembered, however, that the important question is whether children with the C trait die of cerebral malaria. In the future our survey results should be confirmed by a clinical investigation on the lines described by Raper (1956), who demonstrated that the incidence of cerebral malaria was significantly less in children with the sickle-cell trait and that non-sickling children were at a disadvantage. Unfortunately haemoglobin C occurs in its highest incidence in Ghana in areas where medical facilities are limited and necropsies are difficult to obtain.

In Accra the electrophoretic pattern of the haemoglobin is being determined in many necropsies, in particular in all children in whom the cause of death is suspected to be cerebral malaria. So far 10 children have died of histologically proved cerebral malaria. In nine the haemoglobin has been of the genotype AA and the non-sickling haemoglobin of the tenth exhibited a pattern which was considered to be AG. Neither C nor S haemoglobin has been noted. Necropsies on children dying of cerebral malaria are few, but eventually a sufficient number should be obtained to give statistically significant results. The pattern AC has been seen in 18 subjects coming to necropsy and the pattern CC in two. In one child with the haemoglobin C trait the cause of death was considered to be malaria and

bronchopneumonia, and in a second child who was killed in a car accident there were heavy deposits of malarial pigment in the liver and spleen—further indications that C does not protect against malaria. The two individuals suffering from pure haemoglobin C diseases were men aged 20 and 55, and both died of widespread miliary tuberculosis.

It is, of course, possible that haemoglobin C may protect its bearer against some other condition apart from malaria, thus accounting for its high incidence in Northern Ghana.

The following conditions have been responsible for death in the 18 necropsies performed on subjects exhibiting the C trait.

TABLE V.—*Causes of Death in 18 Subjects With the Haemoglobin C Trait*

Injury	7	Carcinoma of lung	1
Cellulitis	2	Malarial anaemia and bronchopneumonia	1
Nephritis and hypertension	2	Pneumococcal meningitis	1
Appendicitis	1	Schistosomiasis	1
Bronchopneumonia	1	Strangulated hernia	1

Thus, in addition to malaria, haemoglobin C is unlikely to protect the bearer against pyogenic and pneumococcal infections, schistosomiasis, and tuberculosis.

Summary

The haemoglobin genotypes of 1,040 Dagombas have been determined and correlated with malarial parasite rates and densities. Haemoglobin S may partially protect the bearer against *P. falciparum* malaria in the younger age groups in Northern Ghana, but there was no evidence that haemoglobin C acted in a similar manner. The results of necropsy findings in Accra are briefly discussed.

We are grateful to Drs. Scott and Ashworth for their interest and help, to Dr. E. Akwei, chief medical officer, for permission to publish, and especially to Messrs. Sackey, Austin, and Frempong for technical assistance.

Postgraduate medical teaching is an important part of the work of the Royal Institute of Public Health. Courses are organized for the diploma in public health and the diploma in industrial health. These courses are held twice yearly, and may be taken either full-time or part-time. Details of the results for 1956 are given in the institute's annual report, which was issued at the annual general meeting last month. The chemical and bacteriological laboratories of the institute are available for the examination and investigation of pathological specimens, water, milk, sewage, and other types of analysis. During 1956 some 2,318 samples were submitted for examination, this being an increase of 81 over the previous year's total. Fourteen public addresses were given during the year, related to the following aspects of public health: social work, mothers, children, air, food, teeth, nursing, nutrition, and industry. These addresses were subsequently published in the journal of the institute. Membership of the institute is generally by examination, and includes medical practitioners, dental surgeons, State-registered nurses, registered medical auxiliaries, bacteriologists, and others whose duties entail a knowledge of public health and hygiene. Full details of the work of the institute may be obtained from the Secretary, 28, Portland Place, London, W.1.

Medical Memorandum

Aplastic Anaemia Due to Phenylbutazone

Fatal agranulocytosis following phenylbutazone is now well recognized, but aplastic anaemia has been reported only by Leonard (1953), whose patient had previously received gold therapy. The occurrence of fatal aplastic anaemia is here reported in a patient who had not previously been exposed to any bone-marrow poison.

CASE HISTORY

A married woman aged 55 complained of pains in the back and various joints over a period of 10 years, and was put on phenylbutazone therapy by her general practitioner in March, 1953. She was also on thyroid, 2 gr. (0.13 g.) daily, from January, 1953, onwards, a diagnosis of myxoedema having been made at another hospital. Phenylbutazone was taken from March, 1953, until November, 1954, the dose at first being 200 mg. three times daily and subsequently 100 mg. three or four times daily. In November, 1954, she complained of bruising easily and of a rash "like blood blisters." She began to feel very weak. She was first seen in hospital when sent up for emergency admission on February 15, 1955.

On examination no objective evidence of joint disease was found and there was no subsequent complaint of the symptoms for which phenylbutazone was originally prescribed. The patient was extremely anaemic, with ecchymoses and widespread petechiae. Haemorrhages were present in the conjunctivae, mouth, and retinae.

There was no evidence of myxoedema, no enlargement of the liver, spleen, or lymph nodes, and the thyroid gland was not palpable. A blood count showed: haemoglobin, 6 g. per 100 ml.; red cells, 1,850,000; colour index, 1.15; white cells, 2,300 (39% polymorphs, 54% lymphocytes, 7% monocytes). The platelet count was 25,000. The sternal marrow was reported on by Dr. J. Davson as follows: "The marrow shows a considerable depression of the red-and-white-cell precursors. Most of the cells present are lymphocytes, reticulum cells, or plasma cells. The picture is that of an aplastic anaemia or panhaemocytopenia."

A course of treatment with cortisone acetate was given, 300 mg. daily for five days, 250 mg. daily for eight days, 200 mg. for a month, and gradual reduction over a further 10 days. After three weeks on cortisone there had been no significant change in the level of red cells, white cells, or platelets and no reticulocyte response, and transfusion treatment was accordingly started. The haemoglobin level was raised from 4 to 8.5 g., but subsequently fell again in spite of further transfusions. The platelet count varied between 5,000 and 40,000 per c.mm. and the white-cell count between 1,700 and 5,000, with polymorphs between 5% and 40%, the remaining white cells being normal lymphocytes and monocytes. Fresh crops of purpura and ecchymoses were appearing, and transfusions were made difficult by haemorrhage into the tissues at the site of venepunctures. The patient's condition deteriorated steadily, and she died following haemorrhage in the alimentary tract on July 27, 1955. She had received a total of 27 pints (15.4 litres) of blood by transfusion.

Post-mortem Findings (Dr. M. C. H. Dodgson).—The body was that of an obese hirsute middle-aged woman. There were severe aplastic changes with some focal haemorrhages in the marrow of the sternum, ribs, vertebrae, right ilium, and right femur; the lymph nodes were hypoplastic. Although deformities characteristic of rheumatoid arthritis were absent, the articular surfaces of the right knee-joint showed moderately severe osteoarthritic changes. Myocardium: fatty degeneration, epicardial and endocardial haemorrhages. Pleurae: bilateral small straw-coloured effusions with induration and congestion of the lungs. A lymph

node draining the left upper lobe contained an area of fibrocaseous tuberculosis, 0.5 cm. in diameter, a similar focus, 1 cm. in diameter, occurring in the lower pole of the right kidney. The left kidney and the remainder of the urinary tract appeared healthy. No macroscopic changes were noted in the brain. Pituitary, parathyroids, and ovaries appeared normal, whereas the thyroid was small, flat, and pale, and the adrenals showed cortical atrophy.

Histological Examination.—The bone marrow of the lumbar vertebrae showed osteoporosis with severe reduction of the haemopoietic tissue, the surviving red marrow, confined to the periphery of the vertebral body, being infiltrated with lymphocytes. Myocardium, kidney, and liver showed severe fatty changes, referable to the anaemia, although haemosiderin-laden phagocytes occurred in lymph nodes, spleen, and bone marrow. The lungs showed passive venous congestion and acute oedema.

COMMENT

Although there have been many reports of the toxicity of phenylbutazone, a review of which has been made by Mauer (1955), this drug is still used on a wide scale. Until recently authors reporting toxic effects have merely urged caution in the use of the drug, and it has been suggested that it should be given only after full hospital investigation and assessment. Caution is, however, no safeguard against many of the lethal complications of phenylbutazone therapy. Gastric ulceration may occur in the absence of any previous dyspeptic history, and may prove fatal through haemorrhage or perforation. Regular white-cell counts are no safeguard against toxic granulocytopenia. Hypersensitivity reactions may occur in patients with no previous history of allergy or hypersensitivity to drugs. Fatal hepatic necrosis may occur, and there is no safeguard against this. The occasional occurrence of severe reactions unfortunately bears no relationship to dosage, so that avoidance of overdosage is no safeguard (Nassim and Pilkington, 1953; Leonard, 1953).

Phenylbutazone is chemically related to amidopyrine, the use of which has already been abandoned in this country. A suggestion that there might be a specific antirheumatic effect of the drug has received little support, and all the evidence points to its beneficial effect upon rheumatoid arthritis being entirely attributable to its analgesic action. Claims have been made that phenylbutazone is superior to aspirin as an analgesic, but there have been no controlled trials to establish this, particularly when aspirin is used in the manner recommended by the Medical Research Council and Nuffield Foundation report (1954). When these recommendations are followed recourse to phenylbutazone therapy need seldom be considered. Phenylbutazone produces an extremely high incidence and wide variety of toxic effects, many of which are potentially lethal. It is therefore considered to be a dangerous drug which should not be used for the treatment of non-fatal diseases, such as rheumatoid arthritis. This conclusion is in agreement with that reached by Fraser (1955) and is in contrast with the acceptance of the drug with reservations by previous authors, who have suggested that it should be used with caution. It is pointed out that caution provides little safeguard against the many different lethal side-effects.

My thanks are due to Dr. R. W. Luxton for permission to report this case, and to Dr. J. Davson and Dr. M. C. H. Dodgson for laboratory, post-mortem, and histological reports.

Reviews

GROWTH, DEVELOPMENT, AND AGEING

The Uniqueness of the Individual. By P. B. Medawar. (Pp. 191. 18s.) London: Methuen and Co. Ltd. 1957.

This book has important things to say to the world of medicine. It is written by a distinguished biologist, in a felicitous style rare among biologists, and entirely free from the intellectual arrogance which commonly infects scientists when they write for the general public. Professor Medawar assembles in this book eight essays written over the last ten years. They are united by one theme: the implications of genetics in the study of growth, development, and ageing. Their relevance to the medical world can be illustrated by reference to the first two essays, which concern ageing. These essays are a masterly piece of reasoning, all the more remarkable because the material they contain is neither recondite nor unfamiliar. The expectation of life of a newborn child has been dramatically lengthened by the application of medical research; the expectation of life of a man of sixty has hardly changed. What are the prospects that medical research will do for the over-seventies what it has done so successfully for the under-fives? Professor Medawar does not attempt to answer this question, but (although he is human enough to hope to live into the seventies himself) he demonstrates that it is of no importance whatever to human evolution that the expectation of life of the over-seventies should be increased. For the destiny of man it is sufficient to conquer the diseases which kill or disable before and during the reproductive period. Once the reproductive period is over a man's health (though it means a great deal to himself and to his relatives) is of no biological importance. One of the consequences of this is that natural selection in man defers until later and later in the reproductive period those deleterious genetic factors which (through bad health or otherwise) impair reproductive capacity; but once the age of reproduction is passed these deleterious genetic characters can manifest themselves undisturbed by natural selection. They constitute the genes for senescence. The ills of the elderly are distressing to the individual who suffers from them, but they are of no importance to the breed; accordingly one expects to find that dangerous diseases in man are "pushed" by natural selection into the racially harmless post-reproductive period. Professor Medawar cites the period of onset of Huntington's chorea as an example that this is indeed happening. Fish, it is commonly believed, never grow old, and it is rare to find a wild animal which is old. This observation confirms Professor Medawar's thesis—that the symptoms of senescence are due to genes whose action is delayed beyond the reproductive phase—for wild animals live so dangerously that few of them survive beyond the reproductive phase, and so they rarely survive into the period when genes become immune from the influence of natural selection. Old age is a condition of domestication.

This is but one aspect of Professor Medawar's theme. He discusses also his own work on tissue-grafting and immunological tolerance, Lamarckism, and (less successfully) the scientific method. The whole book is a model of clarity and relevance. No one who is interested in the scientific basis of medicine should miss it.

E. ASHBY.

GASTRIC PHYSIOLOGY

The Physiology of Gastric Digestion. By A. H. James, D.M., M.D., B.Ch., M.R.C.P. (Pp. 192+xi; illustrated. 28s.) London: Edward Arnold Ltd. 1957.

In this monograph Dr. James has skilfully summarized the large volume of work which has been done on the secretions, the movements, and the sensations of the stomach since the pioneering experiments of Beaumont over a century ago. The problem has proved a difficult one. The

stomach is open at both ends, and it is influenced by a variety of nervous and hormonal stimuli. Moreover, there are three distinct groups of cells in the mucosa—parietal, zymogenic, and mucous, the last almost certainly comprising a number of subgroups. Many of the physiological data have been obtained from the study of isolated pouches in the dog, and they are not necessarily applicable to the intact human stomach. The physiologists speak of the cephalic, gastric, and intestinal phases of secretion, but in normal life they run together like the three phases of a colour print. The book is well produced and clearly written, though a dogmatic summary at the end of each chapter would have helped some readers to see the wood better. It will be of great value to surgeons and gastroenterologists and will prevent them from making the more obvious gaffes in the study of gastric secretion and motility. It leaves one with the feeling that, although acid and pepsin are a *sine qua non* in the genesis of peptic ulcer, they are not of such crucial importance as clinical textbooks and articles would lead one to believe.

L. J. WITTS.

ELECTROCARDIOGRAPHY

New Bases of Electrocardiography. By Demetrio Sodi-Pallares, M.D., with the collaboration of Royall M. Calder, M.D. (Pp. 727; illustrated. £6 15s.) London: Henry Kimpton. 1956.

This book aims at providing a discussion of the scientific foundation upon which electrocardiography is built. It is not merely descriptive, as are so many of the manuals and atlases that just give patterns and pictures. This does more, and does it very well. If the student of the subject has really grasped the underlying laws, then he can "reason out the curve," as Dr. Chavez points out in the preface. Unfortunately, some of the mathematics are likely to be beyond the scope of many readers, but this need not prove an impassable barrier. The foundation on which the writer builds is the work of Einthoven, Lewis, and Wilson. It is interesting to read once more the fundamental work of Lewis that provided the basis of knowledge 35 years ago; the first 130 pages of the book deal with the Einthoven triangle and the electrical axis. To go through all this again in the light of modern ideas is very stimulating. The unipolar limb leads and the precordial leads are then discussed, and the effects of injury of the muscle. At every step there is logical reference to the basic principles which underlie the interpretation. The author concludes that the vectorgram adds but little to the information of the electrocardiogram. There is an interesting section on the effects of variation in potassium and sodium and on the potentials recorded within the cardiac cavities.

This is a remarkable book. It is not easy to read, but it is certainly the best survey of the foundations of modern cardiology that has appeared. The translation is well done. The illustrations are excellent. There are nearly 1,000 references.

TERENCE EAST.

PSYCHIATRIC ESSAYS

Christian Essays in Psychiatry. Edited by Philip Mairet. (Pp. 187. 15s.) London: S.C.M. Press Ltd. 1956.

The ten authors of this small book are agreed on one matter—namely, that life has purpose and meaning. If this be accepted, so runs the argument, it is tantamount to saying that man is naturally religious and that outside man lies a greater power. Various religious systems, of which Christianity is one, describe the supra-individual power of God. The word "Christian" in the title of the book seems to be unnecessary; its scope goes far beyond Christian concepts, and one or two of the essays might well have been written by a believer in any religion. One of the commonest symptoms of neurosis and mild depressive states is that the meaning and purpose of life is lost. And this happens to Christians and non-Christians, to agnostics, and to atheists.

None of the authors argues that the only way to restore the mind to health is to adopt a religious code, although the value of such a belief to those who have it is undoubted. In medical circles the book will be of special interest to the general practitioner and will give him considerable insight into the symptomatology of many patients whom he is inclined to label (and dismiss) as neurotics. Psychiatrists, too, might read it with profit. All of the essays are well written and clearly presented. For originality and sureness of presentation high marks should be given to the chapter by Eve Lewis on "The Development of the Religious Attitude in Children."

E. A. BENNET.

ABDOMINAL SURGERY

The Management of Abdominal Operations. Edited by Rodney Maingot, F.R.C.S. Second edition, in two volumes. (Volume I—pp. 772+lxix; illustrated. Volume II—pp. 654+lxix; illustrated. £8 the two volumes.) London: H. K. Lewis and Co. Ltd. 1957.

When four years ago I had the privilege of reviewing the first edition of this great work it seemed that it must set the standard of surgical practice for many years to come. Such, however, has been the advance of surgery in that short time that a completely new edition has been produced to record its progress. Both in content and in production it is far in advance of its predecessor, and it forms a magnificent tribute to the achievements of British surgery. It is now conveniently housed in two volumes, each with a comprehensive index; it has been largely rewritten; and the illustrations have been greatly improved. It is no mere manual of surgical technique, but is, as its name implies, a most detailed guide to the management of abdominal operations. Indeed, a very large proportion of the book is devoted to the care of the patient both before and after an operation, and it is no doubt to the exercise of this care that we should attribute the brilliant results recorded. It is equally remarkable that just one-third of the book is devoted to considerations which are essentially physiological, in striking contrast to the atmosphere of anatomy in which we surgeons were trained in another epoch.

In such a series of brilliant articles, where every page is full of interest, it is difficult to choose any for special mention. But again the articles by Maingot on the stomach and on the biliary tract are quite outstanding, while Norman Tanner deals admirably with the old and difficult subjects of gastric haemorrhage and perforation; Borrie with the newer but equally difficult problems of the oesophagus and cardia; and Ainsworth-Davis, in a short but most valuable article, with complications which may occur in the urinary tract. But from every point of view the great essay by Gordon-Taylor on abdominal injuries in warfare and civil life remains unique. The whole work is a superb achievement which we may all welcome with gratitude and pride.

HENRY SOUTTAR.

COLPOSCOPY

Atlas der Kolpomikroskopie. By Tassilo Antoine and Viktor Grunberger. (Pp. 244+iv; illustrated. D.M. 64.) Stuttgart: Georg Thieme. 1956.

Microscopic examination of the cervix *in situ* has been the subject of constant and intensive study since its introduction by Hinselmann in 1924. Its development has been largely carried out in Vienna, and now Professor Antoine, for long an assistant and now director of the First Frauenklinik there, gives us in this atlas the results of almost twenty years' work on the subject. The plan of the book is simple, with illustrations on one page and the relevant captions facing. Beneath each "colpograph" is the corresponding biopsy photomicrograph, the more familiar picture providing a very useful basis for comparison.

Whether the claims made for this method of surface microscopy are justified by its results is still a matter of dispute. As with the Papanicolaou vaginal-smear technique, it requires a good deal of training and practice, and even with

these exact identification may be difficult in borderline cases. It is, of course, a safe, simple, and relatively inexpensive procedure, but in established cases of carcinoma it is unnecessary, and in doubtful cases must, anyway, be confirmed by biopsy, so that most clinicians will continue to prefer the latter. But as an experimental method colposcopy must obviously have a considerable future, and this atlas, written in three languages (German, English, and Spanish) and beautifully illustrated, is its most complete description to date.

A. DAVIS.

RENAL PHYSIOLOGY AND PATHOLOGY

Physiology and Pathology of the Kidney. *British Medical Bulletin*, Volume 13, No. 1, January, 1957. Scientific editor: Clifford Wilson. (Pp. 74; illustrated. 20s.) London: British Council. 1957.

As Professor Robert Platt says in his introduction, this is a symposium by clinicians and others in close touch with clinical departments. The emphasis is on the kidney as a homeostatic rather than an excretory organ, and hence there are discussions on the volume control of body fluids, potassium deficiency, amino-aciduria, the nephrotic syndrome, and renal osteodystrophy, as well as more pathological topics and the newer renal investigatory techniques of angiography and venography. The result is a credit to British medicine and a thoroughly absorbing volume with as much to interest the general physician as the renal specialist. One small criticism is the system used for numbering the illustrations, and this is particularly annoying in the outstanding contribution by Stanbury on osteodystrophy, where there are ungainly text references such as Plate V, Fig. Cb.

R. I. S. BAYLISS.

CLINICAL ELECTROENCEPHALOGRAPHY

Systématique et Electroencéphalographie des Encéphalites et Encéphalopathies. By J. Radermecker. Preface by L. Van Bogaert. (Pp. 243+x; illustrated. 2,800 frs.) Paris: Masson et Cie. 1956.

This excellent monograph is the first of a series to be published in the French tongue having as the general theme "Clinical Electroencephalography." Writing from the almost unique experience of the Antwerp school, the author's aim is to correlate clinical, pathological, and electroencephalographic features of the various forms of encephalitis and encephalopathy, both of known and unknown aetiology. After useful descriptive and aetiological classifications each disease is dealt with concisely in turn, and we thus find under one cover a wealth of information, some previously published, some unpublished, which brings clearly to light both the extent and the shortcomings of our present state of knowledge. With the aid of a number of simple diagrams showing the whole neuraxis at a glance, special stress is laid on the different distribution of the main lesions in the different encephalitides and their customary direction of spread. These are the features which are most closely correlated with the types of electroencephalographic abnormality, so that the author, most wisely, does not claim specific changes for specific diseases, but shows how information given by the E.E.G., taken in conjunction with the basic clinical features, can be of practical help in diagnosis and in assessing severity, progress, or improvement. Coming from this source, it is both justifiable and welcome to find considerable space devoted to "les leuco-encéphalites sclérosantes subaiguës" (somewhat unfortunately abbreviated to L.E.S.S.) and reaffirming their identity with inclusion-body encephalitis. In this group alone at present the E.E.G. changes appear to be pathognomonic, and these are beautifully illustrated.

With its extensive bibliography this electroencephalographic publication contains so much basic clinical information that it will be of great value to practising neurologists, paediatricians, and pathologists, and it would well merit translating into English.

EDWIN R. BICKERSTAFF.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JULY 20 1957

THE PRESIDENTIAL ADDRESS

During the past week Newcastle upon Tyne has been the medical capital of the United Kingdom. This northern city, with its splendid traditions of enterprise, hospitality, and learning, has given a warm welcome to members of the Association and to medical visitors from a large number of other countries who have attended the one hundred and twenty-fifth Annual Meeting of the B.M.A. On each of the three previous occasions a physician was elected to the office of President. This year a surgeon, Mr. Weldon Watts, has that honour. It is, incidentally, interesting to see in the light of the present day how wide of the mark a seemingly safe prophecy can be. In 1893 Professor G. H. Philipson, in his presidential address¹ to the B.M.A. at Newcastle, had this to say about the future organization of a health service: "A high medical authority in the Cabinet (of course selected for his transcendent professional abilities, not his political bias) would save an enormous amount of public delay, vacillation, and disagreement on medical subjects between lay public authorities, while at the same time such an appointment would considerably raise the status of the profession."

Mr. Watts has wisely refrained from attempting to forecast the future. In his presidential address, printed in the opening pages of this issue, he reviews the medical history of the city in which he practises. It is an interesting story, probably not very different from the medical sagas of any great regional centre of commerce, education, and culture. Newcastle has always been well served by historians, both amateur and professional, yet the recorded facts of medical interest make a curious patchwork. Mr. Watts tells us of the medical service in the Roman army, and no doubt, as he suggests, the surgeons and medical orderlies attended the villagers living near their forts and camps. What happened when the Romans left? Such evidence as exists points to a large element of magic in Anglo-Saxon medicine,² and it is not until the fourteenth century is reached that Mr. Watts can find any record of a medical man practising in New-

castle. From the fifteenth century onwards developments in the practice of medicine are fairly well documented. Progress has been far from orderly, depending on piecemeal changes made according to the needs, knowledge, and limitations of the day. Readers of Mr. Watts's address must be struck by the evidently strong impetus in the eighteenth century to establish hospitals. Though this was at a time when dogmatic religion was on the decline, "this fresh springing up of human sympathy," according to the historian³ of the Newcastle Infirmary, "had its main source in the religious spirit." This view is borne out by one of the rules of the Infirmary drafted in 1801: "That when patients are discharged cured, they shall be strictly enjoined by the Chairman of the Committee, to return thanks to Almighty God in their respective places of worship and to the subscribers who recommended them." But, whatever the motives of the founders, the hospitals provided the clinicians with patients to treat and diseases to observe. It was a time when the educated man felt it was his duty to unravel the secrets of Nature—a feeling somewhat grandiosely expressed by Mark Akenside (the physician poet, who was born in Newcastle in 1721) in his "Hymn to Science," written when he was only 17 years old:

"Give me to learn each secret cause;
Let numbers, figures, motion, laws
Revealed before me stand;
These to great Nature's scenes apply,
And round the globe, and through the sky,
Disclose her working hand."

Mr. Weldon Watts has with great assiduity assembled facts about medicine in Newcastle in a way that only the historian on the spot can do, and thus is in a position to make a contribution with first-hand authority behind it. From the rich and varied material at his disposal he has chosen with discrimination facts about places and persons, disposed in time, that give the reader a picture of the halting way in which medicine has progressed down the ages, Newcastle being in this a mirror image of what was happening elsewhere. Mr. Watts has with much skill avoided overcrowding the foreground of his canvas with personalities that must have been vividly in his mind's eye. The story of medicine in Newcastle over the past three-quarters of a century would in itself have sufficed for a presidential address, and its modern developments and activities have had an influence far beyond the confines of the city's boundaries. No one can think of Newcastle and the profession of medicine without recalling, among many others, the names of Rutherford Morison, G. Grey Turner, David Drummond, Thomas Oliver, F. A. Bainbridge, Robert Bolam, and James Spence.

Their work and the work of their successors of to-day will provide the President of the next meeting in Newcastle with an admirable opportunity to continue the tale of prowess and service.

INCREASING MUSCLE STRENGTH

The public expects doctors to be able to give authoritative guidance on how to improve physique, yet there are many large gaps in our knowledge of this subject. Since the beginning of the century little new has been learned about muscle function, but an encouraging recent sign of progress is the setting up by the Medical Research Council of a working party to co-ordinate research on methods of increasing the strength of muscles. Speaking at a meeting of the Section of Physical Medicine at the Royal Society of Medicine on the appraisal of such methods, Dr. H. D. Darcus¹ said that, although many different methods of exercising and forms of apparatus had been devised, these had not been of much help in explaining the underlying mechanical, biochemical, vascular, and other changes which accompany improvement in function or strength of muscle. Different training routines are necessary for the development of strength, endurance, speed of contraction, and co-ordination of movement, but to what extent does the training to improve one of these qualities affect the others, either favourably or adversely? The design of exercise depends on which particular facet of muscular activity it is wished to improve and the physiological change required to effect it. These and other variables have to be considered in devising a training routine, and there is no generally accepted method.

Neuromuscular adaptation is an important aid to improved muscle strength and function, and Dr. Darcus pointed out how the effects of training on the central nervous system are manifest in the acquisition of skill, better co-ordination, and greater economy of physical effort to perform certain tasks. Increased motor-unit activity, reduced synaptic resistance, proprioceptive facilitation, increase in the number of pathways to the anterior horn cells and an increase in the number of anterior horn cells stimulated, recruitment of neighbouring muscles—all are examples

of neuromuscular adaptation which can result from training. How an increase in motor-unit activity is achieved is a matter for speculation. Apart from the stimulus to contraction which passes down the pyramidal tract to the anterior horn cells, a local feedback control of motor neurones has been described.^{2,3} Excitation of the small motor nerves causing contraction of intrafusal fibres in the stretch receptors leads to contraction of the main muscle fibres via the stretch reflex arc. This "servo-loop" effect helps to maintain constant tension during muscular contraction.

Some of the practical problems concerned with the measurement of muscle strength were discussed by Dr. D. A. Brewerton⁴ at the R.S.M. meeting. Crude strength, he said, can be readily measured by a subject's performance against a spring gauge or calibrated weights. Such strength can be developed by resistance exercises. Where in a joint range should maximum resistance be applied? Using a special apparatus, Dr. Brewerton has found that in the ordinary knee-extension exercise with a weighted boot the resistance is maximal at full extension; yet for many normal activities—for example, stair climbing—greater strength when the knee is bent may be desirable. He has also found that a quadriceps weak in one position is proportionately weak throughout the range, and the position for applying maximum resistance is unimportant unless the joint is painful. The regime for developing crude strength can seldom be applied for the benefit of patients without some modification.

Empirical methods of increasing muscle strength and function have yielded useful results. Nearly all improved training techniques have been evolved by lay persons practising weight-resisted exercises for the improvement of physique or as a training method in the sport of weight-lifting. The newest methods can safely, certainly, and quickly build strong or large—or strong and large—muscles in any normal individual. Methods of increasing crude strength have outstripped achievements in other athletic spheres. An Olympic total of 1,200 lb. (54.5 kg.) in the heavy-weight weight-lifting class forecast less than three years ago⁵ has already been reached in training, a performance more than 20% better than that of the heavyweight winner of the 1948 Olympics. This has been possible only by improved training techniques for increasing muscle strength, and presumably these methods could be used effectively in clinical medicine. Persistence in the notion that weight-lifting and heavy-resistance exercise may "slow down the reflexes" of athletes is indefensible, for the evidence shows that the reverse is true.⁶ To quote but a few examples, among those who include in their basic training

practice with weights which are very heavy even by weight-lifters' standards are world record holders of the 880 yards and 800 metres sprint, of the discus throw, of the pole vault, and of the 100 metres swim.

A hinged quadrant exerciser with weights loaded at both ends of the arc in varying proportions has for several years been a standard piece of equipment in the weight-resistance exercises devised by their lay exponents. It has been used to apply maximal resistance throughout the range, or in one part of the range, of knee extension or flexion. The full deep-knee bend or "squat" with a barbell across the shoulders is a more popular and in many ways more rational exercise in that it simulates normal hip and knee flexion-extension movements and powerfully exercises the hamstrings and glutei as well as the quadriceps. Pain usually prevents resistance exercise from being effective, since it inhibits muscle contractions powerful enough to increase strength, though resistance may be applied through the least painful part of the range of joint movement and so increase strength in this limited range. This method of exercising a painful joint sometimes also increases the range of painless movement.

The most immediate practical problems of exercise therapy are to determine what degree of resistance to use, how often exercises should be repeated, and at what intervals in order to produce a specific effect in skeletal muscle. R. W. Parnell^{7,8} and W. H. Sheldon^{9,10} suggested that differences in somatotype may account for variations in response to exercise, and further research on this might be rewarding. Exercise when effective increases muscle bulk and power, and this has been shown experimentally to be largely due to an increase in cross-sectional area of the muscle fibres. When low-resistance exercises are repeated at short intervals the effect is actually to reduce the cross-sectional area of the muscle fibres.¹¹ This is exemplified in the "excessive-use atrophy" which sometimes occurs in the forearm muscles of professional file-grinders. Another problem is the scope of muscular activity which should be prescribed. Even simple activities like stair climbing and getting in and out of wheelchairs entail fairly complex movements, and in perfecting their integration individual muscles and muscle groups are not necessarily recruited maximally. Elective progressive-resistance exercise (P.R.E.) to selected muscle groups can, however, be carried out to the point of supramaximal stimulation, and Hellebrandt¹² has said, "The organ system taxed beyond its capacity is the one which demonstrates maximal training." This kind of training also meets two other important requirements—that is, the encouragement

of neuromuscular adaptation and the development of maximal contractile force resulting from maximal muscle stretch prior to contraction. DeLorme and Watkins¹³ have pointed out that "intense concentration and consequently a high degree of cerebration is necessary when trying to overcome heavy resistance . . . in this way P.R.E. improves neuromuscular co-ordination and motor learning. . . . Furthermore, in many of the procedures recommended the weights must be supported between contractions and the length of the muscle being exercised is extended somewhat beyond that characteristic of its resting state." The more recent refinements of P.R.E. described by I. J. MacQueen¹⁴ may further stimulate neuromuscular adaptation and possibly also increase capillarization of muscle.

EFFECT OF PREGNANCY ON COLITIS

One of the interesting but unexplained aspects of ulcerative colitis is its relationship to pregnancy. It is now generally agreed that when ulcerative colitis originates during a pregnancy the chances are that the attack will be a very severe one.¹⁻³ But opinion has been divided about the effect of pregnancy on a woman who already has the disease. Most authorities have regarded a supervening pregnancy as having a bad influence on the course of ulcerative colitis, but others⁴ have found that more than half the patients with active symptoms are improved by pregnancy. Two important studies, one British and one American, have recently been published. I. Macdougall⁵ studied the course of ulcerative colitis in 64 women who went through 100 pregnancies. In 26 of them the ulcerative colitis began during or soon after a pregnancy, and this group contained a large proportion of severe cases, with two deaths, although the author points out that previous work has shown that first attacks are commonly more severe than relapses, so the exact effect of pregnancy is difficult to judge. In established cases of ulcerative colitis Macdougall found that pregnancy occurring when the disease was inactive seldom gave rise to reactivation, only 2 out of 21 cases showing this effect; while of those with active disease at the start of pregnancy, although a quarter of the women suffered from an exacerbation of the illness, about one-half went into clinical remission.

Burrill B. Crohn and his colleagues⁶ paint a somewhat more sombre picture as a result of studying 110 women with ulcerative colitis who went through 150 pregnancies. In 19 patients the onset of ulcerative colitis took place during pregnancy, most commonly during the first trimester. The disease was severe in 13 of these patients,

with one death. Another group of 19 patients developed ulcerative colitis during the first few weeks or months of the puerperium, and about half of them were severely ill. Among patients already subject to ulcerative colitis, when pregnancy supervened during a quiescent phase of the illness recrudescence occurred in about one-half of them; and when the disease was active at the beginning of pregnancy exacerbation occurred in no less than three-quarters of the patients.

There can be little doubt that in general the occurrence of pregnancy in association with ulcerative colitis has a bad effect upon the course of the disease, although it is impossible to predict what will be the effect in any individual patient. Crohn and his colleagues advocate the use of corticotrophin or other related steroids in the treatment of ulcerative colitis during the course of a pregnancy, in addition to the basic methods of maintaining nutrition, combating blood loss, and minimizing secondary infection with sulphonamides and antibiotics. Cortisone increases the chance of obtaining clinical remission in a few weeks, and therefore steroid therapy is worth trial, particularly since there is no objection to its use in pregnancy provided the patient is under careful supervision.⁷ However, cortisone benefits only a proportion of patients, and the others require skilful handling in hospital if the disease happens to be severe. Therapeutic abortion is not usually called for, since there is no certainty that the disease will improve after this measure, but it should be considered if a first attack of ulcerative colitis occurs in the first trimester of pregnancy and does not respond quickly to medical treatment. As to the advice which should be given to a patient with established ulcerative colitis who wishes to have children, it is best to avoid conception while the disease is in an active phase because of the serious risk of exacerbation; but in a quiescent phase the risk is less (and in Macdougall's series no greater than one might expect in any group of non-pregnant women) so that pregnancy is then a reasonable venture.

Both studies agree with earlier work in showing that women who suffer from ulcerative colitis readily become pregnant and that the disease does not exert a bad effect upon the course of the pregnancy, as judged by the numbers of spontaneous abortions and stillbirths. Finally, it should be remembered that, if a woman with ulcerative colitis has been treated by ileostomy and colostomy, this is no bar to pregnancy, and natural birth can occur.^{8,9}

NEW CEREBRAL DEPRESSANT

H. Laborit, who first introduced chlorpromazine as a constituent of a "lytic cocktail" for producing "artificial hibernation," has now, with his colleagues, introduced a new substance which is called S.C.T.Z.¹ We are not told what these initials stand for, but the substance seems to be a derivative of methyl-4- β -hydroxyethyl-5-thiazole, which is part of the molecule of thiamine. It is said to produce sleep without any degree of analgesia or of anaesthesia. S.C.T.Z. is given

¹ Laborit, H., Coirault, R., Damasio, R., Gaujard, R., Laborit, G., Fabrizzy, P., Charonnat, R., Lechat, P., and Chareton, J., *Presse méd.*, 1957, 66, 1051.

by intravenous injection, being available in a 2% solution, of which 20 ml. is contained in one ampoule, and a total of 60 or 100 or even 200 ml. is given. It is said to be useful as one agent in producing general anaesthesia, others being used at the same time; it has no effect on metabolism and it does not cause respiratory depression. For general anaesthesia it was used in 23 cases as a first injection, followed by 50 mg. promethazine and 100 mg. pethidine (intravenously), or it was given as a combined perfusion of 120 to 160 ml. S.C.T.Z. solution with promethazine and pethidine. Sometimes "hydergine" was given as well. Further doses of 5 ml. S.C.T.Z. were given later as required.

Five patients suffering from a severe delirium were given S.C.T.Z. They continued to receive cortisone and sodium chloride. An intravenous injection is reported to have sent them into calm sleep within three minutes which continued from five to eight hours, though one patient required as much as 200 ml. of the S.C.T.Z. solution. The authors think that the new drug may be valuable in prolonged and painful labour, because it does not cause respiratory depression and the foetus should not suffer.

Toxic effects have not so far been detected. The drug does not act on the heart or blood vessels, it does not affect digestion or the alimentary canal, it has no effect on the kidney or on the distribution of ions in the blood, and it has no action at the neuromuscular junction and does not cause ganglion block. A substance related in constitution to part of the thiamine molecule which is so free from toxicity as is claimed might prove to be useful in severe insomnia. S.C.T.Z. must be given by intravenous injection in a large volume, and for this reason it is not likely to be used by patients themselves. It may prove to be a useful tool for the doctor.

WAITING-LISTS

A recent report¹ from Cardiff on the subject of hospital waiting-lists avoids many of the errors which are commonly made in drawing specious assumptions from the study of the available figures. Waiting-lists in the Cardiff area followed in general the national pattern, in that they rose steeply from 1947 to about 1949, remained roughly stationary until 1953, but since then have begun to fall. The report shows that only a part of this fall is a genuine fall in the numbers of patients who are waiting for admission. Wrongly entered names inflate the average waiting-list by about 23%, and a further 10% of persons on the lists do not regard themselves as waiting for admission. At first sight it seems anomalous that while 41% of those on the lists had waited for over a year, 85% of those who were actually admitted to hospital had waited for less than a year. The conclusion from these two figures seems to be that the longer a patient waits the less likely he is to accept admission when it is offered to him. In Cardiff, as elsewhere, the three departments which are responsible for the greater part of the whole waiting-list for the hospitals (in this case 93%) are general surgery, gynaecology, and orthopaedic surgery.

¹ "A Study of Hospital Waiting Lists in Cardiff (1953-1954)."

The report deals at length and in an interesting fashion with the human problems of patients who are waiting for admission to hospital. Of those who were in employment, 33% were unable, while they were waiting, to work as usual. On the other hand, as the report points out, it is possible to give a very different impression by putting this the other way round and saying that over three-quarters of all those who were waiting for admission were able in the meantime to lead perfectly ordinary lives. The recommendation is made that entries in waiting-lists ought in future always to be divided into two categories—those who would be able to accept admission at short notice and those whose circumstances would require special consideration. It is also suggested that more use of health visitors should be made during the waiting period.

The authors of the report are careful to avoid generalizations and state that the mere size of a waiting-list is not a good index of bed deficiencies; indeed, a long but stationary waiting-list is no indication at all of a current shortage of beds. They conclude that there has been no serious overall shortage of beds in the Cardiff area during the last few years. In fact, had it been possible to provide 134 extra beds for a period of one year, the whole of the waiting-lists in all specialties would have been completely cleared. A further important recommendation is that all waiting-lists ought to be reviewed at frequent intervals by a senior member of the medical staff: the handling of waiting-lists ought not to be left solely to registrars.

DETECTION OF DEAFNESS

Because "the family doctor can do more than anyone else to secure early diagnosis and treatment" in cases of deafness, the Ministry of Health has recently sent to all general practitioners in the Health Service a small memorandum on the subject.¹ Some approximate figures collected nearly ten years ago—the most recent available—show that something over 100,000 people in Britain are totally deaf or nearly so, while about a million and a half are moderately deaf. Yet in addition to these there are probably many more deaf people who, if ascertained, could be offered help. The family doctor can play a particularly decisive part at two points—by detecting deafness in young children so that they may receive treatment and, if necessary, training before it is too late, and by advising elderly people how best to meet a disability that may well be both puzzling and progressive. The prejudice against hearing-aids has much diminished, and, though they are more troublesome than a pair of spectacles, it has been found that children of 3 years and even younger can be induced to wear them cheerfully.² Early detection of these cases is especially worth while now that the methods of analysing the disability are being increasingly refined,³ with consequent improvement in the prospects of successful

treatment. A diagnosis of deafness can be made in young infants and treatment can often be started before they are a year old, with much better prospects of success than if it is delayed. Chronic otitis media deserves special attention. Anyone who served in the armed Forces during the last war must have been struck by the number of otherwise robust young men whose hearing and even general health were impaired by this somewhat intractable disease. In spite of therapeutic advances, it remains a serious public health problem. J. A. H. Lee found⁴ a rejection rate of 26 per 1,000 for E.N.T. conditions among National Service recruits. This was the largest single category and was composed "almost entirely" of cases of chronic otitis media.

HYPERTENSION IN PREGNANCY

The Institute of Obstetrics and Gynaecology organized a symposium on "Non-toxic Hypertension in Pregnancy" at the Postgraduate Medical School of London early this month. The discussion ranged widely and showed a need for more systematic accumulation of accurate data in this important field. Professor Clifford Wilson, on the basis of his extensive experience of patients attending the renal and hypertensive clinic at the London Hospital, showed that women with chronic nephritis could nearly always undergo successful pregnancies. Both clinically and experimentally pregnancy sometimes seems to lower the level of the pre-existing hypertension, an opinion with which Dr. F. B. Byrom concurred. Dr. Alan Brews and also Dr. Malcolm Milne reported the birth of living babies from malignant hypertensive mothers undergoing treatment for their disorder with hypotensive drugs. Patients who have had the fully developed syndrome of eclampsia can pass through subsequent pregnancies without any difficulty.

Professor J. C. McClure Brown referred to his work showing that hypertension from whatever cause diminishes the flow of blood through the maternal side of the placenta. This impairment of placental function is the main factor compelling the obstetrician to induce labour early in such patients, and it probably also contributes to the occasional complication of retroplacental haemorrhage. Mr. Trevor Johnson demonstrated his method of estimating placental function by measuring the transfer of radiosodium to the foetal sac. He claimed that this technique enabled him to predict more carefully when to advise termination of pregnancy. In spite of the often premature ending of pregnancy by natural events or by obstetric interference, Miss Gladys Dodds had found that the babies born of hypertensive mothers were not necessarily small but could be of normal weight, or even overweight. Mr. G. W. Theobald, basing his data on cardiovascular deaths documented by the Registrar-General, thought that married women had no higher death rate from subsequent development of vascular disease than single women. This raised the question of whether hypertension in pregnancy is simply an early manifestation of an essential hypertension which will develop later. Dr. Poul Bechgaard quoted the figures of Hertel, who

showed a high incidence of essential hypertension in patients who had suffered from pre-eclampsia. His own data showed that women whose hypertension began in pregnancy had nearly twice the death rate of women with similar levels of blood pressure unrelated to pregnancy. He therefore thought that hypertension developing after a pregnancy toxæmia ran a more serious course. Most of the physicians present regarded a blood pressure of 160/90 before middle life as indicative of a hypertensive vascular disorder. The obstetricians, dealing generally with women of a younger age, took 140/90 as suspicious. Dr. J. A. Fraser Roberts showed the slightly skewed frequency curve of blood pressure in the general population which had been recorded by Professor Pickering and his collaborators at St. Mary's Hospital, repeating that there was no dividing line between normal and abnormal levels, and also emphasizing the tendency to hypertension in the relatives of those who had higher than average pressures. Professor McMichael felt that there might be two overlapping populations, basing his definition of the pathological on Bechgaard's 20-year survey of the mortality rates in over a thousand patients with pressures over 160/90.

Dr. Robert S. Duff showed that the reaction of the blood vessels in the hand to adrenaline differed in normal and hypertensive subjects and that normal vessels could be made to react like hypertensive vessels by intra-arterial infusions of minute amounts of hydrocortisone. It thus seems possible that adrenal cortical influences might be implicated in hypertension. In the early stages of hypertension it was believed that there was probably no anatomical lesion in the arterioles even of the kidney, but this view, based on biopsies taken at sympathectomy, was criticized, since the vascular lesions might be patchy. Professor H. L. Sheehan thought that the intimal elastic tissue proliferation in small arteries might be a response to fusiform dilatation of the muscular coat and he believed these lesions were present from an early stage of hypertension.

The opportunity was also taken at the symposium to discuss other secondary hypertension. Dr. J. F. Goodwin showed that pregnancy could be carried to a successful conclusion in the presence of coarctation. He felt that operation could be deferred, but a minority of the obstetricians present thought that pregnancy was quite a convenient time for cardiovascular operations. Sir Arthur Gemmell discussed phaeochromocytoma as an occasional cause of disaster, if overlooked.

The great importance of pyelonephritis as a cause of hypertension was repeatedly emphasized in discussion. It seemed that the interstitial variety of this disorder, with little in the way of overt manifestations, was more apt to be followed by hypertension. The recognition of this disorder is by no means easy, and even the most elaborate investigations may leave the physician in doubt when it is suspected: it should certainly be sought in all hypertensive patients under the age of 35 (Platt's law). Ophthalmoscopic examination was only occasionally mentioned, but the importance of observation of the smaller blood vessels by direct methods was emphasized by Dr. R. Landesman, who showed a film of abnormal

reactions in the conjunctival arterioles, capillaries, and venules in hypertensive pregnant women.

The conference did much to bring interested physicians and obstetricians together in a mutual appreciation of the problems which they face. Even such basic matters as the technique of blood-pressure recording was discussed. Differing standards of measurements of the diastolic pressure in this country and in the United States may lead to confusion. Fat arms were said to be responsible for erroneously high readings. These elementary problems require some systematic and concerted efforts at settlement before much further progress can be made.

P.R.C.S.

Sir James Paterson Ross was last week elected President of the Royal College of Surgeons in succession to Sir Harry Platt, who had held the office since 1954. Appointed professor of surgery in London University at St. Bartholomew's Hospital in 1935, Sir James Paterson Ross is among the world's foremost surgeons, a master of his craft, and in particular an international authority on the surgery of the sympathetic nervous system. He had the onerous task, with others, of caring for King George VI when he was seriously ill in 1949. In the last decade or so the Royal College of Surgeons has come to the front as a great institution for research and teaching, having many friendly links throughout the British Commonwealth, the U.S.A., and elsewhere with individual surgeons and surgical departments. The conduct of this great enterprise requires uncommon qualities, and none will doubt that in Sir James his surgical colleagues have chosen a man exceptionally fitted to bear these responsibilities with distinction.

CAMBRIDGE REGIUS PROFESSOR

The Queen has approved the appointment of Professor J. S. Mitchell, F.R.S., as Regius Professor of Physic at Cambridge University. He succeeds the late Sir Lionel Whitby. Professor Mitchell is the first occupant of the chair of radiotherapeutics established at Cambridge in 1946 and he has been director of the radiotherapeutics centre at Addenbrooke's Hospital since 1943. In 1952 the Royal Society elected Professor Mitchell a Fellow for his outstanding work on the mechanism of the therapeutic action of radiations. At a time when everyone who can is feverishly helping himself to the contents of that Pandora's Box the atom, it is particularly fitting that the new Regius Professor should be one whose main study is of the use to which atomic radiations can be put in medicine. Moreover, his department has recently been investigating substances which may have some protective action against radiation. A member of the M.R.C. committee which reported last year on the hazards of nuclear radiations, Professor Mitchell was joint signatory of the appendix which indicated the probability of a proportional relationship between dose of radiostrontium, even at low levels, and frequency of tumours.

British Medical Association

ANNUAL MEETING, NEWCASTLE UPON TYNE, 1957

SUMMARY OF PROCEEDINGS

THE SECTIONS

SECTIONS OF OBSTETRICS AND GYNAECOLOGY AND GENERAL PRACTICE

Monday, July 15

Pre-eclampsia

Professor H. HARVEY EVERS (Newcastle upon Tyne), president of the Section of Obstetrics and Gynaecology, took the chair at this joint session when Dr. KATE HARROWER (Glasgow) opened a discussion on pre-eclampsia. She said that in our present state of knowledge thorough antenatal care was our best weapon against the dangers of toxæmia because it made for the earliest diagnosis and for prompt treatment. Even in an integrated maternity service the ultimate responsibility for the well-being of the pregnant woman should be in the hands of one person, most suitably the general practitioner. She had seen over the last thirty years amazing advances, not only in medical science and practice, but also in the attitude of women towards pregnancy. From the intimate contacts of general practice she was convinced that fears and stresses in the pregnant woman contributed to her tendency to toxæmia. The provision of educational classes for expectant mothers was therefore to be encouraged as likely to eliminate fear of the unknown. Dr. Harrower pointed out that the diagnosed incidence of pre-eclampsia varied according to what the individual doctor regarded as the upper limit of normal blood pressure; but the acceptance of a figure as low as 120/80 mm. Hg could do nothing but good in the preventive sense. The patient who had a raised level at first consultation but not thereafter was to be regarded as a candidate for toxæmia. In mild degrees of pre-eclampsia the general practitioner could give close supervision without alarming the patient. Rest, mild sedation, reduction of salt intake, and careful watch on weight-gain were important in management. Other than mild cases required transfer to hospital, where the number of antenatal beds should be based on the total population at risk, not merely on the number of bookings. Dr. Harrower concluded with a tribute to the foresight of the late Dr. J. W. Ballantyne, of Edinburgh, over 50 years ago and to his pioneer work in the field of antenatal care.

Mr. O. VAUGHAN JONES (Bangor, Caerns) dealt mainly with the dangers of pre-eclampsia to mother and baby. In eclampsia the aim of treatment was to control the fits. Even in a rural area such as his this was best done in hospital, the patient first receiving morphine gr. $\frac{1}{2}$ (32 mg.) and atropine gr. 1/60 (1.1 mg.) at home. In his unit a modified Stroganoff regime of sedation was followed, with labour being induced as soon as practicable. In 110 cases the maternal mortality had been 4.5% and the foetal loss 28.4%, figures comparing well with those obtained by other forms of treatment. In imminent eclampsia with no response to deep sedation the baby must be delivered quickly. If its maturity was less than 36 weeks caesarean section under local analgesia, supplemented by thiopentone at the time of the uterine incision, markedly improved the baby's chance of survival. Of 28 babies weighing 5½ lb. (2.5 kg.) or less delivered this way, only three were lost. In concealed accidental haemorrhage the aim was delivery within six hours, but even then there were risks of fibrinogenopenia and of renal cortical necrosis. To avoid all these severe manifestations of pre-eclampsia even mild cases should be admitted to hospital, as only there could a constant watch

be kept on the march of the condition. Mr. Vaughan Jones then described how in his area of North Wales a comprehensive integrated antenatal service had been established. It was based on a central hospital, but worked through local authority clinics although these were conducted by members of the hospital staff. As a result the incidence of eclampsia and the maternal death rate from toxæmia had both fallen. The uncorrected perinatal mortality for toxæmia was 9.8% over the past nine years, and this could have been still further improved by earlier resort to termination of pregnancy.

Dr. J. H. FISHER (Abingdon) contributed the viewpoint of a general practitioner in a small country town with a general-practitioner maternity unit of 25 beds. The general practitioners there maintained close and friendly liaison with the regional specialist-staffed maternity hospital. Patients were encouraged to seek antenatal care very early in pregnancy, and whenever there was a history of past toxæmia or there seemed to be a prospect of pre-eclampsia developing a diet which reduced intake of salt and carbohydrate was prescribed. Labour was induced in any case of mild toxæmia during the last month of pregnancy that did not respond to treatment. More severe cases were transferred to the parent hospital; there were 14 such in the years 1954-6, during which time 1,367 women were delivered in the general-practitioner unit with no maternal deaths and with a total perinatal loss of 17 babies. He believed that the general practitioner had a most important part to play in the fight against toxæmia. He should be encouraged to regard himself as a part of a regional team and he should have some obstetrical beds at his disposal, but he should also appreciate the scope and limitations of general-practitioner obstetrics.

In the subsequent discussion Dr. H. B. MUIR (Fife) drew attention to the necessity for interavailability of records between different branches of the maternity services. Mr. M. S. WILLIAMSON (Durham) was a strong upholder of the use of the "Flying Squad" for cases of eclampsia. Dr. MERVYN GOODMAN (Liverpool) noted the risks of increased sodium intake from drugs taken to relieve heartburn in the causation of pre-eclampsia. Dr. R. M. S. MCCONAGHEY (Dartmouth) advocated the provision of free home-helps to allow the patient to rest better at home. Dr. A. ELLIOTT (Ilford) pleaded for better co-operation between the three branches of the maternity services, a plea reinforced by Mr. J. A. STALLWORTHY (Oxford).

Practitioner Responsibility in Gynaecology

Dr. H. F. WATTSFORD (Newcastle upon Tyne), president of the Section of General Practice, took over the chair when Dr. A. J. GRAY NEWTON (South Broomhill, Morpeth) described a field study of gynaecology in a general practice in Northumberland, undertaken by himself, his partners, and Dr. J. K. RUSSELL (Newcastle upon Tyne), the last later contributing the viewpoint of the specialist gynaecologist. During one year 178 of the 3,000 females over the age of 12 in the practice consulted their doctor because of some gynaecological condition. There were in addition occasions when the family doctor considered it his duty to offer unsolicited advice to patients. The commonest complaints were abnormal vaginal bleeding, vaginal discharge, and dysmenorrhoea. In cases of irregular bleeding in women under 30 the general practitioner might temporize, but in older women early referral to a specialist was advised. Vaginal discharges could not be treated rationally without preliminary investigations, which were best carried out at a hospital clinic. Primary dysmenorrhoea lay in the sphere of the family doctor unless proving intractable, but the secondary variety usually betokened some underlying pelvic lesion. Marital problems were also best tackled by the family doctor, although cases of infertility usually required specialist attention. The decision to give hormone treatment was also best left to the gynaecologist. The main contribution of the general practitioner lay in his appreciation of the significance of various symptoms and signs and in his knowledge of when to seek specialist assistance. Too early

reference to a consultant might focus undue attention on a complaint which the family doctor could treat adequately while failure to refer other cases at once might delay the diagnosis of important pathological conditions. Textbooks and teaching programmes, although they dealt adequately with the management of common gynaecological disorders, often failed to guide the student about the respective roles of the general practitioner and specialist.

Dr. E. D. FORSTER (Matlock) said that the responsibility of the general practitioner lay largely in deciding if and when to give the patient access to specialist attention. The close co-operation between family doctor and consultant was particularly desirable in gynaecology, a field which involved human relationships and personal happiness. Dr. T. P. McB. KELLY (Garvagh, Ulster) and Dr. G. M. MILLER (Newcastle upon Tyne) were among those who participated in the discussion from the floor.

ENDOCRINE ASPECTS OF BREAST CANCER CONFERENCE IN GLASGOW

[FROM A SPECIAL CORRESPONDENT]

The University of Glasgow made last week a valuable contribution to the progress of research on the endocrine control of breast cancer. Under the chairmanship of Professor C. F. W. ILLINGWORTH 86 workers in this field, many from abroad and representing all the relevant disciplines, met there on July 8, 9, and 10 to discuss their current views. Since this review involved the delivery of 34 papers and many hours spent in informal discussion, only the major trends of opinion can be discussed here. The conference assumed general agreement that in breast cancer both primary and also some secondary growths are at least partially dependent for their survival upon hormones derived from the ovaries, adrenals, and hypophysis, and that the removal or destruction of these glands benefits the condition. Many indeed go further and emphasize particularly the role of the sex or steroid hormones, because of the important part played by the adrenal and ovary.

Adrenalectomy and Hypophysectomy

The discussions were opened by papers from Sir STANFORD CADE (London) and by Dr. J. HELLSTRÖM (Stockholm) dealing with a total of 332 adrenalectomies. The majority of the latter's patients had also been subjected to previous ovariectomy, but nevertheless the results were similar, 50 to 60% of the patients showing some objective improvement. But little firm indication emerged of the type of patient particularly likely to benefit from this procedure, except possibly that in a few instances the response to previous steroid administration might be helpful.

Mr. H. J. B. ATKINS (London) had developed a philosophical attitude to the really difficult basic problem of assessing the results of treatment in these patients. Enlarging on his recently published work, he was now inclined to the view that the advantage of hypophysectomy over adrenalectomy was rather less than it had at first seemed. However, provided the functional reduction in the dependent glands is sufficient, hypophysectomy still appears to offer advantages—a view reinforced later in the conference by the implication of growth hormone and prolactin as further factors of possible importance. Pituitary ablation and its effects were thus prominent subjects of discussion. Dr. R. LUFT reviewed the Stockholm results of surgical hypophysectomy and Dr. B. S. RAY those at the New York Hospital. This gave a total of 169 patients whose improvement was strikingly similar to that recorded above for adrenalectomy. Although at present impracticable, it was considered probably important to remove all the cells of the anterior pituitary, and the value of using Zenker's fluid to distinguish any remaining cells at operation was stressed. Hepatic, intracerebral, and possibly pulmonary metastases were suggested as contraindications to successful operation. Dr. Ray's experience suggested that hypophysectomy might even be useful following relapse after adrenalectomy and ovariectomy.

New Methods of Pituitary Ablation

The anatomical location of the anterior pituitary favours the use of other methods besides surgery for its destruction, and several of these were discussed by Mr. A. P. M. FORREST (Glasgow), Dr. K. H. BAUER (Heidelberg), Dr. J. D. N. NABARRO (London), and others. These included the use of electro-coagulation, implantation of radon seeds, radioactive gold (^{198}Au), and radioactive yttrium (^{90}Yt), and the injection of colloidal chromic phosphate containing radioactive phosphorus (^{32}P). There appeared to be a definite danger of damaging the optic tract and vision with γ -ray emitters, and the most promising substance was the β -ray emitter yttrium-90 in doses of about 13 millicuries. These seeds can be implanted in a few minutes, with minimum trauma, by the paranasal or nasal routes—in itself a great advantage—and the use of an x-ray image intensifier facilitates their insertion.

Much discussion centred on the necessity for complete hypophysectomy, and, judging from some of the results, this may not always be needed. Nevertheless, Professor E. BOYLAND's experience with hormone assays on patients at the Royal Marsden Hospital seemed to support continued endeavour to achieve a more complete ablation, and for the present this should be the aim. Dr. J. D. N. NABARRO related his experiences with patients subjected to pituitary-stalk section: about half the patients with good functional results as judged by post-operative depression of thyroid and adrenal activity showed clinical remission. However, after a few weeks there was evidence of some return of thyroid function.

Evidence from Hormone Assays

Three problems to which much time was devoted were the evaluation of the completeness of gland ablation by hormonal studies, the extent to which hormone secretion should be reduced for successful results, and the detection by hormone assay of those patients most likely to respond to treatment. None of these questions could be wholly answered. The unresolved problem of the possible importance of accessory adrenal tissue is aggravated by the frequent presence of pituitary chromophobes and eosinophils in accessory nasopharyngeal groups, as Dr. W. MÜLLER (Cologne) pointed out. The use of the relatively simple technique of radioactive iodine uptake as a measure of thyroid function received support from Dr. O. H. PEARSON (New York) and others as a measure of the completeness of pituitary destruction. On the other hand, it could not be ignored that, in the experience of Dr. R. LUFT and others, tumours might respond even in the absence of what might be considered an adequate fall in this index. Other techniques advocated, apart from the cortisone-withdrawal test, involved the more difficult methods of chemical assay of steroids or bioassay of pituitary hormones. Methods are available for only some of these, and in some cases there is lack of sensitivity or of specificity, especially in the determination of trace amounts. It was again emphasized by Professor G. F. MARRIAN, F.R.S. (Edinburgh), that in such circumstances only methods satisfying the most rigorous criteria could be relied upon and were worthy of use.

Dr. J. A. LORAIN (Edinburgh) reported a hopeful pointer in that urinary gonadotrophin was found to be significantly lower in a group of post-menopausal patients responding to stilboestrol therapy than in an unresponsive group. Dr. J. B. BROWN (Edinburgh), realizing that his estimates neglected some of the newly discovered oestrogens, emphasized the present difficulty in estimating trace amounts remaining after oophorectomy and adrenalectomy. The importance of these residual hormones still awaits evaluation, although some of Dr. E. F. SCOWEN's (London) and of Mr. A. P. M. FORREST's patients were improved in spite of continued excretion of significant quantities of oestrogen. The occurrence of such trace amounts after operation was also noted by Dr. A. E. KELLIE (London) in his study of androgens. Several speakers, including Dr. G. BIRKE (Stockholm) and Dr. KELLIE, agreed that differences were not observable in the excretion of oestrogens, ketosteroids, and corticoid

metabolites in untreated cancer patients compared with normal individuals of corresponding age. A divergence from this view was hinted at by Dr. BROWN, who found a tendency to increased oestriol excretion in cancer patients compared with normal individuals, but this finding is probably not specific.

Hormones and Carcinogenesis

The role of hormones in carcinogenesis was discussed. This question is largely speculative, but the concept that hormone action may be of greatest significance in a pre-tumorous phase of epithelial proliferation might be important. Alternatively, perhaps, only a proportion of cells in an otherwise autonomous tumour may be hormone-dependent. The histological studies of Dr. A. T. SANDISON (Glasgow), showing persistence of epithelial activity in mammary lobules well after the menopause, irrespective of the degree of cellularity of the ovarian stroma, were highly relevant in this connexion.

Dr. S. J. FOLLEY's (Reading) review of the hormonal factors in mammary growth and function widened the horizon in drawing attention to the importance of growth hormone and insulin in addition to that of oestrogen, progesterone, prolactin, corticoids, and thyroid.

In experimental animals mammary tumours are found which are highly hormone-dependent, although perhaps defying reasoned histological classification, and, while not necessarily directly applicable to man, such studies are of great importance. Dr. O. MUHLBLOCK (Amsterdam) stressed that most mouse mammary tumours were hormone-independent and many were complicated by the requirement for "mammary tumour agent." He had found spontaneous tumours whose rate of growth was retarded by hypophysectomy. There were also suggestions that hormones might stimulate early epithelial hyperplasia. Dr. J. FURTH (Boston) considered hyperplasia unimportant, but described an elegant experimental system in rats. This consisted in the grafting of radiation-induced pituitary tumours composed of "mammatrope" cells which induced mammary adenomas. The behaviour of the latter could be influenced by steroid hormones, probably acting initially through the pituitary tumour. Another system was that of Dr. K. MAINZER (Chicago)—a mouse fibroadenoma responsive to all the methods of surgery used in man and stimulated by both oestrogen and progesterone. Dr. L. FOULDS (London) had observed mouse tumours waxing in pregnancy and waning after parturition.

The possible importance of prolactin was also suggested in Dr. FURTH's work. In a review of Dr. G. HADFIELD'S (London) researches, which suggest that urinary prolactin may be of great importance in man, it was evident that as yet it largely lacked confirmation in the hands of Dr. R. E. WILLIAMS (Glasgow). In spite of new data, much more rigorous proof was still needed that the urinary substance involved was indeed prolactin.

The Conference left many questions unanswered. In particular there is a serious lack of knowledge of the precise nature of the hormones of importance in human mammary cancer and no available means of subclassification of these tumours. Pending such information attempts at endocrine therapy defy further rationalization.

ORDER OF ST. JOHN OF JERUSALEM

The *London Gazette* has announced the following promotions in, and appointments to, the Venerable Order of the Hospital of St. John of Jerusalem:

As *Knights*: Colonel C. H. S. Redmond, T.D., M.B., Dr. W. R. Russell, C.B.E., F.R.C.P. As *Associate Knight*: Lord Cohen of Birkenhead. As *Commanders (Brothers)*: Surgeon Rear-Admiral A. A. Pomfret, O.B.E., M.B., Q.H.S., Lieutenant-General Sir W. A. D. Drummond, K.B.E., C.B., F.R.C.S., Q.H.S., Major-General D. Bluet, C.B.E., M.B., Q.H.P., Brigadier S. G. U. Shier, O.B.E., M.D., Q.H.P., Colonels L. K. Ledger, C.I.E., O.B.E., M.R.C.S., and W. A. Jones, O.B.E., V.D., M.D., F.R.C.P.(C.), Lieutenant-Colonels S. H. Heard, M.B.E.,

M.R.C.S., L.R.C.P., and A. S. Lewis, M.D., F.R.C.S., Mr. G. W. A. Keddy, M.D., F.R.C.S.Ed., Drs. K. D. Bean, W. E. H. Bull, M.C., J. Prentice, E. R. A. Merewether, C.B., C.B.E., F.R.C.P., M. I. Dick, E. Dwyer, and C. B. Weld. As *Commanders (Sisters)*: Drs. Hilda M. Davis and Marian Maxwell Reekie. As *Officers (Brothers)*: Surgeon Captain D. M. Beaton, O.B.E., L.R.C.P.&S.Ed., Q.H.P., Surgeon Commander F. P. Ellis, O.B.E., M.D., M.R.C.P., Colonel H. C. Benson, M.B., Lieutenant-Colonels A. D. Young, D.S.O., M.B., and R. J. Gray, M.B., Mr. A. Croll, M.D., F.R.C.S., Drs. W. Fraser, G. S. Mather, A. Strang, R. K. Brooks, E. W. M. Williams, A. F. McDonald, H. A. Robertson, D. F. Barrett, E. R. Hafner, J. H. W. Hutchinson, V. S. Kaufman, P. J. Kerley, C.V.O., C.B.E., K. F. Alford, and N. L. Lloyd, C.B.E. As *Associate Officers (Brothers)*: Drs. E. Schwartz and L. Guttmann, O.B.E. As *Officer (Sister)*: Dr. Sibyl G. Horner. As *Serving Brothers*: Surgeon Commanders W. J. Elliott, M.D., R.C.N., and R. A. G. Lane, M.D., Colonels E. H. Ainslie, M.D., F.R.C.P.(C.), and A. L. Kerr, M.D., Group Captains E. O'F. Campbell, M.D., and D. G. M. Nelson, M.D., Mr. F. M. Hanna, F.R.C.S.Ed., Drs. J. C. Rogers, J. T. Bleasdel, J. C. H. Bird, J. W. Pickles, P. H. A. Jonason, H. G. Vyse, O.B.E., G. A. Garrett, J. W. Notley, J. McKee, J. Clay, J. R. McDonald, M.C., T.D., T. E. Lloyd, R. C. U. Warrington, A. J. A. Robertson, R. L. MacQueen, J. L. Egan, H. M. Chappel, F. H. Vollam, J. E. Baird, R. M. L. Anderson, E. S. Boyle, G. H. Clement, J. H. Davidson, R. Felton, C. E. C. Harris, A. H. Harrop, J. A. Johnston, N. F. Murphy, and F. F. P. Thompson. As *Associate Serving Brother*: Dr. W. W. Cowen.

Nova et Vetera

BRADFORD ROYAL EYE AND EAR HOSPITAL 1857-1897

By the early part of the nineteenth century Bradford was already established as the centre of the woollen industry in Britain. Among the occupational hazards of workers in this trade, diseases of the eye and ear were prominent. Before 1857 the need for the treatment of such conditions in Bradford was in some measure met by a dispensary established by Dr. Edward Brönnner, a political refugee from Germany. Brönnner was a native of Wiesbach, in Baden, where he practised until 1848. He took a prominent part in the revolution of that year and was eventually obliged to leave the country. He went to Paris and there studied diseases of the eye and ear. Coming to England in 1852, he settled in Bradford, where he soon built up a large practice. At the same time he established a free dispensary at 25, Brunswick Place, for the treatment of the poorer classes suffering from diseases of the eye and ear. The number of patients grew to such proportions that Dr. Brönnner called a meeting on June 10, 1857, to consider the taking over of the house as a public institution, and as a result of this meeting the Bradford Eye and Ear Hospital came into being, with Dr. Brönnner as medical officer and Dr. J. H. Bell as junior medical officer. Brönnner remained until his death in 1886 and was succeeded as physician by his son Adolph.

Bell was appointed surgeon in 1864 and retired in 1897. During his forty years of service at the hospital he initiated and brought to fruition several advances in his subject. About 1878 anthrax ("wool-sorters' disease") began to assume serious proportions in Bradford. Bell advocated methods of disinfection of wool. His reports of cases led to an official inquiry by the Local Government Board, and an investigation into the pathology of anthrax was at the same time conducted by Professor W. S. Greenfield at the Brown Institution, London. Legislation and statutory regulations followed.

In 1865 the old hospital was abandoned for a new building in the present site in Hallfield Road, to which additions were made in 1884, 1911, and 1926. In 1907, the hospital's Jubilee year, King Edward VII granted permission for the prefix "Royal" to be used in its title. During the last war the hospital was designated as a general casualty hospital. In 1948 it was integrated into Bradford (A) Group Hospital Management Committee.

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Tuberculin Reactions

SIR,—Following your annotation on tuberculin reactions (*Journal*, June 29, p. 1522) it seems possible that a wider use of tuberculin in an oily vehicle may occur. I feel it right, therefore, to draw attention to our findings at the Hospital for Sick Children. Using P.P.D. in an oily suspension in 200 cases, we obtained a very large number of unpleasant local reactions to oil itself, particularly in babies and toddlers. The worst was a deep ulcer, one inch (2.5 cm.) in diameter; the least reactions were red indurated areas which have persisted now for a year. These reactions have occurred also among adults, but not so frequently.

I believe, therefore, depot tuberculin in oil should only be used with the greatest caution in children.—I am, etc.,

London, W.C.1.

MARCIA HALL.

SIR,—I have repeated some of O'Grady's work on Mantoux reactions¹ mentioned in your annotation (*Journal*, June 29, p. 1522), with an initial dose of 3 T.U. instead of the 1 T.U. used by him. A larger proportion of tuberculous patients showed a positive response to this first dose, and correspondingly fewer of them showed an accelerated or "tuberculous" response than was the case in O'Grady's series. This tends to confirm his original suggestion that an accelerated response is often due to a second dose of tuberculin following rapidly upon a first, ineffective dose. It is in fact possible to produce such an accelerated response by suitable spacing of the test doses both in tuberculous patients and in controls who have shown a response of normal duration to the initial injection of tuberculin; it is probably easier to obtain this acceleration in patients with active pulmonary tuberculosis than in controls. In a small series of controls, however, I have found one who had an initial accelerated response; moreover, it is possible to produce a normal response in a tuberculous patient with an initially accelerated response, again by suitable spacing of the injections.

These confusing findings serve to emphasize two points: that an accelerated Mantoux response is not pathognomonic of active tuberculosis, but is an expression of a state of tuberculin sensitivity more often found, or more easily produced, in patients with pulmonary tuberculosis; and, secondly, that in the interpretation of a tuberculin test it is important to know of any other recent injections of tuberculin.—I am, etc.,

Wroughton, Wilts.

PAUL MESTITZ.

Dangers of Cigarette-smoking

SIR,—Sir Ronald Fisher's criticisms (*Journal*, July 6, p. 43) of your leading article (*Journal*, June 29, p. 1518) on this subject would not be so unfair if he had specified what alternative explanations of the facts still await exclusion.

The first annual report of the Tobacco Manufacturers' Standing Committee, prepared in consultation with Sir Ronald Fisher, appears (it is an imprecise document, perhaps intentionally so) to suggest two alternative explanations. The first is that there is a genetic predisposition to lung cancer associated with a genetic predisposition to smoke tobacco. To explain the facts it is necessary to assume that the genetic predisposition to lung cancer is proportional to the amount smoked and is greater in those who are destined to smoke cigarettes than in those who are destined to smoke pipes, that it has increased rapidly over the past 30 years, more rapidly in this country than elsewhere, more rapidly in men than in women, and more

rapidly in towns than in rural areas. It is further necessary to assume that the genetic predisposition to lung cancer is now changing equally rapidly in women as in men and in rural areas as in urban areas. If this is not already stretching credulity too far it is also necessary to assume that the genetic predisposition to lung cancer is less in those who are destined to give up smoking than in those who are not.

The other alternative explanation is that tobacco-smoking acts in association with some other factor such as atmospheric pollution. Even if the evidence in support of this was consistent, which it is not, it should not preclude action to bring the hazards of cigarette-smoking home to the public. To argue otherwise would be rather like saying that, since fast driving is most dangerous in association with bad road conditions, it is only necessary to tackle the latter.

The Medical Research Council have said that the most reasonable interpretation of the evidence (my italics) is that the relationship between tobacco-smoking, particularly in the form of cigarettes, and lung cancer is one of direct cause and effect. I suggest, Sir, that this is one of those masterly understatements for which we as a nation are famous.—I am, etc.,

Garboldisham, Norfolk.

ROBERT N. C. MCCURDY.

SIR,—After careful study the Medical Research Council has come to a definite conclusion regarding the connexion between lung cancer and cigarette-smoking (*Journal*, June 29, p. 1523). Perhaps the following questions may be answered by the M.R.C. in order to help those who seriously doubt the recent premature conclusions. (1) What test or evidence has been produced to determine whether or not an individual will develop lung cancer in the future, irrespective of smoking? (2) Why should the rate of lung cancer be so high in towns as compared with the country? (3) Why is there a much higher rate of lung cancer in some countries than in others? (4) Cancer of the lung and leukaemia are on the increase. The rate of both will increase considerably in the future. Both are due to the same basic cause. Can smoking be a factor in both? (5) Can the M.R.C. give the answers to the questions circulated by the medical committee of the Society for Investigating the Nature and Cure of Cancer in 1802, and later published in the *Edinburgh Medical and Surgical Journal*? Two of these questions concerned (1) the role of heredity, and (2) whether cancer is related to other diseases. It would appear that these two questions are more important than the speculative relationship of smoking.—I am, etc.,

Blackpool.

J. G. BYTH.

SIR,—I read with interest and sympathy the letter by Sir Ronald Fisher (*Journal*, July 6, p. 43) on publicity regarding smoking. As my council has been publicly mentioned by the Minister of Health as the agency through which education of the public concerning cancer will be done, I think we may be able to put Sir Ronald's mind at rest.

It is certainly not the intention of my council to introduce an atmosphere of anxiety and guilt into what is after all a time-honoured social custom. My council has for some years considered that cancer should be treated as a major public health problem, and in this connexion the evidence that smoking is associated with lung cancer has been carefully studied. The rapid increase in lung cancer makes it even more essential that this particular form of the disease be considered as an urgent public health problem. We are satisfied that the work carried out in Britain, the U.S.A., and other countries shows conclusively that those who smoke run a considerably greater risk of cancer of the lung than those who do not, that cigarette-smoking involves a greater risk than smoking pipes or cigars, that the risk increases with the number of cigarettes smoked, and that giving up smoking is effective in decreasing the risk.

We feel that the public should be informed of these facts unemotionally and as thoroughly as possible, and that we

would be neglecting our professional duty if this information were withheld. What people do with the information is finally their own responsibility. This is perhaps the difference between education and propaganda.—I am, etc.,

London, W.C.1.

JOHN BURTON,
Medical Director, Central Council for
Health Education.

SIR,—This subject has been very much in the news this week. Many facts and figures have been published both in the scientific and in the daily press; some of the latter seem to show that, far from being a "yellow peril," tobacco has been a veritable "golden angel."

I am referring to an article in one of the national dailies on July 3 which stated that the revenue from tobacco is in the region of £700 million per annum and covers the national expenditure on the Health Service, family allowances, and war pensions. Where would the revenue have come from had there been no smokers? One feels that tobacco has saved the nation, and kept political parties alive. The Health Service has been the biggest and best "vote-catcher" yet devised, followed closely by family allowances, with a good place for war pensions. Without these three no party could survive. Without smokers these three could not survive. May we therefore honour these men by building an arch at the Whitehall entrance to Parliament Square, a memorial befitting those who are about to lose their greatest pleasure, only to gain a burden of heavier and heavier taxation, and boldly inscribe on the stone: "To the British Smoker, who Risked Health and Fortune for His Country, and a Puff."—I am, etc.,

Pontypool, Mon.

A. A. GREGORY DEAN.

Snake-bites

SIR,—I have just read with the greatest interest Dr. H. A. Reid's article on the above subject (*Journal*, July 6, p. 26). Adder-bites seem to be occurring more frequently in this country, and we had two in this district last summer. As the number of the population who have had some form of horse-serum injection increases, so will the danger of severe serum reactions following antivenene, and one has reached the stage of wondering whether this form of therapy is justified at all except in exceptional circumstance, such as very young children. Regarding local treatment, it was interesting to read that Dr. Reid did nothing. As long ago as 1942 we were told at the Liverpool School of Tropical Medicine that local therapy was utterly useless—whether this was an *ex cathedra* statement I do not know. At all events, I think there is little doubt that the cases in which one hears of gangrene of an extremity following snake-bite are more likely due to misapplied tourniquets. Dare one suggest that the safest treatment for adder-bite in this country is to admit the patient to hospital, and do nothing except "careful observation"?—I am, etc.,

Slough.

ROBIN BURKITT.

Veno-occlusive Disease of the Liver

SIR,—The paper by Dr. H. Stein (*Journal*, June 29, p. 1496) on veno-occlusive disease of the liver in African children is of great interest in confirming that this disease is not confined to Jamaica. The report by Wurm,¹ however, of a similar condition affecting the small hepatic veins in eight young infants in Germany seems to have escaped general recognition. Five of these infants were town-dwellers, and there is nothing to suggest that they received anything equivalent to "bush-tea." The author considered a number of aetiological possibilities, and concluded that a bacterial toxic poisoning associated with an early start of artificial feeding was responsible. Bras *et al.*² have recently reviewed the evidence that pyrrolizidine alkaloids from plants may cause the condition in Jamaican children. It is well known that in this country ingestion of ragwort, usually in hay, causes liver disease of this type in cattle, and this disease may be chronic and unrecognized for some time. It is possible, though

unproved, that milk from such animals is contaminated. The possibility that infants suffering from veno-occlusive disease have been given milk from sick animals deserves further consideration.

The statement by Dr. Stein, that veno-occlusive disease differs from the classical Chiari's disease by the total absence of thromboses in the major hepatic veins, cannot be allowed to pass unchallenged in that form. Chiari³ described a condition of endophlebitis, not of thrombosis of the major hepatic veins. Although this is usually complicated by secondary thrombosis at the time of death, and although thrombosis of the main hepatic veins gives rise to identical clinical manifestations, an experience of 10 cases of obstruction of the main hepatic veins has convinced me of the truth of Chiari's contention that a condition of stenosing endophlebitis can exist at this site as a rare entity and that it can be distinguished pathologically from simple occlusive thrombosis.—I am, etc.,

Belfast.

Hospital Confinement

SIR,—Why is there so much disagreement on the question of hospital or home confinement? Surely because the hospital obstetrician and the general-practitioner obstetrician are dealing with different problems, and do not properly understand one another's point of view.

In hospital the baby is cared for by a well-trained nursing staff, who weigh it at birth, and must see that it regains its birth weight by the day of discharge. So they put the baby to the breast, ten minutes to each breast to stimulate lactation in each breast. Why? Don't they know that the milk will come in on the third day even if they do not fiddle it about? If the nipple is sore it is hurt every four hours, whereas one breast to one feed gives it a rest of eight hours. If the milk supply is plentiful how can an ordinary infant's stomach empty both breasts? If not emptied, how long before they fail to refill? Is the mother ever told that quite soon the baby will take a comfortable stomachful in much less than twenty minutes? On the tenth day the baby is triumphantly presented to the mother with the announcement that he has regained his birth weight. The implication is clear. We are so pleased, because the milk might have failed, and on this note mother and baby go home.

Arrived home. What emotions! The husband has so far only been seen as a visitor, but his emotion cannot be satisfied because grandmother is bursting with suppressed pride and possessiveness, but she must be almost warded off if baby is to be mother's. If there is a 2-year-old it does not even recognize mother, and is unsettled for some time. Straightway it is time to change the nappy, which mother may never have done in hospital, an ordeal in this company, with the thought of to-morrow's first bath. I have known a primipara to come home without even once having watched this procedure. Quite apart from all this emotional confusion the mother is now on her feet, with a consequent slight increase in lochia and decrease in milk, and a duty to make the baby feed ten minutes at each breast. No wonder so many are on the bottle so soon.

With the baby born at home, husband and grandmother take their appropriate parts, knowing when to send for nurse, maintaining the supply of cups of tea and coal for the fire, and grandmother in particular is supporting nurse, not taking charge on the strength of her out-of-date experience. On the very first morning, nurse leaves a pile of nappies within reach, and mother handles her baby for every change. Daily she watches the bath till allowed to bath the baby herself. By the tenth day, when baby has regained his birth weight, and nurse will be coming in less frequently, there is no emotional disturbance, but a well-integrated stability and security which later will withstand stresses and reduce the work of the psychiatrist by 60%.

There is no greater anxiety in general practice than a worrying maternity case, and we are only too thankful for the modern improvements in hospital facilities for suitable cases. But we do not want to hospitalize unsuitable cases—normal cases. No obstetrician, hospital or general practitioner, starts by being old and experienced. I suggest that, to get on the general-practitioner obstetric list, if such a list is necessary, the candidate (a qualified registered practitioner already) should summon an obstetric consultant or registrar to supervise a number of domiciliary confinements—and, *per contra*, that in order to obtain the M.R.C.O.G. a candidate should have attended or supervised a number of domiciliary confinements.—I am, etc.,

Crowthorne, Berks.

H. D. FORBES FRASER.

SIR,—With reference to the letter by Dr. D. S. Foster (*Journal*, May 11, p. 1120), I quote: We must not be hidebound by traditional ten-day lying-in periods."

We in this rural Canadian general practice clinic have had the experience in the past five years of converting our practice of obstetrics from home confinement to a small cottage hospital—35 beds. The tendency in North America has been in this direction for the past 25 years or more. The process is so nearly complete now that some of our large teaching hospitals have discontinued their home obstetrical services entirely. Five years ago in this very rural district home confinements were the rule. Last year fewer than 5% of our cases were delivered in the home. There is no doubt in my mind that hospital delivery is safer for both mother and child. My records are too eloquent on this point. The tendency to hospital delivery has been the main factor in lowering our maternal and perinatal death rates. Public health authorities agree on this point, and the Government-supported post-war hospital building programme is rapidly producing the necessary beds.

In our local hospital we depart rather radically from what seemed the rule in the U.K. two years ago. Our mothers are up and about 12–24 hours after delivery. Breast-feeding is gently discouraged for various reasons, some of them social—i.e., the unwillingness of Canadian mothers to continue breast-feeding for more than a few weeks—and others medical—i.e., the stubbornness of staphylococcal breast abscesses. The majority of mothers are discharged on the fifth post-operative day, a few on the fourth. These mothers go home feeling fit to cope, and few have much home help except from neighbours. The babies begin solid feeds at one month or earlier, and most double their birth weight in three to four months. At four months the baby is having milk, cereal, vegetables, fruit, egg, and meat. By six months they have had three combined diphtheria, pertussis, and tetanus shots. Antenatal, natal, and postnatal care in Canada is still in the hands of the medical profession. There is no midwife system.

In conclusion, I must agree with Dr. Foster when he makes a case for hospital delivery as opposed to home care, though I am at a loss to understand why it should be necessary to admit district midwives to already well-staffed hospital maternity facilities. Of course it is no affair of mine—happily—but surely "we must not be hidebound" by traditions.—I am, etc.,

Wakefield, Quebec.

J. H. S. GEGGIE.

SIR,—How refreshing to read Mr. Frank Stabler's profound common-sense answer (*Journal*, June 29, p. 1530) to this vexed question of hospital confinement.

It is not so very long ago that I was one of those junior residents struggling and sweating with breech and forceps deliveries and retained placentas under "remote control." Now, however, I am fortunate to be in a partnership where midwifery is enjoyed and cherished as the essence of family doctoring. We cannot offer our patients caesarean section or replacement transfusion, but we can and do offer them regular and conscientious antenatal care, consultant opinion when in doubt, and personal attention at every confinement. Even for those unforeseen emergencies which can arise in

the course of an apparently normal labour, we feel that with local analgesia, intravenous ergometrine, intravenous plasma, a second partner on the job too, and the confidence and courage to use these techniques, we are still offering our patients the best of services.

Obviously it is not a matter of choosing between the hospital and the home, but between doctors, good ones and bad ones, those who care and those who do not; and if we are bad doctors then surely our teachers, the hospital doctors, should at least share some of the blame. I am pleased that Mr. Stabler, as an obstetrician and teacher of established repute, has been so outspoken. Perhaps his word will carry more weight than the words of inarticulate family doctors.—I am, etc.,

Gt. Yarmouth.

G. HURST.

SIR,—Mr. F. E. Stabler (*Journal*, June 29, p. 1530) is surely right; the attendant matters more than the place, and home confinement with a good general-practitioner obstetrician is as safe as hospital. If the public knew this, the demand for hospital confinement would decrease. Would it not be more economic to tell them, and at the same time raise the average standard of general-practitioner obstetrics to the level of the best, than to build expensive and unnecessary maternity hospitals?—I am, etc.,

Newcastle upon Tyne.

ANDREW SMITH.

Physique and Mental Illness

SIR,—There are two reasons why most physicians find difficulty in accepting the relationship between physique and mental or physical illness. The first is that many methods of classifying human physique have been tried and found wanting, so that at present there is no mutually acceptable method available. The second is that, using the same method of physique classification, the results from different centres conflict rather than harmonize.

Between 1952 and 1956 we attempted to estimate a Sheldon somatotype on the majority of male students entering Leeds University, using both the photographic technique described by Drs. Dupertuis and Tanner¹ and the deviation chart of physique introduced by Dr. Parnell,² who has done so much for constitutional medicine in this country. We have now abandoned somatotyping, but published some of our results in the *University of Leeds Medical Journal*.³ As our findings in Leeds were so different from those reported by Dr. Parnell (*Journal*, June 29, p. 1485), the following summary may be of interest.

There was no significant difference between the somatotype distribution of students at Oxford and Leeds. The somatotypes of 71 students who were suffering from psychosis, psychoneurosis, or allied disorders of such severity as to warrant hospital in-patient or out-patient treatment or prolonged attendance at the student health centre did not differ significantly from those of the general student population; certainly mesomorphy was no guarantee against mental breakdown in Leeds, as it seems to be in Oxford; the endomorphic ectomorphs were certainly no more prone to mental breakdown than were other physical types; the 452 physique was just as common amongst the mentally ill as the controls, and the 325 was no more common among the unstable. Dr. Parnell⁴ also found, as you mention in your leading article (p. 1520), that the endomorphic ectomorphs were the best examination performers. In Leeds the best examination performers were mesomorphs or mesomorphic ectomorphs, just as they were the commonest somatotypes in the student population, and we found it difficult to relate examination performance to somatotype.

We are most interested in the relationship between physique and various aspects of health and behaviour. Since 1956 we have been using a method of physique classification which compares individuals with regard to relative fatness, relative weight of the fat-free body or active tissue mass, and relative shape. This method was described at the eighth Conference on Student Health in

British Universities and Medical Schools held in Bristol in July, 1956. We hope to publish our observations as they become available, but in the meanwhile any satisfactory explanation of the differences so far observed between Oxford and Leeds would be most rewarding.—I am, etc.,

Leeds, 2.

S. E. FINLAY.

Physique and Medicine

SIR,—Apropos of a remark in one of your leading articles (*Journal*, June 29, p. 1520): "Medicine appears to attract those with the same body build that is associated with good all-round achievement in sport and academic life and with the least likelihood of having to consult a general practitioner about mental illness." If so, perhaps this would account for the backwardness of medicine to-day where it comes to the treatment of the whole man rather than the technological manipulation of bits of his anatomy and physiology. Are the physical and mental "hearties" likely to make the best healers? Or to initiate researches the more likely to prove fertile because based on deeper understanding of those fallible men and women who fall ill?—I am, etc.,

Haslemere, Surrey.

H. HARRIS.

Nocturnal Enuresis

SIR,—Mention of successful treatment of nocturnal enuresis by hypnosis in the most interesting articles by Dr. A. Fry (*Journal*, June 8, p. 1323) and Dr. H. Stewart (p. 1320) has prompted me to describe a new method, simpler than hypnosis, of treating this most troublesome complaint.

I started with the same assumption as Dr. Fry, that removal of worry about bed-wetting and installation of hope of recovery are essential for successful treatment, and decided to test the claims of the makers that "oblivon-C" (methylpentynol carbamate) is a specific for nervous tension by giving it to a series of bed-wetters in my practice. The results, summarized in the table, far exceeded my expectations. Some of the patients had already received psychotherapy without any improvement. The position, however, was considerably changed when methylpentynol carbamate was included as an adjunct to the psychotherapy.

Age Distribution in Years	No. of Cases	Previous Treatment (including Psychotherapy)		No Better	Much Improved	"Dry"
		Yes	No			
0-5	3	2	1	—	2	1
5-10	2	2	2	—	—	2
10-20	4	2	2	—	1	3
20+	1	—	1	—	1	—
Totals	10	4	6	—	4	6

Two short histories are given for illustration: (1) Male, aged 7: duration of enuresis 12 months; urine analysis, normal. Dose of methylpentynol carbamate, 200 mg., three times a day for six weeks. Result: gradual improvement with eventual disappearance of symptoms. The patient remained "dry" over a two-month follow-up. (2) Female, aged 15: a known bed-wetter for 12 months but suspected of having concealed the disability for much longer. Forced to go to the surgery by parents and refused urine analysis. A specimen obtained later, however, was normal. Treatment: sulphafurazole tablets, 2 three times a day; mist. pot. cit., ½ fl. oz. (14 ml.), three times a day; methylpentynol carbamate, 200 mg., three times a day. After six days the sulphafurazole was stopped, but symptoms still persisted. Methylpentynol carbamate was continued, and after three further weeks the symptoms cleared up. This was confirmed by the mother, who inspected the bedding daily. The girl

has been symptom-free during a full three-month follow-up period.

Admittedly, this is a small series. But the cases were unselected and the results so good that I felt it worth while to describe them. Methylpentynol carbamate also has the merit of being safe.—I am, etc.,

Leek, Staffs.

Is This a Record?

SIR,—Dr. G. I. Watson's experience of a 3-year-old who swallowed a screw (*Journal*, June 8, p. 1362) prompts me to record a worrying time I had with a 3-year-old girl. She swallowed a 12-sided threepenny-piece on June 14, 1953, at 7 p.m. I saw her two hours later, and as there was nothing abnormal on examination I reassured the mother and arranged to see the child regularly. On June 16, however, she started vomiting everything back, including fluids, and for the first time complained of pain in her throat. I sent her up to the Bromsgrove General Hospital, where Dr. D. I. Harries kindly screened her, and located the coin just below the cricoid. Accordingly I admitted her to the local thoracic unit, where she was examined next day. The report (dated June 18) read as follows: "By now this child will have returned home. We oesophagoscoped her but the threepenny bit proved most elusive and could not be extracted with the forceps. It passed into the stomach, and an x-ray, taken yesterday at noon, suggested that it is already in the colon. I have spoken to her mother and told her exactly what the situation is, and, should she be in the least bit worried, we will see the child straight away."

Unfortunately, the surmise that the coin had left the stomach proved over-optimistic; and as the coin had not appeared by June 25 I took her up to see Dr. Harries again for screening. The coin was found lying in the stomach. At my suggestion Dr. Harries agreed to attempt massaging the coin through the pylorus after I had first administered atropine. This failed, so I next tried atropine methonitrate without success, and finally amyl nitrite. Even inhaling from 3-minim (0.2-ml.) capsules proved ineffective, and the refractory coin remained *in statu quo*. I continued observing the child and reassuring the mother, as the child remained well and happy. On June 29, fifteen days after being swallowed, the coin was passed naturally in a normal stool. The previous day the child had been taken on a Sunday school outing to Barry Island, and had been on the "big dipper." My opinion is that the tremendous excitement or fright might somehow have effected the passage of the coin through the pylorus. I do not know, but I was on the same outing and went on the big dipper myself, and found it a most alarming and hair-raising experience.—I am, etc.,

Bromsgrove, Worcs.

R. A. F. JACK.

Tropical Pulmonary Eosinophilia

SIR,—Dr. A. Wildervanck in his letter (*Journal*, May 11, p. 1119) on tropical eosinophilia (eosinophilic lung) concludes that it would be desirable to do blood examinations for microfilariae in these cases, while treatment with diethylcarbamazine might be considered. Since April, 1956, I have used the latter drug in the treatment of this condition and have published a preliminary report¹ of its curative effect in the first ten cases so treated; a final report on a total of 110 cases is in preparation. The result of this study has shown that diethylcarbamazine has a specific action in patients suffering from eosinophilic lung which can be compared very favourably with that obtained in cases treated with organic arsenicals. Besides symptomatic improvement, clearing of the abnormal radiological picture, and decrease in the elevated erythrocyte sedimentation rate to normality, a distinctive feature is a fall in the circulating eosinophils as occurs with arsenotherapy. This decrease, which begins on the first day of treatment, continues rapidly throughout the first five days and then more gradually till counts below 2,000 eosinophils per c.mm. are finally reached. Three out of 110 cases relapsed, but showed the same response to

second courses of diethylcarbamazine. There are no significant toxic symptoms with the dosage used, which is 6 mg. per kg. body-weight per dose three times a day for a period of five days. Treatment of a further 50 cases has confirmed the earlier findings. In my opinion diethylcarbamazine is a safe and effective drug in the treatment of eosinophilic lung and should replace organic arsenicals, the use of which has sometimes resulted in encephalopathy and death, an unfortunate result in a disease which, although incapacitating, has no mortality in itself.

Blood examinations for microfilariae in patients suffering from this disease have consistently been negative. Out of a group of 150 patients which I observed and reviewed in 1951,² nocturnal blood films for microfilariae were negative in the 61 cases examined. Again in the present series of 110 cases, examination of blood samples taken at night, using Knott's concentration technique, failed to reveal the presence of microfilariae. However, in view of the successful therapeutic results obtained with diethylcarbamazine, an antifilarial drug, it was decided to examine the sera of subsequent cases for complement-fixing antibodies using as antigen a 1% alcoholic extract of dried powder of *Dirofilaria immitis* according to the method described by Fairley³ and Ridley⁴ with slight modifications. Positive reactions in high serum dilutions were obtained in all of 12 patients suffering from eosinophilic lung, becoming negative subsequent to treatment.⁵ The filarial complement-fixation test was positive in relatively low titres in only some of the sera from cases of bancrofti and malayi filariasis, and from dogs infected with *D. immitis*, but in 10 patients with mild eosinophilia and pulmonary symptoms who were not cases of eosinophilic lung and in 25 healthy controls the test was negative. All of a further 50 patients suffering from eosinophilic lung have shown an initially high filarial complement-fixation test antibody titre with decline after treatment, but at the date of this communication the tests have not yet become negative. In none of these patients was there clinical or parasitological evidence of filariasis.

A human filarial aetiology has been previously advanced for eosinophilic lung on the basis of the histological findings of microfilariae in lymph nodes of a few patients with hyper eosinophilia, lymphadenopathy, and pulmonary symptoms,⁶ but valid objections still exist to this hypothesis. True eosinophilic lung, even in cases of fairly long standing, is not accompanied by any of the classical clinical features of filariasis, such as lymphangitis, adenitis, or elephantiasis, nor have microfilariae been demonstrable in blood or sputa of such cases. Conversely, hyper eosinophilia is not a usual feature of filariasis, while pulmonary symptoms, although sometimes recorded,⁸ are rare. The clinical pictures of eosinophilic lung and filariasis present reasonably distinct differences. Nevertheless, the aetiological possibility of a filarial infection, not necessarily human, should be considered in view of the response to treatment with diethylcarbamazine, and the finding of sensitivity to filarial proteins in cases of eosinophilic lung.—I am, etc.,

Speed Warning Device

SIR.—The letter from Mr. William Gissane, of Birmingham (*Journal*, July 6, p. 46), is interesting but leads me to suggest that he cannot be old enough to remember the earlier days of motoring, the days of the model "T" Ford, when thirty miles an hour was fast and forty was speeding. A device said to be popular in America then showed a red light on the dashboard at forty miles an hour and played "Nearer, my God, to Thee" at fifty.—I am, etc.,

D. T. DICKINSON.

Chester.

Compulsive Swearing

SIR.—The case of Gilles de la Tourette's syndrome described by Dr. R. P. Michael (*Journal*, June 29, p. 1506) is of particular interest, because, so far as I am aware, it is the first published account of the treatment of tics by carbon-dioxide inhalation. It is notable that fifty years ago Meige and Feindel¹ recorded in their classic monograph on the treatment of tics that the inhalation of chloroform and ether was of some avail, and it therefore seems relevant to question whether the mode of action of these gases is similar.

Dr. Michael's hypothesis that there may be a self-perpetuating process in the genesis of tics, coprolalia, and echolalia by which the muscular and vocal discharges themselves provide the stimulus for a further discharge, is original but does not explain the many clinical features of tics. My own impression, based on a study² of a large number of child tiqueurs, is that the stimulus for the motor discharge is generated by the underlying psychological and possibly physiological tension occurring in certain constitutionally predisposed individuals. I am surprised that Dr. Michael's patient showed no change in tic-frequency under stress, and wonder whether there was in fact any evidence of increased tension during the recording sessions.

Dr. Michael's postulate that carbon dioxide alters the plasma hydrogen-ion concentration, and thereby lowers the excitability of the synapse, might explain the symptomatic improvement resulting from interruption of the hypothetical self-perpetuating system. Thinking along similar lines, I attempted to investigate experimentally³ whether tics in childhood are associated with neuromuscular hyperexcitability. The results were inconclusive, but if the hypothesis is correct it is conceivable that carbon dioxide may act by raising the threshold of excitability. However, I should have thought it more likely that the beneficial effect of carbon-dioxide inhalation in the case described was due to the discharge of tension. Whatever the mechanism, I hope that Dr. Michael's article will stimulate further research on the value of carbon dioxide in the treatment of tics.—I am etc.,

Slippery Hospital Floors

SIR.—Unfortunately the craze for "spit and polish" still exists in some hospitals, in spite of the occurrence of fractures among members of the administrative and nursing staffs from falls on slippery floors, often made more slippery by the use of the "bumper." Convalescent patients should be accompanied by an attendant when first out of bed, and encouraged to walk bare-foot, thereby getting a sense of position in space: the firmness of the cold floor giving a feeling of security and confidence, thereby diminishing the risk of faintness or falling.—I am, etc.,

London, W.1.

B. WHITCHURCH HOWELL.

Post-maturity

SIR.—May I be permitted to use a few lines of your valuable space to make a few comments on Professor F. J. Browne's interesting article, "Foetal Post-maturity and Prolongation of Pregnancy" (*Journal*, April 13, p. 851), particularly as several of the quoted hospital report figures (F, M, N, O, and P) are concerned with our teaching obstetrical units at the University of Capetown?

The majority of the patients admitted to our institutions, apart from hospital O and part of F, were non-white (Bantu and coloured), more than 20% of whom were non-booked, of a very poor type, and living under conditions of extreme poverty, and a large proportion of whom suffered from chronic ill-health—i.e., pre-eclampsia, eclampsia, antepartum haemorrhage, etc. It should also be mentioned that the high foetal and maternal mortality occurring in hospital P (almost entirely non-white and largely non-booked) was

almost entirely due to the fact that this institution dealt only with the medical complications of pregnancy, such as the toxæmias, eclampsia, diabetes, cardiacs, etc.

The reason for the anomalous almost non-existence of post-maturity in non-whites, as compared with white patients, was simply the unreliability of menstrual histories among the majority of non-whites, with the result that post-maturity was hardly ever surgically induced among the latter. Until recently, too, post-maturity was not recognized in our white patients for other reasons.

In a recent paper on stillbirth¹ it was found that 15.7% of the causes of stillbirth at our obstetrical units was unknown. I am sure that it is within the realms of probability that among these cases post-maturity occurred not infrequently, especially among non-whites. Of course it would be difficult to prove with accuracy, not only for the reason given above, but also because 85% of these infants were macerated at birth. However, to state that post-maturity was practically absent among our non-whites is in all probability a misrepresentation of fact.

The high stillbirth loss after forceps and caesarean section due to asphyxia in post-mature infants, particularly in the presence of foetal distress and meconium staining of the liquor,² further increases my belief of the seriousness of pregnancy prolonged to the 42nd week and beyond.—I am, etc.,

Toxic Effect of Streptomycin

SIR.—The paper on the toxic effect of streptomycin upon balance and hearing by Mr. T. Cawthorne and Mr. D. Ranger (*Journal*, June 22, p. 1444) reminds one of the problem in rehabilitation posed by patients so affected in general medical wards.

None of the patients seen in the Gloucestershire Royal Hospital have suffered from the more dramatic features of acute labyrinthine failure. Their condition has been marked by an economy of movement, especially of the head, which they prefer to cradle in pillows or cushions, whatever the position of the trunk or legs. In this posture they have all appeared relaxed and content, but as soon as they have attempted to sit forward or adopt any posture with the head unsupported their facial expressions have become tense, agitated, and anxious. Speech stops, they stare fixedly ahead, and grip tightly on to anything rigid and handy until they readjust themselves with a variable degree of success or fall back in defeat. If the head is steadied and the cervical spine immobilized by a felt collar, these same patients are apparently able to sit forward and stand with little or no difficulty. As might be expected, this manoeuvre does not prevent symptoms arising when acceleration or deceleration is rapid in any plane. With the collar in position, the patients say that they feel more steady and the ward sister's attempts to mobilize them now meet with enthusiasm and success, whereas formerly they met with unremitting despair and failure. Usually the collar is soon discarded, but an elderly woman who was given streptomycin during five days' anuria, due to an attack of acute pyelonephritis, was offered a collar twelve months later and she uses it at her own discretion during what she describes as her "off days." Since starting to use it, she has been able to do useful work about the house, having been virtually bedfast.

It seems that these patients are better able to recognize reliable spatial information coming from their retinæ, peripheral muscles, and skin, in the face of scrambled messages from their damaged labyrinths, when there is no longer any need to balance the head upon the top of the cervical spine. Having once learned that balance has now become to some extent a conscious process, omission of the support for the head does not seem to offer a serious problem any longer.

This is perhaps a facile explanation, but it would be interesting to know whether Mr. Cawthorne considers that support for the head in this fashion, used in conjunction with the balancing exercises devised by himself¹ and Cooksey,² will further speed the rehabilitation of these patients. Further, reiteration of his head and balancing exercises in more detail, with a note of the response which may be expected, would probably be widely appreciated by general physicians.—I am, etc.,

G. V. BALMFORTH.

Chimerism in Authorship

SIR.—The article on blood chimerism in a pair of twins (*Journal*, June 22, p. 1456) is attributed to seven authors. Have you any limit to the number of authors an article is allowed to have? May I suggest a maximum of three, and a preference for two or less? It is impossible for seven people to write one article together, and the multiplicity of names robs the real authors of credit, makes reference-tracing harder, and entitles people who played hardly any part in writing an article to list it in their published works qualified by the parenthesis (jointly).

Chimerism in authorship is usually caused by politeness, by the idea "Everyone to do with this must have their name put down or they might be offended." Despite my protests I once had my own name listed as co-author of an article which I have never read. Most medical work demands joint effort, but auxiliary workers can be thanked at the end of articles. The people listed as authors of medical articles should be those who wrote them (excluding editors).—I am, etc.,

RICHARD ASHER.

London, W.1.

POINTS FROM LETTERS

Herpes Zoster

Dr. R. W. H. TINCKER (Painswick, Glos) writes: In the *Journal* of October 13, 1956 (pp. 864 and 865), under the heading "Medical Memoranda," were two interesting articles dealing with herpes zoster. Since that date there have appeared articles and letters on different aspects of the same subject, but as yet no one has mentioned the one form of treatment which is effective in causing recession of the rash, relief from pain, and rapid recovery with early return to work. Over 20 years ago I contributed to the *Journal* (1934, 1, 363) a short note on the use of pituitary extract, and since that time I have found it to be the only satisfactory treatment for herpes zoster, with no contraindications despite variations in age, blood pressure, etc. I am now using tab. pituitary (whole gland) gr. 2 (0.13 g.), one tablet every four hours, and with early cases find remission of all symptoms to be rapid and complete. In patients with conjunctival involvement there is no residual scarring, and relief from pain is achieved in most cases in about 24 hours. With later cases when vesiculation has been present for several days there is not the same striking result.

Time to Change?

Dr. J. S. MEIGHAN (Tilbury) writes: Surely the time has now come to denote all blood pressures by the simple method of separating the two figures by a stroke—e.g., 140/80—the systolic always coming first. There is no need whatever to add, ponderously and pedantically, "millimetres of mercury" or "mm. Hg." No person would think, in his wildest dreams, of attempting to estimate blood pressure in inches or feet of Bass or Guinness. Millimetres of mercury are universally used, and this should be understood. Surely the time has equally come to express penicillin dosage (and that of a few other antibiotics) in terms of the mega unit, from 0.1 up, thus avoiding those tedious strings of zeros when expressed in simple units. I beg to submit that the American term "spinal tap" is a far better one than "lumbar puncture," which merely indicates making a hole somewhere in the lumbar area. Spinal tap shows that one is withdrawing fluid (as is actually the case) from a definite site, the spinal canal. Further, "eye ground" is a much simpler and more easily understood term than the pedantic "fundus oculi."

Medical Notes in Parliament

Alcoholic Psychoses

Dr. A. D. D. BROUGHTON (Bartley and Morley, Lab.) asked the Minister of Health on July 9 what was the number of patients in England and Wales certified as being of unsound mind due to alcoholic psychoses in 1954, and how this figure compares with that for 1955. Mr. J. K. VAUGHAN-MORGAN told him that 99 certified patients were admitted to mental hospitals in 1954 on account of alcoholic psychosis or alcoholism. The corresponding number in 1955 was 114.

Fortified Wines

Sir ALFRED BOSSOM (Maidstone, Con.) asked the Minister of Health on July 10 what advice he gave to Health Service doctors in his notes on prescriptions in regard to the prescribing of fortified wines, including port, for convalescent invalids in appropriate cases; and how much port had been so prescribed in recent years. Mr. VAUGHAN-MORGAN stated that the National Health Service Act did not provide for the supply, on the prescription of a general practitioner, of preparations which were not drugs or medicines, and an independent advisory committee had recommended that alcoholic beverages should normally be regarded as foods and not as drugs. Alcoholic beverages might be prescribed for individual patients in hospital as an item of diet where the doctor in charge of the patient considered this desirable on medical grounds. No case had come to notice in which port wine had been prescribed.

Lung Cancer and Smoking

Mr. R. HORNBY (Tonbridge, Con.) asked the Minister of Health, as representing the Lord President of the Council, whether he would request the Medical Research Council to study the report of Sir Ronald Fisher, F.R.S., on the statistics concerning the relationship between lung cancer and smoking and to report its conclusions thereupon. Mr. VAUGHAN-MORGAN said the Minister had not yet received this report, by one of the scientific consultants to the Tobacco Manufacturers Standing Committee, but he was sure that the Medical Research Council would give it most careful study.

Instruction in the Schools

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked the Parliamentary Secretary to the Ministry of Education on July 11 what steps he was taking to ensure that senior pupils in schools were made acquainted with the latest conclusions of the Medical Research Council on the probable relationship between cigarette-smoking and cancer of the lung.

Sir EDWARD BOYLE said the Minister had sent copies of the statement in the House of June 27 to local education authorities and to all independent schools. The Minister considered that it must be left to teachers themselves to decide how to make their senior pupils acquainted with these conclusions. He hoped, however, that they would in any case also encourage young people to use their own judgment on the choice of the best directions in which to spend their money.

Smallpox and Asian Influenza

Mr. HECTOR HUGHES (Aberdeen, North, Lab.) on July 15 asked the Minister of Health if he was aware of the increased incidence of smallpox and Asian flu in Great Britain; whether he had been able to trace the sources of infection; and what further steps he was taking to protect the British people from these infections. Mr. J. K. VAUGHAN-MORGAN replied that there had been three confirmed cases of smallpox; the source was believed to have been a traveller returning from Lagos. In the four cases where influenza of the Asian type had so far been identified, the infection had occurred in persons recently arrived from Asia. Normal routine action in the case of epidemics was being taken.

Doctors' Superannuation

Mr. A. BLENKINSOP (Newcastle upon Tyne, East, Lab.) asked how many doctors would become entitled to draw superannuation benefit on retirement from the National Health Service in 1958. Mr. VAUGHAN-MORGAN said there would be about 3,500 general medical practitioners and part-time specialists. Figures for doctors employed full-time in hospital were not readily available.

Protection of Assistants

Mr. BLENKINSOP asked what action was proposed to protect doctors acting as assistants to general practitioners under the National Health Service, in view of the unsatisfactory conditions of service of many young doctors at the present time. Mr. VAUGHAN-MORGAN said he was not clear what conditions of service Mr. Blenkinsop regarded as unsatisfactory or what action he wished the Minister to take, bearing in mind that assistants were in private professional contract with their principals.

Smoking and Disease

Mr. M. EDELMAN (Coventry, North, Lab.) asked if the Minister would send a circular to local authorities recommending that there should be a ban on smoking in all public confined spaces within their control. Mr. VAUGHAN-MORGAN stated that there is nothing to prevent local authorities from banning smoking within their own premises as proprietors of some theatres had done. But this was not a matter for a Government circular.

Mr. KNOX CUNNINGHAM (Antrim, South, U.U.) asked to what extent cigarette smoking was responsible for disease of the heart and in particular coronary thrombosis. Mr. VAUGHAN-MORGAN said he understood that a statistical correlation between smoking and coronary thrombosis had been suggested but not so far established.

Mr. JOHN HOWARD (Southampton, Test, Con.) asked if the Minister of Health would make the services of his department available to provide a course of treatment designed to cure the tobacco habit when a person wished to give up smoking but was unable to master the habit. Mr. VAUGHAN-MORGAN said he did not think the department would be equipped to undertake such an operation, even if it were practicable.

Psychiatrists in the Forces.—There are 50 psychiatrists serving as commissioned officers in the medical branches of the three Services. In addition, the Services employ 15 civilian consultants and four part-time civilian psychiatrists.

Crash Helmets.—The Minister of Transport states that last year the lives of at least 70 motor-cyclists would probably have been saved had they been wearing crash helmets when they were involved in accidents. There would also have been a considerable saving of life of pillion passengers.

Dental Ancillaries.—The draft Dental Ancillary Workers Regulations, 1957, were approved on July 10.

Medico-Legal

DIMINISHED RESPONSIBILITY

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On July 5, 1957, the Lord Chief Justice in the Court of Criminal Appeal gave judgment on the first appeal involving the defence of "diminished responsibility" now available in prosecutions for murder by reason of s. 2 of the Homicide Act, 1957.¹

The appeal was by Ronald Patrick Dunbar from his conviction of capital murder at Newcastle Assizes before Mr. Justice Ashworth. Dunbar had killed a woman of 82 by striking her several times on the head with a lemonade bottle

¹ The Times, July 6, 1957.

² 1945 S.C.(J) 55.

while burgling her house, and his only defence was that he was suffering from such abnormality of mind as substantially impaired his mental responsibility for the killing. A psychiatrist called for the defence said that in his opinion Dunbar was a psychopath and was suffering from an abnormality of the mind, and the evidence of the prison doctors had been that in their opinion he was not.

At the trial counsel for the defence contended that, although under the Act it was for the defence to prove diminished responsibility, the burden of proof on them was to establish it only upon the balance of probabilities. Counsel for the prosecution had contended that the burden on the defence was to establish it beyond reasonable doubt. The judge, in summing up, gave no express directions to the jury on these conflicting contentions, but left the matter to them in the terms of the section, simply saying that the burden was placed by Parliament fairly and squarely on the defence. The jury found Dunbar guilty of murder.

In his judgment the Lord Chief Justice said that the Act had borrowed the defence of diminished responsibility from the law of Scotland, and, as the case of *Lord Advocate v. Braithwaite*² showed, the burden was that of preponderance of probabilities. The judge in summing up had nowhere pointed out to the jury that the burden of proof on the defence was not as heavy as the burden on the prosecution. Even if he had given that direction it was highly likely that the jury would have returned the verdict which they did. However, in a matter which made the difference between a capital sentence and a sentence of imprisonment the court felt that a verdict of manslaughter under the section ought to be entered instead of one of capital murder. Dunbar was sentenced to imprisonment for life.

Universities and Colleges

UNIVERSITY OF OXFORD

The honorary degree of D.Litt. was conferred on June 26 on Professor J. F. Fulton, M.D., F.R.C.P., Sterling Professor of the History of Medicine in the University of Yale.

UNIVERSITY OF CAMBRIDGE

Dr. P. A. Merton has been appointed a University Lecturer in the Department of Physiology with tenure from October 1, 1957, for three years, and Dr. G. S. Brindley a University Demonstrator in the Department of Physiology with tenure from October 1, 1957, for two years.

Dr. J. M. Walshe has been appointed an Assistant Director of Research in the Department of Experimental Medicine with tenure from October 1, 1957, for five years.

The following degrees were conferred in Congregation on June 1:

M.D.—M. C. Joseph, D. Scott, G. A. Gresham, J. J. McMullan, M.B., B.Chir.—J. P. Clayton, *C. U. Abengowe, *R. M. Potlock, Mrs. Jacqueline A. N. Arnold.

*By proxy.

In Congregation on June 13 the honorary degree of Sc.D. was conferred on Sir Geoffrey Jefferson, F.R.S., Emeritus Professor of Neurosurgery in the University of Manchester.

In Congregation on June 15 the following degrees were conferred:

M.D.—G. Scott, M.B., B.Chir.—J. M. L. Goddard (by proxy), R. C. M. Kew, M.B.—P. J. Lachmann.

Dr. P. J. Randle has been elected to an official Fellowship at Trinity Hall.

The following candidates have been approved at the examinations indicated:

FINAL M.B.—Part II: 123M. J. Absolon, 12R. A. Aiken, 123A. A. Akiwumi, 123C. F. Allenby, 123P. N. Awdry, 123R. Banerjee, 123D. W. Barkham, 123R. A. Barron, 123D. G. Beynon, 123J. H. L. Bland, 123D. Bond, 123R. Bright, 23J. H. D. Briscoe, 123A. Brockman, 123T. R. C. Brodie, 123M. Bulmer, 123P. R. Butler, 23A. J. Cameron, 123P. Cannon, 23J. V. F. Catto, 123P. A. F. Chalk, 23L. J. Chaistrey, 123E. Reynolds, J. Rivers-Kirby, H. R. M. Roberts, V. Rudralingam, D. E. Side, R. O. S. Sims, G. I. Sinclair, C. E. R. Thompson, J. C. Twomey, J. Weston, G. E. Winbolt, M. C. Woodhouse.

¹Passed in principles and practice of physic. ²Passed in principles and practice of surgery. ³Passed in midwifery and gynaecology.

UNIVERSITY OF ST. ANDREWS

At a Graduation ceremonial held on June 27 the following degrees were conferred:

M.D.—D. A. R. Simmons (with a University Gold Medal), 12George Smith (with a Rutherford Gold Medal), 12J. McL. Baird (with a Rutherford Silver Medal), 23H. D. Attwood, 23A. T. Sandison, J. S. Garrow, Elizabeth G. W. Barker (or Gore), D. A. McGreal, George Williams, J. S. Young, M.B., Ch.B.—12J. M. Breckenridge, 12Heather M. Mitchell, 21A. Harper, 23Sheila M. Russell, 23Margaret R. Mellor, 12Isabel L. Wilson, G. J. Albers, Letitia R. Arnett, D. M. Bearpark, R. S. Blueglass, W. R. Boraston, A. J. Chalmers, E. M. Clark, R. V. Clark, Mollie D. Cratchley, J. R. N. Curt, H. W. R. Davidson, R. C. Deacon, A. K. Dewar, A. G. Dunlop, H. O. Fadahunsi, Josephine S. Foils, Sheila B. Forbes, A. R. Gale, D. P. High, Huddleston, G. Illingworth, Christine M. L. Kerr, M. Kostyn, Ruth Lewy, D. E. Lyons, J. L. McIntyre, Jessie C. M. MacRae, Patricia A. R. Miller, Robina W. Moar, Judith F. E. Moody, L. Mullins, P. E. North, D. L. Parsons, R. L. Payne, J. M. Penman, D. A. Pikeately, D. Pope, G. B. Rae, W. E. Rees, W. Russell, H. J. C. Scrimgeour, G. M. E. Sewell, M. Sheridan, B. Smith, B. D. Smith, G. O. Sfoluwe, H. W. Sutherland, Patricia A. Thomas, Nesta M. H. Tullis, Ann F. Tuxford, F. L. M. Waiyaki, C. M. Wiseman, Mrs. Annie M. Wolff.

¹With honours. ²With commendation.

UNIVERSITY OF GLASGOW

The following degrees were conferred on July 6:

M.D.—D. Cameron, A. A. Charteris, 12D. H. Clark, R. S. Ferguson, 23W. M. Fyfe, 12W. T. Irvine, 23B. Isaacs, A. A. McKirdy, 23A. J. Nelson, 23J. M. Reid, 12G. B. S. Roberts, M.B., Ch.B.—C. M. Abaccheta, R. C. B. Aitken, M. A. T. Aiso, F. D. Allan, W. Allan, K. D. Allardyce, C. J. Allen, Phyllis M. Auchinclose, A. T. K. Baillie, D. McC. Barr, G. F. Berry, T. F. Beveridge, J. P. K. Binnie, I. F. S. Black, G. A. W. Borland, 23D. S. C. Brown, Jean W. Brown, G. Buchanan, Margaret E. Burns, D. G. S. Campbell, I. Capperault, J. A. Clarke, J. W. Collins, J. P. Colquhoun, Jean L. Cooper, Ann M. Crowder, A. Cumming, C. S. Cunningham, D. N. M. Cuthbert, J. H. Dagg, L. J. Davidson, Eileen M. Dixon, T. Donaldson, C. N. Donoghue, H. S. Fletcher, Jean H. Fraser, T. L. Fraser, C. A. Gourley, B. W. Grace, B. M. Groden, G. Hannah, R. Hannah, A. M. Harper, F. O. Hemming, D. T. Herriot, W. R. Hesson, A. G. Jamieson, Irene R. Jamieson, T. E. Kellie, M. Kennedy, C. W. Kerr, Catherine C. King, R. W. Logan, Helen P. Macallister, Elizabeth Macaulay, J. A. McBride, E. A. McCabe, Harriet McCallum, Maureen McCann, Ann P. Macfarlane, D. B. Macfarlane, Mary W. Macfarlane, Janet McCr. McGrath, Fiona M. McGregor, J. H. McKay, T. McLean, Margaret S. Macleod, D. L. Macphie, J. D. G. Malley, L. R. Massiah, I. Maxwell, Susan M. Mechie, M. T. Mellington, Agnes McCr. R. Menzies, G. C. Miller, Margaret K. Miller, R. Miller, S. Miller, Elizabeth Murray, J. N. Norman, J. Notman, K. A. Oduro, Margaret M. O'Neill, W. I. B. Onulabo, I. G. Philip, D. Pollock, 23B. M. Rifkind, Irene J. Robertson, W. A. I. Rushford, J. C. S. Russell, W. B. Russell, J. Shields, W. O'N. Shields, Annetta Smith, J. D. S. Smith, M. W. J. Smith, Jessie M. Steele, S. Stern, D. J. D. Stevenson, Isabella Stewart, W. A. Stewart, C. D. Strang, D. A. Stuart-Smith, Eileen F. Sweeney, W. S. Syme, W. M. Tait, Mary M. Tannahill, J. C. Taylor, T. R. Taylor, J. S. Templeton, S. A. P. Tindal, G. F. Waddell, Lorna B. M. Webster, Patricia H. R. Welsh, D. R. Westfield, J. A. White, R. Wilson, C. R. R. Wylie, Drissa McCQ. Yilla.

¹With honours. ²With high commendation. ³With commendation.

On June 20 the Diploma in Public Health was awarded to the following successful candidates:

J. Dow, G. C. Franklin, D. C. R. Gemmell, B. J. Green, J. S. Green, Frances M. W. Hamilton, J. L. Hastings, W. Holmes, Christina C. McEwan, W. McIntosh, E. D. Mackie, P. McKillop, R. McLaren, A. MacLean, W. J. Patterson, J. D. Terrell, H. L. C. Young.

UNIVERSITY OF DUBLIN

SCHOOL OF PHYSIC, TRINITY COLLEGE

The following degrees were conferred on July 4:

M.D.—R. Indar, I. R. Moore, Eleanor B. Outon.
M.B., B.Ch., B.A.O.—M. Murray-Alston, A. H. Bakker, F. A. Best, Ruth T. Blackall, D. P. Brattman, R. K. Brennan, P. Byrne, A. P. M. Cahill, F. E. M. Cahill, H. B. Devlin, Rose A. Fisher, Shirley M. Gittins, Kathleen C. M. Hackett, Ruth M. Harris, Pamela C. Harrison, Ann E. Heatley, Danuta M. Jarosz, C. F. G. Jones, P. T. MacDonnell, W. A. Marshall, J. B. O'Regan, L. C. Prozesky, L. R. Redman, R. Shapiro, A. H. Simpson, Hilda A. Stoddart, D. C. Thomas, Eunice V. Turner, A. F. Watson, B. E. White.
L.M., L.Ch., L.A.O.—N. M. Cocks.

UNIVERSITY OF LONDON

Dr. C. E. Newman has been nominated for reappointment as representative of the University on the governing body of the West London Hospital Medical School.

Dr. H. B. May and Professor J. Z. Young, F.R.S., have been appointed to serve under category (d) on the board of the Faculty of Medicine in place of Professor W. J. Hamilton and Mr. H. E. Harding, who have become members in other categories.

UNIVERSITY OF MANCHESTER

The following candidates have been approved at the examinations indicated:

Ch.M.—G. R. Carr.
FINAL M.B., Ch.B.—B. W. Barnes, B. Bazeley, G. Beaumont, H. D. C. Bell, J. A. Bell, B. Bethell, Eileen M. Booth, G. Brooks, P. P. Carter, A. J. Chadwick, Myra Chadwick, Anne G. Cooper, H. Dawson, Patricia A. Doran, A. J. Dutton, J. M. Evanson, Joyce M. Eyre, A. W. F. Fisher, Muriel Francis, K. W. Hancock, B. D. Hewitt, L. P. J. Holt, B. D. Hughes, W. R. Lee, L. M. Lines, M. Longson, G. Macdonald, A. W. Marr, J. P. Mideley, Joyce M. Morris, R. W. K. Neill, T. G. Ramsell, Sylvia J. A. Raymond, J. Roberts, M. G. Roberts, Barbara J. Rostron, I. A. Rudin, C. Salkin, Garrioch Sedman, M. Seal, Margaret W. Seymour, M. P. Smith, G. A. Steele, Sheila D. Sutherland, W. E. N. Taylor, G. Thomas, W. Wagstaff, J. S. Whitaker, K. S. Williamson, P. A. Yates.

UNIVERSITY OF WALES

The following candidates at the Welsh National School of Medicine have been approved at the examination indicated:

M.B., B.Ch.—J. B. B. Moule, *P. H. Adams, June E. Burton, C. Davies, G. L. Davies, *D. B. Evans, A. Fisher, Mary E. Granger, Hawys W. Griffiths, Agnes M. Hood, *W. L. Hooper, Margaret R. M. James, W. A. Jerrett, A. B. C. Johnson, A. B. Jones, *Gwyneth M. Jones, D. R. Langley, M. A. Lewis, *D. Lovell, Hilary M. Morgan, *J. B. Penry, *Ruth M. Plummer, *Beit R. Price, Dorothy M. Rees, Euryl Richards, *Patricia R. Smith, Patricia M. Sullivan, W. R. G. Thomas, Helen W. E. Walters, J. B. Williams, R. M. Williams, *P. S. Comer.
TUBERCULOUS DISEASES DIPLOMA.—M. Alam, A. A. R. Al-Sabti, G. Ashe, S. Y. Bokhari, P. Z. Fisher, M. A. Ghani, Ko Gyl, K. Jayakody, W. P. Lau (with distinction), N. Mallick, A. L. McKnight, B. P. Mozoomdar, S. H. Sadiq, D. Sarma, V. N. Sharma, M. M. Soomro, B. Sunakorn, T. K. Sweeney, P. Weerasuriya.

*With commendation. *With distinction in pharmacology and therapeutics. *With distinction in pathology and bacteriology. *With distinction in surgery. *With distinction in medicine (including psychological medicine) and child health. *With distinction in midwifery and gynaecology. *With distinction in social medicine and public health. *With distinction in human anatomy. *With distinction in forensic medicine and toxicology.

UNIVERSITY OF BIRMINGHAM

Professor C. F. V. Smout, Professor of Anatomy and Sub-Dean of the Faculty of Medicine, resigns these appointments on September 30, 1957, and has been invited to accept a part-time professorship in the Department of Anatomy from October 1.

Dr. S. S. Shulman resigned his temporary appointment as Lecturer in Anatomy on April 30, 1957.

Dr. P. Eckstein, Lecturer in Anatomy in the University, has been elected to the council of the Society for Endocrinology and appointed editor of the Society's *Proceedings*.

UNIVERSITY OF LEEDS

G. C. Turner has been approved at the examination for the degree of M.D.

UNIVERSITY OF BRISTOL

The dissertations submitted by F. G. Bolton and L. A. D. Tovey for the degree of M.D. have been approved.

The following candidates have been approved at the examinations indicated:

M.D.—N. G. Sanerkin.
M.B., Ch.B.—Janette A. Hockin, J. S. C. J. Shortman, F. I. Akinsete, T. J. Betteridge, Pauline M. Bland, D. E. Bowden, C. C. L. Brewer, W. L.

Burland, G. F. Counsell, S. M. Daniels, Norma St. C. Dansie, H. G. K. Douglas, *Bethia M. Dowell, J. M. English, Sheila A. Faint, C. G. Falkner, D. Faulkner, I. D. Fraser, Joyce Fung, D. MacD. Innes, C. W. Jenkins, Audrey King, J. O. Koney, G. W. Manley, *Jean Moffatt, A. Morgan, H. O. N. Onubogu, D. C. Pengelly, K. T. Rackham, D. A. S. Robertson, A. L. Rose, J. F. Shaw, M. E. Sheard, P. R. Stock, G. B. Sutton, Margaret Taylor, I. Thompson, D. C. Weeks, H. G. Wotherspoon. In Group I, completing the examination: G. T. Curtis, H. E. Millen, R. W. Prescott, J. R. Stamper, D. W. Zutshi. In Group II only, C. N. Bruton.
*With second-class honours. *With distinction in public health.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

The following were admitted as Licentiate and Members of the College on June 7: Dr. J. P. Alexander, Dr. T. Haran, Dr. B. J. Lemass, and Dr. J. R. McCarthy.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

The following candidates have been awarded the Diploma in Obstetrics:

D. A. Aitken, R. W. Allin, A. A. Allison, A. Armstrong, G. A. E. Baker, V. Balachandran, A. Banerjee, A. F. Barrett, R. W. Beard, Felicity M. Bedford, K. Bhalla, J. T. Binless, P. M. Binns, G. C. Bird, Sybil D. Bonuini, W. M. S. Boyd, R. T. Boyle, P. V. Briffa, K. G. Buckler, Mary E. Budleigh, M. F. D. Burton, Sheelah Caldwell, D. J. C. Cameron, J. J. Camp, H. A. Campbell, P. J. S. Cannon, G. Caplan, J. M. Carr, B. R. T. Carroll, Leela M. Chacko, J. E. Charlewood, R. R. Charwood, Helen Clarke, B. J. Clayton-Payne, D. J. Cliffe, D. T. Cousins, A. F. Crowley, G. H. C. Daley, S. N. Das, D. J. Davies, Edna L. Davies, W. F. T. Davies, Pauline, M. Dean, H. Van Zyl D. Klerk, L. P. De Souza, R. Dingley, Pamela M. Dodson, Marion R. H. Donald, A. M. Donaldson, B. G. Dooley, R. B. Dorofaeff, B. J. Drake, R. E. Draper, Florence M. Duckenfield, G. H. H. Dwyer, Judith M. Edmundson, P. A. E. Edmundson, P. E. Elwood, M. Entwistle, J. E. Evans, L. W. S. Eyears, Edith Fairman, D. Fairbairn, F. G. Feinstein, Elizabeth A. Fisher, A. F. Floyd, Beryl M. Foley, H. K. Ford, E. J. H. Foster, J. Frame, A. T. R. Fuller, R. Gardner, Ethel F. E. Gelber, S. K. Ghal, S. K. Ghosh, H. R. Gibson, B. B. Gil, S. L. Goodman, C. M. Green, Evert C. Green, W. F. Griffith, P. Griffiths, D. S. Hamilton, J. J. Handler, D. C. Harris, F. A. S. Harris, R. Harrison, D. F. Hawkins, E. S. N. Hazel, Anne Heath, Rita Henryk-Gutt, M. D. Heyman, R. F. Heys, E. P. Hilary-Jones, J. G. Hill, Molly Hill, W. G. Holland, J. A. Hopson, J. M. Hughes, S. Hyndman, F. L. Johnstone, Audrey Jones, F. W. Jones, R. J. B. H. Jones, J. A. Kay, Sylvia J. Keet, R. M. B. Kerr, P. J. King, J. A. Kirkland, Iris M. Krass, Dorothy K. C. Kwan, Z. K. Langdana, J. F. Leeton, Penelope A. Leighton, W. G. H. Leslie, E. H. Loxton, A. R. Lyall, H. D. MacEwan, J. A. W. McKelvey, Irene E. McLaren, Elizabeth M. McNab, I. S. McRobbie, J. Maguire, K. Mahabir, Dorothy Mainwaring, R. B. Malcolm, E. Mallett, Pauline A. Manfield, B. H. Markham, Veronica Mercer, G. C. Metcalfe, J. S. B. Meyer, J. G. Millar, H. F. Molloy, P. L. C. Monier-Williams, R. M. A. Moore, Sheila M. L. Moore, T. Moore, J. M. Munn, Mira V. Muzumdar, B. E. H. Neal, H. I. L. Nicholls, T. M. Nott-Bower, F. J. O'Connell, Mary G. Orell, S. C. Paget, E. G. Palmer, P. Paramaswami, D. C. Pearson, L. J. T. Pearson, L. G. Pereira, Frances K. Phillips, A. D. Prowse, P. W. Quinn, F. A. Raja, G. L. S. Rankin, M. A. H. Rayman, E. Redfern, K. W. Reed, B. F. Reeves, C. B. Rennick, Hilary A. Roach, T. H. Roach, T. L. Roberts, B. Robertson, G. F. C. Rosser, A. J. Rowland, S. Roy, N. D. Royle, M. F. Russell, Betty V. Scott, J. A. Seddon, M. S. Shalom, C. A. Sharples, A. J. Shaw, J. Smith, R. W. G. Stewart, J. S. Surden, J. F. W. Sutherland, E. P. W. Tatford, G. A. Taylor, M. G. Taylor, M. B. Teal, Ann Thomas, D. K. M. Thomas, M. C. Thornton, M. Tobias, Patricia A. Topham, J. M. Trivedi, R. Unwin, Alice E. M. Van Waterschoot, J. Vernon-Parry, A. P. Walker, G. P. Walker, E. Wallace, R. F. Warnock, J. R. Watson, Marjory I. K. Watt, J. Whewell, G. T. Whitaker, Joan W. Whitaker, Margaret White, Agnes E. Whitter, J. D. Wigdahl, I. T. D. Williams, W. A. Williamson, Mary Younie.

ROYAL AUSTRALASIAN COLLEGE OF PHYSICIANS

At a meeting of the General Body of Fellows of the College held in Brisbane on May 29 the following were elected and admitted to Fellowship of the College: Under Article 44: Professor R. R. H. Lovell, of Victoria. Under Article 42: Dr. J. L. Adams and Dr. J. D. Willis, of New Zealand; Dr. R. C. Angove, Dr. W. M. Irwin, and Dr. R. A. A. Pellaw, of South Australia; Dr. G. C. de Gruchy and Dr. H. J. Sinn, of Victoria; Dr. G. V. Hall, Dr. A. J. May, and Dr. T. E. H. Spark, of New South Wales; Dr. H. W. Johnson, Dr. W. G. Livingstone, Professor J. H. Tyrer, Dr. L. D. Walters, and Dr. H. G. Wilson, of Queensland. The following candidates, who were successful at an examination held in New Zealand, were admitted to Membership of the College on May 28: Dr. N. H. Brooke, Dr. D. G. Campbell, Dr. D. R. Hay, Dr. I. C. Isdale, Dr. W. B. Jackson, Dr. B. J. Kelly, Dr. G. B. Kiddle, Dr. R. G. Lawrence, Dr. C. M. Luke, Dr. C. A. Macleod, Dr. D. J. K. North, Dr. L. H. Stevens, and Dr. R. C. Tait.

The following candidates, who were successful at an examination held in Australia, were admitted to Membership of the College on May 28: Dr. P. D. Bredahl, Dr. B. M. King, Dr. I. H. McKenzie, Dr. M. L. Mashford, and Dr. P. J. Nestel, of Victoria; Dr. H. A. Copeman, Dr. N. J. Nicolaides, and Dr. W. S. Rowe, of Queensland; Dr. D. J. Deller, Dr. A. H. Gibson, Dr. D. J. Harbison, Dr. E. J. Lines, and Dr. A. P. Skyring, of New South Wales. Dr. R. A. Barter, of Victoria, was admitted to Membership under the provisions of Article 37.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications (uncorrected) in the week ending July 6 (27th week of the year) were as follows, with the figures for the previous week in parentheses: paralytic 68 (73), non-paralytic 65 (46), total 113 (119).

The Table below shows the districts with populations of 15,000 or more in which the notification rate per 100,000 in the year to date exceeds 30:

District	Incidence per 100,000 of Population	Total Cases in 27 Weeks	
		Paralytic	Non-paralytic
Barnet U.D. (Herts)	70.23	14	4
Colchester M.B. (Essex)	75.95	27	20
Tendring R.D. (Essex)	52.91	3	10
Harpden U.D. (Herts)	38.37	3	3
Stevenage U.D. (Herts)	49.91	4	7
Brighton R.D. (Devon)	54.36	6	12
Maidstone C.B. (Sussex)	31.51	18	32
Redditch U.D. (Worcs)	45.05	8	17
Harlow U.D. (Essex)	38.23	9	3
Abertillery U.D. (Mon.)	40.23	6	6
	33.59	7	2

Diphtheria and Whooping-cough Immunization

In view of recent reports from the Medical Research Council on neurological lesions in relation to inoculation,¹ and on the efficacy of pertussis vaccine,² the Central Health Services Council has given the following advice to the Minister of Health and Secretary of State for Scotland:

(1) Non-alum-precipitated antigens should be recommended for use by local health authorities and general practitioners against diphtheria.

(2) There is a risk of provoking poliomyelitis in using antigens in combination. Some of these risks have been measured; others such as might occur in using combined whooping-cough and tetanus antigens or combined diphtheria and tetanus antigens have not yet been measured. Antigens should, in general, preferably be used separately, though the advantages of this must be weighed against the psychological dangers of giving frequent injections to the child.

(3) If non-alum-precipitated antigens are used singly they may be used throughout the year, subject to the discretion of the medical officer of health.

Because of this advice, some changes will be made in the supply of materials to local health authorities for immunization.

Diphtheria Prophylactic.—Hitherto, the materials available have been alum-precipitated toxoid (A.P.T.), purified diphtheria toxoid aluminium phosphate precipitated (P.T.A.P.), formol diphtheria toxoid (F.T.), and diphtheria toxoid antitoxin floccules (T.A.F.). Supplies of alum-containing toxoids will be discontinued and the central supply will consist of F.T. and T.A.F. It is suggested that the primary course of immunization should consist of two injections each of 1 ml. of F.T. at a minimum interval of 28 days and a single injection of 1 ml. should be used for reinforcing doses. T.A.F., which contains antitoxin, is recommended in a 1-ml. dose for the reinforcing dose in the children over 5 years of age who have been primarily immunized with A.P.T., P.T.A.P., or combined diphtheria-pertussis vaccine and who may in consequence be unduly sensitive to F.T. There is no change in the advice that immunization against diphtheria should take place at about 8 or 9 months of age so that protection can be completed before the first birthday, with a reinforcing dose in the fifth or sixth years. Where local health authority arrangements provide for further reinforcing doses, the dose of F.T. should

¹ *Lancet*, 1956, 2, 1223.

² *British Medical Journal*, 1956, 2, 454.

be reduced—e.g., 0.5 ml. at age 10 and 0.25 ml. at age 15—in order to limit the effects of undue sensitivity.

Whooping-cough Vaccine.—To provide protection at an age when the disease is most apt to have serious results, the first injection should be given to children before they are 3 months old.

Combined Antigens.—If a local health authority considers it expedient to use non-alum-containing combined diphtheria and whooping-cough antigens, it should pay special regard to the prevalence of poliomyelitis infection in the locality and to the period of highest risk of provocation.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1948–56 are shown thus - - - -, the figures for 1957 thus ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest falls in the notifications of infectious diseases in England and Wales during the week ending June 29 were 4,727 for measles, from 22,144 to 17,417, 60 for acute pneumonia, from 312 to 252, 38 for whooping-cough, from 1,592 to 1,554, and 25 for dysentery, from 489 to 464, and the only large rise in incidence was 79 for scarlet fever, from 357 to 436.

A fall of 100 or more in the number of notifications of measles was reported from 18 counties; the largest falls were 705 in Yorkshire West Riding, from 2,897 to 2,192, and 565 in Warwickshire, from 1,806 to 1,241. The largest exception to the general fall in measles was a rise of 52 in Somersetshire, from 189 to 241. The largest variations in the trends of scarlet fever were a rise of 28 in Lancashire, from 36 to 64, and a fall of 21 in Essex, from 41 to 20. The largest fluctuation in the returns of whooping-cough was a rise of 36 in Lincolnshire, from 48 to 84. 4 cases of diphtheria were notified, being the same number as in the preceding week.

The largest returns of dysentery were Yorkshire West Riding 93 (Bradford C.B. 35, Leeds C.B. 14), Lancashire 87 (Irlam U.D. 19, Liverpool C.B. 15, Bolton C.B. 12), London 40 (Islington 11), and Surrey 28 (Croydon C.B. 10).

Scotland in First Quarter

The birth rate in Scotland for the first quarter of 1957 was 19.5 per 1,000 population and was 1.0 above the average of the five preceding first quarters. The infant mortality rate was 32 per 1,000 registered live births and the neonatal death rate was 19; these rates were respectively 1 above and 1 below the rate for the corresponding quarter of 1956. The death rate was 12.7; this was 2.3 below the rate for the preceding March quarter and 1.8 below the five years' average.

Deaths attributed to the principal epidemic diseases numbered 60 and included 29 from influenza, 17 from whooping-cough, 9 from measles, 4 from meningococcal infections, and 1 from scarlet fever. 203 deaths were ascribed to respiratory tuberculosis and 15 to other forms of tuberculosis. The death rate from respiratory tuberculosis was 16 per 100,000 population and was 12 below the five years' average. Deaths from road accidents numbered 103, and there were 591 deaths from other forms of violence; these were respectively 3 fewer and 19 more than in the first quarter of 1956. Deaths from malignant disease numbered 2,547, and were 104 fewer than in the first quarter of 1956.

Week Ending July 6

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 400, whooping-cough 1,631, diphtheria 3, measles 15,510, acute pneumonia 266, acute poliomyelitis 133, dysentery 462, paratyphoid fever 3, typhoid fever 2.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending June 29 (No. 26) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Medical News

Royal College of Surgeons.—As recorded elsewhere (p. 152), Sir JAMES PATERSON ROSS was elected president of the Royal College of Surgeons at the council meeting on July 11. Sir RUSSELL BROCK was re-elected a vice-president, and Sir ARCHIBALD MCINDOE was elected to similar office. The Blane medal was presented to Surgeon Commander S. MILES, R.N., by the Medical Director-General of the Navy, Surgeon Vice-Admiral R. C. MAY. Professor G. WALD, of Harvard, was appointed Edridge-Green lecturer for 1957, and Dr. D. J. TREVAN and Dr. D. C. ROBERTS were appointed Imperial Cancer Research Fund lecturers for 1957.

Society of Apothecaries.—The honorary freedom of the Society of Apothecaries was conferred on Sir ROBERT A. YOUNG, the distinguished chest physician, last Tuesday by the Master, Dr. MACDONALD CRITCHLEY. The society's gold medal in therapeutics was bestowed on Professor ERNST CHAIN, F.R.S., who played a leading part in the development of penicillin as a therapeutic substance.

Royal Society of Health.—Professor HAROLD BURROWS, professor of veterinary medicine in the University of London, presided last week at the annual luncheon of the council of the Royal Society of Health. Proposing the health of the guests, Professor Burrows mentioned that the society, which was 81 years old, was the largest public health organization in the world. Many representatives of local authorities were among the guests, and the speaker welcomed them with an unusual tribute: "Local authority," he said, "is a sweet word—it stands between us and dictatorship." After Mr. R. MCKINNON WOOD, chairman of the London County Council, had replied, Sir HARRY PLATT, P.R.C.S., proposed the toast to the society. Wondering why a surgeon had been chosen for this speech, Sir Harry remarked that surgeons were interested in health—that was in fact one of the benefits of surgery—and he quoted Sir John Bland-Sutton, who had described robust health as the greatest attribute of a surgeon. Sir ARTHUR MASSEY, chief medical officer to the Ministry of Pensions and National Insurance, replying to the toast, mentioned that the membership of the Society was 17,000, of whom 1,000 were Americans.

Knowledge of the Brain and its Functions.—On July 15 the United States ambassador, Mr. J. H. WHITNEY, opened an exhibition at the Wellcome Building in London. The exhibition aims to illustrate "The History and Philosophy of Knowledge of the Brain and its Functions," the theme of an Anglo-American symposium sponsored by the Wellcome Foundation as a curtain-raiser to the First International Congress of Neurological Sciences in Brussels (July 21-28). The exhibition contains panels prepared in the United States, illustrating the growth of knowledge of the brain from antiquity to the nineteenth century, including reproductions from many classical works. The Wellcome Museum and Library have supplied texts and documents concerning the principal contributions to neurology of Sir Charles Sherrington and Sir Victor Horsley, and skulls and models illustrating the development of trephining and phrenology. Among the exhibits are temperance posters sponsored by Horsley and the manuscript of a poem by Sherrington.

Amputees.—The Ministry of Health has issued a booklet (H.M.S.O., 2s. 6d.) entitled "The Rehabilitation of Amputees." It is intended to give "broad general principles which should be followed in rehabilitating an amputee." Remedial exercises are described in some detail. Various types of surgical amputation are discussed and artificial limbs and other appliances illustrated in use. The booklet was originally written by a committee under the chairmanship of Mr. R. LANGDALE KELHAM.

Lister Institute.—The latest report of the Lister Institute of Preventive Medicine gives a brief survey of some of the research being carried on there. Inheritance in bacteria is

being studied with *Salmonella* and *Escherichia*, and the many other bacteriological studies include an investigation into the aetiology of non-specific urethritis. Investigations into capillary permeability are being carried out for the light they throw on the mechanisms of inflammation, and they include studies of such substances as histamine and 5-hydroxytryptamine. Elaborate studies of the human blood group substances include researches into new methods of isolating them and an analysis of them in chimeras.

Fluoride Court Action.—Some citizens of Andover who oppose the borough council's action in adding sodium fluoride to the town's water supply are to seek a declaration in the High Court that the action is *ultra vires*. Andover is one of the four areas in Britain selected by the Ministry of Health to demonstrate the effects of fluoridated water. The other three are Anglesey, Kilmarnock, and Watford.

Research on Ageing.—The Ciba Foundation announces that the following have been awarded sums of £200 to £350 for papers on research relevant to the problems of ageing: Dr. HEDWIG SAXL (Leeds), Dr. G. F. WILGRAM (Toronto, Canada), Dr. R. J. BOUCEK (Miami, U.S.A.), Dr. B. T. DONOVAN (London) and Dr. J. J. VAN DER WERFF TEN BOSCH (Leyden) (jointly), Dr. R. F. HELLON (Oxford), Dr. H. G. ISLER (Montreal, Canada), Professor L. HARANGHY (Budapest), and Dr. PATRICIA LINDOP (London). The awards are being offered again in 1958, and the closing date for entries is January 1, 1958. Further information may be obtained from the Ciba Foundation, 41, Portland Place, London, W.1.

Foetal Metabolism.—The Royal Society has appointed Dr. M. J. R. DAWKINS to be Stothert Research Fellow from October 1, 1957. Dr. Dawkins will carry out research in foetal metabolism at University College Hospital Medical School.

Osler Club.—The annual dinner and oration took place on July 12, when Dr. W. S. C. COPEMAN presided. The orator was Professor CHARLES BEST, F.R.S., of Toronto, and Professor ROBERT PLATT and Sir ERNEST GOWERS also spoke. Other guests were the High Commissioner for Canada, the Italian, German, Swiss, and Costa Rican Ambassadors, H.E. Dr. Cheng, the Councillor of the Austrian Embassy, the vice-chancellor of the University of Adelaide, Lord and Lady Evans, Sir James Paterson Ross, and Sir Henry Dale. The orator described the history of the discovery of insulin, the joint achievement of the late Sir Frederick Banting and himself. He was at that time (1921) a fourth-year medical student who had forgone his long vacation to complete the relevant experiments.

Polio Research.—The National Fund for Poliomyelitis Research has made a grant of £35,000 to build, equip, and staff for three years an experimental resettlement unit in the grounds of the Nuffield Orthopaedic Centre, Oxford. The unit will be under the supervision of Professor J. TRUETA, Nuffield professor of orthopaedics. The hospital authorities have offered to supply the electricity, gas, water, heating, and catering for the new building. From the end of the third year it is planned, if the result is satisfactory, to continue the work of the unit under the authority of the Oxford Regional Hospital Board.

COMING EVENTS

Lung Function in Respiratory Illness.—Postgraduate medical course, September 9-13, Sully Hospital, Penarth, Glam., organized by the Joint Tuberculosis Council and National Association for the Prevention of Tuberculosis. Details from the secretary, Dr. HARLEY WILLIAMS, Tuberculosis Educational Institute, Tavistock House North, Tavistock Square, London, W.C.1. Fee for course £5 5s.

Eighteenth International Postgraduate Medical Course.—September 16-21, at Karlovy Vary (Carlsbad), Czechoslovakia. Papers in English, French, German, and Russian. Details from the Czechoslovak Physiatric Society, 7, Albertov, Prague, 2.

Medical Photography.—Eighth conference of the medical group of the Institute of British Photographers, September 20-22, Manchester. Open to all interested in medical illustration. Details from the medical secretary, Institute of British Photographers, 38, Bedford Square, London, W.C.1.

International Scientific Film Association.—XIth Congress in Amsterdam, September 21-27. There will be sessions on tropical medicine, "endoscopic cinema," and cineradiography. Inquiries to Scientific Film Association, 164, Shaftesbury Avenue, London, W.C.2.

Industrial Ophthalmology.—Postgraduate course, September 23-27, Birmingham and Midland Eye Hospital (fee £5 5s., or £2 12s. 6d. for morning sessions only). Details from the Secretary, Industrial Ophthalmology Course, Birmingham and Midland Eye Hospital, Church Street, Birmingham, 3.

World Congress of Doctors for the Study of Present-day Living Conditions.—Second international conference. Cannes, September 27-29. Details from the secretariat, Wollzeile 29/3, Vienna, 1, Austria.

Stoke Mandeville Games.—The annual games for partially disabled athletes from many countries will be held at Stoke Mandeville Hospital, Aylesbury, Bucks, on July 26-27, admission 2s. The DUCHESS OF GLOUCESTER will open the meeting at 11.30 a.m. on July 26 and the finals of the games will begin at 2 p.m. on July 27. During that afternoon Sir ARTHUR PORRITT will take the salute at a parade of the athletes.

NEW ISSUES

Thorax.—The new issue (Vol. 12, No. 2) is now available. The contents include:

THEORY AND PRACTICE IN THE USE OF A PUMP-OXYGENATOR FOR OPEN INTRACARDIAC SURGERY. John W. Kirklin, Robert T. Patrick, and Richard A. Theye.

THORACIC ACTINOMYCOSIS. Michael Bates and Gordon Cruickshank.
THE PATHOLOGICAL ANATOMY OF DEFICIENCIES BETWEEN THE AORTIC ROOT AND THE HEART, INCLUDING AORTIC SINUS ANEURYSMS. Jesse E. Edwards and Howard B. Burchell.

AGENESIS OF THE LUNG WITH PERSISTENT DUCTUS ARTERIOSUS. Rowan Nicks.

THE SIGNIFICANCE OF VASCULAR CHANGES IN AN ACCESSORY LUNG PRESENTING AS A DIAPHRAGMATIC CYST. D. Heath and G. T. Watts.
PERICARDIOTOMY FOR CONSTRUCTIVE PERICARDITIS. C. Havard.

A CRITICAL REVIEW OF THE RESULTS OF LUNG RESECTION FOR PULMONARY TUBERCULOSIS. B. J. Bickford, F. Ronald Edwards, J. R. Esplen, J. H. Gifford, O. F. Thomas, and J. K. B. Waddington.

THE SURGERY OF PRIMARY PULMONARY TUBERCULOSIS IN CHILDREN. J. T. Chesterman.

LONG-STANDING INTRABRONCHIAL FOREIGN BODIES. J. S. A. Linton.
MILITARY SHADOWS IN THE LUNGS DUE TO MICROLITHIASIS ALVEOLARIS PULMONUM. M. J. Greenberg.

A NOTE ON THE DIMENSIONS OF THE BRONCHIAL TREE. C. H. Barnett.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Archives of Disease in Childhood.—The new issue (Vol. 32, No. 163) is now available. The contents include:

THE NEPHROTIC SYNDROME IN EARLY INFANCY: A REPORT OF THREE CASES. H. McC. Giles, R. C. B. Pugh, E. M. Darmady, Fay Stranack, and L. I. Woolf.

ACUTE CEREBELLAR ATAXIA. D. G. Cotnam.
WATER DIURESIS IN CHILDREN AGED 1-3 YEARS. H. Schnieden.
CONGENITAL DIABETES MELLITUS AND NEONATAL PSEUDODIABETES MELLITUS. Gunnar Engleson and Per Zetterqvist.

DIABETES MELLITUS IN A 2-MONTH-OLD CHINESE BABY. Wong Hock Boon.
DIFFUSE PROGRESSIVE INTERSTITIAL FIBROSIS OF THE LUNGS IN CHILDHOOD. H. S. Barr and Frances Braid.

APPENDICITIS AND ENTEROBIASIS IN CHILDREN. F. Duran-Jorda.
EPIDERMOLYSIS BULLOSA HEREDITARIA "LETALIS": REPORT OF A CASE SURVIVING FOR TWO-AND-A-HALF YEARS. Henry K. Silver.

VACCINIA GANGRENOSEA AND AGAMMAEULINAEEMIA. Kris Somers.
A SUGGESTED MEDICAL CLASSIFICATION OF HANDICAPPED CHILDREN. K. S. Holt.

THE IMPORTANCE OF AUDITORY COMMUNICATION. L. Fisch.
FAILURE OF HYPERIMMUNE GAMMA GLOBULIN TO PREVENT WHOOPING-COUGH. David Morris and J. C. McDonald.

MALIGNANT HYPERTENSION DUE TO PHAEOCHROMOCYTOMA IN A CHILD. F. E. Higgins.
OS INTERMETATARSEUM. G. E. Dunkerley.

A CASE OF OSTEOSCLEROSIS WITH HYPERCALCAEMIA AND RENAL FAILURE. Ronald F. Fletcher.

EFFECTS OF A.C.T.H. ON A CASE OF TUBERCULOUS MENINGITIS. I. M. Leck.
TRANSIENT RASH AND HAEMATURIA AFTER EXERCISE AND EMOTION. R. S. Illingworth and K. S. Holt.

Issued six times a year; annual subscription £3 3s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Annals of the Rheumatic Diseases.—The new issue (Vol. 16, No. 2) is now available. The contents include:

CORTICOSTEROID METABOLISM AND RHEUMATOID ARTHRITIS. H. F. West.
HAND DEFORMITIES IN RHEUMATOID DISEASE. D. A. Brewerton.

ELECTRON MICROSCOPIC STUDY OF THE EFFECT OF PROLONGED HEAT AND ULTRA-VIOLET LIGHT ON HUMAN DERMIS FROM DIFFERENT AGE GROUPS. M. K. Keech and R. Reed.

INTRA-CUTANEOUS CONGO RED IN RHEUMATOID ARTHRITIS. F. T. Shannon, W. J. Fessel, and E. G. L. Bywaters.

MYALGIC SYNDROME WITH CONSTITUTIONAL EFFECTS. H. Stuart Barber.
HYALURONIC ACID IN HEBERDEN'S NODES. D. S. Jackson and J. H. Kellgren.

HONEYCOMB LUNG AND CHRONIC RHEUMATOID ARTHRITIS. A. St. J. Dixon and J. Ball.
EMPIRE RHEUMATISM COUNCIL ANNUAL REPORT, 1956.
HEBERDEN SOCIETY ANNUAL REPORT, 1956.
NEW ZEALAND RHEUMATISM ASSOCIATION.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Abstracts of World Medicine.—Issued in the first week of each month, this journal contains abstracts of important papers selected from the current medical literature of the world. Annual subscription £4 4s., single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked •. Application should be made first to the institution concerned.

Monday, July 22

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.—5.30 p.m., special university lecture by Dr. G. C. Paffenbarger (American Dental Association, Research Division): Transfer of Research Findings in Dental Materials to the Practice of Dentistry.

NUFFIELD DEPARTMENT OF PLASTIC SURGERY.—At Maternity Department Lecture Theatre, Radcliffe Infirmary, Oxford, 6 p.m., lecture on plastic surgery by Professor Frantisek Burian (Prague): Some Problems About Cleft Lip and Cleft Palate.

Wednesday, July 24

BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—At 36 Harborne Road, Edgbaston, 8 p.m., Professor J. Elkes: Neuropsychological Agents: Methods of Assessment in Animals and Man.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.—5.30 p.m., special university lecture by Professor M. Massler (Illinois): Dentistry for Children: Histological Background to some Clinical Problems.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Urology Lecture by Dr. F. K. Mostofi: Genito-Urinary Tumours in Children.

Thursday, July 25

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—At Hospital for Tropical Diseases, 4, St. Pancras Way, N.W., 7.30 p.m., clinical meeting.

Friday, July 26

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. F. H. Scadding: clinical demonstration.

APPOINTMENTS

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—M. S. Luckhoo, M.B., Ch.B., Medical Registrar, North Cambridgeshire and Clarkson Hospitals, Wisbech; G. A. D. Lavy, M.B., B.Chir., F.R.C.S., Surgical Registrar, Norfolk and Norwich Hospital; M. C. G. Mantell, M.B., B.Chir., Anaesthetic Registrar, West Suffolk General Hospital; W. J. Abel, M.B., Ch.B., M.R.C.P.Ed., D.P.M., Consultant Psychiatrist, Hellesdon Hospital.

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—Audrey S. Willis, M.B., B.Chir., M.R.C.P., Senior Medical Registrar at Frenchay Hospital, Bristol; R. K. Greenwood, M.B., B.Chir.(Cantab.), F.R.C.S., Surgical Registrar at Gloucestershire Royal Hospital, Gloucester; D. J. H. Barlow, M.B., B.Ch., Registrar in Psychiatry at Moorhaven Hospital, Ivybridge, S. Devon; G. N. Lumb, M.B., B.S., F.R.C.S., and H. M. Pringle, M.B., B.S., Surgical Registrars in Bath Group of Hospitals.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Brentnall.—On July 1, 1957, at University College Hospital, London, W.C., to Hazel (formerly Otridge), S.R.N., and Edward W. Brentnall, M.B.E., M.B., B.S., a daughter—Jane.

Dobson.—On July 8, 1957, to Margaret (formerly Barker), M.B., Ch.B., wife of Sydney F. Dobson, Stockport Road, Marple, Cheshire, a third son.

Hayhurst.—On July 5, 1957, at Plateau Nursing Home, Jos, N. Nigeria, to Mabel, wife of R. J. Hayhurst, M.B., Ch.B., a son.

Hingorani.—On July 8, 1957, at Sunderland General Hospital, Sunderland, to Vera Hingorani, M.B., B.S., D.R.C.O.G., wife of Dr. I. B. Hingorani, a daughter—Monica.

DEATHS

Collar.—On July 4, 1957, at his home, Bridgethorpe, Lympstone, Exmouth, Devon, Frank Collar, M.R.C.S., L.R.C.P.

Cruickshank.—On July 3, 1957, at Ridgeway, Long Crendon, Bucks, Adam Lind Paterson Cruickshank, M.B., C.M., aged 89.

Dowling.—On July 2, 1957, at The Gleanings, Folkestone, Kent, Francis Thomas Dowling, M.B., B.Ch., Lieutenant-Colonel, R.A.M.C. (retired).

Woodforde.—On July 2, 1957, at Weston-super-Mare, Somerset, Robert Edmund Heighes Woodforde, M.R.C.S., L.R.C.P., formerly of Ashwell, Herts.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Exanthem Resembling Measles

Q.—For the past few years I have been struck by the increasing incidence of an illness which looks like measles but yet apparently is not. It occurs in infants and toddlers. There is a very definite widespread morbilliform rash, with a distribution exactly as in measles, but there are no Koplik spots, no coryza, etc. Usually the child is not ill, or, if so, then for a few hours only; and the malaise is not in proportion to the rash. Post-eruption staining is not marked; certainly less so than with measles. Such children frequently develop true measles at a later date. Is this a clinical entity, and, if so, what is its cause? Is there any practicable method (laboratory or otherwise) of clinching the diagnosis in these cases?

A.—Infection with adenovirus (A.P.C. virus) or with one of the Echo viruses may produce rashes. These rashes are usually too sparse or fleeting to suggest measles, although sometimes they are well developed and resemble rubella. They are accompanied by mild upper respiratory symptoms, and often other members of the household suffer from similar respiratory symptoms. Garglings and faeces may be sent for virus isolation and acute and convalescent samples of serum for antibody titration.

Rubella itself occurs in young children, and in the absence of well-marked adenitis is not always easy to diagnose from measles. Exanthema subitum (roseola infantum or pseudo-rubella) occurs in children over 6 months and under 2 years old. There is a short sharp febrile illness lasting for a day or two, followed by a rash resembling rubella. When the rash is out, the child appears quite well. It is not very infectious as a rule, but outbreaks have occurred in nurseries. There is no laboratory method of clinching the diagnosis.

Genito-urinary Tuberculosis and Absence of Ejaculate

Q.—Following genito-urinary tuberculosis treated with antibiotics, a patient complains of inability to achieve an emission. He has no difficulty in obtaining an erection and orgasm. (1) Is this a well-recognized complication of genito-urinary tuberculosis, and, if so, what is the anatomical nature of the lesion? (2) The patient is extremely anxious to have a child. What treatment is advised and what is the prognosis?

A.—(1) The absence of seminal emission is a complication of genito-urinary tuberculosis which is becoming more generally recognized owing to the increasing interest in male subfertility. Diminution or absence of ejaculatory fluid can be due to (a) congenital absence of the vesicles, (b) regurgitation of the vesicular fluid back into the bladder rather than forward into the membranous urethra, (c) a moderately severe urethral stricture, perhaps again causing regurgitation into the bladder, or (d) tuberculous destruction of the vesicles. It is assumed in the case described that the absence of emission is recently acquired, thus excluding a congenital lesion. The presence of a urethral stricture will have been excluded during the urological treatment of the disease, as also will gross destruction of the prostatic cavity by tuberculosis, which could also allow regurgitation of vesicular fluid. By far the most likely lesion is tuberculous involvement of both seminal vesicles. Since practically all of the ejaculate fluid comes from the vesicles, their destruction leads to a progressive diminution in the volume of the ejaculate and finally complete absence of emission. The slow destruction of the vesicles may produce no specific symptoms and the patient may be quite unaware that he

has any disease at all unless he notices the diminution in the volume of the ejaculate. It is not uncommon to find bilateral vesiculitis without any involvement of the vasa or epididymides, so that the patient may retain a high sperm density in spite of a progressively diminishing ejaculatory volume, until finally there is insufficient ejaculate fluid to carry the sperms to the exterior. Alternatively if both vasa or epididymides, but only one vesicle, were involved, the patient would be azoospermic though having an ejaculatory volume within normal limits.

(2) The questioner does not state the degree of involvement of the genital tract, but the prognosis regarding fertility must be considered very bad. If both vasa or epididymides are involved the patient will be permanently sterile. If one epididymis, vas, and ampulla are patent the prognosis may not be quite hopeless. The ejaculatory volume tends to vary considerably before it finally disappears, and there is a remote possibility that some function may return to one vesicle or that its duct may discharge its caseous contents and open up again. I do not think that any active treatment in the nature of trying to catheterize the ejaculatory duct would be of any great help, though it should obviously be attempted. The possibility that sperms are reaching the ampulla but are not being carried along by vesicular fluid should also be investigated. If sperms can be obtained from the prostatic urethra or bladder the possibility of artificial insemination could be considered.

Bathroom Aids for Elderly Arthritics

Q.—What aids are useful in helping elderly arthritic patients, particularly those with arthritic hips, in getting out of their baths?

A.—The requirements are: (1) A bathroom stool the same height as the top rim of the bath; (2) a seat within the bath, which may be a board which fits across the inside of the bath and is held securely by integral rubber-covered wedges which grip the sides of the bath, or a small teak bath stool designed for the purpose; (3) a handrail securely fixed to the wall or top rim of the bath; (4) a rubber mat for the floor of the bath held in position by suction cups.

The patient first sits on the bathroom stool as close as possible to the edge of the bath. The legs are lifted into the bath, aided by the hands if necessary. Grasping the handrail and the side of the bath, he then transfers his buttocks from the bath stool on to the seat in the bath. Most patients can lower themselves from the bath seat to the floor of the bath, and the rubber mat helps to prevent their feet slipping. For those who cannot do so, the Levit bath lift can be used. It comprises a bath seat which is raised or lowered by hydraulic pressure from the bath tap.

Aetiology of Toxaemia of Pregnancy

Q.—What are the more convincing theories regarding the aetiology of toxæmia of pregnancy currently held? Which appears the most acceptable?

A.—The term "toxæmia of pregnancy" is still used to describe pre-eclampsia, since in the past the condition was thought to be due to a toxin coming possibly from the bowel or from placental infarctions. There is now an increasing tendency to believe that the condition is due to an upset in the normal physiological changes which occur in pregnancy, possibly an endocrine imbalance. It seems probable that the pituitary and adrenal glands are very much concerned.

The facts that the disease occurs typically in primigravidae, and that even if it has been severe in the first pregnancy it seldom recurs in the second, suggest that the mother acquires an "immunity" or in some way learns to make adjustments more effectively to the changes of pregnancy. But speculation on its aetiology seems hardly worth while at present and the current tendency is rather to collect facts. This should be much more possible in the future than it has been in the past, since methods of assessing

placental function and measuring the output of some of the hormones are now becoming available. In normal pregnancy considerable changes occur in various physiological processes—*inter alia*, alterations in distribution and volume of the body fluids and their chemical constitution. Many of these substances have been found in abnormal amounts in pre-eclampsia. Such substances are the pressor amines, antigens, "toxic" proteins, and thromboplastin, but there is no convincing evidence that they are of aetiological significance. It is unlikely that a single substance could cause the widespread changes occurring in pre-eclampsia.

The observations that pre-eclampsia may occur in the early months of pregnancy in a very severe form in cases of hydatidiform mole, and that the incidence of the condition is much increased in twin pregnancy, suggest that the output of chorionic gonadotrophin plays a part. Excessive weight gain during the middle trimester of pregnancy predisposes to pre-eclampsia. The calorie intake seems to be more important than the quality of the diet. Nevertheless a similar or even greater weight gain in a second pregnancy is not usually accompanied by a recurrence of the condition. Such clinical features as hypertension, oedema, and albuminuria are likely to be end-results rather than primary changes.

Safety of Chlorpromazine in Haemorrhagic Shock

Q.—Is the administration of chlorpromazine (with morphine) to a patient suffering from mild shock due to blood loss (a haematemesis) likely to precipitate collapse? The latter occurred in the absence of any clinical evidence of further haemorrhage. Does considerable blood loss contraindicate its use?

A.—The details in this question provide insufficient basis for a conclusive answer. For example, the initial signs of shock may have been mild despite a very serious blood loss (compensated by vasoconstriction). It is stated that there were no clinical signs of further haemorrhage, but surely the subsequent collapse may have been such a sign. The dose and route of administration of the drugs are not stated.

There are a considerable number of reports of the use of chlorpromazine and opiates with satisfactory results in shocked patients; indeed, some workers have enthusiastically advocated this method of treatment. Recent experimental work has failed, however, to demonstrate a specific protective effect of chlorpromazine against haemorrhagic shock in animals.

Certainly in "mild shock" moderate dosage of chlorpromazine (25 to 50 mg.) combined with morphine (15 mg.), given intramuscularly or by slow intravenous infusion, must be considered reasonable treatment. Despite the fact that it is a vasodilator, facial pallor often follows the administration of chlorpromazine and mental apathy is a characteristic effect. Such signs (similar to those of established shock) might have been interpreted as collapse. The rapid intravenous injection of chlorpromazine and morphine in the compensatory phase of shock would lead to tachycardia and fall of blood pressure. If there has been considerable blood loss, this combination of drugs, if used, should be given by slow intravenous infusion and only in sufficient dosage to produce the required degree of sedation.

NOTES AND COMMENTS

Tumour Infiltration.—Drs. F. N. GHADIALY and G. WISEMAN (Sheffield) write: In answer to a question on the problem of tumour infiltration ("Any Questions" June 15, p. 1430) your expert suggests that a major role is played by pressure created by the growing tumour at the junction of the neoplastic and normal tissue. He suggests that infiltration depends on the lack of appreciable pressure, and, because of that, lack of formation of a resistant connective tissue capsule. Although this concept has been often suggested and accepted, it does not appear to us to be an adequate explanation of the important phenomenon of the ability of neoplastic cells to infiltrate normal tissues. The pressure hypothesis suggested supposes that the pressure produced will act locally and will not produce appreciable effect

away from the growing edge of the tumour. This seems unlikely in the absence of a resistant capsule or membrane, and we suggest that the pressure which is caused by the increasing tumour mass will be transmitted fairly equally throughout the fluid system of the combined tissues in the area (cellular and extracellular). A localized increased pressure could, of course, be built up within an encapsulated area after a resistant membrane has been formed. Further, it is difficult to see why the supposed increase in pressure, reducing the blood supply to the neoplastic-normal tissue interface, should kill the normal cells but leave the neoplastic cells undamaged. An objection to the concept of an appreciable rise in pressure at the neoplastic-normal tissue interface, producing ischaemia and death of cells, is supported by the known facts about the blood supply of the neoplastic-normal tissue interface. A nodule of growing tumour is most vascular at its periphery,¹ and it is the centre which is poorly supplied with blood and hence often necrotic. Thus the ischaemia postulated by the supporters of the pressure concept seems to us to be unlikely to exist. Instead of viewing infiltration of normal tissues by neoplastic cells as being due to the lack of a restraining capsule, we wish to suggest in its place the most likely explanation of tumour infiltration—namely, the metabolic superiority of the neoplastic cell. By metabolic superiority we mean the superior ability of the neoplastic cells (compared with normal cells) to capture from the environment in which they and the normal cells live (the sea of the extracellular fluid) materials vital for growth and multiplication. When such superior ability is sufficiently advanced the normal cells are unable to compete effectively for the essential metabolites, and degeneration and death of the normal cells occur. It is for this reason, in our opinion, that the normal cells at the periphery of the growing tumour suffer most. This hypothesis has good experimental fact in support of it. During the past few years it has been shown that certain neoplastic cells (Ehrlich ascites tumour cells; RD₂ sarcoma cells) are able to capture amino-acids from the extracellular fluid to an extent surpassing that of normal tissue.^{2,3} Also, the competition by the amino-acids for the cellular uptake mechanism is of such a nature as to affect the neoplastic cells less than the normal cells, and this has been shown *in vitro* and *in vivo*.⁴ It seems likely to us that neoplastic cells are probably superior in their ability to capture not only amino-acids but other essential materials. Thus we may picture the normal cells at the edge of a growing neoplasm being deprived of essential metabolic materials, and, on their death, their position being taken by the neoplastic cells. Less malignant—that is, less metabolically superior—growths will therefore advance slowly and evenly as compared with the more malignant neoplasms. Briefly, then, one could say that infiltration is merely the expression of the metabolic superiority of the tumour cell over the surrounding normal tissue. Benign tumours probably have little or no metabolic superiority, with the result that they grow slowly and do not infiltrate.

THE AUTONOMIC NERVOUS SYSTEM IN ITS RELATION TO SOME FORMS OF HEART AND LUNG DISEASE*

I. HEART DISEASE

BY

RAYMOND DALEY, M.D., F.R.C.P.

Physician to the Cardiac Department, St. Thomas's Hospital; Consulting Physician to the Chelsea Group of Hospitals

William Harvey performed several experiments on a son of Count Montgomery, a friend of King Charles I. The poor child had suffered a severe accident which left him with his heart exposed and its beating easily seen. Touching the heart produced no sensation. Therefore it was assumed that the seat of the soul was insensitive. What, then, is the cause of cardiac pain? Is it direct mechanical stimulation or the product of anoxaemia? Before trying to answer this question I should like to remind you of the anatomy and physiology of the cardiac nerve supply.

Anatomy

The sympathetic fibres arise from cells in the inter-medio-lateral grey columns of the first to the fourth or the second to the fifth thoracic spinal segments. They pass as white or mixed rami communicantes from the spinal nerves to the ganglia of the paravertebral sympathetic trunks. Communication with the heart is made by the superior, middle, and inferior cervical nerves. They all send many filaments to form the cardiac plexus, which is situated between the heart and arch of the aorta and between the aortic arch and tracheal bifurcation. The superior cervical sympathetic cardiac nerve also sends fibres to the pre-aortic plexus which overlies the ascending aorta. The thoracic cardiac nerves arise on each side from the second to the fourth or fifth thoracic sympathetic ganglia and enter the cardiac plexus directly, or having united and then parted from other sympathetic fibres destined for different mediastinal structures. Efferent accelerator fibres and afferent pain fibres pass in these nerves.

The parasympathetic nervous supply to the heart is by the vagi which have synaptic connexions in the ganglia of the cardiac plexus or in the intrinsic cardiac ganglia. The cardiac fibres arise in the neck and thorax in three groups—superior, middle, and inferior—which interconnect with sympathetic branches and other nerves (Mitchell, 1956).

From the cardiac and pre-aortic plexuses many branches containing sympathetic and parasympathetic fibres pass to the pulmonary vessels and caeae. Others pass to the coronary arteries, forming plexuses and supplying them. Much smaller fibres leave the vicinity of the coronary arteries and ramify over the surface of

*The first Goulstonian Lecture, delivered at the Royal College of Physicians of London on January 17, 1957.

the heart and penetrate the myocardium even as deeply as the subendocardial layer. The foci of impulse formation and the paths of impulse conduction in the heart are well supplied with bundles of nerve fibres. Finally, there are a number of intrinsic cardiac ganglia, especially in the atria and the atrio-ventricular grooves.

Afferent impulses arising in the heart travel centrally by the vagi and sympathetic nerves. There has been much discussion of the proportion of atria and ventricles supplied by each system. Much of the experimental evidence surrounding this discussion has been obtained by ablation experiments and subsequent observation of the site of nerve degeneration. One fairly widely accepted thesis was that of Woollard (1926), who was later supported by Nettleship (1936). It was found that after removal of the stellate ganglion there was considerable degeneration of nerve fibres in the media of the larger coronary arteries, but that there was much less degeneration in the smaller arteries and arterioles. It was thought that the larger arteries were supplied by both sympathetic and parasympathetic fibres. If this is so, it suggests that the parasympathetic mainly supplies the larger vessels of both ventricles but plays little part in the supply of the adjacent myocardium.

Physiology

Reflexes from the Cardiac Wall

Most of the information concerning reflexes from the cardiac wall has been derived from innervated heart-lung preparations or from cross-circulation techniques in which blood flowing through either side of the heart is isolated.

De Burgh Daly and Verney (1926) found that in an innervated heart-lung preparation with constant aortic pressure increasing pressure in the left side of the heart led to cardiac slowing. Subsequent workers have shown that this reflex arises in the left ventricle and is abolished by division of the vagi. Similar experiments on the right heart reveal that increasing right-sided perfusion pressure causes bradycardia and hypotension, which are not necessarily dependent upon each other. This reflex originates in the right auricle and again is abolished by division of the vagi.

It will at once be seen that the view of Bainbridge (1931) that the tachycardia of exercise is due to a rise

in right auricular pressure is contradictory to these experimental findings. Also, Lagerlöf and Werkö (1948) have shown that during exercise the right auricular pressure rarely rises and often remains the same or even falls slightly. It has been suggested by Kao and Ray (1954), using cross-circulation experiments in which the exercising hind legs of a dog are perfused by a donor animal, that the increased cardiac output of exercise is a neural and humoral mechanism originating from the exercising legs. This state of affairs is not true of diseased hearts, when exercise is accompanied by a rising right auricular pressure. In the fibrillating heart Blumgart (1924) found that exercise produced an initial slowing of ventricular rate followed by a prolonged increase. Atropinization of such patients eliminates these rate changes.

It is becoming increasingly probable that such rate and blood-pressure changes are due to varying pressure transients activating baroreceptors located in many parts of the heart and great vessels.

Reflexes from the Coronary Vessels

Inhibitor and constrictor fibres are said to predominate in the vagus, and dilator and accelerator fibres to predominate in the sympathetic nerves. Gregg (1950) reports that Eckstein *et al.* observed a considerable decrease in coronary inflow when the peripheral vagi were stimulated and in the presence of a somewhat lower blood pressure.

Stimulation of the stellate ganglion increases coronary inflow without necessarily a concomitant change in heart rate or blood pressure. It also increases the vigour of contraction.

Whether these are true reflex mechanisms remains unknown, and it is quite possible that they are chemico-metabolic responses. Similarly, despite a great deal of experimental work, there is no definite information that the autonomic nervous system plays an important part in the cardiogenic shock of coronary occlusion. After reviewing the available evidence Aviado and Schmidt (1955) state that: "The management of myocardial infarction is influenced by judgment as to the state of the heart and peripheral circulation. Those who regard a primary reflex vasodilation from cardiac receptors as a protective mechanism to reduce heart work while regarding a secondary reflex vasoconstriction from the low pressure in the carotid sinuses as harmful have proposed two procedures; veratrum alkaloids intravenously and procaine block of carotid sinuses. Those who regard the state of hypotension as harmful because it further reduces coronary blood pressure have proposed the use of pressor amines. These diametrically opposite therapeutic interventions epitomize the unsatisfactory state of existing evidence bearing on the significance of coronary reflexes."

Cause of Coronary Pain

The circumstance causing cardiac pain appears to be a disproportion between the inflow of the proper quantity of coronary blood of adequate quality, and the work of the heart. It remains unknown whether it is oxygen deficiency in coronary arterial blood which is directly responsible for stimulation of pain-carrying afferent nerve endings or whether oxygen deficiency alters myocardial metabolism, leading to nerve stimulation by excessive or abnormal metabolites. It is not disputed that relative anoxia is essential for the production of pain, but it must be realized that the metabolic effect of myocardial ischaemia is slight or absent if the oxygen supply and demand are proportionately reduced, as in hypothermia. When the oxygen-carrying capacity of blood is reduced as in anaemia, angina pectoris is likely, especially if there is pre-existing coronary narrowing. Breathing such a mixture as 10% oxygen in nitrogen is likely to provoke attacks of angina in those subject to them, although I do not wish to suggest that I regard such a manoeuvre as a test of coronary integrity, because I do not. Experimental occlusion of a coronary artery leads to myo-

cardial necrosis. It is therefore probable that myocardial anoxia of less intense degree and of briefer duration is invoked in the pain of angina pectoris. The pain of myocardial infarction is sometimes improved by inhalation of oxygen, even in the absence of pulmonary oedema and central cyanosis, presumably by increasing arterial oxygen tension and plasma oxygen content. When myocardial anoxia becomes extreme ventricular fibrillation is very likely, and, as Bing (1955) has pointed out, the metabolic changes within the heart muscle are then very extensive. The glucose, pyruvate, lactate, and potassium concentration in coronary-vein blood are elevated above those in arterial blood.

The problem of coronary spasm is also unsolved. The evidence in favour of its occurrence is the occasional attack of angina at rest unaccompanied by tachycardia; sudden death without evidence of major coronary arterial occlusion; and as an explanation for the mechanism of action of small doses of nitroglycerin when it is effective in relieving pain without alteration in cardiac output or blood pressure. The evidence against the occurrence of spasm is that tachycardia is far from universal even when coronary occlusion is known to have occurred; that properly authenticated reports of sudden cardiac deaths without arterial disease are very rare, especially if injection studies are made; and that, as described below, there is another explanation for the action of nitroglycerin. Coronary flow does vary greatly and is altered by various reflex mechanisms, but whether these changes are associated with primary changes of arterial calibre or are due to altered cardiac output on coronary arterial filling pressure is not known. I feel that, while spasm of any tube in the body may occur, until it is proved to me I regard it as a resort of the diagnostically destitute.

To this maze of contradiction and conjecture I should like to add further conjecture of my own.

A Curious Example of Anginal Pain

Mackenzie's hypothesis of segmental and extrasegmental sensory irradiation is used to explain the wide somatic reference of anginal pain and may extend to include any or all dermatomes from the third cervical to fourth thoracic, and the occurrence of facial pain indicates a very widespread irradiation. In rare patients in whom the peripheral site of the pain affects chiefly the temple, cheek, and jaw but spares the nose and central parts of the face, it suggests that there is a central origin and is consonant with excitation of the lower part of the sensory nucleus of the fifth nerve, which extends into the cord as far as the second cervical segment. Cardiac pain may be accompanied, or even replaced, by erythema or sweating in the area of pain reference. Also at the height of the pain there may be excess salivation, colour changes, and polyuria. Succeeding the pain there may be disordered muscle function and trophic skin changes. All these phenomena can hardly be explained otherwise than as viscerosensory reflexes excited by irradiation from cardiac ischaemia.

In 1945 Dr. Henry Miller and I had a patient under our care who demonstrated some of these things most dramatically (Miller and Daley, 1946).

An officer aged 48 was well until August, 1943. At this time, and at the end of a strenuous ten-day battle course, he was climbing a high wall when he had a sudden attack of severe gripping pain in the chest accompanied by breathlessness. At 3.30 the next morning he was awakened by a severe pain in the left elbow and forearm. Later exertion produced well-defined pain and tingling in the ulnar forearm and fingers, and if the exertion was continued the pain spread to the radial side of the hand and to the thenar muscles.

One day in October he was cycling uphill and already feeling rather breathless, when he suddenly became aware that his left eye was running and that tears were streaming down his face on this side. He attributed this to the cold wind, and when he dismounted his bicycle five minutes later there was a burning pain on the left side of his face affecting chiefly the temple, eye, cheek, and angle of the

lower jaw. At the same time he noticed that his left face felt warm and sticky. He lectured for nearly an hour in this condition, and was then suddenly seized by a severe pain which was mid-sternal and involved the whole of the left forearm and hand simultaneously.

From this time on all the severe attacks began in the same way—with watering of the left eye, followed by pain in the left face, which was observed to be warm, congested, and moist to the touch. He noticed that if he sat down at the onset of lacrimation the subsequent chest pain was much less severe.

He continued thus until mid-December. One afternoon, just as he was recovering from an attack of postprandial exertional pain, he had his photograph taken. When this picture came back from the printers he noticed that his left eye was practically closed. This was the first occasion on which ptosis was noted, and after this time he observed a gradual drooping of the left lid simultaneously with the onset of the other ocular symptoms in every attack. The ptosis was such that in a severe attack he could not see except by raising the lid manually.

When he inhaled amyl nitrite the chest and arm pain gradually disappeared over a period of time up to about fifteen minutes, depending on their severity. The pain in the face disappeared simultaneously, but the drug had no effect on the weeping or the ptosis. Careful inquiry showed that the weeping and ptosis were always accompanied by mild mid-sternal discomfort and dyspnoea, and always followed by facial pain, and then by chest and arm pain unless he rested absolutely at the onset.

The following observations were made during the half-hour preceding the onset of chest pain. The pulse rate showed no change, but the blood pressure rose. There was flushing of the whole of the left face with hyperhidrosis, extreme conjunctival congestion, left pupillo-dilatation with retention of normal pupillary reactions (evident only in a dim light and therefore sympathetocotonic), striking dilatation of the retinal veins on ophthalmoscopy, and left ptosis of moderate degree and gradual onset. Electrocardiography during an attack showed inversion of T II. Conjunctival instillation of one drop of 1/1,000 adrenaline, carried out at his suggestion, revealed left sympathetocotonia as shown by left pupillo-dilatation, the right pupil being unaffected. Radiological examination of the skull was normal.

The phenomena described above as preceding and accompanying the patient's attacks of angina pectoris are not easy to explain. The features shown in the face and eye appear to comprise two clearly defined components. First, there is evidence of irritation of the cervical sympathetic in lacrimation, hyperhidrosis, vasodilatation, pupillo-dilatation, and abnormal pupillary response to adrenaline. Secondly, there is evidence of a partial paralytic lesion of the third cranial nerve, in ptosis and paresis of the superior rectus muscle, producing diplopia.

Wide irradiation of different impulses in the spinal cord might be related to the first group of symptoms, but would not explain the second. Of intermittent pressure from a dilated or aneurysmal vessel within the skull the reverse is true. Yet the constant association and close time-relation of the two components of the syndrome indicate the probability of an equally close relation in their mode of production.

The sympathetic pupillo-dilator fibres originate in cells of the posterior hypothalamic nuclei, having connexions there with cortical levels, and they pass down through the medulla and cervical spinal cord in close relation with the pyramidal tracts, to terminate in the cilio-spinal centre situated in the lateral horn of grey matter at the levels of the eighth cervical to the second thoracic segments. Here pre-ganglionic fibres originate, and, passing out with the lowest cervical and upper two thoracic anterior roots, make their way via the white rami communicantes to the inferior cervical (stellate) ganglia. These fibres course up the sympathetic chain to the cell-station in the superior cervical ganglia, where post-ganglionic fibres arise to be distributed

to the eye by way of the coat of the internal carotid arteries and their branches. The sympathetic supply to the other parts concerned in Horner's syndrome—the tarsal muscles, the muscle of Müller, the facial sweat glands, and blood vessels—follow a similar, if less clearly defined, route.

These two pathways, the one afferent and the other efferent, therefore have part of their course (between the stellate ganglion and the spinal cord) in common, except that the bulk of the afferent fibres probably pass in the posterior, and the bulk of the efferent fibres in the anterior, roots of the same segments. More significantly, their cell-stations within the spinal cord are in close proximity. The cilio-spinal centre lies in the lateral horn of the grey matter between the eighth cervical and second thoracic segments, with the related sympathetic efferent cell-stations close by, while the synaptic connexions between the cardiac visceral afferents and the cells of origin of the spino-thalamic tract lie at the base of the posterior horns at the same levels of the cord.

In the present case, therefore, it is suggested that the sympathetocotonic phenomena were due to central irradiation within the spinal cord. The nature of the recurrent partial paresis of the oculo-motor nerve indicates a peripheral lesion, recoverable and probably involving only the superior ramus of the nerve that supplies the two muscles involved (levator palpebrae superioris and superior rectus). The delayed onset and slow recovery of the third-nerve signs support a mechanical causation, and it is suggested that the paresis may have been due to local pressure on the superior ramus of the nerve by a dilated artery. The anterior site of the third-nerve involvement, and the failure to elicit any evidence of impaired function in the first division of the fifth nerve on repeated testing during and between attacks, suggest that the ophthalmic artery or one of its branches rather than the internal carotid was responsible, and in its distension both the widespread sympathetic vasodilatation and pre-anginal rise in blood pressure may have played a part.

This patient, of course, had most florid and unusual symptoms, but the following are more common. Facial pallor and sweating are often seen in patients suffering from myocardial infarction. At times the sweats may be drenching and sometimes precede by several hours the time when the infarction, as judged by other means, is believed to have occurred. On other occasions sweating is limited to the left shoulder or to the hand and arm, which is painful. I have seen a patient who had severe angina pectoris at rest in bed, and when it developed the painful left hand became as white as the sheet on which it lay and left a pool of moisture. The painless right hand remained pink and dry. Within a few minutes of the cessation of pain both hands become normal and alike. These phenomena are presumably sympathetically mediated.

The stiff and painful shoulder which may follow myocardial infarction, usually several weeks after the attack, is always more severe in the shoulder to which the pain is referred and hence is more common on the left side. The symptoms may vary from only mild stiffness to complete inability to use the shoulder, the so-called "frozen shoulder." They have a natural tendency to remission, as do "frozen shoulders" unaccompanied by heart disease, but this may take up to two years, and even then recurrence is likely.

When cardiac pain is particularly severely felt in one or other arm it has been followed by swelling and stiffness. At a later stage there may also be pain and swelling of the small joints of the hand with glossy skin, purplish-red discoloration, irregularity of the nails, trophic ulceration of the hand, and even a Dupuytren-like contracture.

The aetiology of these "shoulder-arm-hand" syndromes is far from clear. One theory has been that disuse of the shoulder has exaggerated a mild pre-existing peri-arthritis. Also, disuse has been blamed for the arm changes analogous to the changes in an arm after prolonged encasement in plaster. Such explanations are not satisfactory, because it

is not a feature of patients with coronary infarction to keep their arms still, and it is well known that angina pectoris is not precipitated by arm movements as in bench workers. An alternative theory is that as cardiac pain produces vasoconstriction the changes are due to anoxia. This, of course, does not adequately explain the occasional delayed onset, often several weeks after the cessation of cardiac pain, or that when "shoulder-arm-hand" stiffness and pain do accompany cardiac pain nitroglycerin relieves the latter and not the former.

As in so much of medicine, aetiology may be suggested by therapeutic response, and in this instance, while physiotherapy in its more conventional forms may alleviate, a most successful form of treatment is repeated stellate ganglion block. The aetiology which this suggests is no more than an implication of the sympathetic nervous system, but it is a beginning of understanding.

Excessive flatulence, bloating, and belching are well known to occur frequently with myocardial infarction or angina pectoris. Two examples of this stand out in my mind. The first, an obese middle-aged squadron leader at the end of the war was given a farewell demobilization dinner. At the end of the evening he had painless uncontrollable belching. He later had a sleepless night with a feeling that "I want a flue brush to clear my swallowing tube." He had a posterior infarction. The second patient did not have an infarction or even chest pain on exercise, but at the long second hole of his golf course he began to belch, and this recurred for about half the round before he literally lost his first wind. The occurrence of decreasing anginal pain on continued effort has, of course, been described before. Some months later the electrocardiogram became abnormal, revealing the cause of his disability.

This gas can clearly reach the stomach only by air-swallowing. The situation is somewhat comparable to the belching which often accompanies paroxysmal tachycardia. I have watched two patients who have developed paroxysmal tachycardia while being observed on the x-ray screen, and, as the paroxysm continued, so did the stomach fill with air. In them it was not excessive gastric distension which precipitated the attack but that during the attack uncontrollable air-swallowing occurred. This is regarded as a further example of a visceral-reflex mechanism.

Some Other Examples of Visceral Cardiac Reflex Mechanism

I should like here to discuss the relationship between the knuckle form of hiatus hernia and angina pectoris. The pain of such a hernia is usually felt beneath the lower sternum and may radiate to the back. Sometimes it may differ from this pattern and be identical with the pain of angina in that it is felt higher in the chest, radiates to the throat or one or both arms, and is provoked by effort. When it does this, successful repair of the hernia often cures the pain although it may recur several years later. There are two possibilities to account for this type of radiation of pain provoked by an oesophageal lesion. One is that oesophageal pain actually does so radiate: the other is that the pain originates in the heart and is induced by a disordered oesophagus. Support for the latter possibility comes from animal experiments: a balloon inflated in the lower end of the oesophagus in healthy anaesthetized dogs causes reduction in coronary artery flow as great as 50%. It could therefore be that, if coronary flow is already reduced by atheromatous coronary arterial narrowing, further reflex reduction in flow might cause anginal pain. I have actually never seen a hiatus hernia in a young person cause typical anginal pain with arm radiation, and believe that coronary arterial narrowing is necessary for its occurrence. This would explain why surgical repair of the hernia will produce relief of anginal-like pain for several months or years but the pain ultimately returns as coronary disease progresses, without the hernia having recurred. I understand that this is not always the experience of others, but one can only discuss what one sees.

There is considerable discussion concerning the relation of the gall-bladder to cardiac pain. I do not wish to discuss here the relationship between high serum cholesterol levels, gall-stones, and coronary atheroma, or the fact that pain from cholelithiasis can aggravate cardiac pain as can any pain anywhere else in the body. The sympathetic supply of the gall-bladder is usually via the fifth dorsal ganglion. If the supply happens to be too high or there is spread of impulses within the cord it is quite likely that gall-bladder disease may cause pain very similar in distribution to anginal pain. There is, however, another explanation. Just as the ingenuity of man has led to inflation of balloons in the oesophagus, so it has led to mechanical stimulation of the extrahepatic bile ducts (Allegri *et al.*, 1956), and the effect on coronary flow appears to be identical. Once again there is a reduction in coronary blood flow, albeit with a concomitant reduction in systemic blood pressure. Which-ever explanation is used, the improvement in angina following removal of a diseased gall-bladder is often dramatic. The most interesting case of Friedberg (1951), in which infarction of a gall-stone coincided with myocardial infarction, does support the contention that there might well have been a sudden reflex diminution in coronary flow when the stone impacted.

Attempts to Relieve Cardiac Pain by Surgery

Two main approaches have been made in order to try to relieve cardiac pain by surgery. The first is by severance of the pathways of the afferent sympathetic pain. The second is in attempts to revascularize ischaemic areas.

Sympathectomy and Revascularization

Sympathectomy has suffered many vicissitudes, mainly because early attempts were too limited and removal of the stellate or cervical ganglia alone produced substantial pain relief only on very rare occasions. The credit for extending the operation to include not only the stellate ganglion but also the second, third, fourth, and sometimes fifth is given to White and Smithwick. The original suggestion that sympathectomy of some sort would help anginal patients came in 1899 from François-Franck, who was then professor of physiology in Paris. Pioneer operations were carried out by Jonnesco (1923) in Bucharest. Because of the variability of results Sir James Mackenzie in 1924 said that discussions on the painful mechanisms involved in angina pectoris were usually futile, as they simply consisted of the replacement of one speculative hypothesis by another. The pessimism of Sir James has not stood the test of time, and upper dorsal ganglionectomy is now a standard and satisfactory procedure. I have heard of unilateral operations producing pain relief when pain was strictly limited to one side of the chest or to one arm, and have been intrigued by reports of successful operations for right-sided angina in patients with dextrocardia, but the patients whom I have had operated upon myself have all required a bilateral operation. It is interesting in this connexion that Wyburn-Mason (1948) believes that the heart, embryologically, is a midline structure and has nervous connexions with the two sides of the body which correspond to its right and left components.

Following adequate sympathectomy there is usually complete relief of chest and arm pain, but the "warning" of angina is not abolished, as there is left mild, and not too unpleasant, pain under the jaw provoked by the circumstances causing the pre-operative true angina. This pain must be vagally mediated.

With this form of sympathectomy there is no suggestion that the calibre of coronary arteries is increased by the release of some sort of coronary spasm. What is dramatic at times is the decrease in heart rate, especially at the conclusion of operation on the second side. The heart, nevertheless, still has the ability to increase in rate after exercise, although not to the same extent as before operation. This must be due to vagal inhibition.

The second form of operation has many variations, but the common principle is revascularization. Such work was pioneered in this country before the last war by Laurence

O'Shaughnessy (1935). He brought a piece of omentum through the diaphragm and attached it to the scarified epicardium. In the United States of America Claude Beck has devoted many years to the problem, and one of his more recent ideas has been retrograde perfusion of the myocardium by introducing an arterial feed into the coronary sinus. Other methods have been the attachment of any adjacent structure to the heart such as pectoral muscle or lung, the adherence of the pericardium to the epicardium by the insertion of irritant material, and the fixing of the central bleeding end of one of the internal mammary arteries into a myocardial tunnel.

How do these operations produce relief of cardiac pain—and without doubt the majority of them do? With the O'Shaughnessy cardio-omentopexy it is probably from the records, which I have compared with those of Lindgren's (1950) extensive series of sympathectomies, that the expectation of life was not increased by the attempt to increase the vascularity of ischaemic areas of myocardium, although the great difficulties of assessing results must be stressed. The late Professor Barnard told me that only on very rare occasions was he able to demonstrate significant anastomotic channels between the omentum and the myocardium. In other anastomotic operations, such as stitching the lung or pectoral muscle to the myocardium, no adequate anastomoses have ever, to my knowledge, been shown when there have been adequate post-mortem injection studies. These remarks do not apply to the insertion of the proximal end of the internal mammary artery into a myocardial tunnel (Vineberg, 1954), for in this operation there is experimental evidence in its favour, and in any case it is too new for adequate assessment of long-term results.

Similarly, there have never been any proper post-mortem studies which clearly show collateral blood vessels between the pericardium and epicardium after the insertion of various substances into the pericardial sac.

Phenol and Talc

In an attempt to explain why pain relief is not accompanied by demonstrable increased cardiac vascularity I must make a short digression. In 1948 Mr. Norman Barrett, at St. Thomas's Hospital, had devised an operation to increase the vascularity of the lungs in children suffering from cyanotic congenital heart disease and inadequate pulmonary blood flow. He stripped the upper two-thirds of the pleura and inserted powdered asbestos in order to produce vascular adhesion between the chest wall and lung. These operations have, in the course of time, been shown to produce good clinical results.

However, on one occasion, instead of using asbestos he painted the lung with phenol. Three months later the patient returned to hospital, and a registrar thought that he would show, by artificial pneumothorax, that the lung was firmly adherent to the chest wall. The lung collapsed without any evidence of adhesions, but it was noticed that the original operation had resulted in Horner's syndrome. The presumption was that the sole effect of the introduction of phenol was to paralyse the dorsal sympathetic chain. Acting on this idea, Mr. F. B. Cockett successfully sympathectomized a number of dogs by painting sympathetic ganglia with phenol. Is this method of sympathetic ablation applicable to the cardiac nerves? Judging by a few recent reports such as that of Harken *et al.* (1955), and by some of our own patients at St. Thomas's, it is a satisfactory procedure, and direct painting of the epicardium with phenol prevents anginal pain in patients with ischaemic heart disease. In one of our patients, who subsequently died several months after this operation of a myocardial infarction, there were no vascular adhesions and his infarction was painless.

Is it possible that other operations in which the epicardium is injured cause relief of pain mainly because of nerve destruction? I believe that this is very likely. A study of patients operated upon by Mr. Kent Harrison who have had talc dusted into the pericardial cavity have often lost their anginal pain, but instead of being halted by pain they are

halted by dyspnoea. Electrocardiograms taken before and after operation show exactly the same depressions of the ST segment after equivalent amounts of exercise, and, interestingly, now dyspnoea rather than pain is relieved by nitroglycerin. If this idea is correct, then other conditions in which there is presumably firm attachment between the pericardium and epicardium should not be accompanied by the symptom of angina pectoris. This is in the main true, and while it may occur I have never seen a patient with constrictive pericarditis suffering from angina pectoris. Similarly, before operation about 10% of patients suffering from mitral stenosis have in addition angina pectoris. After operation, angina is exceedingly rare. Two of our patients who lost their anginal symptoms after mitral valvotomy became increasingly dyspnoeic two and three years respectively after operation, and cardiac failure and pulmonary hypertension compelled further operation. Neither had a recurrence of angina and both had adherent pericardiums and considerable mitral stenosis.

Patients suffering from aortic or pulmonary stenosis nearly always lose their angina after valvotomy, and I should like to submit that, independent of how satisfactory the valvotomy may have been, opening of the pericardium and the resulting haemopericardium can destroy sympathetic pain fibres.

I should like to quote two examples of the talc and phenol operations.

A crane repairer aged 55 developed typical angina pectoris in 1950. The pain spread across the chest and down the left arm to the wrist. It gradually became worse, so that by the end of 1954 he could walk 600 yards before meals, but only 10 yards afterwards. The pain never occurred at rest and was promptly relieved by nitroglycerin. There were no abnormal physical signs and the blood pressure was 140/90. In the electrocardiogram there was a little depression of the ST segments in leads V₁ and V₂, which became more pronounced when he exercised until he had pain. In January, 1955, Mr. Kent Harrison performed a thoracotomy and put two teaspoonfuls of talc into the pericardial sac, which was free from adhesions. Since that time the patient has not used a nitroglycerin tablet and climbs to the top of cranes without difficulty. The electrocardiogram is unchanged and the ST-segment depression occurs after the same amount of exercise as before, but now is accompanied by dyspnoea.

An epileptic man aged 50 had an anterior myocardial infarction in 1950 which was followed by increasing angina pectoris until early in 1954; the distance which he could walk was only about 30 yards. The pain was felt across the chest and in both arms and the jaws. The blood pressure was 150/90 and there was loud presystolic triple rhythm. The electrocardiogram confirmed the old anterior infarction. In March, 1954, Mr. John Pullan performed a bilateral upper dorsal sympathectomy from thoracic ganglia one to four on the right, and one to five inclusive on the left. After the operation the patient lost the chest and arm pain, but his walking distance was not increased because of the persistence of jaw pain. As he insisted that something more must be done for him Mr. Norman Barrett, in January, 1955, performed a thoracotomy, opened the pericardium, and painted the coronary artery with phenol. This removed his jaw pain without altering his physical signs or electrocardiogram, but again he can walk no further than before, because he now has dyspnoea and right-leg claudication after 30 yards. I think that he must have had one of the most complete cardiac sympathectomies ever carried out.

This explanation of the mode of action of these operations does not mean that they should not be performed, because dyspnoea is a much less unpleasant symptom than angina pectoris. It has not happened to our patients yet, but it is conceivable that they might exercise "through" the dyspnoea and harm themselves. They should be warned to be careful.

Effect of Nitrites on Coronary Pain

While the effect of nitrites on coronary pain may not strictly come under the heading of some effects of the autonomic nervous system on the heart, the subject is worthy of discussion for the very reason that the mode of action of nitrites may not be via the autonomic nervous system. It is a remarkable state of affairs that so little is known

about the action of nitrites, although it was as long ago as 1867 that Lauder Brunton introduced amyl nitrite. As Gregg points out, the innumerable studies carried out with nitrites and other drugs on the isolated heart, the fibrillating heart, and the heart-lung preparation are not really significant, because not only can a drug have different effects on the hearts of two different preparations, but also the extra-cardiac effects may be so profound that they themselves alter the cardiac load or vasomotor state so that the local coronary effect is overshadowed. The only really valid experiments are those performed on the heart *in situ*.

In all experiments it appears that nitrites exert a vasodilating effect on the coronary vessels, but, as Gregg again states: "The fact remains, however, that alterations in coronary blood flow in the intact animal may differ significantly in extent and even in direction from what would be anticipated as a result of active changes in the size of the coronary vessels because of varying degrees of extravascular compression by the contracting cardiac muscle, changing cardiac output (mechanical, reflex, and metabolic effects), and alterations of blood pressure." The vasodilating effect could be a direct action on the coronary vessels, but it could be brought about by an alteration of cardiac metabolism or work.

Dr. Richard Gorlin (1955, personal communication) has allowed me to quote the results of his experiments with nitroglycerin in men. He found that the cardiac output remained essentially unchanged, but as the mean blood pressure fell there was a decrease in peripheral vascular resistance. The pulmonary capillary, pulmonary artery, and right auricular pressure usually decreased, and more strikingly in the more abnormal patients. There was no instance when the fall in right auricular pressure was greater than that in the pulmonary capillary; thus there was no change in pulmonary vascular resistance. Hence the work of the left ventricle may decrease but not that of the right as a result of nitroglycerin.

There is now, as a result of other experiments, a strong suggestion that nitroglycerin greatly alters myocardial metabolism. Bing (1955) produced coronary occlusion in dogs by injecting plastic microspheres coated with gum acacia. Apart from a drop in blood pressure he found that glucose and lactate appeared in increased concentrations in coronary-vein blood. Nitroglycerin is known to reverse these metabolic effects in man.

Therefore, nitroglycerin produces coronary vasodilatation and almost certainly has a metabolic effect, and the two may be related. The speed of action of nitroglycerin does not necessarily infer any reflex nervous path, and it can be agreed that other drugs such as adrenaline can produce a very rapid metabolic response.

Role of Sympathectomy in Cardiac Arrhythmia

Sympathetic efferent nerve impulses are concerned with cardiac acceleration, while vagal impulses are mainly concerned with slowing of heart rate, although Okinaka *et al.* (1951) believe that some of the vagal fibres are accelerator. Kuntz (1953) found that stimulation of the right vagus slows both auricles and ventricles proportionately and hence suggests that it may have its main action on the sino-auricular node. Stimulation of the left vagus did not appear to have much effect on the auricles but might produce partial heart-blocks. It is our experience in anaesthetized dogs that stimulation of either vagus reduced sino-auricular and hence ventricular activity. Stimulation of the sympathetic on either side in man or anaesthetized dogs causes cardiac acceleration with apparently equal facility.

Unlike the effect on most other blood vessels in the body, sympathetic stimulation leads to coronary vasodilatation and vagal stimulation to vasoconstriction. This is teleologically satisfactory, as with increasing heart rate there is increased vasodilatation. Knowing these facts, it is hardly surprising that upper dorsal sympathectomies have been tried for uncontrolled rapid heart-beating. I do not think that anybody has great experience of these procedures, but

they have been practised since, at least, 1928, when Leriche reported the successful treatment by stellate ganglionectomy of two patients suffering from paroxysmal fibrillation. One of these remained in normal rhythm for over four years. Since then infrequent reports have been published of the effect of sympathetic ablation on auricular tachycardia and fibrillation. White, Smithwick, and Simeone (1952) state that they think that alcoholic interruption of the sympathetic chain is not satisfactory and that attempts to predict the results of ganglionectomy by previous paravertebral injections of procaine are not accurate. Most surgeons now agree that the most satisfactory procedure is removal of the upper four or five thoracic ganglia, and they vary only in their technique concerning whether the stellate ganglia are removed or isolated. If these operations are successful the heart rate is satisfactorily reduced, but still has some, although less, ability to increase on exercise, and is probably due to vagal accelerator fibres.

There are three groups of patients in whom upper dorsal ganglionectomy may be reasonably considered. The first is in children with paroxysmal tachycardia which does not respond to usual therapeutic measures. Many of these children have no structural heart disease, and, provided they can be tided to puberty, have a strong tendency to spontaneous remission. Meanwhile, if they develop heart failure their life may be in jeopardy. The second is in adults with frequent recurrent paroxysmal auricular tachycardia, often considerably aggravated by emotion. This is clearly not a dangerous condition, but it can be most disabling, and at times the emotional storm may be so strong that pills even in poisonous dosage cannot quieten the turmoil and maintain normal rhythm. The third is in a few patients suffering from mitral stenosis and auricular fibrillation in whom digitalis is quite unable to slow the ventricular rate.

In the first group I have seen two children in whom sinus rhythm returned at the end of the operation and at least several months later the ectopic focus had not again become master. In the second group I have no first-hand knowledge of successful surgery, but in two such patients drugs have completely failed and surgery is seriously contemplated. In the third group of fibrillating mitral stenotic patients I have personal experience of four and am grateful for a report on a fifth. In my patients the ventricular rate was always between 120 and 160 a minute; it was not possible to revert them to normal rhythm with quinidine, and digitalis was ineffective in slowing the ventricles; failure persisted, as left ventricular diastolic filling time remained inadequate. In two patients a ventricular rate could be maintained after operation between 80 and 90 without digitalis. In the other two the fall in rate was not dramatic, but it became possible to control it with digitalis for the first time. Mr. Belsey and Dr. Davies, of Bristol, have kindly allowed me to report the following case.

A woman of 39 had the symptoms and signs of mitral stenosis following an attack of rheumatic fever. Fibrillation was occurring with a ventricular rate at rest of about 112 a minute. When any member of the medical staff appeared in the ward this increased to 170 or higher. Digitalis had no effect in controlling this, and at the time it was thought that she was quite unfit for mitral valvotomy. A bilateral upper thoracic ganglionectomy was performed which reduced her ventricular rate to the region of 80 and eliminated the tendency for the pulse to rise on the slightest emotional provocation. Her condition improved considerably, and eighteen months later a successful mitral valvotomy was carried out. Several years later she was still well and was doing a full day's work.

Another use of cardiac denervation procedures suggested itself to us a year ago for the treatment of Stokes-Adams attacks when the condition of the coronary arteries appeared to be reasonably good. In the absence of structural heart disease recurrent Stokes-Adams attacks are presumably due to vagal overactivity. Severance of the cardiac vagal fibres is not possible except in the region of the heart, because so many branching fibres are distributed to the heart from as high as the neck. Removal, therefore, of the cardiac plexuses involves removal of both sympathetic and parasympathetic systems. It is unlikely that sympathetic denervation

at that level has any positive disadvantage. The doubt only remains that denervation of the cardiac plexuses can be so complete that it is effective.

The following case report suggests that it can be.

A man aged 41 had repeated Stokes-Adams attacks for five years. Several of these lasted intermittently for up to seven hours at a time. The electrocardiogram showed complete heart-block, and during attacks there was ventricular arrest. The attacks could not be prevented or treated by ephedrine, atropine, adrenaline, or intravenous lactate. He was operated on by Professor Kinmonth, and the left antero-lateral side of the arch of the aorta was cleared of connective tissue and nerve fibres from before backwards. Further pieces of nervous tissue were removed behind the aorta and the pulmonary artery. The impression was gained that the superficial, deep, and para-aortic plexuses had been removed. Before the operation the heart rate was 34 a minute; at the conclusion he was in normal rhythm at 90 a minute. Eleven months later he had had only one attack of giddiness, but his doctor reported that his pulse rate had never been below 60 a minute. He was then back at work.

Summary

The autonomic nervous supply of the heart pursues a diffuse and complicated course in both its afferent and its efferent components. Its role is often in doubt, but slowly it is becoming clarified.

The nature of cardiac pain is discussed and the metabolic changes consequent upon myocardial infarction are stressed. Coronary "spasm" has no factual evidence to support its occurrence.

A case is described in which the patient suffered a variety of autonomic disturbances when he developed cardiac pain; they are best explained by central radiation within the spinal cord.

The "shoulder-arm" syndrome and excessive flatulence, sometimes associated with coronary artery disease, are probably concomitant autonomic phenomena.

The association between cardiac pain, gall-bladder disease, and hiatus hernia may be more than reduction of pain threshold, and either condition may cause reduction in coronary arterial blood flow.

The evidence is that most operations designed to re-vascularize ischaemic hearts diminish pain by destroying sympathetic afferent pain fibres.

Upper dorsal sympathectomy and direct denervation of the heart may well have a place in uncontrollable auricular fibrillation and sometimes in repeated Stokes-Adams attacks.

TREATMENT OF COMPLETE PROLAPSE OF THE RECTUM

BY

E. S. R. HUGHES, M.S., F.R.C.S.

L. W. GLEADELL, F.R.C.S., F.R.C.O.G.

AND

JOHN TURNER, M.S., F.R.C.S.

Royal Melbourne Hospital

The conflicting reports on the results of treatment of complete prolapse of the rectum have caused confusion, and this is reflected in the large number of operations which have been advocated for the condition. Dickson Wright (1949) was able to find 51 procedures described in the literature up to 1949, and more have appeared since. In this report we describe the two types of operation we have performed since 1951 and record the progress results; we have endeavoured to correlate this experience with published reports.

In complete prolapse of the rectum there is a peritoneal sac extending distally between the vagina (or prostate) anteriorly and rectum posteriorly. As such a peritoneal sac may be present without rectal prolapse it is probable that the latter appears only when the pelvic fascia and the muscles surrounding the pelvic aperture are defective.

Present Series

Since 1951 we have operated on 30 patients suffering from complete prolapse of the rectum. In each case the rectum prolapsed at least 3 in. (7.5 cm.) and in some cases as much as 9 in. (23 cm.). There were 28 females whose ages ranged from 27 to 87 years (average 54), and 2 males aged 36 and 40 years. One patient was very obese and another very thin from malnutrition; one patient had long-standing cardiospasm with secondary nutritional changes; a fourth patient had severe rheumatoid arthritis with almost complete fixation of the hip-joints; a fifth had had an amputation of an arm and a leg in the past for an obscure vascular disease.

The series has been divided into two groups according to the type of operation. In group 1 are 17 patients who were operated on between July, 1951, and November, 1955, and in group 2 are 13 patients who were operated on since January, 1956.

Treatment of Patients in Group 1

Each of the 17 patients in group 1 was subjected to a synchronous combined operation. The patient was placed on the Lloyd-Davies lithotomy-Trendelenburg leg-pieces. Through a lower midline incision the abdomen was opened and the small intestine displaced from the pelvis into the upper abdomen. The fundus of the peritoneal sac, having been freed by the perineal surgeon, was grasped from above, invaginated into the peritoneal cavity, and amputated. The pelvic peritoneal cavity was obliterated as completely as possible with multiple encircling purse-string sutures and the abdomen closed.

The perineal surgeon exposed the fundus of the sac through an incision placed between the vagina (prostate) and rectum. After pushing it through to the abdominal surgeon a perineorrhaphy was performed by suturing the puborectalis and pubo-coccygeus muscles and related fascia together with chromic catgut size 2, anterior to the rectum. In 14 of these patients additional reconstruction was carried out behind the anal canal. A longitudinal incision behind the anus was deepened through the coccygeal attachments of the external sphincter and levator ani muscles and the fascia of Waldeyer to enter the presacral space. The rectum and

anal canal were displaced forward and held in this position by interrupted sutures of chromic catgut passed from one side to the other.

Results.—There were no deaths and no serious complications. The longest follow-up after the operation was 5½ years and the shortest 15 months. There have been three recurrences. In one, a married woman aged 72 who suffered from advanced rheumatoid arthritis, the prolapse reappeared within six months of the operation; the perineal wounds were severely infected and it was thought that this was responsible for the failure. She declined further treatment. In a man aged 36 the operation was effective for 15 months before the prolapse recurred, and a second repair was performed in the way described for group 2 cases. At the second operation the peritoneal pouch was found re-formed and in every way similar to that noted at the first operation, despite the fact that encircling silk sutures were used to obliterate the pouch. A married woman aged 75 was satisfactory for two years before the prolapse recurred. In the remaining 14 cases the results continue to be satisfactory. Four patients have remained well for 4 years or more, three for 3½, 3, and 3 years respectively, five for 2 years or more, one for 18 months, and one for 15 months. Each of these 14 patients has enjoyed adequate continence, although imperfect sometimes if the motions become loose. On straining, mucous membrane may appear at the anal verge (two cases). The tone of the anal sphincter muscle improved, but did not always recover completely, despite the absence of prolapse.

FIG. 1.—Appearance at laparotomy for repair of complete prolapse of rectum.

FIG. 2

FIG. 2.—Peritoneal sac is inverted and excised. FIG. 3.—Sutures approximating the levator ani muscle and inserted by the perineal surgeon can be seen. Pelvic fascia is sutured with a series of "purse-string" silk sutures passed through the fascia on the four walls of the space opened up between rectum and vagina. FIG. 4.—Upper parts of the lateral ligaments are approximated anterior to rectum; utero-sacral ligaments are sutured together above the fascial repair.

FIG. 3

FIG. 4

Treatment of Patients in Group 2

The 13 patients in this group had the same perineal operation, but the abdominal procedure was changed. After exposing the pelvic peritoneal cavity the peritoneum was incised on either side of the rectum, and these incisions were continued distally to meet anteriorly to the rectum (Figs. 1-4). The fundus of the peritoneal sac was excised to expose the fascia on the posterior wall of the vagina (prostate and seminal vesicles), on the anterior wall of the rectum, and on either side of these structures. A series of silk sutures (size 4) were placed in this extraperitoneal space between the rectum and vagina (prostate and seminal vesicles). Each suture encircled the space, passing through the fascia on each wall. The first of these sutures was placed immediately above the levator ani muscle, which represented the upper limit of the perineal repair. The subsequent sutures were placed at short intervals above the first, ending at the level of the cervix (upper end of seminal vesicles). The peritoneal floor was closed by uniting the lateral peritoneal flaps with a continuous suture anterior to the rectum. In nine of the cases the posterior reconstruction was performed in the way described for group 1 patients.

Results.—Treatment was conducted without mortality despite the frailty of a number of the patients. There were no complications except wound infection in the perineum. The longest follow-up is only 13 months and the shortest 3 months. There have been no recurrences, and continence has been satisfactory, although imperfect if the motions lose their solid consistency. In one patient straining caused the anus to evert, exposing the mucous membrane of the anal canal, but there was no prolapse. The sphincter muscle appeared capable of recovering normal tone.

Discussion

The obvious procedure, amputation of the prolapse, was popularized by Mikulicz (1888), by Miles (1933), and later by Gabriel (1948). As might be expected, this operation, known as rectosigmoidectomy, gave good immediate results, but the later recurrence rate has proved high, which is not surprising, because the operation does little to remove the cause of the prolapse (Thompson, 1949; Pemberton *et al.*, 1953).

The Moschowitz Approach

The first to advocate a procedure designed to correct the cause of the prolapse was Moschowitz in 1912. He pointed out that normally there was a fascial weakness where the rectum left the abdominal cavity and that this weakness might be greater than usual and allow a peritoneal sac to indent the anterior wall of the rectum and finally force it through the anal orifice. Moschowitz favoured an abdominal operation; the hernial sac was obliterated with purse-string sutures placed around it and including the pelvic fascia. This operation also proved unsatisfactory: Brintnall (1952) reported that of 11 patients so treated the condition recurred in 8; Pemberton *et al.* (1953) found that 29 of 46 cases treated at the Mayo Clinic by the Moschowitz operation and followed for two years or more had recurred, while Swinton and Mathiesen (1955) infer that the results at the Lahey Clinic were also poor. In the one case in our series, the patient was subjected to operation following an unsuccessful Moschowitz type of repair; the peritoneal sac had re-formed without leaving trace of the original encircling sutures.

Roscoe Graham (1942) also called attention to the Moschowitz conception of the pathology and treatment of complete prolapse of the rectum, and, like him, advocated an abdominal repair, but one which was more complete. The levator ani muscle was exposed and the two halves were joined together anterior to the rectum with interrupted sutures; the pelvic fascia was sutured and the pelvic peritoneal pouch obliterated in the way suggested by Moschowitz. Snellman (1954) reported 12 cases treated in this way with good results, but the follow-up was too short to permit firm conclusion; one patient was traced four years after operation, another three years, and three for two years, but the remainder had had their operations less than two years prior to the report. Brintnall's one case recurred. Lloyd-Davies (1949) described a modification of this procedure; six loosely tied slings of floss silk, attached firmly at the sides of the rectum by deep insertion into the sacrospinous ligaments, were placed between the rectum and vagina. No results were given. Hayes and Burr (1948) report two cases in which the lateral ligaments of the rectum were sutured together anterior to the rectum. They claimed cures, but no follow-up times are given.

These attempts by Moschowitz, Graham, Snellman, Lloyd-Davies, and Hayes and Burr were made through an abdominal approach, although undoubtedly the levator ani muscle and lower pelvic fascia are more accessible through a perineal incision. This was recognized by Moschowitz (1912) because in half of his cases some type of perineal operation was combined with the closure of the pouch of Douglas, although performed at a separate operation. McCann (1928) described a perineal operation in which the levator ani muscle and fascia of the rectum were sutured anterior to the rectum, but three patients so treated at St. Mark's Hospital all developed recurrences. Orgias (1954) reported a similar operation, performed on two patients, but was careful to remove as much of the peritoneal sac as possible; however, the longest follow-up was only four months, so that no conclusion can be reached concerning the efficacy of the method. When the perineal herniotomy has been performed by excising a portion of the rectum and sigmoid colon as in rectosigmoidectomy the reported results have been fairly good provided the levator ani muscle and fascia are sutured anterior to the rectum. Altemeier *et al.* (1955) reported 13 cases treated in this way with only one recurrence; the longest follow-up in their series was 4½ years. However, Dunphy (1948) and Dunphy *et al.* (1953) were less satisfied; two of their three cases developed prolapse of the rectal mucosa within three months of the operation.

Dunphy's Operation

If the abdomen is open during these procedures performed entirely through the perineum it is apparent that a deep pelvic peritoneal sac persists even after a carefully done

operation. The logical procedure would appear to be a combined abdomino-perineal operation, and Dunphy (1948) was one of the first to realize the advantages of such an operation. His operation was done in two stages. Through a perineal approach the prolapsed segment of the rectum was excised, the hernial sac removed, and the levator ani muscle sutured anterior to the rectum. Some days later the abdomen was opened, the rectum mobilized, the transversalis fascia sutured, the hernial sac and pouch of Douglas closed by circular sutures, and the pelvic colon fixed to the lateral wall of the pelvis. All 12 cases so treated (Dunphy *et al.*, 1953) remained satisfactory, although one patient had a mucosal prolapse and was incontinent after the operation. Butler (1954) advocated a combined abdomino-perineal procedure performed in one stage, and he reported five cases without recurrence, but the longest follow-up was only two years. The Butler operation accomplishes the same results as that described by Dunphy. The patient is placed in a lithotomy-Trendelenburg position; the colon and rectum are mobilized and excised from above and an end-to-end anastomosis is completed from below. The levator ani muscle is repaired from below and the hernial sac obliterated from above.

Method in the Present Series

In our series a combined abdomino-perineal operation was performed by two surgeons working simultaneously; the perineal part of the operation was conducted by a surgeon with gynaecological training and experience, whilst the abdominal part was performed by a surgeon accustomed to pelvic dissections. The operation in group 1 cases consisted of complete abdominal excision of the peritoneal sac combined with perineal perineorrhaphy. The results of the operation in this group were imperfect, and accordingly in group 2 cases the abdominal part of the operation was changed. In addition to the two manœuvres described the pelvic fascia above the levator ani muscle was repaired with a series of interrupted silk sutures. Brintnall (1952), Dunphy *et al.* (1953), and Newell (1954) have all described a similar operation; in the present series the perineal and abdominal phases were performed synchronously, whilst in the cases described by Brintnall, Dunphy *et al.*, and Newell they were done consecutively.

The procedure appears formidable, but there have been no deaths and no serious complications have endangered life. In the first group of 17 cases there have so far been three recurrences; of the 14 cases which have remained satisfactory, four have been followed for four years or more. In the second group of 13 cases there have been no recurrences, but the first of the group was subjected to operation only 13 months ago, so that it is too early yet to decide if the results in this group are better. Brintnall (1952), reporting two recurrences in six patients so treated, noted that in one the recurrence appeared 16 months after operation and in the other it had developed after only three months; the four successful cases had been traced for periods ranging from 20 to 36 months. Dunphy *et al.* (1953) were satisfied with the two cases treated by them, although they commented upon the tendency of the mucous membrane to slide through the anal orifice after operation, and this was also noted in our series. The result of the operation in Newell's (1954) case was good 10 months after operation. In our series, 23 cases had a posterior reconstruction of the levator ani muscle; whether or not this is a useful procedure has not been decided, but in each of the three recurrences this additional part of the operation was done.

In our series no bowel has been excised, although a number of authorities believe removal of redundant bowel to be an essential step. Mikulicz (1888), Miles (1933), Gabriel (1948), and others have removed a considerable part of the rectum and sigmoid colon through the perineum, whilst Butler (1954), Muir (1955), Swinton and Mathiesen (1955), and others have excised the bowel through the abdomen. It is certain that recurrence occurs after resection of this bowel unless it is combined with a repair of the pelvic musculo-fascial floor. In this series an attempt has been

made to perform this repair without removal of the rectum and sigmoid colon, and subsequent experience and comparison with other follow-up studies will decide whether it has been successful.

Other Procedures

Some operations devised are based on the principle of fixation of the rectum and sigmoid colon to rigid neighbouring structures. For example, Pemberton and Stalker (1939) and Pemberton *et al.* (1953) have been impressed with the results of an abdominal suspension-fixation operation; the rectum and sigmoid colon are freed to the upper surface of the levator ani muscle, pulled taut, and sutured to a higher level. The authors felt that adherence of the rectum to the anterior surface of the sacrum prevented recurrence, and recommended that in a large prolapse a pack be left in the hollow of the sacrum for about a week to promote this adherence. Orr (1947) performed a similar operation, but inserted fascial strips to aid the suspension, while Stabins (1951), Mills and Lawler (1956), and Tendler (1956) have reported the same type of suspension operation, but in addition have resected redundant bowel. Muir (1955) advocated an anterior resection of rectum and sigmoid colon with end-to-end anastomosis, and without any special attempt to repair the pelvic floor or to "suspend" the bowel. He believed that firm adhesion of the anastomosis to the sacrum prevented recurrence. It is to be hoped that these authors will report the long-term results of these suspension-fixation procedures. Lockhart-Mummery (1910) gave an extensive trial to posterior fixation of the rectum to the sacrum, but it proved a complete failure (Hughes, 1949). Furthermore, nine cases of sigmoidopexy (two with obliteration of the pouch of Douglas) performed at St. Mark's Hospital all proved unsuccessful (Hughes, 1949). Brintnall (1952) reported a recurrence after anterior resection and anastomosis of the bowel and at the Lahey Clinic procedures based on fixation have fallen into disuse (Swinton and Mathiesen, 1955).

Conclusions

In this series of cases of complete prolapse of the rectum treated by operation, a procedure has been used which entails abdomino-perineal removal of the hernial sac and abdomino-perineal repair of the defect. Both abdominal and perineal phases have been performed simultaneously. No bowel has been resected and no attempt has been made to achieve success by "fixation" or "suspension" of the bowel. The operation performed in group 2 is a technical improvement on that used in group 1 and continues to be used as our method of choice.

Summary

A series of 30 patients suffering from complete prolapse of the rectum have been subjected to operation. They have been divided into two groups according to the operation performed.

In group 1, comprising 17 patients, a synchronous combined abdomino-perineal repair was performed. A perineal perineorrhaphy was carried out after complete excision of the peritoneal sac from above. The pelvic cavity was then obliterated with encircling sutures of silk. In this group three patients have suffered a recurrence, but the remainder have remained satisfactory for periods up to 5½ years.

In group 2, in which there are 13 patients, a synchronous combined abdomino-perineal repair was performed. Perineorrhaphy was carried out after complete excision of the sac. The pelvic fascia between the rectum and vagina (prostate) was sutured with a series of interrupted silk sutures, after which the remaining pelvic peritoneum was obliterated as in group 1. No recurrences have yet occurred, but the longest follow-up is only 13 months.

The results of procedures utilizing solely the abdominal or the perineal route do not appear to have been uniformly satisfactory.

A combined abdomino-perineal operation has become widely used in the past decade, but it is difficult to assess results.

Many operations which have been designed for complete prolapse of the rectum have entailed excision of rectum and sigmoid colon. The procedures used by us have consisted of removal of the hernial sac and repair of the defect without removal of the bowel.

The repair has been designed to correct an anatomical defect and does not rely on "fixation" of the bowel to or "suspension" from neighbouring rigid structures.

SUBCUTANEOUS HEPARIN WITH AND WITHOUT HYALURONIDASE

BY

ARTHUR HOLLMAN, M.D., M.R.C.P.
Research Assistant, Cardiac Department, University
College Hospital

AND

R. E. NAGLE, M.B., B.Chir.
House-Physician, University College Hospital

It is usual to commence anticoagulant therapy with heparin given intravenously every four to six hours. Such a regime is time-consuming for the doctor, and a number of attempts have been made to overcome the necessity of giving heparin by the intravenous route.

Intramuscular heparin was used by Abrahams (1950), who included procaine in the injection to prevent local pain. He found that the clotting-time was satisfactorily prolonged with twice-daily injections and noted haematoma in only 10% of cases. Gubbay and Pash (1953) also found that the intramuscular route was satisfactory and free of complications. However, Bauer *et al.* (1950) and Wynn and Goodwin (1952) noted that intramuscular haematoma occurred quite often with such treatment, and in the latter series forced cessation of therapy in 25% of cases. Marks *et al.* (1954) gave intramuscular heparin mixed with hyaluronidase four-hourly for four doses, and state that the hyaluronidase overcomes the disadvantages of pain, local bruising, and variable absorption found with intramuscular heparin alone.

Subcutaneous heparin has been the subject of several trials, and attempts have been made to prolong its action by incorporating it in a gelatin mixture (Pitkin menstruum) and by adding vasoconstrictors. Most observers have found that Pitkin menstruum and similar preparations frequently give rise to pain and tenderness and that the effect on the clotting-time is variable and unpredictable (Goodwin and MacGregor, 1950; Hauch and Barker, 1951). Vasoconstrictors do prolong the action of heparin to some extent (Loewe, 1947). Plain aqueous heparin given subcutaneously has been favourably reported on by Cosgriff *et al.* (1948), who gave 3,000 units every three hours after an initial priming dose intravenously. They obtained clotting-times of two to four times the control value in 95% of cases and found pain and bruising to be rare. Duff *et al.* (1951) confirmed the efficacy of this method but considered local bruising and induration to be not uncommon. Tuchman and Moolten (1950) treated three patients by infiltrating an area of skin with hyaluronidase and then injecting heparin into it. A definite prolongation of clotting-time was found within six hours of the injection, and less pain was noted when this technique was compared with heparin alone in 10 other subjects.

It seemed to us that hyaluronidase might considerably promote the absorption of heparin from subcutaneous tissue, and a trial was therefore made of subcutaneous heparin with hyaluronidase in the hope that it would produce a rapid and well-marked elevation of the clotting-time.

Methods

A few trials on normal subjects soon showed that an unpleasant burning pain was produced when heparin was injected into an area with little subcutaneous fat. Therefore the injections were always made into an area of flabby subcutaneous tissue, usually over the buttock, using a 22 S.W.G. (serum V) needle. The Benger preparation of hyaluronidase called "hyalase" was used and 1,000 "Benger" units (equivalent to 450 turbidity-reducing units) was dissolved in the heparin solution immediately before the injection. Clotting-times were determined by the method of Dale and Laidlaw (1911), and in the short-term experiments were done hourly for six hours or until the clotting-time returned to normal.

Both short- and long-term observations were made on the efficacy of subcutaneous heparin with hyaluronidase, and they are described separately. The patients were under the care of Dr. Kenneth E. Harris.

Short-term Experiments

The object of these observations was to compare the clotting-time prolongation obtained with (a) subcutaneous heparin with hyaluronidase, (b) subcutaneous heparin alone, and (c) intravenous heparin in the same dose in the same subject. This was done on eight subjects, and injections of 15,000 units of heparin were given on each of three successive days.

In four subjects the subcutaneous heparin either with or without hyaluronidase prolonged the clotting-time by less than 25% of the control, and in two subjects both methods gave a 50% prolongation of the clotting-time. In the other two subjects heparin with hyaluronidase led to a doubling of the clotting-time, which returned to normal by six hours, whilst heparin alone had little or no effect. In all eight subjects the intravenous dose led to a fourfold or more increase in the clotting-time (Fig. 1). In a further four subjects the skin was first infiltrated with 1,000 units of hyaluronidase in 2 ml. of saline and 15,000 units of heparin was injected into the area 20 minutes later; this is the method described by Simon and Narins (1949), and is similar to that used by Tuchman and Moolten (1950). A minor increase in the clotting-time (less than 25% above the control) was found three to four hours after the injection in each subject, and a moderate or large bruise was produced every time.

Fig. 1.—Degree of prolongation of clotting-time over control value obtained within six hours with varying methods of administration following a single dose of heparin of 15,000 units.

In 11 cases of venous thrombosis or cardiac infarction the clotting-time was followed for several hours following an initial treatment dose of subcutaneous heparin in a usual dose of 15,000 units. In the eight patients in whom hyaluronidase was given with the heparin the clotting-time was unchanged in two, and prolonged by 50% in five and by 400% in one case given 25,000 units. In the three cases in which heparin alone was given the clotting-time was prolonged by 50% in each patient. Thus out of 20 subjects

FIG. 2

FIG. 3

FIG. 4

Fig. 2.—Representative case of long-term treatment with subcutaneous heparin and hyaluronidase of a woman aged 51 with femoral vein thrombosis. 15,000 units t.d.s. prolonged the clotting-time to between two and three times normal. The same dose twice a day proved inadequate, whilst four times a day it was too strong. Fig. 3.—Woman aged 62 with cardiac infarction. Late culmination, leading here to haemorrhage at the eighth day, that may occur with long-term subcutaneous heparin. Note also the delay (20 hours) before a therapeutic level of clotting-time is attained at start of treatment. Fig. 4.—In a man aged 73 with angina pectoris clotting-time took two days to return to normal after heparin was stopped, suggesting long-continued absorption from the skin.

a single subcutaneous injection of heparin with hyaluronidase increased the clotting-time over the control value by two to four times in only three subjects, by 50% in 7, and had no effect in ten.

Local reactions in the form of tenderness occurred in 15 out of 23 injections given with or without hyaluronidase, and this was slight in 12 and moderate in 3. Bruising occurred four times. Tenderness was most common when a strong solution of heparin (25,000 units per ml.) was given, and was diminished in these particular cases when hyaluronidase was used.

Long-term Therapy

In eight patients with venous thrombosis or cardiac infarction subcutaneous heparin with hyaluronidase was given two or three times a day for a period of from 7 to 14 days (after which phenindione was given), the usual dose being 15,000 units t.d.s. (Fig. 2). In all patients it was found possible to maintain a clotting-time of twice or more the control time on this regime, but it took from 8 to 36 hours, with a mean of 14 hours, to reach this level (Fig. 3).

It thus became apparent that there was a definite cumulative effect with subcutaneous heparin, which was for two reasons unexpected. Firstly, in the short-term experiments the effects of a single injection had always passed off by six to eight hours; and, secondly, it was thought that heparin would become inactivated if it remained long in subcutaneous tissue. However, the cumulative effect was undoubted, and, furthermore, in two cases which were carefully followed after heparin was stopped the clotting-time took one and three days respectively to return to normal, suggesting that heparin was being absorbed (and certainly not inactivated) for a long time after its administration (Fig. 4). The cumulative effect was not always confined to the initial one to three days of treatment. In two cases the clotting-time on the same dose of heparin rose progressively to the cessation of therapy on the sixth to eighth day (Fig. 3). The dose of heparin required to maintain the clotting-time at two to three times the control value was 15,000 units t.d.s. in six patients, 25,000 t.d.s. in one patient, and 25,000 q.d.s. in one patient.

In four of the eight patients on long-term therapy subcutaneous heparin alone was substituted for heparin with

Fig. 5.—A man aged 61 with venous thrombosis. Long-term subcutaneous heparin administration is equally effective either with or without added hyaluronidase.

considerable haematuria in three, one also having a slight haematemesis, and of haemoptysis in the fourth. Heparin was stopped and protamine sulphate given. The clotting-time when haemorrhage occurred was $7\frac{1}{2}$ and 9 minutes (four to six times the control) in two cases, $3\frac{1}{2}$ minutes (twice the control) in one case, and only $2\frac{1}{2}$ minutes (same as the control) in one case.

Local reactions were noted fairly often. Local tenderness occurred with just under half the courses of treatment and was most common when strong heparin solution (25,000 units per ml.) was used. Bruising occurred in half the cases; but it was not always painful, and was severe in only two cases.

Discussion

The results obtained in this investigation have shown that hyaluronidase materially speeds the absorption of sub-

cutaneous heparin in only 15% of cases. This figure is in keeping with the findings of Banks *et al.* (1949), who found that hyaluronidase increases the rate of absorption of radioactive plasma protein from the skin by $1\frac{1}{2}$ to 3 times, but that by 24 hours, even so, only 9% of the injected dose had been absorbed compared with 4% without hyaluronidase. Similarly, Simon and Narins (1949) found that the absorption of a subcutaneously injected radio-opaque substance ("neo-iopax") was hastened by only a third when it was given with hyaluronidase. Thus, although it has been found by McClean (1942) and by Meyer (1947) that heparin may inhibit its action, it seems that hyaluronidase does not greatly promote the absorption of other substances with a rather high molecular weight.

Our results, even when using their own technique, do not confirm the statement of Tuchman and Moolten (1950) that heparin absorption is very rapid when used with hyaluronidase, but their conclusion was based on only three cases, and from their graphs it would appear that the clotting-time took six hours or more to reach a peak. Subcutaneous heparin absorption is in fact usually slow, whether hyaluronidase is mixed with the injection or not, and cumulation of eight-hourly doses is necessary to produce a therapeutic level of clotting-time which was reached in this series after an average time of 14 hours. Therefore, if subcutaneous heparin is to be used, the suggestion of Cosgriff *et al.* (1948) of an initial priming dose intravenously should be followed. The slow absorption from the skin is also evident from our finding that the clotting-time remained elevated for one to three days after the last injection. This makes it necessary to give repeated doses of protamine should haemorrhage occur. Bleeding occurred, in fact, in four of eight patients given subcutaneous heparin for four to ten days, and it occurred in three cases when the clotting-time was only between one and two times normal. It seems as if haemorrhage is unusually likely to take place when heparin is given for several days, although we have no explanation of why this should be so.

Local bruising is a common finding with subcutaneous heparin therapy, and we have produced bruises as large as 6 by 3 in. (15 by 7.5 cm.) after a single injection of 15,000 units preceded by hyaluronidase, with a clotting-time prolongation of only a half. From this type of observation it seems likely that the bruising is due to a local action of the heparin. The bruising is not avoided even by great care with the injection technique, and pain was severe in a quarter of our cases. Hyaluronidase does not in our experience alter the local pain or bruising of subcutaneous heparin, with the exception that it diminishes the local irritant burning pain of strong heparin solution. Marks *et al.* (1954) claim that bruising with intramuscular heparin therapy can be prevented by hyaluronidase, but the short period of administration (16 hours) may have been the preventive factor in their series. We have shown that just a small saline injection into a muscle, when the clotting-time is prolonged, can produce a large haematoma.

Summary

The clotting-time has been compared following the subcutaneous injection of heparin mixed with hyaluronidase, of subcutaneous heparin alone, and of heparin given intravenously. Hyaluronidase hastened the absorption of heparin from the skin to a significant extent in only 15% of cases and did not diminish local bruising.

Eight-hourly subcutaneous injections of heparin, with or without hyaluronidase, satisfactorily maintained the clotting-time at two to three times normal after an initial delay averaging 14 hours. Severe local bruising occurred in 25% of cases.

The help of Mr. D. A. W. Edwards and Sister C. Britell is gratefully acknowledged, and we are indebted to Mr. V. K. Asta for preparing the graphs.

PULMONARY TUBERCULOSIS IN A RURAL AREA IN SOUTH SCOTLAND

THE ANNANDALE SURVEY*

BY

J. B. COCHRAN, M.B., B.Sc., F.R.F.P.S., M.R.C.P.

AND

CHRISTOPHER CLAYSON, M.D., F.R.C.P.Ed.
D.P.H.

WITH

W. BELL FLETCHER, F.S.S.

Organizing Secretary

(From Dumfries and Galloway Sanatorium, Lochmaben)

This paper describes a community x-ray survey in South Scotland designed primarily to measure the prevalence of pulmonary tuberculosis in a rural area. For convenience of administration and organization the survey area was defined by parish boundaries, with Lochmaben Sanatorium approximately at the centre. The sanatorium undertakes the routine tuberculosis service of the area, and this was of great advantage in organizing the survey and in obtaining an accurate overall measurement of prevalence, distinguishing between previously known and hitherto unknown cases.

The survey began with a private census on March 7, 1956, and the x-raying was completed by August 7, by which time 95.13% of the population of 8,658 had been x-rayed.

Methods

Survey Team.—The team comprised a medical director, organizing secretary, records officer, radiographer (untrained), and two home visitors—all full-time. In addition, the county medical officer of health seconded a tuberculosis health visitor for four afternoons a week. This health visitor worked voluntarily on many evenings, and a retired farmer also freely devoted a great deal of time to the survey. There were other part-time occasional workers. An overall estimate of the strength of the team in terms of full-time personnel would be seven or eight. The clinical aspects of the survey—including examination of recalls—were undertaken by the medical director with sanatorium nursing and x-ray staff.

Survey Area.—This measured 136 square miles (352 square kilometres) of mainly farm land in the valley of the River Annan, in Dumfriesshire. There are eight parishes

*The survey was financed by a grant from the Royal Victoria Hospital Tuberculosis Trust, Edinburgh.

and two small burghs. One of the burghs (Lockerbie) is a small market town, while the other (Lochmaben) is a residential burgh with no industry. The area is predominantly agricultural. The only industry is a small cheese factory. About 12% of the working population are employed in factories and offices outside the survey area in or near the towns of Dumfries and Annan.

The population density for the whole area was about 11 per 100 acres (40 hectares). This figure varied widely, reaching almost 600 in the burghs and declining to 2 per 100 acres (40 hectares) in the remoter landward areas (General Registry Office, 1953).

Survey Population.—This was initially defined by private census. Any population may, of course, vary from day to day. The total area was roughly divided into sectors (30 in all), and the subjects were x-rayed from a central point in each sector. The defined population comprised all persons over the age of 5 years who were resident on the last day of the main x-ray session for each sector. A person was considered resident in the area if he or she normally slept there at least two nights a week. Although all sectors were revisited at least once throughout the survey, changes in population since the original visit were largely ignored. Children at boarding-school outside the area, H.M. Forces at home on leave, and resident sanatorium staff were excluded. Residents at two boarding-schools within the area were included. The population "at risk" was eventually found to be 8,658.

General Method of Work.—The success of the survey depended on a 90 to 100% response, and to this end reliance was placed on personal contact with the population. The team of four or five home visitors (including the medical director) undertook a preliminary private census, and later, during the x-raying, the same team carried out persistent door-to-door canvassing. The x-raying was done in halls or in a specially constructed van, using a mobile Schonander x-ray unit throughout.

Results

The defined and x-rayed populations, analysed for age and sex, are shown in Table I. In Fig. 1 the population responses to x-ray examination are shown for Annandale and the Vale

of Glamorgan (Cochrane, Miall, and Clarke, 1956), a similar 95% rural survey in South Wales. There is a striking similarity in the response of the two areas and a clear relationship with age. The only obvious disparity is in males aged 65 and over, which may be related to the inclusion of a small number of domiciliary x-ray examinations in the Welsh survey. Cochrane, Cox, and Jarman (1955) have drawn attention to the sharp drop in response around the age of 20 observed in Norway and the U.S.A. This decline is also present to a slight degree in the Welsh survey, but in Annandale there is a uniform relationship with age for both sexes. In Annandale 95.1% of the defined population over the age of 5 years submitted to x-ray examination. An attempt has been made to analyse the 5% lapse rate. Invalidism and infirmity accounted for one-fifth of the lapses—that is, 1% of the population were physically unfit to attend for x-ray examination. Of the remainder no clear-cut reason for declining x-ray examination was volunteered, but it is believed that fear was the major factor. One-tenth of all

Fig. 1.—Population response in two rural x-ray surveys.

lapses actually admitted to fear of x-ray examination. A similar number, mainly in the younger age group, lapsed almost certainly because they were difficult to contact—for example, long-distance drivers.

The percentage x-rayed in the various parishes varied from 93.6 to 99.1 (Table II). A large number of factors may well have influenced the response in separate parishes—for example, proximity to the sanatorium, number and situation of x-raying points, density of population, amount of home visiting, etc. When the results are analysed, for the age group 5 to 44 years the percentage x-rayed is not only higher in all parishes but also more uniform. This suggests that the varying parish responses at all ages are to some extent affected by the proportion of elderly residents. That this is not the sole factor is evident when the actual percentage

of persons aged 5 to 44 years is compared with the overall response in each parish (Table II).

Twelve new cases of active pulmonary tuberculosis were found in the survey. These people attended for x-ray examination without persuasion; thus there was no relation between the finding of tuberculosis and the order in which people came to be x-rayed. Again this is in agreement with the Vale of Glamorgan survey (Cochrane *et al.*, 1956).

Pulmonary Tuberculosis

The prevalence of pulmonary tuberculosis in the survey area is summarized in Table III, which shows the number of previously known and newly discovered cases within the various age groups. The prevalence, including arrested disease, is shown diagrammatically in Fig. 2. The overall

FIG. 2.—Prevalence of post-primary tuberculosis in Annandale. (Note: The width of each column represents the number in each age group.)

amount of clinically significant (active and quiescent) disease was low—4.9 per 1,000 (5.2 per 1,000 for males and 4.5 per 1,000 for females). Prior to the survey the corresponding figures were 2.2 (males 1.7 and females 2.6). The rate for new cases was therefore twice as high for males as for females.

As regards infective tuberculosis, four of the seven new active male cases had positive sputa, and these men were aged between 44 and 47 years. No new infective disease was found in the female population.

Other interesting findings which emerge from the survey are: of 1,642 schoolchildren x-rayed, only one (aged 6 years) had active primary tuberculosis; only one new case of active tuberculosis (not infective) was found in the population over 60 years of age; only one case of active tuberculosis was found in the female population aged 15 to 44 years.

Comparison of Results in Annandale and the Vale of Glamorgan

The Annandale and the Vale of Glamorgan (Cochrane *et al.*, 1956) surveys are unique in that 95% of truly rural populations have been x-rayed. The outstanding finding is the low level of clinically significant pulmonary tuberculosis in each area. The actual rates of infective disease were 0.7 per 1,000 in Annandale and 1.1 per 1,000 in the Vale. The yield of previously unknown infective tuberculosis was 0.5 per 1,000 in Annandale and 0.9 per 1,000 in the Vale. In both surveys the male prevalence of infective and active tuberculosis is predominantly in middle or later life, while in females the prevalence is mainly in the 15 to 44 age group. From attack-rate studies (Springett, 1951; Cochrane *et al.*, 1955; Long and Jablon, 1956) it is likely that in middle-aged males there is occurring a breakdown of disease contracted in young adult life.

As regards infective tuberculosis, the ratio of male to female prevalence is approximately 2:1 in the Vale and 6:1 in Annandale. The Vale Survey was carried out in 1955, and the Annandale Survey in 1956. The corresponding ratio in the first Rhondda Survey (Cochrane *et al.*, 1952), is 0.8:1. Therefore the ratio of male to female cases of infective tuberculosis increases from Rhondda to Vale to Annandale. We suggest that this may, in fact, be the tendency as the tuberculosis epidemic recedes.

Discussion

The principles and techniques of community chest x-ray surveys have been established in this country by the work of Cochrane and his colleagues in South Wales (Cochrane *et al.*, 1952, 1955, 1956). The highly successful surveys achieved by Cochrane and by the Welsh Mass Radiography Service (Welsh R.H.B., 1952-4) have not been repeated anywhere else in the United Kingdom. Cochrane *et al.* (1956) where else in the United Kingdom. Cochrane *et al.* (1956) attribute success to three factors: (1) the taking of an accurate census, (2) persistent home visiting of non-attenders, and (3) suiting the objectives to the size of the team. The Annandale Survey was based on these three principles. The overall result of a 95.13% survey compares favourably with the Welsh work and serves to underline the techniques developed there. It is evident that the successful Welsh work is related to technique and not to any special quality of the population.

There seems little doubt that the complete community chest x-ray survey is the most certain method of detecting and thereby eradicating the residual tuberculosis infection in any area. So long as chest x-ray examination remains voluntary it is important to try to find out what special techniques can be employed to encourage the population to come forward for it. It is quite obvious that a short visit from an M.M.R. unit with some newspaper propaganda will attract only a very small percentage of any population. At the other extreme there is the community survey undertaken by a specially trained unit, with its private census, extensive propaganda, and persistent home visiting. In Annandale, certainly a widely scattered rural area, it nevertheless took five months to x-ray 8,200 people. This was accomplished by a staff of approximately seven to eight personnel, who had to work very hard indeed for long hours. There is no doubt that the eventual result is related largely to the effort expended. Whether the mass radiography service, as at present constituted, could achieve community surveys along these lines is a matter which has yet to be proved. This has been accomplished in Wales (1952-4), although in relatively small populations. Large urban surveys in this country have so far not achieved anything approaching a 90% result (Marshall, 1954; Birmingham R.H.B., 1954; City and Royal Burgh of Edinburgh, 1954). It has yet to be shown whether or not the Welsh techniques could be successfully applied to an urban area.

From our experience in Annandale we would stress the importance of the following factors in any mass radiography campaign: (a) personal contact with the population by responsible and tactful home visitors, especially during the

x-raying period; (b) the active co-operation and participation of the general practitioners concerned during the campaign—many reluctant people, and especially the elderly, will act on the advice of their general practitioner; and (c) prompt notification by letter of normal as well as recall cases.

In Annandale the infective cases were admitted to the sanatorium, and with chemotherapy underwent rapid sputum conversion. Therefore, 95% of the survey population are, for the time being, free of infective pulmonary tuberculosis. It is tempting to draw an analogy with the control of bovine tuberculosis, as the survey was carried out in an "attested" county, and to press for the human problem to be tackled with the same enthusiasm and wholeheartedness as has been applied to the disease in cattle.

Summary

The prevalence of pulmonary tuberculosis in a rural area in South Scotland has been measured. The population was defined by private census and comprised 8,658 persons over the age of 5 years, of whom 95.13% were persuaded to have a chest x-ray examination.

The overall prevalence of clinically significant tuberculosis was low—4.9 per 1,000. The yield of previously unknown infective tuberculosis was also low—0.5 per 1,000. Of 10 cases of active pulmonary tuberculosis discovered in the survey, 7 were middle-aged or elderly males, of whom 4 were infective.

As a result of the survey 95% of the defined population are, for the time being, free of infective pulmonary tuberculosis.

There is evidence that as the tuberculosis epidemic recedes the ratio of active disease as between males and females is increasing.

Techniques believed to be important in persuading people to be x-rayed are discussed.

Details of procedure (publicity, census, home visiting, radiography, and records) are available and can be obtained on application to J. B. C.

We are deeply indebted to the Royal Victoria Hospital Tuberculosis Trust, who bore the cost of the survey. We are most grateful to Dr. A. L. Cochrane, of the Medical Research Council's Pneumoconiosis Unit, for his guidance and encouragement throughout; and to Dr. W. E. Miall, of the same unit, for his criticisms. The staff of the Survey Unit maintained their enthusiasm throughout long hours of very arduous work, and to Miss B. Kearney, Miss E. Bell, Miss A. D. Henderson, and Mr. R. Tait we express our sincere thanks. A survey of this type inevitably involves many people, and it would be impossible to mention individually all those who helped. We would, however, especially like to thank Dr. S. K. Drainer, medical officer of health for Dumfries County, Mrs. J. Berry, tuberculosis health visitor, Mr. J. Brownlee and Mr. J. Wallace, of Dumfries and Galloway Hospital Board, and Mr. A. Marshall, of Lockerbie. To the general practitioners, officials of the local authorities, rural institutes, farmers' associations, and Church guilds, and to other public-spirited people in the area we are deeply grateful. The Western Regional Hospital Board kindly arranged the secondment of one of us (J. B. C.) for the period of the survey. The Oxford Regional Hospital Board gave assistance in mechanical tabulation. And, lastly, we would pay tribute to the people of Annandale, without whose co-operation this report could not have been written.

TWO CASES OF LISTERIAL MENINGITIS IN INFANTS

BY

P. N. EDMUNDS, M.B., Ch.B., B.Sc.

Bacteriologist, Royal Hospital for Sick Children, Edinburgh

D. N. NICHOLSON, M.B., Ch.B., F.R.C.P.Ed.

and Health, University of Edinburgh(From the Bacteriological Unit at the Astley Ainslie Hos-
pital, and the Royal Hospital for Sick Children, Edinburgh)

No published case of human listeriosis has occurred in Britain since 1941, when *Listeria monocytogenes* was isolated from a case of infectious mononucleosis by Webb (1943). The last reported occurrence in this country of meningitis due to this organism was in 1938 (Wright and Macgregor, 1939). This indicates an extreme degree of rarity of human listeriosis which is borne out by most British and American authors—for example, Webb and Barber (1937), Kaplan (1945), and Finegold *et al.* (1954)—but not by German authors, as is pointed out by Murray (1955). In this survey, Murray shows that German writers—for example, Potel (1951), Erdmann and Potel (1953), and many others—list some 150 published cases throughout the world, many of them in Germany, since the organism was first isolated and studied in 1924 by Murray, Webb, and Swann (1926). Murray estimates that human listeriosis occurs in the following clinical categories: meningitis or encephalitis, 33% of cases; "granulomatosis," 29%; septicæmia, 21%; mononucleosis, 8%; and conjunctivitis, 6%. Hoeprich and Chernoff (1955) have also described one case of listerial subacute bacterial endocarditis.

The following two cases of listerial meningitis in infants occurred near Edinburgh, as did the previous case of Wright and Macgregor, mentioned above, and the case of Gibson (1935).

Case 1

Baby Ross, aged 3 months, was born in the Western General Hospital, Edinburgh. He was the first of identical male twins of a normal first pregnancy. Birth weight was 4 lb. 9 oz. (2,070 g.). The infant was well at birth, but became jaundiced on the second day. As the serum bilirubin level was 27 mg. per 100 ml. on the third day, he was given an exchange transfusion. Thereafter he did well and was discharged from hospital when 5 weeks old, with a weight of 6 lb. (2,720 g.). He continued to progress satisfactorily until two days before admission, when his mother noted that he had become irritable and whimpered, and that his eyes looked glazed and rolled about. He took his feeds and slept well, however. The following day he was slightly feverish, tired, and rather inactive. The doctor was called, and, although he could not find any cause for the infant's upset and pyrexia, considered that the child should be sent to hospital for observation.

On admission on April 6, 1956, the infant appeared well nourished, weighing 8 lb. 13 oz. (4,000 g.). He had been fed on national dried milk, and this was continued. He did not look really ill, but had rather a strained facies. Temperature was 103° F. (39.4° C.), pulse rate 160, and respiration rate 40 a minute. There was slight bulging of the anterior fontanelle, but Kernig's and Brudzinski's signs were negative. The eyes appeared normal. There were no petechial spots,

icterus, or cyanosis. The tongue was clean, with healthy mouth and throat. White-cell count was 12,000 per c.mm. (polymorphonuclear leucocytes 64%, lymphocytes 28%, monocytes 8%), haemoglobin 68% (Sahli). Lumbar puncture on admission revealed a slightly turbid cerebrospinal fluid under slight increase of pressure: cell count was 12,000 per c.mm. Examination of the heart, lungs, abdomen, and urine revealed no abnormality. No pathogenic organisms were cultured from a throat swab.

Following the initial examination meningitis of uncertain origin was diagnosed, and treatment was immediately started with one million units of penicillin intramuscularly, followed by 250,000 units six-hourly. Sulphadiazine, 0.5 g. six-hourly, and chloramphenicol, 125 mg. six-hourly, were also administered. An organism resembling *Listeria monocytogenes* was isolated that was fully sensitive to the drugs which were being given. The infant's temperature remained at a level of 102° F. (38.9° C.) for two days and fell to 98.6° F. (37° C.) by the fourth day. Over the next 17 days the temperature varied from 98.6 to 99.4° F. (37 to 37.4° C.), then remained normal until discharge on the 27th hospital day. Penicillin had been given for six days, sulphadiazine for 17 days, and chloramphenicol for 10 days. In view of the slightly fluctuating temperature, chlortetracycline, 15 mg. six-hourly, was given on the 16th day for six days.

The infant was never critically ill during his stay in hospital, and continued to feed well and gain weight. There was no vomiting or diarrhoea. Lumbar punctures on the 7th and 15th hospital days were sterile. On discharge the infant was well and thriving. No clinical abnormality could be found at that time nor when the child was recalled for assessment a month later.

The father and mother were well and had had no recent illness. No evidence was obtained of cases of glandular fever or adenitis in the neighbourhood. There was no history of contact with any ill human being, and the twin was healthy and remained well. The father was an office worker with the National Coal Board and had no contact with rats or other animals. No animals were kept in the home. No dog came into the house. There were two cats next door, and one of these was said to have had contact with the baby's milk five days previous to the onset of the child's illness. The cats appeared healthy. There were no mice, rats, guinea-pigs, rabbits, fowl, cattle, sheep, goats, or other animals in contact with the infant. The family owned their house, which was in a small mining town about 10 miles south of Edinburgh.

Case 2

Baby Fraser was born at home, 20 miles west of Edinburgh, on April 29, 1956, the third child of healthy parents. His brothers were aged 1 year 7 months, and 11 months respectively. The pregnancy, which had apparently been normal in every way, was of 39 weeks' duration and terminated with a normal vertex delivery. The infant appeared quite normal at birth, and he weighed 6 lb. (2,720 g.). His mother had failed to feed her two previous children at the breast, so he was started on a national dried milk formula, which he took slowly. On the second day of life a "foul-smelling" nasal discharge appeared; this persisted till the time of admission, when it was no longer in evidence.

On the afternoon of the 10th day of life the infant choked during a feed, becoming cyanosed. He remained a poor colour and was admitted to the Royal Hospital for Sick Children, Edinburgh, the same day, May 9, 1956.

On admission he was slightly dehydrated, but otherwise no abnormal physical signs could be elicited. He weighed 4 lb. 8 oz. (2,040 g.). His temperature was 97.8° F. (36.6° C.). No nasal or other discharge could be found. A specimen of urine contained a trace of albumin but no pus cells. His haemoglobin was 88% (Sahli), white-cell count 15,600 per c.mm. (polymorphonuclear leucocytes 70%, lymphocytes 24%, monocytes 6%). He took his feeds well the next day and seemed to be improving slightly. Thirty-six hours

JULY 27, 1957

after admission he had a generalized convulsion lasting several minutes. Immediately afterwards no abnormality could be discovered on physical examination and the anterior fontanelle was normotensive. However, a lumbar puncture was carried out and a cloudy fluid under normal pressure was obtained. A film of this fluid showed many polymorphonuclear leucocytes and many bacilli which were presumed to be *E. coli*. He was accordingly treated with streptomycin, 50 mg. twice a day intramuscularly, and sulphadiazine, 0.5 g. followed by 0.25 g. six-hourly by mouth. Later the same day one of us (P. N. E.) reported the organism to be *Listeria monocytogenes*. It was decided, in view of the first case here reported, to replace the streptomycin with chloramphenicol, in a dosage of 125 mg. six-hourly for 12 days. The biochemistry of the cerebrospinal fluid was: protein, 900 mg.; glucose, 12 mg.; chlorides, 600 mg. per 100 ml.

For the next week the baby remained listless, feeding poorly and twitching occasionally. He was therefore given phenobarbitone, $\frac{1}{2}$ gr. (8 mg.) twice a day by mouth. Although the convulsions became less frequent, he had them occasionally until the 33rd hospital day, but none thereafter. Because he fed so slowly, he was tube-fed from the 5th to the 19th day after admission. After that date he sucked well and gained weight. All treatment was stopped on the 35th day, and he was discharged home on June 16, well in every way, weighing 5 lb. 13 oz. (2,635 g.).

When seen on September 17 he weighed 9 lb. 11 oz. (4,395 g.), was feeding well, had had no further convulsions, and no abnormal signs could be elicited.

The father was a miner. There was no history of recent illness in either parent. The condition of the child on admission indicated an unhygienic background. The family kept an apparently healthy dog but no other pets. There was no contact with any livestock, although there were mice and beetles in the house.

Bacteriological Investigations

A Gram film of the turbid cerebrospinal fluid taken from Baby Ross by lumbar puncture on admission showed numerous leucocytes, about 70% of which were polymorphonuclear. A few Gram-positive bacilli, medium-sized with rounded ends and occurring singly and in side-to-side pairs, were seen, both intracellularly and extracellularly placed. Culture on digest human blood agar, incubated aerobically at 37° C. overnight, gave a moderate growth of *Listeria monocytogenes*.

The cerebrospinal fluid taken from Baby Fraser on admission was turbid and showed a similar predominantly polymorphonuclear picture. Numerous Gram-positive bacilli were seen, both intracellularly and extracellularly placed. Culture yielded a heavy growth of *Listeria monocytogenes*. Blood cultured from this case on admission, as well as urine and a rectal swab taken the day after, yielded a growth of this organism.

All the five cultures from these two cases gave smooth grey semi-opaque colonies approximately 2 mm. in diameter after 24 hours at 37° C. on digest human blood agar. Slight haemolysis was present, confirmed by soluble haemolysin test (see Webb and Barber, 1937). Films of the cultures showed Gram-positive bacilli of the same morphology as in the cerebrospinal fluid films, and included many end-to-end V-shaped pairs as well as packets of parallel bacilli. The arrangement of the bacilli was similar to that seen in the case of diphtheroid bacilli, but the individual organisms were more smoothly symmetrical than diphtheroids and lacked the tendency to clubbing often seen in the latter. Overnight broth cultures showed rather scanty motile forms. With end-over-end motion, amongst numerous apparently non-motile bacilli. Later cultures in glucose broth incubated at 25° C. gave much more marked motility. Good growth, but with smaller colonies, occurred on nutrient agar, and very small colonies grew on McConkey's medium after 24 hours at 37° C. Growth also occurred in 6.5% saline broth at 37° C., and slow growth took place in the refriger-

ator on blood agar. Murray's (1955) statement that *Listeria monocytogenes* survives heating at 80° C. for five minutes could not be confirmed for any of the cultures, and the type 4 strain of the organism obtained from the National Collection of Type Cultures (N.C.T.C.5214) also failed to survive in this test. All the cultures, however, resisted heating at 56° C. for five minutes.

Biochemical Reactions

The following sugars were rapidly fermented with acid but no gas: glucose, maltose, mannose,* rhamnose, salicin, dextrin. Late fermentation (first observed between the 3rd and 17th days of incubation) occurred with lactose, sucrose, sorbitol, and glycerol.* No fermentation had occurred by the 17th day in dulcitol, mannitol, inositol, xylose, raffinose, galactose, and arabinose.

No indole was produced, the methyl-red test was positive, and the Voges-Proskauer test very faintly positive after incubation of the reagents for 24 hours (the last three tests were done with the techniques of Wilson, 1935). Urea was not split on Christensen's medium. Neither coagulated serum nor gelatin was liquefied after three weeks' incubation at 37° C. Haemagglutination tests carried out by Dr. J. P. Duguid, Edinburgh University, with 24- and 48-hour 37° C. blood-agar cultures, and the deposits from 48-hour 37° C. digest broth cultures, were uniformly negative against human, horse, sheep, ox, and guinea-pig red cells, both in the cold and at room temperature.

Animal Pathogenicity

Ross Strain.—Two rabbits inoculated intravenously with 0.5 ml. of plate-culture suspension of Brown's opacity 3, and 0.5 ml. of 24-hour broth culture respectively, became ill after 24 hours and were dead within 40 hours. Post-mortem examination showed the usual features of experimental listeriosis, the main feature being the mottled liver consisting of a mass of minute necrotic foci. The organism was recovered in large numbers from the liver and other tissues.

Production of Monocytosis in Rabbits.—Three rabbits were given doses of culture intravenously, which were calculated, as described by Webb and Barber (1937), to be around the minimum lethal level. Differential white cell counts were performed before and after the inoculations, and the results are shown in Table I. In the rabbit receiv-

TABLE I.—Production of Monocytosis in Rabbits

Dose of Culture		Leucocyte Count per c.mm.			
		Ross Strain		Fraser (C.S.F.) Strain	
		Total	Absolute Monocyte Count	Total	Absolute Monocyte Count
0.002 mg./kg.	Pre-injection	9,600	336	9,400	282
	3rd day	9,000	1,350	14,200	3,190
	5th "	21,600	3,880	23,000	5,290
	7th "	19,000	3,230	15,800	2,210
0.008 mg./kg.	Pre-injection	8,200	246	12,600	441

	Died within three days				

ing the intermediate dose, the absolute monocyte count rose from the pre-injection level of 246 to 10,510 per c.mm. The rabbit which was given 0.02 mg./kg. died before the third day. A marked monocytosis was therefore produced by sublethal doses of the organism.

Rabbit Conjunctival Test.—This test was described by Anton (1934) and its specificity for *Listeria monocytogenes* was confirmed by Julianelle (1941). A young broth culture was inoculated on to the conjunctiva by instillation, swabbing, and scarification plus swabbing, respectively, in each of three rabbits. In all three marked kerato-conjunctivitis

*Only the Ross strain was tested for fermentation of this sugar.

cases requiring penicillin, except the most severe where very rapid blood levels were required. For mild and moderate infections the dosage schedule used was 60 mg. four times daily in children, and 120 mg. four times daily in adults. In some rather more severe cases these doses were doubled. This schedule is comparable to that used in this hospital for crystalline or long-acting preparations before the advent of penicillin V, and is contrary to the present tendency towards massive dosage, a practice which Howie (1956) deploras.

This review is of 110 cases treated with penicillin V in the twelve months ending October, 1956. Of these, 100 were pulmonary infections; the remainder are the most important of a miscellaneous group of infections also treated with penicillin V. Scarlet fever and tonsillitis are excluded. The small numbers and variety of infections precluded controlled investigations. Laboratory facilities did not permit the estimation of blood penicillin levels.

Pulmonary Infection

The pulmonary infections are discussed first, and greater emphasis is placed on those untreated before admission. There were 63 such cases. Because of small numbers only those under 1 year and those over 65 years are grouped separately, as in these the death rate might be expected to be higher.

In Table I numbers are given, in Table II the severity is indicated, and in Table III severity is related to age. There were no cases of chronic bronchitis in this untreated group.

Severe ..	3	6	0	9
Total ..	37	18	8	63

The three deaths from bronchopneumonia occurred in cases with concurrent renal or cardiovascular disease, and in two of these other antibiotics were given as well as penicillin V.

The remaining 37 cases of pulmonary infection had had some treatment before admission, in most cases one or two injections of intramuscular penicillin. They are summarized in Table IV.

The two deaths were due to cerebral thrombosis with bronchopneumonia and myocardial failure with bronchopneumonia.

Bacteriological Findings.—In all pulmonary infections sputum specimens were submitted for routine bacteriology, which included direct examination for *Mycobacterium*

TABLE IV.—Cases of Acute Chest Infection Treated with Penicillin V Which Had Had Treatment Before Admission

Disease	No. of Cases	Responded to Penicillin V	Changed to Other Antibiotic	Died	Remarks

tuberculosis. From the young children and infants post-nasal swabs were taken instead of sputum. In 62% of our cases of lobar pneumonia predominant growths of pneumococci were obtained from the sputum. No definite significance can be attached to such results, since the organisms were not typed and it is therefore not known which were potentially pathogenic.

Radiological Findings.—The radiological findings in 78 cases of lobar pneumonia and bronchopneumonia are summarized in Table V. Local arrangements for radiology are

TABLE V.—Radiobiological Findings in 78 Acute Chest Infections

Appearance on Radiograph	No. of Cases
Consolidation of one lobe ..	27
Consolidation of more than one lobe ..	3
Significant infiltration ..	20
Negative ..	25
Not done ..	3

such that in routine work there may be a delay of anything up to 15 days. We consider that this has particularly affected the total number of negative results. Some cases, which with prompt radiological examination would most likely have come under the heading “significant infiltration,” were found to be clear. Positive radiological findings resulted in 67% of cases, rather fewer than in many similar reviews. In the cases of lobar pneumonia the average duration of primary pyrexia was 2.6 days, and in the cases of bronchopneumonia 2.8 days. The rate of resolution observed clinically is not accurate, and the radiological facilities precluded an assessment by that method. We are, however, able to state that in only two cases, both of lobar pneumonia, was there evidence of delayed resolution. Both cases had made a good general recovery within one week of admission, but resolution was not radiologically complete until after a total of eight weeks. No toxic effects occurred, apart from mild looseness of bowels in some cases.

Miscellaneous Group

The composition of this group is given in Table VI. Cases 1-6 were untreated before admission.

TABLE VI.—Miscellaneous Infections Treated with Penicillin V

Case No.	Disease	Response to Penicillin V	Remarks
1	Puerperal sepsis ..	Satisfactory	Pulmonary infarct with super-added infection
2	“ ..	“	<i>Strep. viridans</i> from blood culture
3	Cellulitis ..	None	Penicillin-resistant staph. coag. positive
4	Pyæmia ..	Satisfactory	Penicillin-sensitive staph. coag. positive
5	Pemphigus neonatorum	None	Penicillin-resistant staph. coag. positive
6	Anthrax (cutaneous) ..	Satisfactory	See text
7	Ulcerative endocarditis	None	No response to tetracycline. Post mortem diagnosis
8	Anthrax (cutaneous)	Satisfactory	See text
9	Sinusitis ..	“	
10	Cellulitis ..	“	

The cutaneous anthrax occurred in bone-meal workers. The first patient developed a typical malignant pustule on the left side of his neck. He responded satisfactorily to penicillin V, 120 mg. five times daily for 15 days. The second patient developed a pustule just above his right loin. The constitutional upset was considerable. He had been given 1 mega unit of intramuscular crystalline penicillin just before admission. Thereafter he was treated with penicillin V, 250 mg. four times daily. His fever settled after three days, but, as is known to occur also with intramuscular penicillin (Banks, 1951), the sore continued to develop for five to six days after treatment started. The necrosis was extensive, but healing was complete after six weeks.

An adult male developed pyæmia from a sore on one finger. He was severely ill on admission, and had symptoms and signs suggestive of perinephric abscess. His response to penicillin V was rapid.

Comment

The advantages of the oral route are indisputable. The distress of children when subjected to injection is avoided, and the possibility of sepsis is reduced. The use of compressed tablets or, better still, sealed capsules obviates the occurrence among nursing staff of sensitization reactions. Penicillin can be given without precipitating paralysis by intramuscular injection in those with latent poliomyelitis infection. Also a great deal of time is saved; this is particularly important in small hospitals, such as this, where effective running depends very much on the quality of a small nucleus of trained staff and a large number of untrained orderlies. Finally, there is no significant difference in the cost between penicillin V and the various forms of penicillin G which are injected. Whilst the other oral forms of penicillin G are not injected. Whilst the other oral forms of penicillin G are no more expensive, it must not be forgotten that it is recommended that these preparations should be given in doses four or five times greater than that required intramuscularly. This is not the case with oral penicillin V. Our use of the drug over an extended period has produced results no less satisfactory than those obtained when penicillin was previously given intramuscularly, and we have been able to enjoy all the considerable advantages of oral therapy.

Summary

In the twelve months ended October, 1956, 110 cases were treated with oral penicillin V. Of these, 100 were cases of pulmonary infections. Cases which were wholly untreated before admission are given in greater detail. Penicillin was regarded primarily as an oral drug like the tetracyclines and chloramphenicol, and the results appear to justify that policy.

Over 50 members of the medical section of the Library Association attended a week-end conference in Edinburgh from June 28 to July 1. Members were the guests of the University at a dinner presided over by Professor J. H. GADDUM, F.R.S., after which they were shown some of the medical treasures of the library, including the Harvey tercentenary exhibit. Visits paid to the libraries of the Royal College of Physicians, Royal College of Surgeons, Royal Medical Society, and the Central Medical Library were a reminder that Edinburgh has one of the richest collections of medical literature in the Commonwealth. Other places visited included the National Library of Scotland and the Royal Society of Edinburgh, where the extensive collection of Slavonic and Oriental periodicals of medicine and science were of special interest.

A TRIAL OF PENICILLIN V
RESPONSE OF PENICILLIN-RESISTANT
STAPHYLOCOCCAL INFECTIONS TO PENICILLIN

BY

J. I. BURN, F.R.C.S.

M. P. CURWEN, M.A.

R. G. HUNTSMAN, M.R.C.P.

AND

R. A. SHOOTER, M.D.

From the Casualty, Statistics, and Bacteriology Departments,
St. Bartholomew's Hospital, London

Many patients with staphylococcal sepsis are seen in a busy out-patient department. When the sepsis is serious enough to warrant treatment with an antibiotic, it has been the practice in this hospital to give penicillin by injection. Penicillin has not often been given by mouth because of doubts of its absorption from the alimentary tract, although the use of oral penicillin would save nurses' time, and would be preferred by the majority of patients. Penicillin V (phenoxymethylpenicillin) is more stable in an acid medium than penicillin G, and, probably because of this, blood levels reached after giving penicillin V by mouth are higher and better sustained than those from an equivalent oral dose of penicillin G (Rinsler and Cunliffe, 1956; *British Medical Journal*, 1956).

This paper records the results of a trial carried out in the casualty department of this hospital. The object of the trial was to determine the reliability of oral penicillin V in the treatment of staphylococcal sepsis by comparing its efficacy with that of penicillin by injection. During the trial observations were made on the response to treatment with penicillin of infections due to resistant (penicillinase-producing) staphylococci.

Methods

The trial involved 346 patients attending the casualty department with infections principally due to staphylococci. All except eight were seen by one of us (J. I. B.), and all had septic lesions which were thought to need treatment with penicillin. In general, except for boils on the face, which were always treated with chemotherapy, boils and other minor infections were not treated unless accompanied by appreciable lymphangitis or lymphadenitis. Patients with septic fingers were not included. The series also did not include patients attending other departments such as those of the ear, nose, and throat or the skin. So far as was possible swabs were taken from the patients when first seen, or when the lesion was incised.

In determining how the patients should be allocated to the two treatment groups it was not thought practicable to adopt any method which involved frequent alteration in the routine, and accordingly patients were treated in alternate periods of six weeks by injection or penicillin V by mouth, any local treatment being the same in both groups. There was clearly no question of withholding the nature of the treatment from the patient or the person assessing the results. In common with others we have not thought it justifiable to treat a comparable series of patients without chemotherapy, and there is therefore no control group against which to judge the efficacy of either form of penicillin. We can only compare them with each other.

Patients treated by injection received a single daily dose of 1 ml. of “abbocillin 800 M,” which contained 600,000 units of procaine penicillin and 200,000 units of crystalline penicillin G. Those given penicillin V were instructed to

to treatment with penicillin as infections due to sensitive staphylococci. If these observations are confirmed, it suggests that penicillin is still adequate for the treatment of most forms of staphylococcal sepsis seen in out-patients.

We are indebted to Eli Lilly and Company Limited for the supply of penicillin V.

INFLUENCE OF CORTISONE ON TERATOGENIC EFFECTS OF HYPERVITAMINOSIS-A

BY

J. W. MILLEN, M.D., D.Sc.

AND

D. H. M. WOOLLAM, M.D., M.R.C.P.

Lecturers in Anatomy, University of Cambridge

The important part which environmental factors may play in influencing the occurrence of congenital malformations is becoming recognized as a result of animal experiments in which the dams have been subjected during pregnancy to the effects of a wide variety of teratogenic agents. Amongst the substances whose teratogenic importance is now well established is vitamin A: both hypovitaminosis-A and hypervitaminosis-A in the mother have been shown to result in the birth of young with anomalies of the brain and its coverings. Congenital hydrocephalus has been reported in the offspring of animals fed on a vitamin-A-deficient diet (rabbits—Millen, Woollam, and Lamming, 1954; rats—Rokkones, 1955). In rats, maternal hypervitaminosis-A is known to produce anencephaly, exencephaly, and hydrocephalus in the young (Cohlan, 1953; Giroud and Martinet, 1954).

The investigation reported in the present communication was undertaken to explore the effect of cortisone, administered during pregnancy, upon the incidence of deformities of the brain and calvaria produced by hypervitaminosis-A.

Material and Methods

Female white rats of the Wistar strain were used in the experiments. Each of these rats had previously given birth to a normal litter. At the beginning of the experiment the rats were given 2,000 I.U. of vitamin D and 50 mg. of vitamin E by mouth to ensure that they had an adequate supply of these vitamins.

Daily vaginal smears were taken at 9 a.m. and conception was determined by the presence of spermatozoa. The day on which spermatozoa were found was regarded as Day 1 of the pregnancy. The pregnant rats were divided into three groups, each group consisting of 12 animals.

Group 1 received 60,000 I.U. of vitamin A acetate daily from the 8th to the 13th day, inclusive, of pregnancy.

Group 2 received 20 mg. of cortisone acetate daily from the 9th to the 12th day, inclusive, of pregnancy.

Group 3 received 60,000 I.U. of vitamin A acetate daily from the 8th to the 13th day, inclusive, and 20 mg. of cortisone acetate from the 9th to the 12th day, inclusive, of pregnancy.

Vitamin A was given by intubation. A rubber No. 8 French catheter was passed into the stomach and the dose of vitamin A dissolved in 1 ml. of arachis oil was introduced. The procedure was repeated on the appropriate days. Cortisone acetate was given by subcutaneous injection.

The rats were killed on the 20th day of pregnancy and the young removed from the uterus. The foetuses were inspected for abnormalities and preserved in 10% formalin for further examination. Various deformities were encountered in the young, but only those affecting the brain and the calvaria are considered in this communication.

Findings

The results of the experiments are shown in the Table. It will be noted from this that the number of young in group 3 is much smaller than in the other two groups.

Incidence of Deformities of the Brain and Calvaria Found in the Young

Group	No. of Rats	Total No. of Young	No. of Young with Deformity of Brain and Calvaria	Percentage of Young with Deformity of Brain and Calvaria
1	12	77	6	7.8
2	12	73	0	0
3	12	41	15	36.6

This was due to the resorption of all the young in three animals, and of many of the young of another four animals. Total resorption also occurred in two of the rats in group 2.

Varying degrees of malformation were encountered and are shown in the illustration. In some animals the deformity was in the nature of a small meningocele associated with a marked acrocephaly, whilst in others there appeared to be a complete extroversion of the cerebral hemispheres, so that the chorioid plexuses were exposed on the surface of the brain. In the latter animals the amniotic fluid was invariably tinged with blood pigment.

Discussion

The most significant finding which emerges from this experiment is that cortisone given to hypervitaminotic rats on the 9th to 12th days produces a great increase in the number of young, surviving on the 20th day, which show malformations of the brain and calvaria (36.6%).

It is well known that hypervitaminosis-A in rats results in malformations of the brain and calvaria in their young. As has been stated earlier, anencephaly and exencephaly have been reported by Cohlan (1953) and by Giroud and Martinet (1954). Cohlan (1954) obtained young with a congenital cranial anomaly in 48.7% of the foetuses by giving 35,000 I.U. of vitamin A daily from the 2nd or 4th day to the 16th day of pregnancy. Giroud and Martinet (1956) observed a 6% incidence in the young of rats which had received 20,000 I.U. of vitamin A daily for 12 days from the 2nd or 4th day of pregnancy. The incidence of 7.8% young with gross deformities of the brain and skull obtained in group 1 of the present experiment (rats which received 60,000 I.U. of vitamin A daily from the 8th to the 13th day) is in complete agreement with these earlier reports.

Cortisone alone has not been shown to have a teratogenic action. The animals which received 20 mg. of cortisone daily from the 9th to the 12th day (group 2 of the experi-

The various degrees of deformity of the brain and calvaria (actual size).

EFFECT OF CORTISONE ON THE INCIDENCE OF CLEFT-PALATE INDUCED BY EXPERIMENTAL HYPERVITAMINOSIS-A

BY

D. H. M. WOOLLAM, M.D., M.R.C.P.

AND

J. W. MILLEN, M.D., D.Sc.

Lecturers in Anatomy, University of Cambridge

Cleft-palate may be produced experimentally in the rat by the administration of massive amounts of vitamin A to the dam during the early and middle periods of pregnancy (Cohlan, 1953; Giroud and Martinet, 1954). Fraser *et al.* (1954) have demonstrated that cortisone greatly increases the incidence of cleft-palate in strains of mice which show a genetic predisposition to the spontaneous occurrence of the deformity.

It appeared, therefore, that both hypervitaminosis-A and cortisone may be implicated in the production of cleft-palate in experimental animals. An investigation was therefore carried out in order to determine whether the incidence of cleft-palate produced by hypervitaminosis-A during pregnancy was influenced by giving cortisone.

Materials and Methods

Female white rats of the Wistar strain were used in the experiment. Each of these rats had previously given birth to a normal litter. At the beginning of the experiments the rats were each given 2,000 I.U. of vitamin D and 50 mg. of vitamin E by mouth to ensure that an adequate supply of these vitamins was available. Vaginal smears were taken daily at 9 a.m., and conception was determined by the presence of spermatozoa. The day on which spermatozoa were found was regarded as Day 1 of the pregnancy.

The pregnant rats were divided into five groups, each group consisting of 12 animals.

Group 1 received 60,000 I.U. of vitamin A acetate, by subcutaneous injection, daily from the 8th to the 13th day, inclusive, of pregnancy.

Group 2 received 20 mg. of cortisone acetate, by subcutaneous injection, daily from the 9th to the 12th day, inclusive, of pregnancy.

Group 3 received 60,000 I.U. of vitamin A acetate, by subcutaneous injection, daily from the 8th to the 13th day, inclusive, of pregnancy, and 20 mg. of cortisone acetate, by subcutaneous injection, daily from the 9th to the 12th day, inclusive, of pregnancy.

Group 4 received 60,000 I.U. of vitamin A acetate, by oral intubation, daily from the 8th to the 13th day, inclusive, of pregnancy.

Group 5 received 60,000 I.U. of vitamin A acetate, by oral intubation, daily from the 8th to the 13th day, inclusive, of pregnancy, and 20 mg. of cortisone acetate, by subcutaneous injection, daily from the 9th to the 12th day, inclusive, of pregnancy.

ment) produced no young with malformations of the brain. Fraser, Fainstat, and Kalter (1953), however, found an increased incidence of cleft-palate following the administration of cortisone to mice of a genetic strain in which there was already a low incidence of cleft-palate.

The explanation of the striking increase in the incidence of abnormalities of the brain and calvaria when hypervitaminosis-A and cortisone are combined awaits further experiment. The results of the work reported here suggest strongly that cortisone potentiates the teratogenic effect of the hypervitaminosis-A. It may well be that the increased incidence of cleft-palate observed by Fraser *et al.* in mice genetically susceptible to the condition was also due to the cortisone potentiating the expression of the inherent genetic weakness.

It has been suggested that all environmental teratogenic activity is mediated through the influence of teratogenic agents on genetic weaknesses which, by themselves, do not result in the appearance of congenital malformations (Fraser, 1953). The malformations of the brain and calvaria described above have not been reported in the offspring of normal rats of the strain used in this experiment. Even if the hypothesis of an inherent genetic tendency to the deformity be admitted, it is clear that the effect of cortisone in potentiating the teratogenic action of vitamin A must be of considerable significance.

It will be noted that more resorptions of litters occurred in the rats receiving both vitamin A and cortisone. The probable explanation for this is suggested by the consideration of the possible outcomes of pregnancy. Pregnancy must result in the birth of normal or malformed young or must result in the death and resorption of the foetus. If a teratogenic agent is at work there will be a shift in the direction of total failure of the pregnancy—that is, the death and resorption of the young. Hence with a diminution in the number of normal young and an increase in the number of malformed young one would expect to find also an increase in the mortality of embryos during pregnancy.

It may well be argued that, because of the large doses of the teratogenic agents employed, experiments with animals such as those reported here have little bearing on the possible outcomes of human pregnancy. But, in evaluating the strength of this argument it is necessary to compare the incidence of the naturally occurring malformation in man with its incidence as produced experimentally in laboratory animals. The frequency of anencephaly and associated anomalies in man has been stated to be about 0.25% of total births (Böök and Fraccaro, 1956). The incidence recorded in the present experiment, 36.6%, is 150 times as great as the incidence in man. It appears, therefore, not wholly illogical to suppose that during the early months of pregnancy the situation occurs occasionally where the circulating amounts of cortisone and vitamin A may be of such proportions as to influence unfavourably the development and the survival of the foetus. Such a possibility is at least worthy of further consideration in the light of the findings of this investigation.

Summary

The effect of cortisone upon the teratogenic action of hypervitaminosis-A has been studied in rats.

The incidence of gross malformations of the brain and calvaria in the young of mothers who received both vitamin A and cortisone was greatly increased (36.6%), compared with those from animals which received vitamin A alone (7.8%) or cortisone alone (0%).

These findings are discussed in relation to earlier work upon the teratogenic effects of hypervitaminosis-A and of cortisone.

Our thanks are due to Professor J. D. Boyd for his advice and encouragement in the preparation of this paper. We also thank Mr. J. F. Crane for photographic assistance. The work was supported by a grant from the Nuffield Foundation, which is gratefully acknowledged.

The rats were killed on the 20th day of pregnancy and the young removed from the uterus. The foetuses were inspected for deformities, and preserved in 10% formalin for further examination. Various deformities were encountered in the young. Only those affecting the palate are considered in the present communication.

Findings

The results of the experiments are shown in the Table. It will be noted from this that the number of young in group 5 is much smaller than in the other four groups. This was due to the resorption of all the young in three animals, and of many of the young of another four animals.

Incidence of Cleft-palate in the Five Groups

Group	No. of Dams	Total No. of Young	No. of Young with Cleft-palates	Percentage of Young with Cleft-palates
1	12	69	0	0
2	12	73	0	0
3	12	73	1	1.4
4	12	77	23	29.7
5	12	41	41	100

The deformities of the palate were of varying degrees of severity (see Fig.). In some of the young, absence of the alveolar margin anteriorly was associated with protrusion of the tongue. In no case, however, was there any sign of deficiency in the anterior palate, the cleft being confined entirely to the posterior palate. The type of malformation encountered

in the young of groups 3 and 5, in which the animals received both vitamin A and cortisone, was the same as that of group 4, in which animals received vitamin A only.

Discussion

The nature of the deformity of the palate was precisely similar to that described by Giroud and Martinet (1954) as occurring in the young of female rats subjected during pregnancy to the effects of hypervitaminosis-A. The most striking feature to emerge from the present experiment was the

Illustrating the variations in the degree of cleft-palate encountered. ($\times 1.75$)

greatly increased incidence of cleft-palate in the young of those animals which received both cortisone and oral vitamin A during pregnancy (group 5), compared with the incidence of the deformity in the young of those animals which received oral vitamin A only (Group 4). The absence of cleft-palate in group 1 and its low incidence in group 3 suggest that vitamin A does not possess the same teratogenic activity when given subcutaneously as it does when orally administered. It may be that the slow rate of absorption following subcutaneous administration prevents the vitamin from reaching the foetus until after the most critical stage in the development of the palate. There is also the possibility that the slow absorption does not allow the vitamin to reach the foetus in sufficient concentration to exert a teratogenic effect.

When a pregnant animal is exposed to the effects of a teratogenic agent there are three possible outcomes, depending on the sensitivity of the foetus to the action of that agent at the time when it is administered. The young may die and be resorbed. They may, however, be slightly damaged only and be born with congenital malformations, or they may escape the effect of the agent altogether and be born normal. There is a normal variation in the susceptibility of the individual members of a litter to the effects of a teratogenic agent. Therefore, since the effects of such an agent fall upon the whole litter, if there is an increase in the sensitivity of the litter as a whole to its action, animals which would otherwise be born healthy are born with deformities, and those which would have survived, but only in a malformed state, die and are resorbed. This seems to be what has occurred in the present experiment, and offers a satisfactory explanation for the difference in the findings in groups 4 and 5.

The absence of a single normal offspring and the marked increase in the resorption rate in group 5 must be attributed to the action of cortisone. It seems, therefore, that the action of cortisone is to sensitize the tissues to the teratogenic activity of hypervitaminosis-A. The report by Fraser *et al.* (1954), that cortisone produces an increased incidence of cleft-palate in strains of mice in which there is already, for genetic reasons, a liability to the deformity, taken in conjunction with the findings of the present investigation, suggests that the action of cortisone in potentiating the action of vitamin A may be a general rather than a specific activity.

Summary

The incidence of cleft-palate in the young of female rats which received both oral vitamin A and cortisone was greatly increased (100%) compared with its incidence in the young of animals which received oral vitamin A only. Vitamin A given by subcutaneous injection was less effective as a teratogenic agent than when given orally.

The results of the experiment suggest that cortisone acts by increasing the sensitivity of the developing tissues and thereby enhancing the teratogenic actions of the hypervitaminosis-A.

Our thanks are due to Professor J. D. Boyd for his advice and encouragement in the preparation of this paper. We also thank Mr. J. F. Crane for his photographic assistance. The work was supported by a grant from the Nuffield Foundation, which is gratefully acknowledged.

A meeting of the Osler Club was held last month at the Physic Garden, Chelsea, to commemorate the 250th Anniversary of the birth of Linnaeus. The president, Dr. W. S. C. COPEMAN, presided, and Sir EDWARD SALISBURY, F.R.S., formerly director of Kew, gave an address on "Old Physic Gardens and Herbs." Botany, he said, being a major branch of medicine until comparatively recent times, was taught systematically with the help of physic gardens attached to most of the universities of Europe. Herbs were meant only as reminders for those who already knew the living plants, and so they were able to perpetuate over the centuries very poor-quality woodcut illustrations, which were sufficient for this purpose. These improved as theoretical botany was taught. Herbs also perpetuated the oral therapeutic traditions from very early times. The first English herbal was produced by William Turner, the "father of English botany," in 1551. Gerard's more celebrated volume was published almost a century later. The talk was illustrated with plants and herbs from the Physic Garden and its library.

A COMPARISON OF CORTISONE AND PREDNISONE IN TREATMENT OF RHEUMATOID ARTHRITIS

A REPORT BY THE JOINT COMMITTEE OF THE MEDICAL RESEARCH COUNCIL AND NUFFIELD FOUNDATION ON CLINICAL TRIALS OF CORTISONE, A.C.T.H., AND OTHER THERAPEUTIC MEASURES IN CHRONIC RHEUMATIC DISEASES*

The object of the therapeutic trial here reported was to determine whether patients with rheumatoid arthritis who had already been treated for at least a year with cortisone acetate would benefit by having their therapy changed to prednisone acetate (delta-1-cortisone acetate).

In total, 68 patients entered the trial, of whom 35, selected at random, had their therapy changed to prednisone acetate and the remaining 33 continued to receive cortisone acetate. Both groups have now completed one year in the trial, and an analysis of the findings during this period is presented below.

Type of Patient.—The patients admitted to the trial were drawn from those with rheumatoid arthritis attending hospital out-patient departments at six different centres. To be included in the trial they had to fulfil centres. To be included in the trial they had to fulfil three criteria—namely, (a) be more than 16 years of age; (b) be suffering from polyarthritis of a rheumatoid type and no other disease of a serious nature; and (c) have received cortisone acetate or hydrocortisone for at least a year prior to entry.

Allocation of Treatment.—At each participating centre pairs of patients were matched as closely as possible for age, sex, duration of disease, and duration of previous cortisone therapy. One of each pair, selected randomly, continued to receive cortisone acetate; the other was changed to prednisone acetate. (In two instances there were no pairs to patients transferred to prednisone acetate).

Dosage.—The initial dosage of prednisone acetate was one-third of the cortisone acetate dosage that the patient was receiving at entry; subsequently it was adjusted to the individual patient to obtain maximum benefit without side-effects.

Assessments.—Clinical assessment of each patient was required on entry to the trial and at four weekly intervals thereafter. It included a judgment of the activity of the disease, and an evaluation of the patient's general functional capacity. The strength of grip in each hand was measured and laboratory tests were carried out with respect to blood sedimentation rate and haemoglobin level. Any complications or side-effects occurring during the previous four weeks were noted, and other information routinely recorded included blood-pressure reading and the current use of analgesics by the patient.

*The members of the Joint Committee are: Lord Cohen of Birkenhead (chairman), Dr. E. G. L. Bywaters, Dr. W. S. C. Copeman, Sir Charles Dodds, Dr. J. J. R. Duthie, Professor A. Bradford Hill, Mr. H. Osmond-Clarke, Professor F. T. G. Prunty, Dr. J. Reid, Dr. H. F. West, Professor J. H. Kellgren and Mr. W. A. Sanderson (Joint Secretaries). The subcommittee and the workers participating at each centre were: Dr. H. F. West (chairman) and Dr. G. R. Newns, Sheffield Centre for the Investigation and Treatment of Rheumatic Diseases; Drs. Oswald Savage, M. L. Joule, A. J. Popert, V. M. Leveaux, and D. C. Beatty, West London Hospital and the Arthur Stanley Institute; Drs. E. G. L. Bywaters, B. Ansell, A. Parkin, and F. Shannon, Postgraduate Medical School and Canadian Red Cross Memorial Hospital, Taplow; Professor J. H. Kellgren and Dr. A. St. J. Dixon, Rheumatism Research Centre, Manchester; Dr. J. T. Boyd, Statistical Research Unit of the Medical Research Council, London School of Hygiene and Tropical Medicine.

Results

Of the 68 patients admitted to the trial, 33 were allocated to continued cortisone therapy and 35 to treatment with prednisone acetate. A comparison of the two groups at entry (Table I) reveals close similarity.

TABLE I.—Number of Patients in the Two Treatment Groups at Start of Trial by (a) Age and Sex, (b) Disease Duration, and (c) Duration of Previous Cortisone (or Hydrocortisone) Treatment

Age (Years)	No. of Patients			
	Male		Female

5–9	13	15	2–	9	9
10+	15	15	3+	14	12
Total	33	35	Total	33	35

During the succeeding 12 months the clinical conditions of 6 patients (5 cortisone, 1 prednisone) led to changes from their allocated therapy and a further 3 patients (2 cortisone, 1 prednisone) died. Relevant details of these deaths and treatment changes are as follows:

Deaths.—(1) Male aged 61 (cortisone): Died (week 3) after an operation for perforated duodenal ulcer complicated by haemorrhage. (2) Female aged 53 (cortisone): Sudden death (week 26) from subarachnoid haemorrhage. (3) Male aged 28 (prednisone): "Died of asphyxia (week 10) and at post-mortem was found to have honeycomb lungs."

Changes of Treatment.—(1) Male aged 42 (cortisone): Changed to prednisone (week 24) "Because symptoms could not be controlled." (2) Female aged 27 (cortisone): Therapy discontinued (week 27). "Sudden onset of substernal pain radiating to neck and shoulder . . . dissecting aneurysm of aorta." (3) Male aged 52 (cortisone): Therapy discontinued (week 32) owing to appearance of amyloid disease. (4) Male aged 54 (cortisone): Changed to prednisone (week 37) after developing congestive cardiac failure. (5) Female aged 35 (cortisone): Severe bilateral scleritis (week 46). Therapy changed to adrenal stimulation and subsequently to prednisone. (6) Male aged 44 (prednisone): Was put on cortisone for three weeks (weeks 39–41) by his own doctor after running out of trial tablets.

After these changes of treatment assessments continued to be made for all except the patient with amyloid disease who, after week 32, was unable to attend hospital. In the analyses that follow, the other five patients have been retained in their original starting groups throughout the year.

Clinical Assessment of Disease Activity

The clinical assessments of disease activity are presented in Table II. By definition all patients were suffering from active rheumatoid arthritis on entry, and the two treatment groups had similar numbers of patients with slightly, moderately, or very active disease. After four weeks of treatment a definite improvement was evident among the patients receiving prednisone. The number with only slight disease activity increased from 19 to 27 and a further 3 were in complete remission. This initial improvement was maintained at 12 weeks, but thereafter there were clear signs of a falling back. Thus, while at the end of the year the number of patients in remission had increased to 5, the

TABLE II.—Number of Patients with Given Grades* of Disease Activity at Different Stages of Trial

* Grading of disease activity: 0 = none; 1 = slight; 2 = moderate; 3 = severe.
† No assessment available for one cortisone patient.

number with only slight activity had fallen to 18 and the number with moderate activity had risen to 11—compared with 15 originally and only 4 at week 12. The cortisone group, on the other hand, showed no improvement at any stage during the year and there was even some evidence of deterioration in the slightly increasing number of patients assessed as having very active disease.

General Functional Capacity

At the start of the trial there was little difference between the cortisone and prednisone groups in their distribution over four arbitrary grades of functional capacity (Table III).

TABLE III.—Number of Patients with Given Functional Capacity* at Different Stages of Trial

Time of Assessment	Treatment Group	No. of Patients					
		Functional Capacity				Dead	Total
		1	2	3	4		
Week 0	Cortisone	2	18	12	1	—	33
	Prednisone	4	20	9	2	—	35
" 4	Cortisone	2	16	13	1	1	33
	Prednisone	9	22	3	1	—	35
" 12	Cortisone	1	17	12	2	1	33
	Prednisone	8	19	5	2	1	35
" 24	Cortisone	1	18	12	1	1	33
	Prednisone	9	18	6	1	1	35
1 year	Cortisone	2	16	9	3	2	32†
	Prednisone	8	20	4	2	1	35

* Functional capacity grades were:
1. Fully employed or employable in usual work and able to undertake normal physical recreations.
2. Doing light or part-time work. Only limited physical recreations. For housewives all except the heaviest housework.
3. Not employed and unemployable. No physical recreations. Housewives only light housework and limited shopping.
4. Confined to house or wheel-chair but able to look after themselves in the essentials of life.
5. Completely bedridden.
† No assessment available for one cortisone patient.

No patients in either group were in grade 5—that is, completely bedridden—at any stage of the trial. Their subsequent progress revealed some degree of improvement in the prednisone group, in the numbers of patients reaching the highest functional grading—that is, fully employable; 4 of the 35 patients were capable of full activity on entry to the trial, 9 after four weeks' treatment, and 8 at the end of the year. The group remaining on cortisone showed no significant changes.

Strength of Grip

The strength of grip of each hand was measured by the patient squeezing an oblong rubber bag, 5 by 3 in. (12.5 by 7.5 cm.) inflated at a pressure of 10 mm. Hg. The average levels of the two groups were almost identical at the start of the trial, but, while there was subsequently no material change in the level of performance by the cortisone group, there was a very definite improvement among the patients receiving prednisone therapy (Table IV). This improvement was evident four weeks after the change-over

TABLE IV.—Average Measurements of Strength of Grip (mm. Hg)

Treatment Group	Average Measurement	Week 0	Week 4	Week 12	Week 24	1 Year
Strength of grip (mm. Hg):

		0	17	12	4

and was maintained at week 12. Thereafter there was some loss of this initial gain, but at the end of the year the strength of grip of prednisone patients still remained, on average, appreciably above their starting level. Table V gives the number of patients with different levels of strength of grip (left hand) at the start of the trial and at one year. A similar pattern was displayed by the data for the right hands.

Blood Sedimentation Rate and Haemoglobin Level

Neither in blood sedimentation rate nor in haemoglobin level did the cortisone group reveal any appreciable change during the year (Table VI). An improvement in both was evident for the prednisone group. Thus the average blood sedimentation rate (mm./hr.) of the group was 37 at the start of the trial and less than half this figure after four weeks' prednisone treatment. This improvement was not, however, maintained during the second six months of the trial, though the average E.S.R. at one year (24 mm./hr.) remained below the initial level.

A similar pattern was evident in the trends of the average haemoglobin level for the prednisone group; an initial rise

TABLE VI.—Average Measurements of (a) Blood Sedimentation Rate and (b) Haemoglobin

Treatment Group	Average Measurement	Week 0	Week 4	Week 12	Week 24	1 Year
E.S.R. (mm./hr.)	Cortisone	34	30	28	29	31
	Prednisone	37	17	16	19	24
Hb (g./100 ml.)	Cortisone	12.7	12.9	12.8	12.7	13.1
	Prednisone	12.5	13.4	13.5	13.4	13.0

TABLE VII.—Number of Patients with Given Blood Sedimentation Rates at One Year Related to Their Rates at Start of Treatment

E.S.R. (mm./hr.) at Start of Treatment	Treatment Group and No. of Patients	E.S.R. (mm./hr.) at One Year			
		< 20	20–	40–	60+

		20	9	3	2

from 12.5 g./100 ml. to 13.5 g./100 ml. was followed by a fall during the second six months to 13.0 g./100 ml. at the end of the year.

Looking beneath the E.S.R. averages to individual levels the difference between the two treatment groups was again apparent (Table VII). Taking under 20 mm./hr. as a normal level, 20 of 34 prednisone patients, compared with 11 of 30 cortisone patients, had a normal E.S.R. at one year, while 9 and 11 respectively had an elevated rate (20–39) and 5 and 8 had a considerably elevated rate (40 or over).

Dosage

The average levels of cortisone and prednisone dosage are given in Table VIII together with information on the use of analgesics by the two groups of patients. Prior to

TABLE VIII.—Treatment: (a) Average Dosage of Cortisone and Prednisone at Different Stages of the Trial, and (b) Usage of Analgesic Tablets

of Analgesic Tablets						
	Treatment Group	Week 0	Week 4	Week 12	Week 24	1 Year
Average dosage (mg./day)	Cortisone	64*	62	65	65	60
	Prednisone	62*	20	17	15	14
Analgesics (average No. of tablets/day)	Cortisone	7	7	6	7	6
	Prednisone	6	3	2	3	4

* Both groups receiving cortisone at week 0.

the start of the trial both groups had been receiving an average dose slightly above 60 mg. of cortisone daily. For the cortisone group this level was maintained throughout the year of the trial. The average daily dose of prednisone administered during the first months was 20 mg., but during later months this level was reduced, reaching 14 mg. at the end of the year.

There was no change in the average number (6–7 daily) of analgesic tablets taken by cortisone patients during the year, while for prednisone patients there was a decline from 12. Thereafter their use of analgesic tablets began to increase, and at one year the average figure was 4 tablets a day.

Radiographic Findings

X-ray films of hands and feet taken at the beginning and after one year were available for 51 patients. Of 24 cortisone patients, 10 (42%) had evidence of advance in bony erosion; and of 27 prednisone patients, 9 (33%) showed similar evidence.

Complications and Side-effects

During the year of the trial the following intercurrent illnesses were noted (in addition to those already recorded above under "deaths" and "treatment changes").

1. Female aged 56 (cortisone): Duodenal ulcer (week 15).
2. Male aged 51 (prednisone): Gastric ulcer week 8. This patient had a history of perforated duodenal ulcer 27 years previously.
3. Female aged 32 (prednisone): Gastric ulcer with repeated haematemesis necessitating partial gastrectomy (week 12).
4. Male aged 44 (prednisone): Recurrent cholecystitis, operation week 52.

Two further patients, both on prednisone, showed a rapid and unexplained fall in haemoglobin level during the second quarter of the year.

At each attendance physicians were asked to record the presence or absence of the specific side-effects detailed in Table IX. Patients in the cortisone group showed no marked change in incidence, while for prednisone patients the most marked change was the increased incidence of "moonface" from 11 cases at week 0 to 19 at week 12 and 20 at the end of the year. There was also some increase in the number of patients with dyspepsia, and, in the first month only, with euphoria. The high recorded incidence of oedema among prednisone patients at week 0 may have

TABLE IX.—Number of Patients with Given Side-effects at Different Stages of the Trial

Time of Assessment	Treatment Group	Dyspepsia	Moon-face	Acne	Hirsuties	Oedema	Euphoria	Depression
Week 0	Cortisone	11	12	0	1	4	0	2
	Prednisone	5	11	4	3	11	1	4
" 4	Cortisone	11	12	0	1	2	0	0
	Prednisone	8	12	4	3	4	7	2
" 12	Cortisone	12	11	0	1	2	0	2
	Prednisone	6	19	4	3	2	0	1
" 24	Cortisone	12	13	0	0	5	0	1
	Prednisone	10	20	4	1	2	0	2
1 year	Cortisone	10	10	0	0	2	0	3
	Prednisone	7	20	1	2	4	0	1

been partly due to retrospective recording in that some patients after four weeks' treatment with prednisone were found at week 4 to be pleased with the disappearance of a postural oedema which had not been noted on entry to the trial.

At the start of the trial 12 cortisone patients and 13 prednisone patients were recorded as having a diastolic blood pressure of 90 mm. Hg or over. For all except 6 (3 on each treatment) the diastolic pressure remained at this level at the end of the year (or when the patient was lost sight of). Of the remaining 21 cortisone patients and 22 prednisone patients with an initial diastolic pressure reading of less than 90 mm. Hg, 10 cortisone (48%) and 15

TABLE X.—Number of Patients with Recorded Increases in Diastolic Blood Pressures (a) to 90 mm. Hg and Above, and (b) to 100 mm. Hg and Above

Treatment Group	No. Below Given Level at Start of Trial	No. Showing Rise Above Given Level	
		At Any Time During Year	At End of Year
(a) 90 mm. Hg:			
Cortisone	21	10 (48%)	1 (5%)
Prednisone	22	15 (68%)	6 (27%)
(b) 100 mm. Hg:			
Cortisone	26	7 (27%)	2 (8%)
Prednisone	32	10 (31%)	5 (16%)

prednisone patients (68%) had recordings above this level at some time during the year, and 1 (5%) and 6 (27%) respectively at the end of the year (Table X). This apparent difference between the treatment groups with respect to rising blood pressure was, however, slight when the arbitrary level was raised to 100 mm. Hg.

Summary

Sixty-eight patients suffering from rheumatoid arthritis who had been taking cortisone acetate for one year or more were divided into two equivalent groups. Thirty-five were transferred to prednisone therapy, while the remainder continued to take cortisone. Both groups were followed for a year.

Throughout the year of the trial the patients remaining on cortisone showed, on the average, no material change for better or worse. The prednisone group, on the other hand, showed improvement in the following characteristics—strength of grip, blood sedimentation rate, haemoglobin level, general functional capacity, and disease activity. At the end of the year the disease was judged to be inactive in five of this group but in none of the patients on cortisone.

The benefit to the patients on prednisone was most marked in the first three months. For the group as a whole it gradually diminished thereafter, though it still remained, to a lesser degree, at the end of one year. This partial loss of initial improvement was accompanied by, and may have been partly due to, a reduction of prednisone dosage during the year. The dosage was

adjusted "to obtain maximum benefit without side-effects." Nevertheless, side-effects and complications were noted, and, in particular, the incidence of "moon-face" was much higher in the prednisone group. In view of this, the more favourable results observed with prednisone may be due, in part at least, to the use of a dosage relatively high in comparison with that given in the form of cortisone. Further observations, now being made, are necessary before final conclusions can be drawn.

Medical Memorandum

Desensitization of a Nurse to Streptomycin under Corticosteroid Cover

In individuals who have become sensitized to streptomycin by handling it during their work, reactions to even ephemeral contact with the drug may become severe and disabling. It is possible to desensitize these people by giving increasing small doses of the drug parenterally; but in those with extreme sensitivity this may be very difficult and take several months to accomplish (Crofton, 1953; Cohen, 1954). Though hypersensitivity reactions may occur in patients being treated with streptomycin, these are not usually precipitated by such minute quantities as with streptomycin-handlers, and desensitization is usually easy (Crofton, 1953). When severe reactions are met in such patients, corticotrophin has been of great value in suppression (Houghton, 1954).

It should be particularly useful to give corticotrophin or corticosteroids while desensitizing streptomycin-handlers, who are so much more sensitive to the drug. I have seen no previous report of such use, though in the case described below it was clearly of the greatest benefit.

CASE REPORT

A female nurse aged 27 had had no previous episodes of allergy. For 18 months she had daily prepared and administered injections of streptomycin and declared that during these she had always taken the strictest precautions against personal contact (Crofton and Foreman, 1948). At the end of this period she began to experience severe soreness of the eyes and of the eyelids, with swelling of the latter, whenever she came near open solutions of streptomycin or even near a room where these injections had been given. A patch test was negative, but when 25 µg of streptomycin sulphate was injected intradermally she soon developed local oedema 5 cm. in maximum diameter, with more widespread redness and soreness. Six hours later there was marked redness and soreness of both eyes and lids. When 2.5 µg. was given intramuscularly there was an almost equally severe reaction in both eyes. She was then put on chlorpheniramine maleate, 4 mg. twice daily, and then 0.5 µg. of streptomycin sulphate was given, but was followed six hours later by the same reaction. The chlorpheniramine maleate was continued and 0.25 µg. of streptomycin sulphate given mixed in a solution containing 25 mg. of mepyramine maleate. A slightly less severe reaction occurred, but even with 0.1 µg. it was still marked. At this point the nurse had become despondent, and it was obvious that, even if a smaller dose had been found where no reaction occurred, desensitization would have taken several months and would probably have been very difficult.

She was therefore admitted to sick-bay and prednisolone treatment started with 20 mg. daily—5 mg. being given at 7 a.m., 10 mg. soon after the streptomycin injection in order to achieve a peak concentration at the time when a reaction might be expected, and the remaining 5 mg. at 8 p.m. As she had arrested pulmonary tuberculosis, successfully

treated by artificial pneumothorax from 1937 to 1941, she was given 10 g. of para-aminosalicylic acid and 200 mg. of isoniazid daily, in two divided doses, as a precaution against reactivation of the tuberculosis.

The next day 1 µg. of streptomycin was given intramuscularly without reaction. The day after, 2 µg. was given without reaction, but with 4 µg. there was slight redness of both upper eyelids. The following day 4 µg. was given again without reaction, but with the next dose of 8 µg. there was again slight redness. Next day, with 15 µg., there was no reaction, and the dose was doubled daily until, with 120 µg., there was redness again of the eyelids, which did not reappear, however, when this dose was repeated the following day (the 10th). The dose was then doubled daily until the 15th day, when with 2 mg. there was again slight redness of the lids. On repeating this quantity next day there was no reaction and the dose continued to be doubled daily. After 80 mg. a few tiny follicles appeared over the face and both legs, but these cleared after a few hours; there was no redness of the eyelids. After 150 mg., and again after 300 mg., there was a similar but more marked transient rash with pruritus. There was no rash after 500 mg., but some generalized pruritus. After 1 g. on the 25th day there was headache and slight erythema of both upper eyelids.

Because of these reactions, although they were mild, it was decided that the nurse was not yet completely desensitized. The prednisolone was increased to 25 mg. daily, the extra 5 mg. being given at 8 a.m. On the 26th day there was no reaction with 0.5 g. of streptomycin; the day after 0.6 g. was given without incident, as were 0.75 g., 0.9 g., and finally 1 g. on the 30th day. The nurse resumed full duties next day, including the preparation and administration of streptomycin injections. Streptomycin was continued in the dosage of 1 g. daily for a further 23 days to maintain the desensitized state, while the prednisolone was reduced by 5 mg. every three days until, after 12 days, it was discontinued after a total of 32 days; the last 11 injections of streptomycin were therefore given without any cover. There has been no reaction whatever to the injections, nor has daily contact with streptomycin preparations over the succeeding two months produced any of the former manifestations of sensitivity.

COMMENT

It is clear that in this case desensitization without corticosteroids would have been most complicated and might have taken several months. When prednisolone was given desensitization was rapid and comparatively uneventful. Possibly the quantities of streptomycin were increased too rapidly after 1 mg. or so, because there were slight manifestations of sensitivity from 80 mg. to 1 g.; these, however, did not reappear when 0.5 g. was given later, and after four doses of increasing size 1 g. was reached and maintained uneventfully. It was striking how well the nurse looked and felt during the whole course of desensitization once the prednisolone was begun; this was in contrast to the malaise and despondency caused by the reactions to test doses of streptomycin previously.

In streptomycin-handlers with marked hypersensitivity to the drug it is possible that desensitization may be greatly eased and speeded by suppressing sensitivity reactions with corticosteroids.

I am grateful to Professor J. W. Crofton for his guidance in this case.

Reviews

DIAGNOSIS AND TREATMENT OF POISONING

Clinical Toxicology: The Clinical Diagnosis and Treatment of Poisoning. By S. Locket, M.B., B.S., M.R.C.P. With special sections by W. S. M. Grieve, M.Sc., Ph.D., F.R.I.C., and S. G. Harrison, B.Sc. (Pp. 772+xii; illustrated. £5 5s.) London: Henry Kimpton. 1957.

Most works on toxicology are written by experts in forensic medicine, pathologists, biochemists, or public-health officers who have little personal experience of treating cases of poisoning, or by pharmacologists whose experience is confined to animals and not to patients. This book is different in that it is written by a physician actively engaged in the practice of clinical toxicology and who admits patients suffering from poisoning to his acute general medical wards so that they are treated basically on the same lines and by the same sort of methods as are employed in standard medical practice, which is all to the good. Most of us should know more about poisoning than we do; for example, it has been estimated that in many countries the number of adult males requiring treatment for alcoholism vastly exceeds those in need of treatment for tuberculosis, yet in most medical schools a great deal of formal instruction is given on the latter condition and very little about the former. In England and Wales alone in 1953 there were 2,888 suicidal and 932 accidental deaths from poisoning, and probably at least 2% of all medical admissions to hospital are due to this cause. This book, which contains much useful information, is therefore to be welcomed, but unfortunately it is written in somewhat careless English—sometimes in a florid, complicated style, and at others resolutely in a series of notes in the imperative tense. The subjects considered range over a wide field, and include industrial chemicals, agents used in warfare, venoms, poisonous plants, and therapeutic substances. Every necessary step in treatment is enumerated. The author states that the fear which most practitioners have of treating a case of poisoning is unjustified, since the therapeutic principles are simple. It must be confessed, however, that the directions which follow for the management of a large number of emergencies are hardly calculated to allay the ordinary practitioner's misgivings, since the therapeutic agents advised are so seldom to hand, and he may well quail at the thought of continuing artificial respiration in a case of carbon monoxide poisoning till the patient recovers or is indubitably dead "because of the presence of rigor mortis." The text contains two sections written by experts on the identification of common toxic substances (arsenic and carbon monoxide are not included) and of poisonous plants. The work is handsomely produced with good illustrations and is well documented, but in the numerous references throughout the text the authors' names are printed in capitals, which serves no particularly useful purpose and gives the pages an unsightly appearance.

A SOCIAL STUDY OF TEENAGERS

In Their Early Twenties: A Study of Glasgow Youth. By T. Ferguson and J. Cunison. (Pp. 110+vi. 12s. 6d.) Published for the Nuffield Foundation by the Oxford University Press. 1956.

This is the second volume of a study made by the authors in which they have tried to present a picture of the life-histories of a number of Glasgow boys since they left school at the age of 14 in 1947. Like the earlier volume, *The Young Wage Earner* (1951), the method of inquiry and the manner of presentation are almost exclusively statistical and hence somewhat tough reading even for the expert. In the case of the present volume one cannot help wondering why such a large steam-roller has been employed to crack so small a nut, for the few significant findings could have

been compressed to advantage within the limits of an article. These findings are, however, of vital interest and deserve the attention of administrators, legislators, and all concerned with the ordering of our society.

The study concerns 568 of the original group of 1,349 school-leavers and the record of their careers between the ages of 17 and 22. In essence it is an acute comparison between the group of 346 lads who were called up for so-called National Service and 222 others who were rejected as medically unfit. Incidentally many sidelights are thrown upon the lives of urban youth which add to the depressing picture painted by other investigators in other parts of the country. (Cf. *Some Young People*, by Pearl Jephcott, Allen and Unwin, 1954.) The picture is almost exclusively confined to passive entertainment, lack of cultural pursuits, incidental delinquency, and a generally ambitionless existence. It has to be remembered, however, that these Glasgow youths were born in the lean years of the early 'thirties, grew up to inherit the storms of the war-ravaged 'forties, and may not, therefore, be entirely characteristic of the present rising generation. Amongst the most valuable findings of this study is the fact that as many as 21% of the Glasgow men called up for the Services were seriously unsettled on returning to civilian life and found difficulty in re-establishing themselves in suitable employment. On the other hand, the boys who had been medically exempt, although inferior in many ways at the age of 17, revealed a more satisfactory employment record at the age of 22. Most serious fact of all with regard to the National Servicemen was the great loss of skill upon return to civilian life. Only 59% of those boys in skilled work or serving apprenticeships at the age of 17 were following skilled occupations by the age of 22, and this movement away from skill took place "at all levels of scholastic ability." By contrast the men who had stayed at home had successfully retained their proportion of skilled workers, and so far as the above-average boys are concerned their proportion of skilled workers had actually increased.

The implications of this careful investigation, however quietly stated, cannot be ignored. The nation is losing skill, and one of the contributing factors is undoubtedly the effects of National Service experience. Whether it results from a mental attitude of laziness or of temperamental unsettledness resultant upon military life, or derives from other causes, we do not yet know. But, as the authors tactfully point out, this is not a matter for the Service chiefs to settle or even to consider. In so far as it concerns the whole future of our national economy it is the concern of every thinking citizen, of every employer, economist, and politician. Ways must be found for preventing this wastage of skill amongst the late teenagers conscripted for military service, and research into the whole business of National Service, and its concomitant psychological and social consequences for the whole community, is a matter of some urgency at the moment.

PROBLEMS OF VISION IN FLIGHT

The Problems of Vision in Flight at High Altitude. By Thomas C. D. Whiteside, Ph.D., M.B., Ch.B. (Pp. 162+xvi; illustrated. 35s.) London: Butterworths Scientific Publications for and on behalf of the Advisory Group for Aeronautical Research and Development, North Atlantic Treaty Organization. 1957.

The problems of vision in high-altitude flying are manifold, and, indeed, are increasing from day to day, as higher and higher altitudes and greater and still greater speeds are attained in aeroplanes. This monograph by Thomas Whiteside, sponsored by the Aeromedical Panel of the Advisory Group for Aeronautical Research and Development, is therefore not only of considerable theoretical interest from the point of view of visual physiology, but of great practical importance for both military and civil flying personnel. The author has spent a lot of time in research on the problems involved, and much of the book deals with his own original work. In flying in the stratosphere two curious problems

arise which have serious visual effects. The first is the disconcerting glare due to the reversal of the distribution of light at high altitudes. The greater proportion of the light is reflected upwards from the clouds, while the empty blue sky above is relatively dark. This sets up an intra-ocular scatter of light which casts a haze over the entire visual field—an effect enhanced by slight degrees of anoxia. The second problem is due to the emptiness of space with its consequent absence of detail which can serve as clues to provide sensations of depth and distance in the visual field. As in attempts to see at night or in a fog, an effort of accommodation-convergence is automatically made, with the result that an artificial myopia develops and the pilot searching the sky may end up by focusing the spots of dust on the windscreen. How these problems have been investigated and how they may be partially eliminated provide an interesting story.

STEWART DUKE-ELDER.

AGEING IN TRANSIENT TISSUES

Ciba Foundation Colloquia on Ageing. Volume 2—Ageing in Transient Tissues. Edited by G. E. W. Wolstenholme, O.B.E., M.A., M.B., B.Ch., and Elaine C. P. Millar, A.H.W.C., A.R.I.C. (Pp. 263+xi; illustrated. 36s.) London: J. and A. Churchill Ltd. 1956.

Of the 17 papers published in this volume most, very properly, deal with tissues concerned in mammalian and human reproduction. Ovary, testis, placenta, and the foetus itself are examined for those morphological and physiological changes that occur on the time scale appropriate to them. The human erythrocyte is the subject of two reports, and the female axillary apocrine sweat glands of another. Processes of less immediate human concern are discussed in a fascinating account of the growth cycle of deer antlers, and finally a paper on the metabolism of senescent leaves reminds us that transient tissues need not be animal, let alone mammalian. Indeed, the one serious criticism that can be made of the symposium as a whole is that it ignored the very considerable body of knowledge that we have on the causal relations involved in the atrophy of transient tissues in the lower vertebrate animals. Here radical surgery and transplantation techniques, still impossible in mammals, have yielded information that should have formed the background, at least, of a symposium of this sort. Both the individual papers and the discussions which followed them have all the interest of work in progress or recently completed. The publication, verbatim or edited, of the remarks made in discussion at scientific meetings is rarely worth while, but in this case is justified in the event. To have omitted them would have robbed us of the following statement, which comes, one need hardly say, from a worker in a foreign laboratory: "I have been accused of dealing only with the testes of feeble-minded individuals. This is largely true because they are the only people we can convince that castration is a good thing! We have supplemented our studies with specimens of testes obtained from volunteer prisoners."

D. R. NEWTH.

PSYCHOSYNTHESIS

Psychosynthesis: A "Project for a Scientific Psychology." By John Pardee Crawford, M.D., M.R.C.P., D.P.M. (Pp. 104. 21s.) London: Ash and Co. Ltd. 1956.

Psychiatrists differ greatly in their orientation. There are those who are oriented quasi-neurologically, and in therapy think mainly in terms of physical treatments; and those who think entirely in terms of psychological, or psycho-analytic, mechanisms. There is a need for a synthesis of these opposing views, and in this book Dr. Crawford tries to bridge the gap between the language of neurology and that of the various schools of psychology. It is doubtful whether such a synthesis is possible in the present stage of knowledge; the author has certainly not convincingly

succeeded. He has added to the reader's natural difficulties by a laboured style, of which the quotation marks in the subtitle are typical. He seems to require justification by an authority for the use of even the simplest terms or most banal concepts. The page is overloaded with quotations and references; and behind this screen of the sayings and opinions of others the author and his synthesis are hard to find. The main interest of the book is its presentation of some of the more recent knowledge of the organic basis of psychological functions. It is not, however, sufficiently comprehensive to be recommended as a review; indeed, this would not seem to have been the author's intention.

ELIOT SLATER.

URINARY DISEASES IN CHILDREN

Urologie de l'Enfance. By Gaston Lauret, with seven collaborators. (Pp. 441; illustrated. 3,900 fr.) Paris: Expansion Scientifique Française. 1956.

This is the first French textbook of urology in childhood published. The author claims that urology in the child should not be regarded as just a chapter in adult urology but rather as a branch of paediatrics, and as a result he has obtained the collaboration of physicians and paediatricians as well as urologists in writing the various chapters. He justifies a special study being made of paediatric urology by the fact that malformations are such a predominant feature that the disease is of less importance in itself than is the soil on which it develops and the rapid and grave way in which the child reacts to metabolic disorders, especially dehydration. The book is divided into three parts. The first is devoted to clinical studies, with chapters on urological symptoms in the child, urinary infections, disorders of renal function, disorders of micturition, and clinical and urological investigations. The second part deals with malformations, and includes chapters on embryology and the development of the urinary tract, abnormalities of the kidneys, reduplication of the excretory organs, urinary obstruction causing hydronephrosis, hydroureter, and vesical retention. The third part describes acquired diseases, with chapters on nervous disorders of the urinary system, urinary lithiasis, tuberculosis, and urinary neoplasms. This book contains a very great deal of statistical, pathological, and biochemical information, with excellent illustrations of radiographs and pathological specimens, and indicates clearly methods of investigation and treatment. The aim of the author is to produce a practical clinical guide for the diagnosis and treatment of diseases of the urinary tract, and for this reason diseases of the external genital organs have been omitted, as they are adequately dealt with in textbooks on surgery of childhood. This textbook is written in the best tradition of French urology, with all the facts assembled and carefully elucidated, and should be consulted by anyone writing on urological diseases of childhood.

J. E. SEMPLE.

HEART CATHETERIZATION

Cardiac Pressures and Pulses: A Manual of Right and Left Heart Catheterization. By Aldo A. Luisada, M.D., and ChiKong Liu, M.D. (Pp. 116+vii; illustrated. \$6.) New York and London: Grune and Stratton, Inc. 1956.

This manual is written for the benefit of young cardiologists about to learn the technique of cardiac catheterization, and for this purpose it has something to offer, but not nearly as much as one could have wished for. A young cardiologist studying this technique from a book requires more detail and explanation, and is unlikely to be very interested in what is found in dogs. One might also expect a book of this sort to be of some value to cardiologists who do not themselves undertake cardiac catheterization, but it has no such subsidiary value. One is left wondering just why these distinguished authors should have bothered to write and illustrate this little book.

PAUL WOOD.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JULY 27 1957

THE NEWCASTLE MEETING

Mr. Weldon Watts and his wife, Dr. Sally Weldon Watts, must have gone home at the end of last week well content with the annual meeting of the B.M.A., a more than worthy successor to the three meetings held in Newcastle since 1870. The attendance exceeded the expectations of those who provided the booklets and badges at the registration counter. The number of visitors from other countries was a record. The scientific sessions of one sort and another were so well arranged that the lecture theatres of the university were packed by medical men and women eager to learn what is new and to see the changing scene of modern medicine in illuminating perspective. A programme of colour television was provided from Monday to Friday last week—a much appreciated innovation. Round-table conferences and plenary sessions established themselves beyond doubt as among the most important ways of assembling and conveying information, and this kind of approach was reflected in an increased number of combined sessions between the special sections and symposia on selected problems of clinical and scientific medicine. In fact the university spirit pervaded the whole of the second half of this year's annual meeting, and the university authorities put us all in their debt for the lively interest they showed in medicine and for the hospitality they offered and the practical help they gave in so many various ways. And in the middle distance there were Hadrian's Wall and Roman forts, Durham Cathedral, coal-mines, a mighty river, moorland of austere beauty, and a warm-hearted people.

Much of the burden and heat of the preparatory work before an Annual Meeting inevitably falls on the local general secretary, and it must have gratified Dr. G. W. Anderson to see his labours come to such happy fruition. In one respect the local executive committee was particularly fortunate, and that was in the invaluable co-operation of the University of Durham, which allowed the buildings of King's College to be used for the scientific meetings, the scientific exhibition, and the exhibition of drugs and appliances. Thus compactly and conveniently housed, the meetings and exhibitions attracted large numbers of visitors, who took away an excellent impression of

this great northern university. The vice-chancellor, Dr. C. I. C. Bosanquet, paid a graceful tribute to his guests when at the degree-giving ceremony on July 18 he stressed the great contribution made by the medical profession to his university, saying, "The school of medicine has been the mother of learning here. Its contributions have been immense." The civic authorities too played their part in making the meeting a success. The local government of Newcastle is based on very old traditions, and the smiling and helpful "geordies" were the best possible evidence of true civic pride and dignity.

Visitors to the scientific meeting this year had more to choose from than ever before. The whole programme was notably well balanced, and the organization ran smoothly from start to finish, with the gowned medical students from the University always at hand to act as guides and provide choice tit-bits of local knowledge to the inquisitive stranger. Much of the credit for the success of this side of the meeting must go to the two indefatigable science secretaries, Dr. Ian Rannie and Mr. J. I. Munro Black. Nearly 400 people were in the audience at the first plenary session, on hypertension, which was a model of its kind. Many visitors to the Annual Meeting now expect to increase their knowledge of scientific medicine by wandering round the displays at the Scientific Exhibition, and by the time the week ended some of the demonstrators had made themselves hoarse in their efforts to answer all the inquiries that came their way. This year for the first time awards of merit were made for the best exhibits (see p. 233), and the judges did not find it easy to choose the prize exhibits from among so many of such high standard. The trade exhibition, too, was a great attraction, and with the stalls neatly arranged along the corridors of the Stephenson Building it seemed more easily accessible than usual. There were no doubts whatsoever about the success of the colour-television demonstrations. From Monday to Friday last week every showing attracted an audience of three or four hundred people, and the sponsors of this innovation, Messrs. Smith, Kline, and French, as well as those members of the staff of the Royal Victoria Infirmary who played such important parts in the programme, are to be congratulated!

In his foreword to the printed programme of the meeting the President expressed the hope that while visitors would be able to increase their knowledge from the scientific sections they would take some time off to enjoy the excursions and social functions which the local committees had had the pleasure to arrange. All those who experienced the hospitality offered at Newcastle will have appreciated the

soundness of this advice. Though the weather was not encouraging, there were many pleasant excursions into the countryside, especially those to the Farne Islands and to the Roman Wall. The Ladies' Committee, with Dr. Mona Macnaughton as its tireless secretary, put on a very full programme of entertainments, and the ladies' club in the medical school, transformed for the occasion by a luxuriant abundance of flowers, attracted as many husbands as wives—always a sign of successful organization. To southerners expecting a bleak city Newcastle came as a complete surprise. More than compensating for the grey skies, which unhappily persisted during most of the meeting, the warmth of the friendliness and hospitality extended to the visitors will be the abiding memory of the Newcastle meeting.

THE A.R.M.

This year's Representative Meeting occupied four days of the first week and half a day of the second, and if no startling conclusions were reached Representatives who spoke to the numerous motions showed themselves to be vigilant custodians of Association policy. While they were sensible of the many difficulties at present confronting the Council and its officers they did not hesitate to criticize where they felt criticism was called for. It was encouraging to see among the speakers a greater proportion of young men than is usual, which must have pleased the Chairman of the R.B., Dr. Ian Grant, who in his speech at the Representative Dinner urged Divisions to see that the younger men should take a greater part in the work of the Annual Parliament of the B.M.A. If some of the criticism was forthright it was at all events refreshingly sincere, and showed a vigour of debate which has always been regarded as a wholesome aspect of the political life of this country whether the politics are parliamentary or medical. Medical politics will never run the danger, feared by a contemporary, of falling under monolithic control so long as the representatives have the courage to speak their minds openly and so expose their views to the challenge of debate. If, two weeks ago, they were critical of the past president of the Royal College of Physicians in his medico-political negotiations they were also critical of the Chairman of Council when they feared that their prerogative as a policy-making body was in danger. Though the volume of business was large, no item on the agenda was glossed over and every speaker got a fair hearing. That this was made possible over four and a half days was due in no small part to the excellent and fair-minded conduct of the meeting by Dr. Grant, whose tenure of office now

comes to an end after a very strenuous three years. His kindness and good humour had a moderating effect on the few occasions when this appeared to be needed.

The proceedings of the meeting have been fully reported in the *Supplement*. If this is read in conjunction with the Annual Report of Council the reader will get a comprehensive view of the many-sided activities and problems facing the British Medical Association to-day. It is possible here to comment on only a few of them. The first day of the Meeting was devoted to a debate of the Report of the Constitution Committee, most ably presented by Mr. H. H. Langston. The path of the reformer is always hard, and the R.B. did not see eye to eye with some of the important recommendations made by Mr. Langston's Committee. Apart from the difficulties of accommodation the R.B. could see no valid reason why its numbers should be reduced, and some support for this view came from the fact that nearly 500 Representatives under the guidance of their Chairman were able to cope with nearly 300 motions and amendments without any of them being skimmed. Nor did the R.B. show any enthusiasm for the proposal that the B.M.A. Branches should be so reconstituted as to fit in with the areas of the Regional Hospital Boards; but they agreed that the Branch "as reconstituted should have as its main object the fostering of the unity of the profession within its area." However differing may have been the views on the reconstitution of the Branch the R.B. was entirely in favour of the motion put forward by Mr. Langston that the Association should hold a second scientific meeting during the year. If effectively carried out this should do more than anything else to increase the interest in the country generally in the work of the B.M.A.

Throughout the meeting there were repeated expressions of the need for unity and disquiet at some of the causes thought to lie behind the lack of unity in the profession during the past months in its conflict with the Government. One of the aims behind the Constitution Committee's proposals for reconstitution of the Branch was to make unity more possible by bringing hospital staffs and consultants more intimately into touch with the work of the Association. Consultants and specialists have tended to feel that the Representative Body is to all intents and purposes a general-practitioner body. They forget that since 1911 general practitioners have had to be active in medical politics, whereas it is only since 1948 that consultants have had to adjust themselves to a new and unfamiliar role. It is much to be hoped that they will become more active in the work of the Branches

and of the Divisions and in this way seize the opportunities to increase their representation in the R.B. Since 1933, of the nine Chairmen of the R.B. only two have been consultants and of the six Chairmen of Council over the same period only one has been a consultant. To-day the Chairman of Council and the Chairman and Deputy Chairman of the R.B. are general practitioners—a reflection surely of the fact that general practitioners have had a long experience and training in medical politics since the introduction of N.H.I. 46 years ago. A more widespread and energetic participation of consultants and hospital medical staff in the peripheral and central work of the Association will no doubt in time lead to their representation in these high offices. If there has been some confusion about the separate action by part of the consultant body there has also been a feeling of uneasiness about the autonomous powers of the two largest of the Association's standing committees even though such powers have been used with forbearance and discrimination. When the G.M.S. and the C.C. and S. Committees had these powers renewed for the coming year amendments aimed at restricting them were deferred for consideration next year. The conduct of medico-political affairs and negotiations with the Government have got into a tangle, extrication from which will need constructive statesmanship on the part of the profession's leaders. The guiding principle in this for 70,000 members of the B.M.A. is expressed in the first object of the Association: "To promote the medical and allied sciences, and to maintain the honour and interests of the medical profession" (our italics). Medical men set up a voluntary association for this purpose and continue to join it and belong to it for this purpose.

Many items on the agenda of the A.R.M. were inevitably on remuneration, and it is interesting to note that during the debate on the Report by Mr. T. Holmes Sellors of the work of the Central Consultants and Specialists Committee there was a lively interest in and wholehearted support for motions pressing for increased pay for medical auxiliaries, special reference being made to the need for improving the status, conditions of service, and pay of radiographers. Other motions showed much concern for the position of junior hospital medical staff, and in particular registrars, and the Meeting passed with a large majority the following motion: "That this Representative Meeting is concerned with the prospects and future of registrars and S.H.M.O.s, and with the supply and distribution of consultants. It asks Council to look at the problem afresh in consultation with members of the groups concerned and report back to the Representative Body."

When the B.M.A. holds its Annual Meeting next year under the presidency of Professor A. P. Thomson the Representative Body, under its new Chairman Dr. A. Beauchamp, will probably have before it more contentious and difficult matters than those with which it has had to deal this year. By then the Report of the Royal Commission will probably be available and reactions to it will be various, but if the spirit which informed the Meeting in Newcastle prevails we may be sure that what differences of opinion there may be will be kept within the unity that an ancient profession is, and that all members, whatever their sectional interests are, will recognize that the Association to which they belong exists, in the words of the second sentence of its first object, "to maintain the honour and interests of the medical profession."

PENICILLIN V

The acid-resistant property of phenoxymethyl penicillin was discovered by a fortunate accident in a factory in Austria several years ago, and earlier studies of its therapeutic use were conducted wholly in that country. It became available elsewhere in 1955, and we referred last year in these columns¹ to favourable reports on its therapeutic action from the Mayo Clinic and elsewhere. The facts about its behaviour in the body are simple and well ascertained. Unlike penicillin G, which is destroyed in the stomach to an extent varying inexplicably in different subjects, penicillin V traverses the stomach unchanged, and a constant amount of about 25% of the dose given is excreted in the urine. Absorption is thus regular, but presumably not complete, since after parenteral injection the proportion of the dose recoverable from the urine is about 60%. In antibacterial action penicillin V is not the precise equivalent of penicillin G, for staphylococci are either equally or somewhat more sensitive to it, and streptococci sometimes less. It has the distinction of being the only form of penicillin yet prescribed by weight: 60 mg. is the equivalent of 100,000 units. On theoretical grounds at least it is much the most dependable form of penicillin for oral treatment, and clinical experience in the United States seems to have confirmed this.

Two reports on clinical trials of this form of penicillin appear in the *Journal* this week. Drs. R. Lamb and E. S. Maclean, of Greenock, report that they used it in all cases requiring penicillin treatment, giving a dose of 120 mg. four times a day to adults. Of their 110 patients, 100 had acute pulmonary infections, and 63 of these were untreated on admission. The

¹ *British Medical Journal*, 1956, 2, 1355.

² Eriksen, K. R., and Therkelsen, F., *Acta chir. scand.*, 1954, 107, 456.

irrigation. Other patients were taken off all work and exercise and not permitted to smoke. With all respect to Mr. Tuckwell, some patients had had some serious insults inflicted on their sympathetic systems, from which they were separated in progressively larger degree. Some had had their adrenal glands excised. Others had been given poisonous agents like potassium thiocyanate. More recently, many had been injected every few hours with hypotensive drugs and had been urged to sleep almost vertically upright. The nuisance to the patient and his relatives of so many of these drastic measures, combined with the frustrations and disappointments following initial hopes, had been responsible for many family doctors continuing to treat their hypertensive patients with little more than perhaps a compound tablet of phenobarbitone and theobromine night and morning. But there was much more to the problem of hypertension than that, and each family doctor ought properly to work out exactly how he could help his hypertensive patients.

In diagnosis, the first point was to exclude harmless hypertension in patients feeling nervous. The presence of tachycardia in a patient with a normal heart would suggest this possibility. The diagnosis of hypertension secondary to some other condition was of vital importance. The family doctor could sometimes make the precise diagnosis, but, if not, he should refer the patient to a specialist if he merely suspected the possibility of an underlying lesion. The largest group of patients suffered from essential hypertension, and it was important for the family doctor to realize that this condition could remain stationary for many years; one-third of the patients had no symptoms until complications developed, and death did not commonly occur until 20 or 30 years after their onset. Malignant hypertension might supervene in any patient with secondary hypertension or essential hypertension, but it seldom occurred over the age of 55 years.

With respect to treatment, he believed that patients without symptoms should be left alone, although the young ones should be kept under surveillance. There was no evidence that drugs improved the prognosis of symptomless cases. For those with slight symptoms, such as headache, dizziness, and fatigue, he believed in general measures as described later and possibly also sedatives. For those with severe symptoms, such as cardiac asthma or encephalopathy, hypotensive drugs were indicated. The first general measure to employ was reassurance. The patient should be told that many subjects with hypertension lived for 30 or 40 years without ill effect from their disease. He should be encouraged to adjust his life so that he could live with his high blood pressure without complaint, just as the blind members of St. Dunstan's learned to adapt with remarkable facility to their disability. A quiet, well-ordered life was beneficial: "Fuss, fluster, fidget, flurry, and fury are the things to be avoided." Even ordinary pursuits should be pursued at an even tenor and the hypertensive should learn "to walk like a lady."

Discussion

In the brisk discussion which followed these opening addresses, the following were some of the points made. Professor McMICHAEL did not believe that exercise should be curtailed, because he considered it had a hypotensive action and was not dangerous; he could not therefore agree with Dr. Hunt's view that the hypertensive patient ought to "walk like a lady." Professor McMICHAEL also said, in answer to a question raised by Dr. HUNT as to whether pregnancy should be terminated because of hypertension, that most patients with chronic nephritis could pass through pregnancy uneventfully, as had been shown by workers at the London Hospital. In essential hypertension, the best thing was to allow a pregnancy to proceed if the patient was anxious for a baby; the main danger appeared to be retroplacental haemorrhage. Dr. K. R. MINTO (Nottingham) inquired if there was any useful place for venesection in hypertensive patients aged between 50 and 60 and received a unanimous answer of "No" from the panel of

experts. Dr. ERNST BRAUER (Spennymoor, Co. Durham) inquired if there was any relation between the atmospheric pressure and the blood pressure, to which Dr. HUNT replied that he had no knowledge of any such relationship. Dr. J. ADRIAN PAUL, of Sydney, New South Wales, remarking that hypertension passed through three phases—a labile phase, a fixed phase, and a terminal one of cardiac failure when the pressure might fall—inquired if it was possible to decide when the labile stage had been passed. Dr. HUNT said that it was most difficult to fix a precise dividing line between the labile and the fixed stages.

As to the cause of giddiness in hypertension, Professor McMICHAEL was uncertain but thought the most probable explanation was that the blood pressure was labile and this created the feeling. Dr. COOPE thought it necessary to distinguish between two types of giddiness, one which was possibly a labyrinthitis in which true vertigo occurred, while the other was a neurotic manifestation in which there was a sense of falling. Dr. STEWART asked what level of diastolic pressure should be aimed at when hypotensive drug therapy was being employed. Professor McMICHAEL said it was best to work on the levels of the systolic pressure and to ignore the diastolic. If the systolic pressure was satisfactorily reduced, the diastolic pressure would also be lowered. Dr. H. R. THOMSON (Newcastle upon Tyne) asked if hypertensive heart failure had become less common as a result of modern drug therapy. Professor McMICHAEL replied that his pathologist colleagues at Hammersmith complained that they did not see hypertensive heart disease so often at necropsy as in the past. Dr. H. C. STILL (Halifax, Nova Scotia) inquired if the rejection of a young man by an insurance company because of the finding of hypertension was not likely to create a lifelong neurosis. Dr. COOPE agreed that it was, and stressed the need for reassurance by the family doctor. Dr. J. G. M. HAMILTON (Edinburgh) stated that alcohol might produce an exaggerated effect from hypotensive drugs which doctors should be aware of, especially as some had earlier spoken with commendation on the beneficial effects of alcohol in strict moderation.

SECOND PLENARY SESSION—THE PRESENT STATUS OF PROPHYLACTIC IMMUNIZATION

Thursday, July 18

Sir JOHN CHARLES (London), Chief Medical Officer, Ministry of Health, presided at the well-attended plenary session on "The Present Status of Prophylactic Immunization." Professor ROBERT CRUICKSHANK (London), the opening speaker, dealt with the general principles affecting the nature and choice of biological prophylactics and the justification for their use in the control of specific infections. He said that immunity produced by diphtheria and tetanus toxoids could be quantitatively measured by measuring the antitoxin produced, but with vaccines, either as killed suspensions or living cultures, it was not known whether the demonstrable antibody was a measure of clinical protection. Other things being equal, he preferred killed vaccines, which could be carefully controlled and standardized, to living cultures, which were liable to variation. Two or more doses of a toxoid or vaccine were usually required to produce a satisfactory basic immunity, and the basic immunity could be "boosted" by a further dose at a later period. Adjuvants—for example, alum, mineral oil, or bacterial cells—improved antigenic potency and permitted the use of smaller amounts of antigen. It was important that the first dose of antigen should be sufficiently large, and the interval between the first and second dose could be as long as six months. The booster dose maintained a high level of antibody to toxoids for two or even five years. He thought more than one booster dose of diphtheria toxoids was probably unnecessary. Such doses were apt to cause reactions, especially in pseudo-reactors to the Schick test, and if they were given they must be preceded by a Schick test. Diphtheria immunization had

achieved remarkable results since 1941 in England and Wales, and had reduced the number of cases from 50,000 a year to 51, and deaths from 2,500 a year to 8. Deaths from whooping-cough had also fallen dramatically from about 800 a year in 1941 to 95 in 1956, but this was not the result of vaccination and there had been no corresponding fall in the number of cases. Now that vaccines of standardized potency were available their widespread use should reduce the number of cases, and he thought it unfortunate that the Ministry of Health had decided against making a free issue of pertussis vaccine through local health authorities.

Over the past ten years, continued Professor Cruickshank, an average of 23 cases of smallpox had occurred annually, one-quarter of which had been fatal. In view of the present low level of smallpox immunization, the disease might become a serious problem at any time. Tetanus deaths used to average 60 a year, but recently the number had dropped to about 30. He was not wholly convinced that general immunization against tetanus was necessary. Despite the recent Medical Research Council report on the provocation of paralytic poliomyelitis by alum-precipitated toxoids and mixed diphtheria-pertussis antigens he thought their use was still justified. This was particularly true of mixed diphtheria-pertussis vaccine without alum, which did not appear to carry a much greater risk than pertussis vaccine alone and which substantially reduced the number of injections to children. He recommended the following scheme:

At 3, 4, and 5 Months.—Three injections of diphtheria-pertussis-tetanus antigens in a mixture; or, alternatively, three doses of pertussis vaccine at monthly intervals with, on two occasions, a diphtheria-tetanus mixture given in the opposite limb to the pertussis vaccine but at the same time.

At 6 and 7 Months.—Poliomyelitis vaccine.

At 1 Year.—Smallpox vaccine.

At 3 to 5 Years.—A booster dose of diphtheria-tetanus mixture.

At 10 to 12 Years.—B.C.G.

Immunization in Britain

Dr. JAMES GRANT (Gateshead) discussed in detail immunization against smallpox, diphtheria, whooping-cough, and tetanus. He said it was doubtful if any community could be made completely immune to any infectious disease, for there were always individual persons who failed to co-operate. People varied also in their response to antigenic stimuli. Even in highly immunized communities traditional methods of control—notification, ascertainment, and segregation—were still necessary.

On smallpox vaccination he said that in the whole country only one-third of the infants born were being vaccinated. In some cities the proportion was as low as 2%. Modern air transport made the country very susceptible to the introduction of virus. Successful vaccination gave complete or partial protection up to seven years, and was rarely followed by complications if first performed in infancy. Control in this country was based on the vaccination of contacts, for the incubation period of vaccinia was shorter than that of smallpox and so provided immunity before the development of the disease, provided contacts were vaccinated early. Mass vaccination should never be practised unless there was doubt that all cases and contacts had been traced.

Diphtheria, he said, had been extirpated by immunization, but it had taken a ten-years intensive campaign to achieve this result. With the present virtual absence of endemic diphtheria there was no latent immunization and the community must depend on repeated booster doses to keep up its defences. Otherwise the disease would again become prevalent. The time had come to deal with a single case of diphtheria with the same rigour as a case of smallpox. Unimmunized contacts should be given combined active-passive immunization and immunized contacts should be given a booster dose.

Safe and effective whooping-cough vaccines were now available. He had used mixed diphtheria-pertussis vaccines

since 1947, and the incidence of whooping-cough in the vaccinated was about one-quarter of that in the unvaccinated. Recent studies had shown that paralytic poliomyelitis was two or three times as likely to develop in children within four weeks of the use of some prophylactics—particularly mixed ones—as at other times. Immunization should cease when poliomyelitis began to occur, particularly early in the year. Though there was no concrete evidence that it was less dangerous he thought the subcutaneous route should be used. The buttocks were perhaps the site of choice for the injections, one reason being that paralysed lower limbs were less of a disability than paralysed upper limbs. So far as the order of giving prophylactics was concerned he believed in smallpox vaccination at three months and then three doses of mixed diphtheria-pertussis vaccine.

An American View of the Salk Vaccine

Dr. THOMAS FRANCIS, jun. (Ann Arbor, Michigan, U.S.A.), in discussing poliomyelitis vaccination, said that the Salk vaccine had been clearly established by the field trial in 1954 in the U.S.A. as a highly effective method of preventing paralytic poliomyelitis. For all paralytic cases the effectiveness, assessed by comparing the vaccinated and control groups, was rated at 70%; in cases confirmed by laboratory studies effectiveness was rated at 80%; in bulbo-spinal cases it was rated at 90%. These results were obtained even though some of the batches of vaccine in the trial were less potent antigenically than others. Against Type I infections protection was rather less than against Type II and Type III infections. Little evidence of protection against non-paralytic disease was observed. Immediately after the publication of the report of the field trial widespread vaccination began. Within two weeks cases of paralytic disease were reported soon after vaccination. They occurred 4 to 11 days after injections and the initial paralysis was often at the site of injection. They were associated with certain batches of vaccine only, and subsequent study had demonstrated the presence of live virus in some of these batches.

This disaster led to a detailed study of all aspects of production and testing of commercially produced batches. Since stringent measures had been enforced no further accidents had occurred, though some 70 million persons in the U.S.A. had now been injected. The safeguards could not be lowered, but, provided they were observed, the vaccine was safe. The experience in the United States since 1955 had confirmed the value of vaccination. There had been, for example, a distinct fall in incidence in the 5-9-year age-group (the group in which most vaccination had been done), and in areas where comparative studies were possible effectiveness was rated at 70% or higher. There was no evidence that vaccination caused provocation poliomyelitis even when injections were given during epidemics.

Dr. Francis considered three doses of vaccine were necessary for long-term immunity as measured by antibody tests. The first two injections should be about a month apart and the third should be given seven or more months later. Two doses of vaccine prevented paralysis but did not prevent alimentary infection occurring. Three doses, he thought, might reduce the chances of virus establishing itself in the alimentary tract, but more work was required to confirm this. Studies had shown that vaccine was effective in very young children, and preliminary observations on mixing vaccine with diphtheria-pertussis-tetanus prophylactic had been favourable. By vaccinating mothers during pregnancy a high level of maternal antibody was transmitted to the offspring and this might prove a good basis for protection of the young infant. Salk and similar vaccines, he concluded, were fully established as effective agents, and they should be employed as widely as supplies allowed.

Influenza Vaccines

Professor C. H. STUART-HARRIS (Sheffield), in discussing influenza, said that, despite the work carried on since

influenza virus A was first isolated in 1933, vaccination against the disease was still in the experimental stage. Epidemics appeared to be changing in character, and the figures for deaths had shown a fall over the past 20 years. There was, however, no evidence of a fall in morbidity, and the recent experience in the Far East—where sometimes 20% of a population were attacked with practically no deaths—confirmed the change from a severe to a comparatively mild disease. Such changes had occurred before—for example, between 1850 and 1890—but there was no guarantee that the trend would continue. Indeed, the justification for artificial immunization at present was the fear of the recurrence of the virulent type of influenza of 1918 and 1919.

The fact that the strains in different epidemics differed in their antigenic composition was well known, and vaccines made from single inactivated strains would not produce protection against antigenically different strains. The exact interpretation of the differences in so far as they were related to the vaccination of persons was different on the two sides of the Atlantic. In the United States, a polyvalent vaccine containing old and recent strains was favoured, but in Britain, where such evidence as was available suggested little correlation between age and attack rate and where little evidence of prolonged immunity had been found, a monovalent vaccine made from the most recent strain was favoured. The difference of emphasis between workers in the two countries would be resolved only by field trials. In recent years field trials in Britain had been hampered by the low incidence of infection and by the consequent problem of differentiating true influenza when it did occur from endemic acute respiratory disease due to other agents. While the incidence remained low, trials should be restricted to groups of persons—for example, in schools and residential homes—where accurate diagnosis might be possible and where the incidence, once the disease was introduced, might be high. It would also be wise to study the effect of vaccine on persons with chronic bronchitis and emphysema in whom influenza could still be a deadly disease. In conclusion Professor Stuart-Harris said that there was little chance that large quantities of vaccine would be available against the Far East strain if infection with it became prevalent in Britain in the next few months. Fortunately, so far, there was no evidence that the disease was other than mild and short-lived.

B.C.G.

On B.C.G. vaccination against tuberculosis Dr. P. M. D'ARCY HART (London) said that in Britain the present scheme was to vaccinate home contacts of cases, persons at special risk—for example, nurses, laboratory workers, and medical students—and 13-year-old schoolchildren. The Medical Research Council's trial had shown substantial protection to children of school-leaving age. Protection lasted four years and perhaps longer; further observations on this point were being made. If protection lasted about ten years, then the age of routine vaccination should probably be reduced to 10 or 11 years. He stressed that children found Mantoux-positive before vaccination should be kept under careful observation and periodically examined radiographically for three years afterwards. The incidence of actual disease in these children was high, particularly if the test was strongly positive. A question which would eventually influence policy was whether B.C.G. protected against "adult-type" disease. Most observers were doubtful about its value in this connexion, but some recent Danish results suggested that it might do so. If it did, then clearly it would be of greater value than was believed now. As the incidence of tuberculosis fell, however, the disadvantages of the routine use of B.C.G. became more obvious. These were the loss of the Mantoux test as an epidemiological weapon, and the occasional severe or even fatal sequelae of vaccination. For the present the only substantial change likely to take place in the British scheme was the substitution of freeze-dried B.C.G. for the fluid product.

THE SECTIONS

SECTIONS OF MEDICINE, SURGERY, AND CARDIOLOGY

Tuesday, July 16

Arterial Embolism

With the president of the Section of Surgery, Mr. A. DICKSON WRIGHT (London), in the chair, the discussion was opened by Dr. WILLIAM EVANS (London). In the heart, said Dr. Evans, thrombosis formed in connexion with either septic or non-septic vegetations on valve surfaces, within a cavity lying behind a narrowed orifice as in the left atrium in mitral stenosis, or within an enlarged cavity such as the left ventricle in hypertensive heart failure. In mitral stenosis a past history of embolism should not rule out surgery; indeed, such a history might favour operation, although by itself it should never be the determining factor. At operation the atrium might contain a mass of irremovable thrombus, though more often all the clot could be removed; sometimes the atrium was completely free from clot. In the last two states valvotomy materially reduced the risk of further embolism. Where crucial embolism originated from a much enlarged and failing heart, peripheral embolectomy should be discouraged. In auricular fibrillation caution was needed with quinidine, as restoration of normal rhythm might be associated with crippling cerebral embolism. In the management of thrombosis and embolism, said Dr. Evans in conclusion, the task was now to integrate its medical and surgical components; there was a need for a new specialist, the angiologist.

Sir JAMES LEARMONTH (Edinburgh) summarized an experience of 104 cases of limb embolism. Many cases were recurrent, and the recurrences might be spread out over many years or confined to a shower of incidents over a short period. More than 50% of the latter group showed visceral involvement. Diagnosis was of special importance. Once it was realized that some vascular disturbance had occurred, an obvious cause was apparent in 80% of cases. Pain was commonly a presenting symptom although absent in 25% of cases. Failure to find a pulse might be the result of previous embolus, and collateral pulses should be sought; in 15% of normal subjects there was no dorsalis pedis pulse. Loss of sensation was an early sign of ischaemia; no recovery was possible in muscle that had been deprived of its circulation for 48 hours, though some skin might survive for this period. The effect of an embolus was determined by its site and the existing collateral circulation. The condition of the vessel wall was also important, and consecutive thrombosis took place more readily in elderly subjects. Proximal thrombosis from a popliteal embolus was of little significance, but if thrombosis spread distally it occluded the openings of important collaterals and still further reduced the circulation, and it was essential to use heparin to prevent consecutive thrombosis. In Sir James Learmonth's series 15% died from their cardiac condition and 30% recovered without stigmata of arterial obstruction. In 55% the question of embolectomy was raised. In the differential diagnosis arterial and venous thrombosis had to be distinguished, and each could cause some difficulty. Arterial thrombosis usually took place in previously diseased vessels in elderly subjects, and in doubtful cases a radiograph might show calcification. Acute venous thrombosis was said to be associated with arterial spasm, which might account for difficulty if the arterial pulse could not be felt, but there was always some swelling, and the limb was never so pale or cold as in arterial embolism.

Management of Embolism

Professor CHARLES ROB (London) dealt with the treatment of embolism. Treatment did not necessarily mean an operation; and conservative management, including pre-operative care, was even more important. In few emergencies was the outcome so influenced by correct early management. The first principle was to reduce the metabolic need of the part.

This should be done by exposing it to cold air. On no account should warmth be applied, as this might precipitate gangrene. The general practitioner should institute cooling gangrene. The general practitioner should institute cooling as soon as he made the diagnosis in the patient's home. Local metabolism could also be reduced by local and general rest. Relief from pain and sleep could be best achieved by giving the patient whisky in full dosage; it was rarely necessary to supplement this with pethidine.

The limb should be kept level or slightly dependent and in no circumstances elevated. The development of a collateral circulation was encouraged by heating the patient's body with electric blankets to the point of discomfort in order to encourage reflex vasodilatation. Sympathetic ganglion block was rarely needed unless the patient could not tolerate heating. Vasodilator drugs were of no value except intra-arterially and even then only of doubtful use. Anticoagulant therapy was of vital importance and should consist of heparin in the first place. Heparin did not interfere with subsequent surgery, as coagulability could easily be restored by intravenous protamine sulphate, should bleeding be troublesome. The patient's general condition needed attention; many of these cases exhibited cardiac failure when first seen by a surgeon. About half those with peripheral emboli needed embolectomy because the circulation had failed to recover under this regime.

Embolism of the carotid and mesenteric arteries should always be treated by embolectomy. If the embolus was at the aortic bifurcation, Professor Rob followed an elective policy. Aortic embolus was of three types: (1) a major catastrophic obstruction, this type of embolism requiring surgery to save life and limbs; (2) a less severe obstruction in which the femoral pulses disappeared but a fair collateral circulation was established in about two hours; (3) a minor episode due to an embolus riding the bifurcation without obstructing it: the femoral pulses disappeared as a result of spasm but returned in about two hours. The last two types could be treated conservatively, and in Professor Rob's experience of eleven cases only four had required immediate operation. In the limbs he always advised conservative management for a few hours before deciding about surgery. Femoral embolectomy was an easy operation which was well tolerated by seriously ill patients, but popliteal embolectomy was more exacting, and was necessary in only about half the cases. Where distal consecutive thrombus could not be extracted through the arteriotomy a distally placed arterial cannula might be used to blow it out under pressure. Professor Rob concluded his address by again emphasizing the importance of conservative management.

Cerebral and Mesenteric Embolism

Dr. H. A. DEWAR (Newcastle upon Tyne) confined his remarks to observations on cases of cerebral embolism, including studies of cerebral blood flow. Recurrent embolus might be prevented by mitral valvotomy, but operation should not be advised for this reason alone, as cerebral embolus sometimes occurred at the time of valvotomy. Nor could excision of the left atrial appendage be recommended, as the thrombus was found in the appendage in only 50% of cases. He was against the use of anticoagulants in an acute attack because of the risk of cerebral haemorrhage. Vasodilator drugs might be used, but their systemic effect sometimes resulted in such a severe fall in blood pressure that the cerebral blood flow was lowered. Experiments had shown some increase in cerebral blood flow after the intravenous injection of 25 mg. of tolazoline and also after inhalation of carbon dioxide, and, although he suggested the use of these measures in acute cerebral embolism, Dr. Dewar was careful to point out that as yet there was no clear clinical evidence to support his thesis.

Dr. A. A. KLASS (Winnipeg) recalled that the traditional surgical treatment of acute mesenteric vascular occlusion was extensive bowel resection, and after many such resections the patient was left an intestinal cripple. Nowadays patients with embolism of the mesenteric arteries should always be treated by embolectomy: although the mesenteric

artery was small a good flow could be re-established. Bowel which looked non-viable by the accepted criteria might recover, but the abdomen should be re-explored after 24 hours, when any local area of gangrene could be resected. Follow-up studies on survivors of superior mesenteric arteriotomy showed absorption defects in the small bowel similar to those seen in elderly patients with the syndrome of abdominal pain, followed by weight loss and an increased sedimentation rate and leading to a suspicion of malignancy. It was not unlikely that a fair proportion of these elderly had had in fact sublethal, smaller "mesenteric strokes."

Long-term Anticoagulant Therapy

Dr. CATHERINE BURT (Edinburgh) discussed the use of anticoagulant therapy as a long-term policy, basing her observations on 237 patients so treated. Only 21 of these were cases of recurrent embolism; 49 were cases of recurrent venous thrombosis, and 167 were cases of chronic arterial occlusion. The anticoagulants used were ethyl biscoum-acetate and, more recently, phenindione. The prothrombin activity was kept at 20% to 60% of normal. In most cases anticoagulant therapy was initiated in hospital, but prolonged therapy was given to out-patients provided there was supervision from the general practitioner and the patient was co-operative. After the initial response had been determined it was found possible to continue control with estimation of the prothrombin level as infrequently as every 4 to 8 weeks. Dr. Burt considered that patients with auricular fibrillation and a history of embolus were less likely to have further embolic phenomena when on a regime of continuous anticoagulant therapy.

Dr. M. M. SUZMAN (Johannesburg) concluded the symposium with an evaluation of long-term anticoagulant therapy, with special reference to myocardial infarction. During the last 10 years continuous anticoagulant therapy had been used as a routine prophylactic measure in patients suffering from repeated attacks of thrombosis or thrombo-embolism, in those deemed likely to have a recurrence after recovery from an acute episode, and in those with chronic obliterative arterial disease. Data were presented on 170 patients maintained on continuous long-term anticoagulant therapy who were compared with 514 patients who received anticoagulants for only a short period at the time of the infarction. The most satisfactory anticoagulant was warfarin sodium, which was given in an initial dose of 1 mg. per kg. and maintained at about 5 to 10 mg. a day. The prothrombin time was kept at about twice normal. In follow-up studies extending up to eight years it was found that, although anticoagulants did not give complete protection against further infarction, the incidence and mortality were distinctly lower. The observed differences were greater if the initial attack of infarction was severe.

SECTION OF MEDICINE

Wednesday, July 17

Cortisone in General Practice

With the president, Professor F. J. NATTRASS (Farnham), in the chair, Professor G. A. SMART (Newcastle) opened a discussion on the uses of cortisone in general practice. He began by describing the physiological actions of the three main groups of steroids secreted by the adrenal cortex and the mechanisms which governed the secretory activity of that gland. A large variety of stimuli, often grouped together as "stress," acted on the hypothalamus, which in turn reacted on the anterior pituitary and caused it to secrete additional A.C.T.H., thereby inducing heightened activity of the adrenal cortex. When A.C.T.H. was used as the therapeutic agent it acted by stimulating the adrenal cortex to produce excessive quantities of its hormones, such as hydrocortisone and aldosterone. When cortisone and its analogues (such as prednisone and prednisolone) were used they reduced the normal secretion of A.C.T.H. Hence the rapid termination of cortisone therapy carried the possible danger that natural

Mr. R. A. TENNENT (Glasgow) dealt first with the initial domiciliary treatment of eclampsia. He had adopted the methods of Dewar and Morris, starting treatment with rectal tribromethanol in the patient's own home. Of 106 cases of eclampsia since 1950, 83 had been treated with tribromethanol, 33 of them by the flying squad. There had been six deaths, but in only one of the five fatal cases which had received this drug did death occur during the eclamptic phase. Of the 33 cases treated by the flying squad, only one had fits after the administration of tribromethanol, and that was probably because the drug was given too late in labour. It was important that someone with experience in the treatment of eclampsia should have charge of the initial treatment at the patient's home. Mr. Tennent went on to discuss a second unusual use for the flying squad. This was for prolapse of the cord, where the foetal survival rate fell proportionately with the length of time before delivery until it was about 30% after three hours. Caesarean section was the treatment of choice if the cervix was dilated one-half or less, but if the dilatation was greater the problem of how best to achieve rapid delivery called for experience and judgment. They had decided that cases of prolapsed cord should become the responsibility of the flying squad, which was accordingly equipped to deal with forceps delivery and resuscitation of the baby. As yet they had not

delivered a case at home, but they had been warned by the flying squad by telephone to arrange for immediate caesarean section in one patient seen initially at home and prepared, while *en route*, for operation.

Dr. J. C. A. DOWSE (London), Mr. E. L. NICOLSON (Carlisle), Dr. E. A. GERRARD (Manchester), Professor W. I. C. MORRIS (Manchester), Dr. WILLIAM HUNTER (Newcastle upon Tyne), Mr. LINTON SNAITH (Newcastle upon Tyne), Mr. W. G. MILLS (Birmingham), Professor H. HARVEY EVERS (Newcastle upon Tyne), Dr. J. WILBUSH (Victoria, Australia), and Mr. MERVYN GOODMAN (Liverpool) contributed to a lively discussion.

SECTIONS OF PREVENTIVE MEDICINE, CHILD HEALTH, AND OBSTETRICS AND GYNAECOLOGY

Wednesday, July 17

Puberty and its Problems

With Dr. J. B. TILLEY (Newcastle), the president of the Section of Preventive Medicine in the chair, the Sections of Preventive Medicine, Child Health, and Obstetrics and Gynaecology combined to discuss puberty and its problems.

Professor LESLIE BANKS (Cambridge) opened the discussion with a general review of the subject, including its sociological, legal, and educational aspects. Quoting Dr. Johnson's definition that "puberty is the time of life when the two sexes begin to be acquainted," he emphasized that the changes at puberty are the result of an ancient and stable mechanism designed to fit the male for reproduction and the female for child-bearing. The physiological changes in girls occur sharply and demand an immediate adjustment in their outlook on life. But in boys the changes occur over a longer period and leave more time for adjustment but prolong the gaucheness.

Attainment of Maturity

Some boys and girls reach sexual maturity long before they have developed emotionally and intellectually, and at schools and universities it is common to come across the highly intelligent scholar who is both emotionally and physically retarded and quite unfitted to his or her new life. Professor Banks thought that insufficient attention was paid to late developers: unlike the practice among primitive peoples, there was a tendency in modern society to gloss over sexual changes in favour of intellectual development. It might be ten years or more between puberty and the attainment of full social responsibility.

Supervision and Instruction

Professor Banks had two suggestions to make about the prevention of physical, emotional, and intellectual disharmony. The first was that there should be close supervision at the age of puberty to correlate the progress of physical maturation, mental advance, and emotional stability. He thought it was especially the responsibility of school medical officers to keep children at this age under observation and care. The second suggestion was that children over the age of 12 should be given a full explanation of the biological importance of the changes at puberty and the reasons why society required that intellectual and emotional maturation should also occur before the individual could assume his full responsibilities. All too often the young had to educate each other by word of mouth or by personal investigation. Professor Banks had been shocked at the ignorance of undergraduates on matters of sex and even of more senior members of the university.

An experiment worth trying would be to design a course of instruction for senior pupils of 12 years of age and over. Doctors should take a leading part in such instruction, because they were the only people with the necessary training and experience to do so effectively.

Physical Manifestations of Puberty

Dr. D. V. HUBBLE (Derby) discussed puberty from the viewpoint of the paediatrician. It was as well to remember that though it was a period of entanglement it was also a period of enchantment. The family doctor, as a human biologist who understood bodily functions, was well placed to proffer youngsters the imaginative understanding they so often needed, for they realized he was well accustomed to receiving confidences and notably unready to disclose them. Reviewing abnormal reactions to normal sexual development, Dr. Hubble said that boys were not as a rule disturbed by the physical manifestations of puberty, but in unprepared, shy, or fastidious girls the development of the breasts and the onset of menstruation might be a cause of discomfort, conflict, or rebellion. Anorexia nervosa in girls ashamed of their breast development was more common before the day of Diana Dors. Physicians were to-day more likely to be consulted by the flat-chested. There was no justification for the prescription of oestrogens when girls complained of poor breast development.

Sexual Problems of the Young

Kinsey had provided the evidence on which the doctor could give advice on many of the sexual problems of the young, who were still not at all well instructed in these matters. Masturbation was commoner in boys than girls: recognition of the fact that it was not an abnormal development, and that guilt feelings on account of it were misplaced and noxious, ought not to obscure the fact that in excess it was evidence of frustration and an index of inadequate social contacts between teenagers. Encouragement of heterosexual activity was the only effective preventive measure against homosexuality, which was an exaggeration and extension of a normal phase in development which was environmentally conditioned. There was no evidence that it was constitutionally or endocrinologically determined.

Obesity and Hypogenitalism

Of the deviations of sexual development in boys, obesity often accompanied hypogenitalism. This was a condition—called adipose gynandism by Simpson—which was marked by obesity, tall stature, and feminine habitus. In some males this was a constitutional and individual reaction to overeating, and it should be severely treated by diet and dexamphetamine. Persistence of obesity beyond adolescence Dr. Hubble regarded as a failure in paediatric care.

Hormonal Balance

Dr. T. N. MACGREGOR (Edinburgh), speaking as a gynaecologist, confined his remarks to the problem of girls at puberty, which he defined as the transitional phase between childhood and adolescence. It lasted from four to five years (from 10 to 14 or 15 years of age). Normal balance between the anterior pituitary and the gonads was achieved at the menarche in 60% of girls. In the others the interval between the menarche and the establishment of normal balance might be a few months to some years. During this phase of imbalance there was often irregular uterine bleeding.

The stage of development and adjustment was a time when the security of childhood gave way to feelings of insecurity. The guidance of children at this time was a parental responsibility. Should teachers be asked to take this responsibility? Dr. MacGregor thought not, and that the school medical officer was the most suitable man to impart the necessary knowledge. It was not an educational but a social problem. This sort of instruction should have its proper place in the school curriculum, so that every child was provided with definite information.

Precocious and Delayed Puberty

Dr. MacGregor then reviewed the causes of precocious and delayed puberty. The former was rare, but the parents

must be warned that the child might be in considerable danger and should be guarded. Failure of menstruation after the attainment of the age of 18 was referred to as primary amenorrhoea: there were three causes of this—malnutrition, constitutional factors such as disease in childhood, and gonadal agenesis or lesions of the pituitary gland.

Dr. MacGregor also spoke of pubertal obesity: it tended to retard sexual development, and in the majority of cases was due to overeating. The only effective treatment was a strict diet. If that failed amphetamine could be of very great value.

Sex Education

A lively discussion followed these three papers, and many different views were expressed about the sex education of children. Professor DONALD COURT (Newcastle) began by asking some pertinent questions. What were the parents' responsibilities? Did boys and girls readily go to their parents for advice at the time of puberty? Was it a good idea to separate boys and girls at school? Professor WILFRID GAISFORD (Manchester) thought the family doctor, not the school doctor, was surely the right person to advise on these problems. Dr. F. J. W. MILLER (Newcastle) suggested that proper training began at home. Dr. ARMSTRONG (Northumberland) doubted the capabilities of parents (he mentioned a father giving a serious talk about self-abuse to his son, who was under the impression the talk was about swearing) and thought a good schoolmaster could do better than a school medical officer. Dr. ELSPETH M. WARWICK (Nottinghamshire) discussed the difficulties of giving sex education in schools, and thought it was best given to small groups of children on a discussion basis. There was a very great demand for guidance from youth groups. Impersonal instruction could very well be given to children under the age of 10. Dr. M. GOODMAN (Liverpool) suggested there might be special clinics for children whose parents were unable to explain the facts of life to them. Dr. J. WILBUSH (Victoria) wondered whether something in the way of puberty rites might be helpful. Mr. F. E. STABLER (Newcastle) took the view that there should be no special interview. However young a child was, it should have all its questions answered. Professor BANKS remarked that the teaching of human biology would make all such discussion unnecessary in 25 years' time.

Among others who spoke were Dr. GRANT (Wiltshire), Dr. A. LAMONT (Inverness), Dr. S. D. V. WELLER (Bromley), Dr. A. J. G. NEWTON (Morpeth), and Mr. W. G. MILLS (Birmingham).

SECTION OF SURGERY

Thursday, July 18

Carcinoma of Stomach

With the president, Mr. A. DICKSON WRIGHT (London), in the chair, Mr. JOHN GILMOUR (Newcastle upon Tyne) opened a discussion on the diagnosis and treatment of carcinoma of the stomach. Mr. Gilmour began by referring to the seriousness of the problem confronting surgeons. There were 15,000 annual deaths from this cause. The responsibility for early diagnosis rested with the general practitioner, and hospital clinician. Full use must be made of radiology, gastroscopy, and exfoliative cytology in the investigation of suspicious cases. Symptoms were to some extent determined by the site of the growth, but toxic symptoms or those resulting from secondary anaemia were important early manifestations. In some instances the symptoms resembled those of gastric or duodenal ulcer and medical treatment might afford temporary relief.

Dr. G. A. S. LLOYD (London) reviewed the radiographic appearances. In 80–85% of cases radiographic diagnosis did not present any difficulty. These patients showed large filling defects with absent peristalsis and destroyed mucosal pattern. In the remaining 15–20% of patients diagnosis was less easy. This was an important group, however, for it included patients in whom the growth was in an early stage. When the neoplasm involved the fundus or cardia it was

inaccessible to palpation, but a filling defect shown on the fundus air bubble and dilatation of the oesophagus were important radiographic signs. Distinction between pyloric carcinoma and pyloric stenosis was sometimes difficult, but in carcinoma the edge of the narrowed area was usually more abrupt. Malignant ulcer was difficult to differentiate from simple ulcer. Finally, neoplasm of the stomach sometimes caused deformity like that seen in hour-glass stomach due to peptic ulceration.

Mr. HERMON TAYLOR (London) discussed the scope of gastroscopy in diagnosis of gastric cancer. He emphasized that gastroscopy was not in itself an infallible investigation but should be regarded as complementary to radiography. It was a simple investigation causing little disturbance to the patient. Mr. Taylor drew attention to the fact that in departments of radiology in England and America there was a diagnostic error of about 20% in cases of carcinoma of the stomach. When doubtful cases were re-investigated after a period of medical treatment there was often a delay of 2–3 months. This could be avoided by immediate gastroscopy in a doubtful case. In a series of 128 cases of proved gastric carcinoma the diagnosis was doubtful on radiography in 19. Sixteen of these cases were diagnosed correctly by gastroscopy and in only three did the diagnosis remain in doubt. In a further group of 24 cases radiography showed either a benign lesion or no ulcer. Gastroscopy was done in 20 of these cases and a correct diagnosis of gastric cancer was made in 15.

Dr. R. O. K. SCHADE (Newcastle upon Tyne) summarized his experience with gastric cytology during the past three years. Material was obtained by gastric lavage and the aspirated specimens were centrifuged and the deposits examined after staining by Papanicolaou's method. In 25 of the 2,500 specimens which had been examined the diagnosis was established by cytological examination when other diagnostic methods had given negative results. Dr. Schade showed slides to illustrate the appearance of malignant cells in gastric washings and emphasized that positive results had been obtained in some very early cases in which the growth was still confined to the mucous membrane. Indeed, the investigation gave clearest results in the early growths, for in advanced cases the appearances were confused by an excess of debris. Some of the carcinomas diagnosed in this way were so small that the surgeon had difficulty in identifying them at the time of laparotomy.

In a concluding paper, which was read by Mr. HAROLD EDWARDS (London), Professor DIGBY CHAMBERLAIN (Leeds) outlined the treatment of gastric cancer. In a series of 491 cases operation was undertaken in 71%, and 42% of these cases were resectable. At the end of five years 6% of the patients were alive—or 25% of those who left hospital having had a partial gastrectomy. Total gastrectomy was reserved for cases where growth had extended so high that it was not possible to leave any stomach. Partial gastrectomy was advised in all other cases and routine total gastrectomy was not advised. Palliative partial gastrectomy was justifiable in the presence of hepatic metastases, provided it could be done without undue risk. When irreparable pyloric stenosis was present the surgeon should do a gastroenterostomy, and in many cases the situation of the growth would necessitate an anterior stoma.

SECTION OF PSYCHIATRY

Tuesday, July 16

Symposium on Tranquillizers

Professor ALEXANDER KENNEDY (Edinburgh), the president of the Section, was in the chair for a wide discussion of tranquillizing drugs. Dr. D. R. LAURENCE (London) expressed the astonishment of a pharmacologist at the flimsy evidence which launched new drugs on the tranquillizer market and apparently persuaded clinicians to prescribe them for their patients. The word "tranquillizer" was very loosely used for a number of substances chemically and

pharmacologically diverse, but believed to relieve anxiety and tension with minimal alteration of other cerebral functions. "Meratran" and "frenquel" were not tranquillizers on this definition: they were more like amphetamine, since they could arouse from a barbiturate coma, without, however, altering appetite. He discussed only chlorpromazine, reserpine, benactyzine, meprobamate, and methylpentynol. Most of these had been discovered accidentally to have interesting central nervous effects. Chlorpromazine was an offshoot of study of phenothiazine derivatives for treating malaria; meprobamate was a close relative of mephenesin, originally developed as a possible preservative for penicillin and then found to cause a reversible paralysis which spared respiration; benactyzine was one of a number of atropine-like drugs synthesized to block the peripheral effects of acetylcholine twenty years ago, but tried in 1955 for possible central effects. It soothed both cats and rats exposed to experimental stresses—in situations where chlorpromazine was of no benefit.

In general, drugs for possible use in psychiatry were tested on animals in one of five ways. They might modify the behaviour of animals under stress—for instance, the reaction to something unpleasant like an electric shock encountered just when a pleasant reward of food was expected. They might restore conditioned reflexes previously extinguished. They might have some action on a part of the brain suspected of affecting behaviour of any kind. Substances were also sought which in pharmacological test would antagonize some or all of the actions of the hallucinogenic drugs mescaline and lysergic acid diethylamide (L.S.D. 25), or oppose serotonin, noradrenaline, and other naturally occurring compounds found in the central nervous system. Some tests were exotic: inhibition of aggression in Siamese fighting fish, change of web pattern in spinning spiders, control of fits in mice exposed to high-frequency sounds, prevention of hyperthyroidism in wild hares caught and exposed twice daily to barking dogs. This was clearly a long way from clinical observations in man, such as that benactyzine made people forget what they were going to say, or caused incessant laughter. He felt that the action of a drug depended greatly on the personality of the person taking it, but very little study had been made of this side of the problem. There was a serious shortage altogether of objective clinical facts, and an intellectual chasm separated pharmacologist and psychiatrist. At present the pharmacologist did not really know what the clinician wanted, so he worked on his own lines. But if the clinician could specify the drug actions required and the part of the brain it was desirable to affect, the laboratory worker could design truly relevant animal experiments, and great progress would result.

Dr. L. C. COOK (Bexley) summarized the results obtained in psychotics with chlorpromazine and reserpine at his hospital since early 1954. His impression was that about 30% of chronic patients improved markedly on chlorpromazine, 5% were symptom-free, and nearly one-quarter were unchanged. Reserpine might improve a few whom chlorpromazine had not affected, though the symptomatic indications for the two drugs were much the same. The two drugs could be combined, using smaller doses of each than when they were used alone, and this cut down the complaints of side-effects. Alone, chlorpromazine was used usually at 300 mg. a day, and there was little point in going above 700 mg. Reserpine might need intramuscular doses of 10 or 15 mg. at first, and later a 3 mg. daily maintenance dose by mouth. Both were useful in cases showing excitement, restlessness, aggression. E.C.T. could be given with chlorpromazine, but with reserpine it could cause dangerous collapse. "Pacatal" had an action like chlorpromazine, and, though its side-effects were fewer in number, loss of visual accommodation, a dry mouth, and constipation were all very troublesome. "Sparine" was slower-acting and had no advantages.

Dr. E. H. KITCHING (Manchester) said his experience with out-patients (neurotics, psychopaths, the milder endogenous depressives) was that sodium amylobarbitone was much

better than any of the tranquillizers now on the market. A brief survey of medical literature showed him that doctors were far less enthusiastic about these new drugs than the advertisements implied, and the consensus of opinion was that they had no place, and might even be dangerous, in the consulting-room and the clinic. The excellent comparative trial reported in the *British Medical Journal* of July 13 (p. 63) summed up the situation. He did, however, believe that methylpentynol in a dose of 250–750 mg. was useful in panic states, reducing apprehension. It was safe, provided the patient did not drive a car until four hours after taking it. The risk of addiction was very slight, since the patients whom it benefited were too obsessed about "drugs" to go on taking them for long.

He thought the present craze for tranquillizers and sedatives was partly the result of commercial pressure. Advertisers constantly stressed the strain of present-day life and advocated drugs or foods to allay it. A public relatively educated in science and medicine demanded these drugs, and it was very difficult for doctors to resist them. Forty-eight tons of barbiturates were prescribed in the U.K. in 1955, enough for 20 doses per head of the population. U.S. chemists fulfilled 10 million tranquillizer prescriptions in 1955, and 30 million in 1956, which showed the growth of the craze. People were sometimes taking these drugs before they ever saw a doctor at all.

In the general discussion, Dr. M. H. ELLIOT-SMITH (Sydney, Australia) asked whether tranquillizers were perhaps more effective in the old than in the young, and whether the risks were different with age. Dr. KITCHING replied that he had noticed no difference in effects. Reserpine was sometimes used for hypertension in middle-age, and about once a fortnight he saw a depression due to this treatment: many cases had to have E.C.T. Dr. J. JOHNSTON (Newcastle upon Tyne) wondered whether these drugs were safe for aged psychotics, and both Dr. L. C. COOK and Dr. R. A. BLAIR (Manchester) were emphatic that chlorpromazine was a boon in geriatric wards and safer than barbiturates. Dr. BLAIR also raised the question of epilepsy. He found that chlorpromazine produced fits only in those who had some history of fits, whereas reserpine might cause fits in anyone. Professor A. KENNEDY (Edinburgh) said water-balance studies showed that some individuals on reserpine rapidly increased their tissue water, and this hydration, which might account for half a stone increase in body weight (3.5 kg.), might explain the fits. Dr. R. S. FERGUSON (Gosforth) said the convulsive threshold measured with the electroencephalogram was constant with reserpine. Known epileptics could take tranquillizers without increasing the number of their fits, provided their barbiturates were not cut too quickly. Dr. D. A. POND (London) confirmed this, quoting Dr. J. T. HUTCHINSON's finding that epileptics could be further helped with chlorpromazine if their anticonvulsants were also maintained. He agreed with Dr. L. MINSKI (Sutton) that chlorpromazine was no good for frustrated overactive children, whether epileptic or not. Phenobarbitone made them worse; amphetamine (often in high dose, in spite of which they slept well) was the answer here.

Dr. G. S. R. LITTLE (Greenwich) described a case of delirium tremens which responded excellently to chlorpromazine but became jaundiced. Professor KENNEDY felt that the alcoholic's liver might be specially vulnerable to chlorpromazine, though the drug was useful for the psychiatric symptoms, and indeed also helpful for covering the withdrawal symptoms in drug addictions generally, and he preferred the old-fashioned paraldehyde, with cortisone and B vitamins. He remarked on the curious variation in the incidence of chlorpromazine jaundice from place to place and time to time, which was confirmed by other speakers. Both Dr. KITCHING and Dr. R. ORTON (Newcastle upon Tyne) thought chlorpromazine was good treatment in delirium tremens, since the jaundice, if it came, was reversible. Dr. ORTON also drew attention to the possibility of sex differences in the response to tranquillizers. He thought methylpentynol helped women but was useless for men. He felt the same might be true of meprobamate.

Professor M. ROTH (Newcastle upon Tyne) warned that the clinical trials now so rightly being carried out contained a trap. They assumed that the experimental and control groups were homogeneous and could be compared, but psychiatric classification was in a vague state, and only detailed clinical scrutiny of each patient in a trial could guarantee that the two groups really did contain comparable conditions. Without that guarantee a trial could be worthless.

The PRESIDENT briefly summed up the discussion in both its sociological and clinical aspects, adding a warning on reserpine as a cause of sudden death, and a recommendation of chlorpromazine with morphine for the dying.

SECTION OF OCCUPATIONAL HEALTH

Tuesday, July 16

Management of Pneumoconiosis in General Practice

With the president of the Section, Dr. J. J. O'DWYER (London), in the chair, Dr. A. MEIKLEJOHN (Glasgow) opened the discussion on the management of pneumoconiosis in the general practice. He said that occupational disease of the lungs brought numerous problems to doctors in mining and industrial areas. In 1955, of the 6,000 or more certified cases of pneumoconiosis, 81% were coal-miners. In the same year the Ministry of Pensions and National Insurance received claims from more than 15,000 miners. Thus, out of every hundred claimants, no fewer than 67 did not receive a disablement award.

Many complained bitterly to their general practitioners, who often had more trouble in helping those denied an award than those who received one. He emphasized that many who were certified were not seriously disabled. It was the general practitioner's duty to encourage them to continue their work. With improved methods of dust control in mines and in other industries, such a procedure was possible. He stressed the need for the doctors on the possible pneumoconiosis panels to give less formal and more informal reports to general practitioners and also to industrial medical officers, who could help patients to continue to do suitable work. These doctors should watch for the complication of active tuberculosis. Consultations should not be hurried. Doctors who had time to listen would give support and encouragement which were the most important items of therapy.

At present no workman received an award unless the chest radiograph showed changes conforming to category 2 of simple pneumoconiosis. There were middle-aged workmen severely disabled by breathlessness after thirty years at the coalface. They were diagnosed as suffering from bronchitis and emphysema, for without the "mystic nodules" on the radiograph they were not entitled to compensation. Younger men with shorter exposures, and who had no apparent incapacity either for work or for strenuous leisure, had received awards of 10%. The evidence that chronic bronchitis might be related to employment was steadily growing. Dr. Meiklejohn concluded that the distinction between benefits paid for occupational and non-occupational diseases and accidents was now unrealistic. A single system of benefits was needed. But the real problem was not compensation nor even research but the prevention and control of disease.

Dr. J. C. GILSON (Llandough) said that he fully supported the previous speaker's remarks. But he believed that research was important and necessary because prevention was not yet surely founded on a full understanding of pneumoconiosis, particularly the causes of respiratory disability. The number of new cases of coalworker's pneumoconiosis rising in the rest of the country. Simple pneumoconiosis was the commonest radiological change. It was usually quite symptomless, but the abnormality was enough to bring many cases within the regulations of the Industrial Injuries Act. A further rise in new cases in the rest of the country was expected as the number of miners x-rayed increased.

These figures did not mean that the dust conditions in coal-mines were getting worse. They were an index of conditions ten and twenty or more years ago.

Disagreement in reading films usually upset the patients more than the doctors. Such errors could be reduced by using standard films, by better personal contact between doctors, and by improved film techniques. Physicians often vainly attempted to read pneumoconiosis in bad films, whereas their surgical colleagues refused to use dirty or blunt instruments.

Epidemiological studies by the Pneumoconiosis Research Unit showed that a higher proportion of elderly miners and ex-miners had respiratory disability, as indicated by a test of maximum ventilatory capacity, than men of comparable age who had not mined. Also there was a higher prevalence of bronchitis in miners and ex-miners than in non-miners. Studies in other communities supported the contention that, among elderly miners without radiological pneumoconiosis, there was an unduly high prevalence of chronic respiratory disease. The Industrial Injuries Act did not provide for those who had common diseases such as bronchitis and rheumatism in higher frequency and of greater severity as a result of their occupation. The administration of injury benefits should be made to fit the medical findings rather than to fit the disease to a fixed administrative plan. Those who were really disabled, whatever the cause, should be adequately provided for.

Dr. R. A. TREVETHICK (Sheffield) outlined four ways in which the industrial medical officer helped in the management of this disease. He often made the diagnosis in patients, and he had to determine the prevalence of disease in groups of workers. He advised the management on the steps to be taken to eliminate the hazard. He helped to find alternative work for those who were severely incapacitated or whose radiographs showed rapid progression. The medical officer in industry informed the general practitioner of his findings. It was equally important that there should be a return flow from the general practitioner to the industrial medical officer. Directors of mass miniature radiography units were not allowed to inform industrial medical officers that certain workers had pneumoconiosis, although this information was invaluable in preventing disease.

Dr. FENWICK LISHMAN (Crook, Co. Durham) said that in his practice in Durham 30 years ago coal dust was thought to be quite harmless. Many miners were now diagnosed by the chest physician as suffering from pneumoconiosis, but often it was not confirmed by the panel. The patient was surprisingly disappointed and not relieved to know that he had not got pneumoconiosis. This was because the workman was often not ill and the pension was regarded as "something for nothing." There was a need for miners with pulmonary disease to be followed up, and he suggested that this might be done by the university department of industrial health.

Dr. H. SOMERVILLE (Durham) said that the National Coal Board was making a long-term study of the relation between prevalence of disease and dust exposures. In the future they would be able to determine safe conditions with some precision. Dr. D. MCLEAN (Newcastle upon Tyne), who described the periodical investigation of steel foundry workers in his area, asked for more information from the pneumoconiosis panels about the men referred. Dr. F. J. ROBERTSON (Newcastle upon Tyne) said that the industrial rehabilitation unit in Durham was able to help men disabled by chronic respiratory disease, but after rehabilitation these men expected to be settled in suitable work. This was seldom possible, and as a result their morale was often worse than it was before they came to the unit. Dr. R. C. BROWNE (Newcastle upon Tyne) pleaded for a more critical examination of the meaning of "loss of faculty" and the rating of disability on a 3 or 4 point scale, instead of a percentage assessment, which was often meaningless. Dr. J. D. BALL (Llandough) asked for a change of nomenclature. Simple "pneumoconiosis" was an iatrogenic disease, and it would be helpful to use the term "disease" solely for complicated "pneumoconiosis."

SECTION OF OPHTHALMOLOGY

Tuesday, July 16

Chiasmal Disease

With the president, Mr. J. S. ARKLE (Newcastle upon Tyne), in the chair, Professor NORMAN DOTT, of Edinburgh, opened the discussion on diseases of the optic chiasma. He reviewed the anatomy of the region and enumerated the many conditions which could impair conduction through the chiasma. He stressed pituitary tumours, aneurysms, and meningiomas as being the common causes of pressure on the chiasma; dermoid cysts and hydrocephalic distension of the third ventricle could also compress it. The vascular supply of the chiasma was impaired in arteriosclerosis, tubercular and syphilitic meningitis, and head injury. The most frequent intrinsic diseases of the chiasma were glioma, pituitary epidermoid, and reticulosis, and the chiasma could be involved in disseminated sclerosis. Pituitary adenomata were particularly amenable to surgical treatment, though radiotherapy was usually given following surgery. In Edinburgh the pituitary was often removed by the trans-sphenoidal route, and in 100 operations the mortality had been 2%, with no death in the last 70. The mortality with the transfrontal operation had been higher, but this was partly accounted for by the fact that it was used in more difficult cases.

Dr. A. J. MOONEY (Dublin) was second opener. He gave several examples of how the chiasma could be affected by disease in its neighbourhood, and stressed the great value of perimetry in locating the site of the disease. The accurate testing of the visual fields was also essential in assessing progress. To obtain information on the underlying cause other investigations, particularly plain radiography and angiography, were of great value. Dr. Mooney also stressed the importance of surgery, usually followed by radiotherapy in the treatment of pituitary tumours, though often he had found radiotherapy alone effective. Field defects did not always fit in with what would be expected if impairment of conduction was due entirely to direct pressure. Pressure by tumours probably affected the visual pathways by interference with the vascular supply.

Dr. J. McLELLAND (Edinburgh) described the value of radiotherapy, particularly supervoltage radiotherapy, in the treatment of pituitary tumours. Radiotherapy was used most often following surgery. Eighty per cent. of chromophobe adenomata were radiosensitive, and 100% of eosinophil and basophil tumours were sensitive. The rare pituitary carcinoma was entirely radioresistant. The only effective treatment for nasopharyngeal tumours involving the chiasmal region was radiotherapy.

Dr. C. F. ROLLAND (Carlisle) pointed out that while visual symptoms were at times the main complaint of patients with pituitary disease it was surprising how often a patient would be quite unaware of extensive visual field loss. Accurate assessment of pituitary function was an important part of a full diagnosis. Water excretion, insulin sensitivity, and glucose-tolerance tests should be done. An abnormal E.C.G. was also often found. Replacement therapy with corticotrophin, vasopressin, and sex hormones could be of great value even if started for the first time years after the onset of the initial pituitary hypofunction.

Mr. J. SLOAN ROBERTSON (Glasgow) described cases of tubercular meningitis showing how tubercular granulation and fibrous tissue could cause strangulation of the chiasma. Antitubercular treatment alone was, however, not enough to alleviate this, and surgery was required. Suprasellar calcification was often seen in radiographs of patients who had had tubercular meningitis, but it did not give an accurate guide to the amount of visual impairment to be expected.

Occasional Papers

Mr. P. D. TREVOR ROPER (London) gave a comprehensive review of the ocular changes in leukaemia. The commonest external manifestation was the infiltration of the conjunctiva and eyelids. Subconjunctival haemorrhages were

also common. The ophthalmoscopic changes were those of any severe anaemia showing haemorrhages and retinal oedema, but in leukaemia there was a tendency for the haemorrhages to have a white centre. In the later stages the whole fundus became a pale orange colour. Pathologically all layers of the retina become infiltrated with leukaemic cells, and the choroid was also often similarly affected. Treatment of the chronic leukaemias was by radiotherapy to the enlarged spleen and lymph nodes. In myeloid leukaemia arsenic, urethane, and busulphan were given. In the case of lymphatic leukaemia treatment was usually by nitrogen mustard, R 48, and triethylene melamine. Corticotrophic hormones occasionally brought temporary benefit in acute leukaemia.

Mr. H. VERNON INGRAM (Newcastle upon Tyne) described "cataract surgery under chlorpromazine hydrochloride." The patients were given pethidine, chlorpromazine, and promethazine one and a half hours before operation. The usual dose was 50 mg. of each of these drugs, though hypertensive patients and those over 70 years of age were given smaller amounts. In some cases it was necessary to give an additional 2.5 mg. of chlorpromazine and pethidine intravenously immediately pre-operatively. The main complication was a severe fall in blood pressure in some cases, and methylamphetamine had sometimes to be given to counteract this. No serious complications attributable to the method of sedation were encountered in 142 consecutive cases; the oldest patient was over 90 and the youngest under 30.

SECTION OF HISTORY OF MEDICINE

Tuesday, July 16

Early Surgical Textbooks

Sir ZACHARY COPE presided at the meeting of this Section; before calling on the contributors, he recalled that he was present at the previous meeting in Newcastle nearly 40 years ago.

The first contribution was by Dr. C. E. KELLETT (Newcastle), who took as his subject the *De Dissectione* of Charles Estienne. Dr. Kellett showed a number of slides in a reconsideration of the illustrations of the *Chirurgia* of Vidus Vidius and the *De Dissectione* of Charles Estienne, and discussed the origin of those pictures. [An exhibition concerned with the iconography of the two books, prepared by the department of photography in the Newcastle Medical School, was on display in the Hatton Gallery. The text of the illustrated catalogue was written by Dr. Kellett.]

Mark Akenside

An interesting and exhaustive sketch of the life and achievements of Mark Akenside, eighteenth-century poet and physician, was contributed by Sir JOHN CHARLES (London), who was unable to be present at the meeting but whose paper was read by the president.

After a brief survey of Akenside's poetic achievements, the author continued with details of his life. Born on November 9, 1721, in Newcastle, the second son of a prosperous butcher, Akenside received a foot injury when 7 years of age which "halted him for life." He was a pupil at Newcastle Grammar School, and then at a private academy of a dissenting minister. After one winter at divinity and theology (financed by the Dissenters' Society), in 1739 he became a medical student. During that period he formed his lifelong friendship with Jeremiah Dyson. Akenside seemed to have picked up enough knowledge of medicine to make him a competent practitioner, although he left Edinburgh without taking a degree. He practised as a surgeon in Newcastle in 1741-2, and then or later repaid the money borrowed from the Dissenters' Society. His first great work, "The Pleasures of Imagination," was composed about that time. With the cash he received he settled for a short time in London preparatory to going to the University of Leyden in Holland in April, 1744, there joining

Dyson and other friends. He acquired a doctorate of medicine there in six weeks. Returning to London, he practised unsuccessfully in Northampton for a time, during which he wrote the powerful satire "The Epistle to Curio," and his first book, *Odes on Several Subjects*. He was "rescued" by Dyson in 1745, who brought him to the opulent neighbourhood of Hampstead, where he practised not too successfully.

In 1746 he was appointed editor of the magazine *The Museum*. Two years later Dyson gave him a house in Bloomsbury and an allowance of £300 a year. He became a Fellow of the Royal College of Physicians in 1753, and just before that was admitted by mandamus to the degree of doctor of physic in Cambridge University. At the College he carried out various academic tasks and was described as "diligent in his attendance at the quarterly comitia and discharged his various duties with satisfaction and those requiring the literary graces with every possible distinction." Dyson introduced him to the Royal Society, where he became very popular and was admitted as a Fellow in 1754 at the age of 32.

He obtained no hospital appointment until 1759, when he became assistant physician to Christ's and St. Thomas's Hospitals; three months later he became principal physician at the latter, which post he held until his death in 1770 from "a putrid sore throat" or "a putrid fever."

As a poet Akenside gained recognition for the icy elegance of his style—a poet very near to genius but lacking the essential fire and warmth. As to his work as a doctor, medicine was overshadowed by poetry, yet he was active, competent, and experienced, that latter attribute coming less from private practice than from his assiduous attendance at St. Thomas's Hospital. His medical writings were, broadly speaking, academic in origin and approach prior to his appointment as physician to St. Thomas's; thereafter they presented the findings of a keen observer and the logical conclusions of a physician able to call to his aid a good memory and extensive experience, albeit restricted by the limited pathology of the period.

As a man Akenside was ambitious, arrogant, petulant, conceited, and from time to time wanting in that humanity which should characterize the physician. Contemporary opinions underlined the mixture of genius and melancholy in his personality, at times corrosive but more often, especially in the company of his peers, mellow and kindly. But he was not dissatisfied with his achievements, which had led him from his native northern city to the great metropolis of London endowed only with his natural gifts to become, in the words of his admirer Cowper, "the twofold disciple of Apollo."

Leyden and Edinburgh

Dr. DOUGLAS GUTHRIE (Edinburgh), in presenting the third contribution, dealt with the interesting period of medical history when the centre of medical education became transferred from Leyden to Edinburgh. It was interesting to refer to that Leyden was a direct descendant of Padua, and that the heart of medical knowledge passed from Padua to Leyden and from Leyden to Edinburgh. The early teachers at Leyden were originally students at Padua, and the teachers at Edinburgh were originally students at Leyden. The founders of the College of Physicians were, in fact, students at Leyden.

John Monro, who was an early student at Leyden, was so impressed by the methods of teaching there that he resolved that Edinburgh should have a similar medical school. He also resolved that his son—then aged three years—should become the first professor of anatomy in the new Edinburgh school. It was a bold resolve, but it turned out to be the case.

Among the many distinguished people who were students at Leyden were Peter Goldman, Alexander Leighton, Gilbert Rule, and George Martine. Among the list of American students, Samuel Bellingham might have been the first to graduate, together with Phineas Bond, the founder of the Pennsylvania Hospital, Benjamin Waterhouse, the first

to introduce vaccination into the United States, and William Wells, who pointed out the relationship between rheumatic condition and cardiac troubles.

Leyden, a survivor from the past, was still carrying on a noble and important tradition.

Cholera Epidemics in Newcastle

The next contribution was made by Professor JOHN BOYES (Newcastle), who said he had chosen to speak on the subject of cholera because the first case ever recorded in Britain occurred in Sunderland in November, 1831. From that town the disease spread to become a national epidemic which caused the death of more than 21,000 people in the course of a year.

It was interesting to recall that the epidemic began during the Polish struggle against Russia in 1831, and it crept westwards across Europe until it eventually reached Britain. At that time a committee was appointed by the College of Physicians, and that committee caused no little surprise when it came to the conclusion that the disease was infectious, in opposition both to the opinion of those who had seen cholera in India and to the great majority of those who had witnessed it in north-east Europe.

That cholera epidemic very nearly covered the world, and it did not end its progress in Britain. It was the first occasion on which the progress of an epidemic could be followed week by week in the newspapers. It was also the first occasion on which the layman was well informed about the clinical appearance and treatment of the disease.

John Snow's Place in History

"The introduction of anaesthetics, with the successful demonstration of ether by Morton on October 16, 1846, is a milestone in the history of medicine which marks the opening of the modern period," said Dr. M. H. ARMSTRONG DAVISON (Newcastle), in presenting the final contribution to the session.

The century which preceded the discovery of anaesthesia was one of preparation for the great progress which was to follow. With the implications of the atomic theory still unrealized, the discovery of the quantitative reaction of carbon dioxide with calcium hydroxide by Joseph Black seemed trivial indeed. Similarly, the isolation of the first alkaloid, morphine, by Serturmer in 1806 did not appear of vast significance. More dramatic was Jenner's discovery of vaccination, but when confronted by other diseases, or even by the whole problem of the nature of disease, Jenner's light was simply bright enough to render the surrounding darkness even more impenetrable.

Medicine depended on scientific development for its advances. Curiously enough at that very period medicine lagged farther behind science than it had ever done before or since. But the attitude of John Snow to medicine was identical with the present outlook, and it was that which placed him in the forefront of modern physicians, not only in merit but also in point of time.

In 1832, after the passing of Warburton's Anatomy Act, the first medical school was opened in Newcastle. For the first session eight students were enrolled, and one of those was John Snow. A year later Snow left Newcastle and ultimately set up in practice on his own account in London. He was not at first very successful; and it was because he had time on his hands that he turned his attention early in 1847 to anaesthesia. It was for his outstanding contributions to that subject that his name was chiefly remembered. His grasp of the scientific approach to the subject had never been surpassed and had seldom, if ever, been equalled. The first public demonstration of anaesthesia in this country took place on December 21, 1846, yet Snow's first book was on sale before the end of the following year, and in it he accurately described the course of ether anaesthesia, dividing it into stages similar to those in use to-day. He also gave evidence of numerous animal experiments and described a new ether vaporizer which had important advantages.

Vesicular Eruptions of the Hands

In an occasional paper Dr. S. GOLD (London) considered vesicular eruptions of the hands. Eczema of the hands was a common problem, he said, and there was a close relationship between the palms and soles. The difference between the palmar and plantar skin and that elsewhere determined the different character of eczema at these sites. It was difficult to rest the hands, whose skin was subject to trauma of various types, irritation, and sensitizers. Palmar vesiculation was seen in both "contact" and "constitutional" eczema, in seborrhoeic and hyperkeratotic eczema, and in endogenous reactions following infection and invasion of the skin by fungi, parasites, viruses, and bacteria. It was also seen as an endogenous reaction to food and drink. Cheiropompholyx was a variety of endogenous eczema. There was no evidence that sweat retention occurred on the palms and soles. During its course through the keratin layer the duct had no limiting membrane, and sweat escaped from it and helped keep the horny layer properly hydrated and supple.

Dr. A. GIRDWOOD FERGUSON (Glasgow) followed with a further paper on vesicular eruptions of the hands and feet. He divided these into four categories: (1) eczematous, often discoid and sometimes industrial, but often with an endogenous factor in addition; (2) pompholoid, which might be due to autosensitization and was associated with hyperhidrosis; (3) acrodermatitis perstans and pustular psoriasis; (4) a miscellaneous group including erythema multiforme, scabies, the vesicular type of pityriasis rosea, and epidermolysis bullosa. He briefly touched upon treatment.

In the discussion which followed Dr. P. BORRIE (London) agreed that most cases were eczematous and did not think that detergents had increased the incidence. Dr. R. MASON BOLAM (Newcastle upon Tyne) stressed the emotional aspect. In reply to Dr. H. M. DIXON (Newcastle upon Tyne), Dr. S. GOLD (London) thought that between 5 and 10% of cases of pompholyx of the hands were dependent upon ringworm of feet. Dr. DIXON had found a high incidence of candida infection of the feet in schoolchildren.

Neurodermatitis

Dr. S. T. ANNING (Leeds) presented a paper on neurodermatitis, or lichen simplex, a chronic local thickening of the skin which results from rubbing or scratching and occurs in adults, more commonly in women than men. The pruritus was primary and was often provoked by touching the area or by a sudden emotional upset, and increased to a crisis, accompanied by furious rubbing or scratching until a kind of orgasm was reached. Eventually there was a well-defined, slightly raised lichenified plaque, often oval in shape. In colour it was reddish purple with varying degrees of pigmentation, especially around the margin. It was seen more commonly in certain sites—e.g., the nape and sides of the neck, the eyelids, the outer aspects of the forearms, the inner and upper parts of the thighs, the ankles, and the ano-genital region. The finger-nails were usually brightly polished, and clothing over the lichenified plaque might show signs of wear.

Although lichen circumscriptus was mentioned by Willan the condition was first described (under the name "lichen simplex chronicus") by Vidal in 1883, and Brocq clarified its aetiology in 1891. Brocq had noted "the influence which nervousness appears to have in the genesis of this dermatitis" and said that it was in reality a "*neurodermite circonscrite*." His conclusions were reached as much by a careful history of his patients and assessment of their personalities as by physical examination, and were the beginning of psychosomatic medicine.

In the differential diagnosis psoriasis and lichen planus might require consideration, but in these conditions it was usual to find typical lesions elsewhere. The absence of previous vesiculation made the diagnosis of eczematous dermatitis unlikely, and it was seldom so well circumscribed as neurodermatitis.

The patient's appreciation of the nature of his affliction and insight into its cause were of the first importance. To

bring this home required a detailed history and a careful physical examination. Tar had long been a useful application to allay itching and reduce lichenification. Podophyllin in Lassar's paste (1:1,000) or as a paint (1–10% in tinct. benzoin. co.) was also sometimes most useful. Hydrocortisone in an ointment or lotion was certainly effective in allaying itching. Fractional doses of x rays or Grenz rays were often required. Sedatives (bromide or phenobarbitone) or a tranquillizer were usually essential. Nevertheless, whatever treatment was employed, little would be achieved unless the patient understood the cause of the affection and was prepared to co-operate in breaking the habit of scratching, for until the skin was no longer being injured lichenification would persist.

In the discussion Dr. A. J. ROOK (Cambridge) did not think that all patients would produce lichenification from rubbing, and Dr. I. B. SNEDDON (Sheffield) wondered why podophyllin paste should cure the condition if it had a central origin. Dr. J. T. INGRAM (Leeds) asked whether neurodermatitis might not occasionally arise spontaneously like lichen planus; he did not think that the condition always cleared under occlusive dressings. Dr. J. FERGUSON SMITH (Glasgow) stressed this in relation to lesions on palms and soles, and Dr. R. MASON BOLAM (Newcastle upon Tyne) mentioned the association of hypertension.

Dr. R. L. CORMIE (Glasgow) raised the question of the relationship of pruritus vulvae et ani to neurodermatitis, and wondered if there was any risk in the use of tar on these parts.

SECTIONS OF GENERAL PRACTICE AND PREVENTIVE MEDICINE

Wednesday, July 17

Infectious Diseases and the School Child

On Wednesday afternoon a joint session was held on "Illness of the School Child." The first part, under the chairmanship of Dr. H. F. WATTSFORD (Newcastle upon Tyne), was concerned with infectious diseases, the second with emotional problems.

Dr. R. W. ELDRIDGE (Lancs County Council) opened the first session with a paper on the question of whether children with infectious disease, or who had been in contact with one, should be excluded from school. He referred first to the general principles governing exclusion of cases and contacts, and indicated how the changing pattern of infectious disease had resulted in a gradual change of policy. Selective exclusion of schoolchildren according to individual circumstances had replaced the older order of routine exclusion of all contacts. This change had made it very necessary for there to be an agreed policy in each area, and co-operation between family doctor, school doctor, teacher, and parent was essential. General practitioners could assist greatly by informing public health departments promptly of all cases of infectious disease, whether statutorily notifiable or not.

Dr. G. K. HODGKIN (Redcar) discussed the rotation of infectious diseases in general practice. The presence of one type of bacteria could sometimes protect an individual from infection by a more virulent organism, he said, citing as illustrations of this thesis the invasion of the gut by virulent staphylococci after its virtual sterilization by antibiotics and the fact that penicillin-resistant staphylococci were less likely to invade the nose of hospital patients if penicillin-sensitive staphylococci were already present. Perhaps a similar relationship also existed between viruses. Might the disappearance of one type of virus from a community result in its replacement by one more virulent, with the consequent development of an epidemic? The results of a long-term study of virus diseases amongst the children of his practice might help to answer this problem. Records had now been kept for three years, and the epidemics of measles, chicken-pox, and mumps which had occurred had alternated rather than overlapped. The practice served two adjoining but relatively self-contained

estates, and it looked as if an epidemic of mumps on one estate might have prevented the spread of epidemics of measles and chicken-pox from the other estate. The period of the study was much too short for any firm conclusion, but the figures so far did suggest that an epidemic of one virus might protect a child community at least temporarily from other virus infections. He had also observed a fall in the number of tonsillitis cases in the practice for ten days before, and during, each of two influenza epidemics which had occurred. Did this mean that virus and bacteria competed for the tenacity of the throat?

Dr. E. G. BREWIS (Newcastle upon Tyne) gave as the two main reasons for exclusion from school the prevention of infection and public opinion. Many circumstances determined what action should be taken, and he instanced a small circumscribed outbreak of 14 cases of diphtheria in Newcastle in 1952 in which the most rigorous measures had been used. He considered the latter had been fully justified, as the epidemic rapidly came to an end. Discussing individual diseases, he thought that both cases and contacts of scarlet fever should be dealt with together, and that prophylactic oral penicillin was justified for contacts. Bacteriological control of Sonne dysentery had failed and should be replaced by clinical control. Most danger came from children actually suffering from diarrhoea and from unhygienic sanitary accommodation. With regard to meningococcal infections, he thought that if contacts were treated with sulphamide there was no need for exclusion. Dr. Brewis doubted whether there was much to be gained by excluding poliomyelitis contacts for as long as three weeks, although this might have value in a rural area and was probably necessary at present in order to allay public anxiety. Dr. J. W. BROWN (Sutton Coldfield) suggested that children with chicken-pox, rubella, and mumps might be allowed to return to school at a very early stage in order deliberately to disseminate infection, but Dr. ELDRIDGE replied that he did not favour such a course on general principles, and he would be apprehensive about the possible spread of rubella to women in the early stages of pregnancy.

Emotional Troubles

Under the chairmanship of Dr. MONA MACNAUGHTON (Newcastle) Dr. A. MODEL (Stockport) opened the second half of the discussion with a paper on the child who refuses to go to school. He gave statistical details about 17 children who had refused to go to school after a period of normal attendance. Such children, who were usually of good intelligence, were not generally found amongst "social problem families." The peak age of breakdown was in the twelfth year, but, contrary to expectation, this did not appear to be due to anxiety over the 11-plus examination. He went on to describe three of the cases which had been treated in a psychiatric clinic. They illustrated the commonly found association of dependence and hostility between mother and child; the fact that the ultimate refusal to go to school was the accumulation of long-standing difficulties; and that the timing of the child's return to school must be related to his total character disturbance. Dr. Model ended by emphasizing the importance of the general practitioner's knowledge of the family and his awareness of likely sources of conflict, and his opportunities for early intervention before breakdown occurred.

Dr. G. S. ROBERTSON (Liverpool) spoke about the emotional problems of schoolchildren from the point of view of a school medical officer primarily concerned with prevention. After excluding children with educational problems, he had analysed a hundred consecutive cases seen at a child guidance clinic, and in no fewer than 82 the parents were judged to be unsatisfactory in one way or another. This survey indicated that there are cases where children would definitely benefit by removal from their homes. Step- and foster-parents should be helped by advice on the handling of children, and it was important that adoptive parents should know about a child's intellectual capacity. Where educational difficulty was a cause of

emotional upset, early recognition of the fact was most helpful. Many such problems became apparent about the age of 7 when a child was transferred from infant to junior school. Problems were particularly apt to arise if there had been difficulty in learning to read. Very few cases of emotional upset due to the 11-plus examination were seen, and those that were seen were due to parental anxiety.

SECTION OF ORTHOPAEDICS

Wednesday, July 17

Pain in the Arm

With the president, Mr. C. GORDON IRWIN (Newcastle upon Tyne), in the chair, a discussion on pain in the arm was opened by Mr. R. ROAF (Liverpool). He said that arm pain (apart from peripheral causes) was usually due to a disorder of the cervical spine. Gross disorders—e.g., tuberculosis, neoplasms, dislocations, and spondylitis—were comparatively rare causes of brachialgia, but must be excluded by careful clinical and radiological examinations. The "cervical rib" syndrome was considered a rare cause of pain in the arm, and operation for removal of cervical rib was not usually followed by good results unless the main indication for operation was a vascular one. Referred pain from disorders of the cervical spine was due to direct involvement of a nerve root or to stimulation of a deep-seated structure such as a spinal ligament which had poor cortical representation. He described three main syndromes: (1) the disk prolapse syndrome, (2) disk atrophy, and (3) disk fibrosis (osteoarthritis). In discussing the aetiology of these syndromes Mr. Roaf drew attention to the importance of stereoscopic vision in man, with the consequent development of increasing rotation in the cervical spine and strains on the disk structure. He described the various forms of conservative treatment—traction, plaster fixation, supporting collar, neck cushion, and attention to posture. Mr. Roaf had given up manipulation and believed that operation was rarely indicated, and then only when symptoms were severe and not responding to conservative treatment or when there was gross paralysis.

Mr. J. K. STANGER (Newcastle upon Tyne) described the peripheral conditions causing pain in the upper limb. Capsulitis of the shoulder was the commonest cause after spondylosis. He thought that Furlong's remark that the shoulder became frozen, stayed that way for many months, and then thawed was most suitable. Treatment of this condition should not be active, and he warned against the use of manipulation. Ulnar neuritis associated with abnormalities in the bony contour of the elbow was usually amenable to surgery. De Quervain's syndrome was a frequent cause of pain in the forearm, wrist, and thumb, and with carpal-tunnel syndrome was the most satisfactory operative material in the orthopaedic field. Tennis elbow was also a common cause of arm pain, and though a few cases were suitable for manipulation a greater number responded to injections of hydrocortisone. A considerable number of cases of tennis elbow, however, needed no treatment other than avoidance of the activity that aggravated the condition.

Dr. M. KREMER (London) discussed all the causes of arm pain from the neurologist's point of view. Rare causes could usually be detected by physical and radiological examinations, and he mentioned in particular the thalamic syndrome with spontaneous unilateral burning pain, and pointed out that patients with syringomyelia, haematomyelia, and multiple sclerosis sometimes presented with brachialgia. He agreed that spondylosis was the commonest cause, and pointed out that pain from cervical causes could occur as low as the iliac crest because of the myotome level. He stated that in nine years 600 cases of carpal-tunnel syndrome were seen in his hospital, whereas there were 12 examples of proved cervical-rib syndrome in the same period. He suggested that early operation was indicated for ulnar neuritis before the onset of muscle paralysis, because this complication was often irreversible.

Lord COHEN OF BIRKENHEAD summed up the conclusions of the previous speakers and went on to discuss epilepsy as a social problem. He said that there were no fewer than 100,000 and probably nearer 200,000 epileptics in Great

Britain. These cases varied greatly in severity, but at least 80% of epileptics could lead a normal, satisfying, and useful personal and communal life. The major problem was one of spreading the truth about epilepsy and disabusing the minds of parents, victims, and the public of the widespread but mistaken notions which have led to the epileptic being regarded as a pariah. Parents must be informed that not every fit in childhood meant lifelong epilepsy; they must not be over-anxious, over-protective, or feel a sense of guilt—all these reacted on the child. Care must be taken to avoid accidents in the home. Apart from the family doctor, many voluntary agencies could give advice upon problems of management. Lord Cohen pointed out that 80% of epileptic children could be educated in ordinary schools, but teachers and classmates must know of the tendency if alarm was to be avoided. The remaining 20% might require special schooling.

A suitable job for the adult had therapeutic value. Economic security brought a sense of independence and social adjustment and did much to counter apathy and depression. Certain hazardous occupations had to be avoided, but there were statutory provisions by the Ministry of Labour which helped to secure for the epileptic a place in industry. The colonies for epileptics (formerly custodial and communal) should become increasingly rehabilitative.

ROUND-TABLE CONFERENCES

Wednesday, July 17

SOME PREGNANCY ALARMS

For the round-table conference arranged by the Section of Obstetrics and Gynaecology, the section president, Professor H. HARVEY EVERS (Newcastle), was chairman and Dr. WILLIAM WALKER (Newcastle) and Mr. C. K. WARRICK (Newcastle) were the members of the panel. The discussion was on the subject of "Some Causes of Public Alarm in Pregnancy."

Rh Iso-immunization

The first cause of public alarm ventilated was the topic of Rh iso-immunization. Dr. WALKER said it was important to put the risk to the baby in proper perspective. In only 13 out of every 100 marriages was the husband Rh-positive and the wife Rh-negative, and in only 1 in 20 of these women did antibodies develop. All pregnant women must have their blood groups tested in every pregnancy. If Rh-negative, a test for antibodies must be performed about six weeks before term in every pregnancy. The risk of stillbirth was highest where a previous baby had been severely affected. Half of the stillbirths occurred before the 35th week. This limited the place for premature induction of labour, but where a previous baby had been lost and the husband was homozygous Rh-positive induction was justifiable at even an earlier date. The prime object, however, was to see that any baby born alive stayed alive. There was no doubt that exchange transfusion had brought about greatly improved results. In 1952 to 1955 the mortality from haemolytic disease in liveborn babies was less than 3.5%.

Many points were brought out by speakers from the floor. The general feeling was that the facts of the matter were not properly explained to the Rh-negative woman. It was suggested that for the doctors the Central Health Services Council might produce a leaflet as they had done with regard to pregnancy toxæmia. Rh iso-immunization was not a cause of miscarriage or repeated abortion. The pregnant Rh-negative woman should be reassured that there was no risk to her and that any baby leaving hospital well would remain well. Finally it was agreed that the presence of Rh-antibodies was an indication for delivery not merely in a hospital but in an institution where there were facilities for the prompt and adequate treatment of the baby, if affected. Those who joined in the general discussion included Dr. ELEANOR M. REECE (London), Dr. A. BARKER

(Whitstable), Dr. J. W. HOPE-SIMPSON (St. Albans), Mr. S. BENDER (Chester), Professor W. I. C. MORRIS (Manchester), Dr. J. WILBUSH (Victoria, Australia), Professor A. S. DUNCAN (Cardiff), and Mr. LINTON SNAITH (Newcastle).

Antenatal Irradiation

Mr. J. A. STALLWORTHY (Oxford), a vice-president, took over the chair when Mr. C. K. WARRICK (Newcastle) introduced the second subject, on which there had been general anxiety and alarm—irradiation during the antenatal period. There were three possible dangers. First was direct irradiation injury to the embryo during the first two or three months, resulting in congenital abnormalities. It might be wise to restrict all non-emergency radiography of the pelvic area to the first half of the menstrual cycle so that an undiagnosed pregnancy might not be affected. The second hazard was of genetic injury from irradiation of the gonads of mother and foetus leading to acceleration of the mutation rate of genes with deleterious effects on future generations. There was no exact information on this point, but there might be no threshold for such genetic injury and the effects might be cumulative. However, the radiologist should try to minimize the dose received by the gonads in patients who had not passed the age of reproduction. The third cause for alarm was the report that the very small doses of whole-body radiation received by the foetus in obstetric radiography caused an increased incidence of leukaemia and malignant disease in the first ten years of life. This risk appeared to be about one additional case for every 1,500 live births submitted to antenatal pelvic radiography. Against all these possible disadvantages must be set all the very valuable information provided by obstetric radiography. It was the responsibility of the radiologist to get the maximum information without unnecessary exposure of the patient. And it was the responsibility of the clinician to make sure that there was adequate medical justification for x-raying the pregnant woman.

Professor W. I. C. MORRIS (Manchester) said that public anxiety in this matter had been largely contributed to by doctors who were not well informed. His approach was to tell the patient that the risk to the baby from the x rays was about one-eightieth of the risk if a necessary x-ray was not taken. Mr. FRANK STABLER (Newcastle) and Dr. ELEANOR M. REECE (London) also spoke.

LOW BACK PAIN

This discussion, held under the chairmanship of Dr. HUGH BURT, president of the Section of Physical Medicine, attracted an audience of about 70 members, who heard a lively discussion, with plenty of difference of opinion firmly expressed. The panel consisted of Dr. D. R. L. NEWTON (London), Mr. N. M. ROBERTS (Liverpool), Dr. S. JOSEPHS (Newcastle), Mr. I. N. MACIVER (Newcastle), and Mr. W. MILLS (Birmingham).

Introducing the difficult and controversial problem of low back pain, Dr. BURT pointed out that the members of the panel had agreed that in the present state of knowledge it was impossible to determine in every case exactly what was responsible for the production of symptoms, though many people had their particular theories.

Mr. W. MILLS (Birmingham), speaking as a gynaecologist, said that patients with low back pain were commonly referred to the gynaecologist because it seemed at first sight that any pain that occurred in relationship to the menstrual cycle or first developed during pregnancy or the puerperium must necessarily be of pelvic origin. In his experience backache of pelvic origin was diffuse, symmetrical, confined to the sacral region, and did not radiate to the legs. Sometimes it formed but a minor symptom of obvious pelvic inflammatory disease, malignancy, or severe prolapse; in other cases it appeared to be related to a chronic parametritis, a condition diagnosed by the occurrence of pain on moving the uterus and cured by hysterectomy. As for backache related to the menstrual periods,

much had been heard of fluid retention, but perhaps it was forgotten that the premenstrual phase was also a period of emotional tension. Backache coming on during pregnancy or the puerperium might well be the result of relaxation of the pelvic ligaments and joints. Mr. N. W. ROBERTS (Liverpool) said that as an orthopaedic surgeon he knew of no evidence to suggest that physiologically relaxed joints remained relaxed pathologically, while sacro-iliac strain did not appear to occur at all.

"Fibrositis"

Dr. D. R. L. NEWTON (London), speaking as a specialist in physical medicine, said that the once popular diagnosis of fibrositis now appeared to be made very much less frequently in departments of physical medicine, because, owing to the increased awareness of the various mechanical disorders that occurred, patients complaining of backache were more fully examined than they used to be. Many lesions of the lumbar spine were associated with points of referred tenderness which previously were regarded as the cause of the pain. From time to time one was forced for want of a better term to use "fibrositis" as a diagnosis when local muscular tenderness was the only demonstrable abnormality. An open mind should be maintained in these cases, because the absence of any other apparent abnormality, either clinical or radiological, could well be regarded as an indication of the shortcomings of physicians and surgeons as diagnosticians. Many cases falling within this restricted and diminishing group nevertheless derived great relief from local procaine injection. Mr. ROBERTS stressed that as yet very little was known concerning the nature of the mechanical disorders which affected the lower part of the back, and in that all treatment was therefore necessarily empirical. In his view there were only two forms of treatment—movement and rest.

Radiological Diagnosis

Dr. S. JOSEPHS (Newcastle) said that the radiologist's contribution to this problem was purely negative, in that he could usually exclude the presence of unsuspected severe inflammatory or neoplastic disorder. But in the great majority of patients complaining of low back pain there was no radiological abnormality in the lumbo-sacral spine. He felt strongly, however, that all cases should be x-rayed before any manipulative procedure was carried out, since this could prevent possible unfortunate consequences.

The Place for Manipulation

Mr. I. N. MACIVER (Newcastle) said that the neurosurgeon now tended to see many more early cases of low back pain due to disk lesions than previously, particularly if associated with the rapid onset of sciatica. Many of the female patients appeared to him to be in a state of chronic overtiredness and were often depressed. He felt that many more cases of acute backache deserved "acute treatment," but a spell of convalescence often did more good than anything else. If there was no improvement after 7 to 10 days' rest and the neurological signs were not of a severity demanding immediate operation, the patient should be manipulated by simple hyperextension of the lumbar spine under pentobarbitone anaesthesia with a relaxant. Many patients were thus relieved of their sciatica, though the back pain tended to persist for longer. If early in the course of the illness the straight leg raise was severely diminished, leg pain was very severe, or there was rapid loss of reflexes associated with sensory disturbance, a large disk protrusion was present which demanded immediate laminectomy.

Mr. ROBERTS felt that the absolute criterion for the diagnosis of a disk lesion was the onset of neurological signs, but since many of his patients had a past history of lumbago without sciatica it seemed likely that this had been due to the same cause, though it could not be proved. He could not agree that manipulation was indicated in the treatment of disk protrusions, despite the fact that spontaneous remission was known to occur—as, for example, when one of his own patients fell while being lifted from the ambu-

lance in the course of admission for laminectomy. Mr. MACIVER felt that relief of sciatica was gained by the use of manipulation because the nerve root was allowed to slide away from the apex of a disk protrusion: this had actually been seen to occur when the manipulative manoeuvre was carried out in the course of laminectomy.

Dr. NEWTON said that the experience of those who employed manipulative methods of treatment without anaesthesia seemed to point to the fact that the patients who did best were those who had suffered the sudden onset of symptoms without sciatica, and certainly without neurological signs. This group, however, contained most of the cases of low back pain which recovered spontaneously in a short period or dramatically with the type of accidental or self-manipulation quoted by Mr. Roberts. All the claims made for the success of manipulation were based on clinical impression, and controlled clinical trials were needed with large numbers of cases so that adequate attention could be paid to the natural history of the disorder. So far only one such trial had been published,¹ but the number involved was small and the results were inconclusive.

Mr. MILLS felt that more attention should be paid to the question of whether low back pain was brought on only after the patient had been standing for some time or whether it was present on waking. Many women derived great benefit from the use of such devices as a high stool when ironing or washing, thus avoiding a great deal of the strain that falls on the back under such conditions.

INJURIES RESULTING FROM ROAD ACCIDENTS

Mr. J. I. MUNRO BLACK (Newcastle upon Tyne) was chairman of the panel which discussed injuries resulting from road accidents. The other members were Mr. G. F. ROWBOTHAM (Newcastle upon Tyne), Mr. F. FENTON BRAITHWAITE (Newcastle upon Tyne), Mr. W. GISSANE (Birmingham), Professor JOHN BOYES (Newcastle upon Tyne), and Professor T. POMFRET KILNER (Oxford).

The panel expressed concern regarding the adequacy of the road accident service. The first fatality in a road accident involving a vehicle driven by an internal combustion engine was in 1896, and since then there had been a quarter of a million deaths. The rapidly increasing density of road traffic and the increased speed of vehicles were creating an accident problem which the present hospital service could not deal with effectively. In the large centres the creation of accident departments attached to general hospitals was advocated. Specialist services did not exist on a similar scale at the periphery, and a serious defect was the lack of properly trained general surgeons capable of treating cases of multiple injury. Careful thought must be given to the postgraduate training of surgeons in the specialist subjects, and some return to general surgery must take place if seriously injured people were to receive the best treatment.

The Multiple Sclerosis Society, in its annual report for 1956, states that "one of the basic tenets of the Society is to encourage scientific research into the causes of and the cure for Multiple Sclerosis." In 1956 the society received a gift of £8,500 from King's College, Newcastle, to finance three research projects. These are (1) to carry out a survey of the disease in N.E. England, (2) to examine the psychiatric features of the disease, and (3) to subsidize the training of a young pathologist as a future member of a medical team carrying out this programme. A great deal of the work of the society is carried out voluntarily by branches and groups throughout Great Britain. There are now thirty-five branches, whose aim is to "arrange for every member on their books to be visited, and for their particular requirements to be met as far as possible." The financial security of the society was considerably improved in 1956, mainly owing to the donation of a legacy of over £12,300. The head office of the society is at 9, Grosvenor Crescent, London, S.W.1.

¹ Coyer, A. B., and Curwen, I. H. M., *British Medical Journal*, 1955, 1, 705.

THE SCIENTIFIC EXHIBITION

The organizers of the Scientific Exhibition have long realized that there are disadvantages, technical and financial, in the present method of erecting temporary display stands at each Annual Meeting. A welcome feature, therefore, of the 1957 Exhibition at the Stephenson Building, King's College, Newcastle upon Tyne, was the display of two experimental mobile stands, specially designed as permanent equipment for the purpose. This display, produced by the department of photography and illustration at the Westminster Medical School, showed the admirable flexibility of the model stands. Their introduction, however, would not solve all the related problems—the main ones being lack of space to stand sufficiently far back when viewing an exhibit, and the spreading of the exhibition over two or more floors. These drawbacks can be obviated only by obtaining each year a hall with sufficient floor area to allow a spacious display. Crowding of material on a single stall is less evident than in former years, but it is still not always completely appreciated that *multum in parvo* is an inappropriate motto on these occasions.

Surgery

In the field of general surgery, the department of surgery at the Queen's University, Belfast, contributed two clear and simple displays. The first illustrated the techniques of gastroscopy and peritoneoscopy, while the second was devoted to the nutritional sequelae of gastric surgery. The Royal Victoria Infirmary, Newcastle, and King's College, University of Durham, presented the results of a three-year study of the cytodiagnosis of gastric carcinoma. This included an impressive demonstration of the abnormal cells found pre-operatively, and of the histology of the operation specimen from the same case. At another stall the same exhibitors illustrated the use of radioactive sodium to measure vascular efficiency in calf muscle, and showed the application of this technique to cases of intermittent claudication. The department of plastic surgery at the Churchill Hospital, Oxford, demonstrated the development of skin-grafting over the past 70 years. From the Royal Marsden Hospital, London, there was a striking exhibit dealing with haematuria, a symptom associated with a tumour in the urinary tract in over 50% of cases seen in a urological clinic.

The Sunderland Royal Infirmary illustrated, with scale models, plans, and photographs, an efficient dressing system for a casualty department. The Royal Victoria Infirmary, Newcastle, showed an electromagnetic foreign-body locator, the use of which greatly reduced the time taken for the surgical removal of most foreign bodies. In the sphere of orthopaedics, the Bradford Hospitals and Bradford Institute of Technology showed a study of the degeneration with age of the human intervertebral disk. The departments of orthopaedic surgery and medical illustration, Manchester Royal Infirmary, displayed a challenging demonstration of the aetiology and treatment of the "slipped disk." A review of 612 fractures of the calcaneum was presented by King's College Medical School and the Royal Victoria Infirmary, Newcastle. The Victoria Hospital, Swindon, showed the model of a flat where rehabilitation of disabled housewives could be undertaken; and the Odstock Hospital, Salisbury, illustrated the use of thermo-electric clothing for post-traumatic vasospastic conditions.

Neurosurgery was represented by the exhibit of the Institute of Psychiatry at the Maudsley Hospital, London, showing the diagnosis and surgical treatment of temporal-lobe epilepsy. Highlights of paediatric surgery were displayed by the department of medical illustration at the Hospital for Sick Children, London, with drawings, photographs, and specimens depicting operative techniques, clinical conditions, and pathological states. The repair of hypospadias, the surgical treatment of Hirschsprung's disease, and open cardiac surgery under hypothermia were among the subjects

covered. St. Thomas's Hospital, London, included surgical treatment in their comprehensive exhibit on aortic stenosis. The sole obstetrical contribution was from the Princess Mary Maternity Hospital, Newcastle, illustrating in detail the work and equipment of their obstetric "flying squad": a photograph of Professor Farquhar Murray was appropriately included in this demonstration. The department of gynaecology at the University of Durham presented a gynaecological display designed primarily as an adjunct for undergraduate teaching. Carcinoma of the cervix was chosen for particular demonstration.

Medicine

Among the outstanding displays in the field of medicine was one dealing with sarcoidosis, from the Institute of Clinical Research at the Middlesex Hospital, London. The protean clinical manifestations were emphasized and the indications for treatment with cortisone defined. Another comprehensive exhibit, on diverticulitis, was from the Gordon Hospital, London. The departments of haematology and medical illustration at the Manchester Royal Infirmary depicted the changing face of pernicious anaemia, the classical clinical picture of 30 years ago having now become uncommon. The exhibit was based on a series of some 2,000 cases. The Welsh National School of Medicine illustrated the pathology of chronic pulmonary beryllium disease. Auscultation of the heart, illustrated by phonocardiographic records, was the subject of a demonstration from St. George's Hospital, London. The Sutherland Dental School at the University of Durham exhibited colour transparencies, of a welcome large size, illustrative of the oral lesions in prenatal and acquired syphilis. In dermatology there was a stall set out by the Royal Victoria Infirmary and King's College, Newcastle, showing how papular urticaria, often attributed in the past to dietetic, allergic, or psychological factors, was caused by fleas. The Institute of Dermatology (British Postgraduate Medical Federation), London, illustrated by wax models and photographs pigmented lesions of the skin.

The Work of General Practitioners

Last year saw the first contribution by the College of General Practitioners to the Scientific Exhibition, and this year the North-east England Faculty displayed a three-part exhibit. The first part was concerned with Bornholm disease, its distribution and clinical features. The second was an interesting and valuable poster showing the relative incidence of certain diseases as seen by one member during his student days, his hospital residency, and his general practice. Thirdly, there was a table of suggested modifications in the syllabus of medical students to ensure some introduction to general practice during undergraduate days. The most popular suggestions for instruction were on practice organization, and on the types of cases seen in general practice and their relative incidence as compared with hospital practice. A lecture on the doctor's bag was surprisingly near the tail-end of the suggestions.

Armed Services and Public Health

The Royal Navy Medical School presented a review of the physiological problems of diving and underwater swimming. A display of diving and equipment aboard H.M.S. *Reclaim* formed the other half of the exhibit of the Royal Navy Physiological Laboratory. This ship, the only one of its kind in the world, is equipped for experimental deep diving, and visitors were shown the submersible decompression chamber, the recompression chamber, and the elaborate and weighty equipment required for surface and deep diving. Highlight of this display was a specimen dive by one of the fourteen divers in the crew. The Royal Air Force Medical Branch showed a scale model of the man-carrying centrifuge at Farnborough, an internally illuminated sight test type, and an anaesthetic apparatus incorporating a new vaporizer for field use. There was also a research apparatus which showed the reaction of the individual to difficulties and adversities in the performance of a task requiring a high degree of skill.

In the sphere of public health, there was an informative exhibition by the Pharmaceutical Society of Great Britain showing the stages in the manufacture and testing of poliomyelitis vaccine. The Nuffield Department of Industrial Health, Newcastle, depicted the causes and cost of hand injuries, and also offered a timely illustration of atmospheric pollution from diesel omnibuses—pollution which varies according to the adjustment of the engine and the type of fuel used. The Ministry of Supply, Chorley, appropriately demonstrated a unit for the determination of air contaminants.

Many were attracted by the drawings and models of a proposed new hospital for West Cumberland by the Newcastle Regional Hospital Board. It includes the provision of staff houses for married male nurses, while it is also intended that senior nurses would be able to rent flats on the hospital site.

Methods in Medicine

Each year more stalls are devoted to methods in medical research and teaching. The departments of pathology and physical chemistry at the University of Durham showed some of the ways in which the electron microscope can be used for medical research—an investigation into endocardial fibroelastosis being given as an example. The Royal Photographic Society and the Institute of British Photographers showed the general scope of photography in medicine. The department of surgery at the University of Durham similarly illustrated the techniques of the work of a medical artist. The same department also exhibited a space-saving polyvinyl slide-holder, ideal for easy storage and easy transport.

Altogether, as in previous years, the Exhibitors must have felt amply repaid by the close interest shown by members, many of whom made copious notes of matters which concerned their own branch of medical practice.

Awards of Merit

This year for the first time awards of merit were made to the most successful exhibitors. For judging purposes the displays were divided into two categories.

In the first category the award was made for the exhibit "judged to be of the highest excellence of presentation." The winning display was that on "Sarcoidosis," submitted by Dr. D. GERAINT JAMES and Dr. A. D. THOMSON, of the Institute of Clinical Research at the Middlesex Hospital, London.

In the second category the judges had to decide which exhibit was of "the highest scientific merit and originality." This proved a difficult task, and the award was given in respect of two exhibits: on "The Cytodiagnosis of Gastric Carcinoma," submitted by Dr. R. O. K. SCHADE and Dr. ERNEST W. WALTON, of the Royal Victoria Infirmary, Newcastle, and King's College, University of Durham; and on "The Diagnosis and Surgical Treatment of Temporal Lobe Epilepsy," submitted by Dr. D. A. POND and Dr. W. A. KENNEDY, of the Departments of Clinical Neurophysiology, Neurosurgery, and Neuropathology at the Institute of Psychiatry, the Maudsley Hospital, London.

Preparations and Appliances

MODIFICATION TO THE DRAFFIN
BIPOD

Mr. D. F. N. HARRISON, chief assistant, Throat and Ear Department, Guy's Hospital, writes: Suspension rods for the Boyle-Davis gag, first introduced by Mr. D. A. Draffin, are of unquestionable value. Not only is the design simple, but by removing all thrust from the patient's chest they lessen the problems of the anaesthetist. However, with

either of the two available sizes it is not always possible to arrange the inclination of the rods to allow the patient's head to rest upon the table, and the ends of the rods require protection to prevent slipping and to avoid tearing of the antistatic rubber. The following modification has been designed to avoid these disadvantages while maintaining the advantages of the original model.

Around the 14-in. (35.5-cm.)-long Draffin rod is fitted a n outer casing ending in a simple ball-and-socket joint. The latter is attached to a footplate the under surface of which is ribbed to ensure a non-slipping surface, and at the upper end of the outer casing is a pinch bolt. When using the bipod the rings at the upper end of the inner rods are placed around the loop of the Boyle-Davis gag; the footplates rest upon the rubber sheeting on the operating table. The patient's head is then flexed until it rests upon the table, the pinch bolts being tightened (see diagram). Thus one model is suitable for any age group.

I thank Mr. T. Gunter, of the Newport Technical College, for his advice and help in the design and construction of this apparatus.

INTRAVENOUS DRIP REGULATOR

Dr. W. N. VELLACOTT, consultant anaesthetist, South Worcestershire Group of Hospitals, writes: Much work is being done in an effort to improve transfusion-giving sets. Little progress, however, is made with the metal regulator, which is an important part of the sets.

These regulators should have two special qualities: that they be capable of fine adjustment, and that this adjustment should most easily be obtained with the use of one hand (an anaesthetist's other hand, for example, is often busy squeezing a bag). The model which has been distributed for so long with giving-sets is notably lacking on both these counts. It therefore seems justified to draw attention to simple modifications (shown in the photograph) which overcome these drawbacks by increasing the diameter of the screw-head, and by the addition of a suitable metal handle.

These modified regulators may be obtained from Medical and Industrial Equipment Ltd., 10-12, New Cavendish Street, London, W.1.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Compulsory Powers over Mental Patients

SIR,—Paragraph 5 of the report of the Royal Commission on the Law Relating to Mental Illness states that "most people are coming to regard mental illness and disability in much the same way as physical illness and disability." The report then proceeds to recommend (paragraph 296) that "mentally disordered patients should be admitted in the same way as other hospital patients" whenever possible. There would be, however, a residue of cases where it would be necessary to use compulsory powers (the euphemism for certification), which, it is advised, should be done without reference to a judicial authority. There should be, the report says, two medical recommendations, one of which would be by a general practitioner, as at present, the other by a psychiatrist, who would replace the magistrate.

This means that society would indeed have decided that mental illness is a purely medical matter, placing the whole onus on the doctors, even allowing them to take away the patient's liberty. Splendid to have a free hand, you say. Yes, but there is a catch in it. For surely it is clear that society cannot avoid responsibility for a procedure which involves the deprivation of liberty of any one of its members: in other words, at this point, if not before, mental illness must be considered to have social as well as medical implications. The existing procedure, which includes a certificate by a magistrate who represents the law and therefore the community, acknowledges this responsibility. The new recommendation seeks to dodge it. This is just neither to the patient nor to the doctors, on whom all the odium will now descend. In cases where the psychiatrist is attached to the receiving hospital (and this is recommended) the doctor-patient relationship will be poisoned from the outset. Then the community, having in effect washed its hands of the unpleasant responsibility for certification, proceeds to justify itself *after the event* by bringing in judicial procedure. Any compelled patient will be able, within six months of admission, to appeal to a mental health review tribunal. The patient will thus be adequately protected *after* compulsory powers have been used, but the doctor is there to be shot at. The legal machinery which was thrown out of the front door has been smuggled in at the back, and the effect will be that the community, instead of safeguarding all parties—patients, doctors, duly authorized officers, and itself—at the beginning, leaves everything to the doctors, so that it is free later to range itself on the side of the patients and their relations in keeping a careful eye on these suspicious characters to whom the buck has been successfully passed. It will be the doctor who is really on trial at the tribunal.

Since compulsory powers are to be used only for the unwilling, none of whom will have agreed to the necessity for use of compulsory powers, logically 100% of those detained should want to appeal. No doubt, by one means or another, this will be whittled down to quite a small number, which unfortunately is sure to include the most awkward, difficult, and vindictive ones. By the time they appear before the tribunal it will be most difficult in some cases to produce, especially to lay people, convincing evidence of mental disorder. For example, the delusions of paranoid cases will have become less urgent or the patients will have learned how to conceal them. It is certain that many will be discharged by these tribunals and that some of these, fortified by the tribunal's decision, will feel encouraged to take legal action for wrongful detention against the doctors who ordered it. Then doctors will be unprotected by a magistrate's certificate. It will be no wonder then if the mental hospital doctors, faced with a difficult patient, a court or tribunal case with a relative (paras. 503, 504), and a prospective tribunal with the patient, sacrificed thoroughness

to speed in treatment and disposal. It would be a race to discharge the patient before he could reach the tribunal. Such slapdash psychiatry would be bad for everybody. Also, since hospitals are to be allowed to pick and choose their patients, quite a competition in dodging the undesirable could develop.

The Royal Commission's fundamental error, therefore, consists in assuming that the stigma attaching to certification will be eliminated by eliminating certification. It does not understand that the stigma resides, not in the outer world, but in the minds of the people and largely in the unconscious at that. It is therefore projected on to the most obvious and convenient scapegoat. The playing down of certification will mean that another scapegoat will have to be found. A benevolent Commission has provided one which adequately fills the bill—the psychiatrist. Instead of conniving at a national neurosis or flight from reality, would it not have been better for the Commission to have encouraged the public to face the facts and shoulder its responsibilities?—I am, etc.,

Southall, Middlesex.

C. R. BIRNIE.

Plastic Surgery of the Middle Ear

SIR,—Your leading article (*Journal*, July 13, p. 90) draws clear and timely attention to progress in plastic surgery of the middle ear, the subject of recent keen discussion at the summer meeting of the Section of Otology, the Royal Society of Medicine. British otologists have been alive to the possibilities of functional restoration with the use of free, full-thickness grafts since they were first mooted, and many have visited the Continent to study original techniques. There is now a good deal of experience available in this country from which to draw first-hand conclusions, and it would appear to me that results are by no means as uniform, nor yet perhaps so optimistic as your article may suggest.

Myringoplasty, strictly speaking, is a simple operation reserved for large dry residual perforations without active middle ear disease, where major mastoid surgery for eradication of sepsis is not indicated. It is a direct successor of older methods of "patching" holes in the membrane such as with cigarette paper, gold foil, or human amniotic membrane. Hearing may certainly be restored to near normal in some selected cases, but I have not found a technique for "swinging in flaps of meatal skin" that gives sufficiently reliable results. Closure of a large perforation with free full-thickness graft can be achieved in a high proportion of cases provided reinfection is eliminated, and only a third of my cases have failed to gain any improvement in hearing.

Tympanoplasty embraces the concept of middle ear and mastoid exploration, eradication of sepsis, and reconstruction of the tympanum. The particular plastic reconstruction required depends on what is left of the conducting mechanism after the sacrifices necessary to eradicate chronic infection. Unless disease is eradicated there would seem no prospect theoretically, nor in my experience in practice, of obtaining a healthy "take" with the graft. It is this microscopical cleansing that is so time-consuming. Tympanoplasty is described by stages according to the conducting remnant left to build on. Stage 1 approximates to a myringoplasty, with the difference that it is applied to a case in which major mastoid surgery is contemplated if exploration reveals the necessity for it. Some opinion would go so far as to abandon the term myringoplasty in favour of stage 1 tympanoplasty.

I feel strongly that, as there is a place for attempting to close small dry perforations by the simple expedient of repeated stimulation of the edges with trichloroacetic acid, there is a definite place for attempting to close large dry perforations by the simple expedient of skin grafting, without intending to do more than close the defect, and that this operation should be designated myringoplasty. It involves the patient in little discomfort except that arising from the removal of skin from a donor site behind the ear, which, site, if properly handled, will heal with a scarcely detectable scar. The stay in hospital need not exceed two days—

(elsewhere it has been performed as an out-patient procedure), and the results are, in my opinion, sufficiently encouraging to deserve its retention.

Tympanoplasty is major surgery, and I do not find the results predictable enough to recommend it to a patient with middle ear deafness unless major surgery is already indicated for the elimination of chronic infection. If, however, active chronic disease is present it may now be considered the operation of choice.—I am, etc.,

STUART MAWSON.

London, S.E.5.

SIR,—I would like to congratulate you on the excellent summary of the principles governing the plastic surgery of the middle ear (*Journal*, July 13, p. 90). I wish to draw attention, however, to one aspect of the problem which has not been mentioned, that of cholesteatoma of the middle ear as a cause of chronic suppurative otitis media. In the present state of our knowledge this disease is not preventable.

In a series of over 150 plastic middle-ear operations it has occurred in approximately 60% of my cases. Cholesteatoma of the middle ear can now be completely cured by these new techniques without destruction of useful hearing, and it is to this type of case that these operations offer the most hope.—I am, etc.,

PHILIP H. BEALES.

Doncaster.

Sterilization of Dressings

SIR,—Dr. Hugo Grant (*Journal*, June 29, p. 1532) is undoubtedly correct in supposing that there are many chinks in the "aseptic line." But in the case of tulle gras or petroleum jelly gauze, the chinks lead in more complicated directions than he supposes.

The sterilization of these materials has been the subject of two papers,^{1,2} in which it was shown that the quantity of moisture normally present in cotton can give rise to a sufficient quantity of steam for sterilization. That it does not always do so is the result of another complication in the physical chemistry of cotton. The assumption that heating in an autoclave is only the equivalent of dry sterilization is therefore quite natural but not in fact correct. The B.P.C. "authority" must be read in conjunction with the tests for sterility, in which any method is authorized *provided that* the bacteriological results are satisfactory. There are so many chinks that nothing but such a test is really capable of dealing with the wide range of conditions which are encountered in practice. Dr. Grant would certainly be correct in assuming that the autoclaving of plain paraffin gauze dressings would succeed only in exceptional circumstances.

The balsam of Peru in tulle gras may or may not alter these circumstances. 150° C. for one hour is not necessarily a recipe for success.—I am, etc.,

R. MAXWELL SAVAGE.

Barnet.

Women's Footwear

SIR,—The letters from your three correspondents (*Journal*, July 13, p. 102) succeed in partially cancelling out their respective complaints. It is gratifying to read that "it is now almost impossible to get a badly shaped child's shoe," and that "the styles of men's shoes during the same period [during last year] have become much more pleasing in appearance and lighter and more comfortable in wear." To suggest that shoes are made for women, including teenagers, without regard for the health and comfort of the wearer is to fly in the face of fact. Manufacturers are neither so irresponsible nor so commercially foolish as to produce styles that are in themselves injurious. They recognize, however, at least the equal of fashion. They recognize, however, the primary importance of helping the customer to buy shoes that fit correctly, and welcome means of awakening the public to an appreciation of the factors that combine to

ensure beneficial wear. That the medical profession is taking a constructive interest in furthering such education will be welcomed by footwear manufacturers.—I am, etc.,

London, W.1.

A. BARKER,

Director, Incorporated Federated Associations of Boot and Shoe Manufacturers of Great Britain and Ireland.

Pink Disease

SIR,—We have recently had a case of pink disease in the Children's Annexe of the Luton and Dunstable Hospital, and on inquiry it was found that the patient had been given a well-known brand of teething powder five weeks prior to admission. It was felt worth while checking on the formula of this teething powder, although the firm has now altered the composition.

It was interesting to find that the powder had not been bought from a chemist but from a village shop, and samples sent to us for inspection showed that they were, in fact, old stock still containing mercury.—I am, etc.,

Luton.

GRAHAME FAGG.

Scapulo-thoracic Crackling in Youth

SIR,—It was with great interest that I read Dr. F. Parkes Weber's account of scapulo-thoracic crackling in youth (*Journal*, May 18, p. 1181). A few weeks before that date I examined a young woman who had been referred for a neurological examination following a motor-car accident. An incidental finding was obvious crackling, both audible and palpable, on rolling the shoulder-blades. The patient was quite unconcerned about it, and its presence was also noted before the accident. I could find no particular reason for it. The only other point of any significance in the patient's history was marked allergy to most of the antibiotic drugs and to many foods. It may be added that x-ray examination of the shoulder-blades was negative.—I am, etc.,

Ramat Chen,
Ramat Gan, Israel.

D. P. KIDRON.

Removing the Pump Handle

SIR,—In your annotation on public health in 1955 (*Journal*, December 22, 1956, p. 1478) you used the incident of the cholera epidemic in Soho in 1854, when Dr. John Snow's advice to remove the handle from the Broad Street pump quickly ended the epidemic, as an illustration for handling the smoking and lung cancer problem. Can you imagine the Soho local authority objecting that there was no proof, other than a statistical one, for the connexion between cholera and the water in that well? Did they require John Snow to separate the cause of cholera from the water and they would then do something about it? It was 1883 when Koch discovered the *Vibrio cholerae*, but the local authority removed the pump handle and ended the epidemic in 1854.

No one was interested in keeping the cholera epidemic alive, but unfortunately many people desire the continuance of the smoking habit. The arguments advanced demonstrate the type of interest involved. They are futile arguments, a sort of smoke-screen for the arguer and his audience. One frequently hears the objection raised that the evidence is only statistical, but what is there against this type of evidence, especially when it involves some 18,000 deaths per annum? A spokesman for the tobacco manufacturers pleaded on behalf of the cigarette that to breathe the polluted air of city streets may be as dangerous as smoking. He is ignoring the M.R.C. statistics there and substituting a guess of his own. Moreover, to give up smoking is a total gain for the smoker, while to give up breathing has obvious disadvantages. The smoker himself makes many excuses, mainly to the effect that it isn't certain that he will be one of the unfortunate ones, and, after all, one has to die of something. No one is so blind as he who refuses to see.

Sir Ronald Fisher (*Journal*, July 6, p. 43) takes you to task for advocating "all the modern devices of publicity."

He seems to equate them with psychological warfare and states his preference for "the mild and soothing weed" rather than "the organized creation of states of frantic alarm." There is no sign of alarm so far. Wide publicity has been given to the risks over the last three or four years, but the consumption of tobacco continues to rise. This certainly suggests that there has been no falling-off in recruitment of young people for the habit. They still continue to imitate the grown-ups and will do so unless they are persuaded otherwise. You are right, Sir, "all the modern devices of publicity" will be needed if any impression is to be made. The Minister of Education seems to be preparing to meet the situation in a constructive way. The impact must be by ear-gate (friendly advice and organized lecture) and by eye-gate (printed matter, films, and film-strips). The educationalists have an important part to play in preparing and using the propaganda material, but it is first and foremost a public health problem, and the medical profession has a heavy and inescapable responsibility. Your annotations on the subject have always been fair and straight, reasoned and reasonable. Please go on keeping the profession up to its responsibility. Something more than words of advice are needed, however, if results are to be achieved. Perhaps the time is at hand when a central committee should be formed to advise the profession and work in conjunction with the Minister of Health and the Minister of Education.—I am, etc.,

Worcester.

I. LLOYD JOHNSTONE.

Smoking and Examinations

SIR,—The main reason for young adults smoking is the pernicious effects of the present unjust examination system whereby a young man's career is at the mercy and caprices, if not generosity of heart, of examiners. Anthropologically speaking, the examination system is a savage survival of early tribal initiation rites. Similarly, the cult of smoking the "pipe of peace" showed that even the savages had advanced their ideas in the socialization of the younger generation. None of my examiners offered me as much. I would be interested in making a correlation study, therefore, between the incidence of smoking and the examination failure rate in grammar schools and universities. As for the eleven plus, since the parents in imagination are sitting the examinations themselves, I would like to correlate this with parental smoking. The abolition of the eleven plus may contribute therefore to a reduction in lung cancer cases.—I am, etc.,

Wolverhampton.

GARETH R. DAVIES.

Cigarette Advertisements

SIR,—I heartily agree with Mr. H. Sumption (*Journal*, July 13, p. 100) that advertising plays a major part in encouraging people, especially young people, to take up smoking; I also endorse Mr. Sumption's suggestion that the advertising code of standards be extended to include tobacco among the commodities which should not be advertised. Your leading article in the *Journal* of June 29 (p. 1518) leaves no doubt that you, Sir, support any action to dissuade the young from acquiring the tobacco habit. I am surprised, therefore, that the issues of the *Journal* for June 29 and July 13 carry advertisements for cigarettes, one full-page and the other half-page: perhaps the cigarette-smoking readers of the *Journal* (a large majority, if the gross aerial pollution at doctors' meetings is a reliable guide) are considered to be beyond redemption. If the official organ of the British Medical Association does not set a good example, the "popular press" can hardly be expected even to consider banning cigarette advertisements.—I am, etc.,

London, N.W.6.

D. M. DIGUES LA TOUCHE.

Smoking and Cancer

SIR,—The statement of the Medical Research Council (*Journal*, June 29, p. 1523) is an authoritative summing-up of the considerable literature on this subject, and I think

it is now generally accepted that the risk of developing cancer of the lung increases in direct proportion to the amount of tobacco smoked, and therefore, presumably, to the volume of smoke reaching the lung tissues. I find it puzzling, therefore, that British investigators have found no difference in the incidence rates as between inhalers and non-inhalers. Surely a person who inhales exposes his lung tissues to a far greater concentration of smoke than the person who merely draws the smoke into his mouth and expels it so that little or none reaches his lungs. Would it not be reasonable to expect a far higher incidence of lung cancer in the former?

Professor Bradford Hill and Dr. R. Doll have reported¹ that an analysis of their cancer patients showed no difference in incidence as between "inhalers" and "non-inhalers," and that the explanation of this is "unknown." Can this matter be dismissed so lightly? Is this not, in fact, an anomaly which strikes at the very basis of the suggested relationship between lung cancer and smoking, which the Medical Research Council have now described as "one of direct cause and effect"? Could we not have some further information on this point?—I am, etc.,

Bexleyheath, Kent.

JOHN LONDON.

REFERENCE

¹ *British Medical Journal*, 1956, 1, 1160.

Temperature of Cigarette Smoke

SIR,—In relation to the recent evidence that there is a higher mortality from lung cancer in cigarette smokers than in non-smokers, it has occurred to me that little stress has been laid on the temperature of the inhaled smoke. Could it not be that the repeatedly raised temperature is the factor which triggers off malignant growth in the bronchial mucosa?

The maintenance of a near-constant body temperature in the human being is a remarkable fact of physiology. Slight deviation from the normal results in ill-health. With regard to individual organs, whose healthy temperature may be slightly different from that of the rest of the body, it seems to me that a local rise in temperature over a period of time might be the cause of tumour formation. I should be grateful to hear of other persons' views on the subject.—I am, etc.,

Manby, Lincs.

D. G. P. BROWN.

Snake-bites

SIR,—The interesting paper by Dr. H. A. Reid (*Journal*, July 6, p. 26) raises some important points. The author is in the exceptional position of being able to supplement his published observations by a personal experience.

The possibility of 250,000 victims receiving antivenene in a period of a year is, I should think, a good deal too high. In India and Pakistan, with an estimated annual death rate from snake-bite of between 20,000 and 36,000, the opportunities for modern treatment, or indeed one might say for any potentially effective treatment, are infinitesimal. The reasons for this are the vastness of the spaces concerned, poverty of rapid communications, apathy, and lack of faith in Western medicine. The fact is that the fate of almost all persons bitten by snakes in country districts is decided at the time the bite is inflicted. In my own experience in eighteen years in India, the number of snake-bite cases likely to be seen in a 230-bedded hospital was four or five a year, and experienced Indian doctors in charge of hospitals in country districts have confirmed a similar situation. Yet every adult Indian villager is familiar with snake-bite as a cause of death. An intelligent headman of a village of about 200 people told me in 1952 that there had been about five deaths caused by snakes in his village in the past ten years, the cobra being most commonly implicated. The largest number of cases I have known to be seen in one hospital in one year was 15; of these, two were dead on arrival, one died of viperine poisoning (the symptoms including multiple haemorrhages, haematuria, and haemoptysis). This man had had earlier symptoms

caused by sensitivity to horse-serum, but the fatal outcome was due to snake venom. Another case bitten by a cobra recovered after treatment with antivenene and antihistamine and intravenous fluids, having at one time been aphasic and aphagic.

I agree that serum reactions are common, and sometimes alarming, in patients who have received antivenene, especially if given intravenously. Nevertheless caution is necessary in ascribing given symptoms to a particular cause in a patient in whom two toxic agents (venom and serum) are operating. Both agents can produce similar effects. The following symptoms occurred in a patient of mine who received no treatment. An intelligent and highly skilled Indian fitter was sitting under a tree, when a snake dropped from the branches on to his shoulders. As he brushed it off he bit him high on the neck close to the occiput. The snake was clearly seen, was thin and green, and was judged by the victim to be 3 feet (0.9 m.) in length and $\frac{1}{2}$ inch (9.6 mm.) in thickness. It was almost certainly *Dryophis mycterizans*, the common whip-snake. This is not regarded as poisonous to man. Five hours later the patient was awakened by stiffness in the eyelids, and on going to the looking-glass he found he had oedema of the face, forehead, and eyelids. This persisted for several days, and constituted the only symptom. Had this man been given antivenene the symptoms would certainly have been ascribed wrongly to the serum.—I am, etc.,

Dover.

W. B. ROANTREE.

Medical Use of Hypnotism

SIR,—May I say, as a general practitioner, how much I have gained from your articles on hypnosis (*Journal*, June 8)? Here surely is something which can restore worthwhileness to the drab routine of much of the time we spend in the surgery. Instead of fobbing off with placebos the 20% or so of our patients whose complaints are primarily psychogenic, hypnosis gives one a therapeutic method whose success has often to be seen to be believed. It may be a little more time-consuming, but both patient and practitioner alike are better satisfied with 10 minutes of radical therapy than two or three minutes of useless make-believe. Here, too, is a specialty particularly suited to the general practitioner with his intimate knowledge of the social background of the patient. In this connexion I take leave to disagree with Dr. J. R. Robson (July 13, p. 103) on the question of the hypnotherapy in hospital out-patient departments. The confident rapport necessary for hypnosis to be successful can hardly be arrived at in the formal atmosphere of an out-patient clinic but rather in the more personal doctor-patient relationship peculiar to family doctoring. There must be many who could wish that instruction, by experts in this field, on the indications and techniques of hypnotherapy were made available to us in provincial teaching centres.—I am, etc.,

Huddersfield.

S. L. HENDERSON SMITH.

Polyneuritis and Illness in Cats

SIR,—As a house-physician in Dorset last year I had two patients with infective polyneuritis of the Guillain-Barré type, both with the usual raised protein in the C.S.F. The first was a man of 40 years, who recovered; shortly after which he gave a healthy cat to a woman of 60 years who lived 30 miles away, this being their only contact. The cat subsequently developed a condition called by the veterinary surgeon "infective feline enteritis," diarrhoea and inary vomiting being prominent, and the animal died after two weeks. Three months later the woman developed infective polyneuritis and died from respiratory failure. I was impressed with this at the time, although three months seemed a long incubation period, but obviously Dr. T. G. Reah has also found this (*Journal*, July 13, p. 100). There is on the market an "anti-feline enteritis" serum, used by veterinary surgeons during epidemics of this condition. Might not

complement-fixation tests and the like, using this serum, prove valuable in elucidating the aetiology of both these conditions?—I am, etc.,

Thorpe Bay, Essex.

PHILIP J. BENNISON.

Pills Through the Post

SIR,—As a doctor's wife I heartily approve of the necessity to encourage parents to keep dangerous drugs out of a child's reach. Yet daily my children are subjected to these dangers through no fault of my own. The offender is the pharmaceutical company which sends unrequested samples to my husband through the post. At least once a week a fatal or dangerous dose is deposited on my doormat. It usually arrives by the mid-morning post, at a time when I am busy in the kitchen. Many of these samples are not packed so that a child would not be able to open the package. They are in an unsealed envelope. I am surprised that such a system is permitted. Cannot some effective protest be made?—I am, etc.,

Sutton, Surrey.

FREDA DALTON.

Coronary Disease

SIR,—Great attention is being given to the influence of dietary fat and of exertion on the production of coronary lesions. So far no mention seems to have been made of postural influences. The disease seems to be most prevalent in countries where bodily comfort is most readily achieved, and I would like to suggest that the slouching position achieved in the ordinary easy chair may have something to do with the appearance of atheromatous lesions in a site usually about 1.5 cm. from the origin of the left coronary vessel.

In the slouch position the capacity of the abdominal cavity is reduced and its contents exert a greater pressure against the posterior part of the diaphragm than when the individual is erect. Such increased pressure will tend to push the apex of the heart forwards and possibly cause a minor degree of kinking of the descending branch of the left coronary. Rolls of fat on the abdominal wall and in the peritoneal cavity would intensify this pressure. The occurrence of fatal "signet ring" patches in the left coronary is seen occasionally in men in the early forties with no sign of arterial degeneration elsewhere, and dietary considerations can hardly account for such localization. The ones I have encountered have been obese and engaged in sedentary occupations. It is not difficult to picture them at home taking their ease after an abundant supper (also pressing upwards against the diaphragm), while their dutiful wives continue their endless chores with the abdominal pressures directed downwards, to the further employment of the gynaecologists. The Victorians' injunction to "Sit up!" at the table may have been sounder advice than they knew.—I am, etc.,

IAN STEWART.

Gonadal Dysgenesis

SIR,—We are most appreciative of the kind remarks made by Dr. G. I. M. Swyer (*Journal*, June 15, p. 1421) regarding the view put forward in our paper on gonadal dysgenesis in normal-looking females (*Journal*, June 1, p. 1281). If we seemed hypercritical, we apologize; we were trying only to make our point strongly—and we must admit that the widened concept of gonadal dysgenesis to-day makes the diagnosis easier for us than it was in 1955.

Certainly it seems to us legitimate to call all varieties of gonadal dysgenesis with male chromatin pattern male pseudohermaphrodites. There is only one danger in pursuing this line of thought—it overlooks the fact that, by definition, it is the type of gonad which indicates male or female pseudohermaphrodite, not the chromatin pattern. A patient with Klinefelter's syndrome and female nuclear pattern is not a female pseudohermaphrodite. Strictly speaking, in

gonadal dysgenesis, when the gonad is indeterminate it is incorrect to speak of male pseudohermaphroditism. Yet current concepts view this variety of gonadal dysgenesis as the extreme of a spectrum which includes male pseudohermaphroditism. Perhaps the most important point to emerge is the wide variety of clinical syndromes which are variants of true gonadal dysgenesis. The patient may not be short, may have good breast development, may have no skeletal anomalies, and may even have menstruated.—We are, etc.,

Capetown.

W. P. U. JACKSON.

Tranquillizing Drugs in Psychoneurosis

SIR,—I read with great interest the paper by Dr. M. J. Raymond and his colleagues (*Journal*, July 13, p. 63) and think that the authors should be congratulated on a most carefully planned and executed trial. Their findings are in line with other investigations comparing amylobarbitone with the newer "tranquillizers," but I feel that there is one criticism which can be levelled at this and similar self-controlled trials. The period during which any one drug is exhibited before switching to another is short, two to four weeks at the most. This assumes that the drug in question produces rapid symptomatic relief. It may well be true that it does, but it is equally possible that more prolonged treatment is necessary to produce results, and it has in fact been suggested that this is so for most of the tranquillizers.

If amylobarbitone produces immediate symptomatic relief and the tranquillizers require a more prolonged period to take effect, then obviously the latter would be at a disadvantage in the short-term trial. I think, therefore, that before rejecting the tranquillizers in the treatment of neurotic states it is necessary to compare them with amylobarbitone over a longer period than has so far been done.—I am, etc.,

Gloucester.

J. LOMAS.

Churches' Council of Healing

SIR,—There was a well-attended gathering at the meeting at Newcastle convened by the Churches' Council of Healing, and, as the Bishop of Lichfield said, this is now a fixture at the Annual B.M.A. Meeting. It certainly gives an opportunity for comments, and I should like to make the following. (1) As a progressive scientific body we should, I feel, be studying intensively spiritual considerations in health and disease, for these are, by most of us, relegated to the background in both theory and practice. (2) As a progressive scientific body we should be investigating continually the means of healing which the Church uses in her healing ministry, for some of these are of great psychological benefit to our patients, and we should be using them along with orthodox medical, surgical, and psychiatric treatments. (3) I hope that next year the B.M.A. will have a section devoted to spiritual considerations in healing and keeping whole, and be able to present studies which demonstrate the interaction of body, mind, and spirit in health and disease—in short, a section on spirito-psycho-somatic medicine, misnamed at present psychosomatic. (4) Finally, I do not think that we shall get very far until we have doubly qualified personnel, people trained theologically and medically so as to be able to bring the dual insight to bear on the problem. Spiritual experience is, of course, much more valuable for practice than degrees, but unfortunately appointing bodies must select degreed rather than experienced candidates, although one would expect that a person who took the trouble to acquire this double qualification would have the necessary experience since he would be "called of God." Perhaps the time is not far distant when universities will be able to create a faculty which can achieve this double qualification in a reasonable number of years.—I am, etc.,

Morpeh.

JANE H. THOMPSON.

Obituary

J. P. HEDLEY, M.Chir., F.R.C.P., F.R.C.S., F.R.C.O.G.

Mr. J. P. Hedley died on July 17 at the age of 81. He had for many years been consultant obstetrician to St. Thomas's Hospital, achieving great distinction in his profession. It was also at St. Thomas's that his elder brother, the late Edward William Hedley, had, as a consultant anaesthetist, attained eminence. A third brother, who died in 1951, was a well-known London magistrate.

John Prescott Hedley was born in January, 1876, the son of John Hedley, M.D., J.P., of Cleveland Lodge, Middlesbrough. Educated at Uppingham School, "Jock" Hedley entered St. Thomas's Hospital Medical School from King's College, Cambridge, in October, 1899. In 1902 he graduated M.A., M.B., B.Chir.(Cantab.), and in 1906 he took the M.R.C.S., L.R.C.P. as a preliminary to higher qualifications. He obtained the M.R.C.P. in 1907 and the F.R.C.S. and M.Chir.(Cantab.) in 1909. He was admitted F.R.C.P. in 1921, F.R.C.O.G. in 1929, and Hon.M.M.S.A.(Lond.) in 1939.

On qualifying, Hedley spent twelve months at St. Thomas's Hospital as house-surgeon, and then he went to the Brompton Hospital as house-physician. Then followed a term as obstetric house-physician at St. Thomas's Hospital. Towards the end of his next appointment at St. Thomas's, that of resident medical officer to St. Thomas's Home, 1905–6, the obstetrical registrar, Hamilton Bell, suddenly died. Hedley was persuaded to apply for the post, and he thus became obstetric tutor and registrar from 1907 to 1910. It was in the latter year that the opening of Mary Ward at St. Thomas's increased the number of obstetric beds, and made a further staff appointment desirable. Hedley became assistant obstetric physician. In 1919 he was promoted obstetric physician, and in 1928 he took charge of the department until his retirement in 1936. Hedley was also consulting physician to the General Lying-in Hospital, York Road; consulting gynaecologist to the National Hospital for Nervous Diseases, Queen Square; and honorary gynaecologist to the Florence Nightingale and Harrow Hospitals, Cobham and Oxted Cottage Hospitals, and the Ministry of Pensions. He was a former president of the Obstetrics Section of the Royal Society of Medicine, and a member (and latterly vice-chairman) of the Central Midwives Board. He was also an examiner for the Board and for the Universities of Cambridge and Edinburgh, the Conjoint Board, and the Society of Apothecaries of London. In the first world war Hedley served in the rank of captain, R.A.M.C.(T.), working at the Duchess of Westminster's Hospital at Le Touquet, and then as one of the surgical specialists attached to the Fifth London General Hospital at St. Thomas's.

His good judgment and wise counsel were greatly valued in committee, and he was a governor of St. Thomas's Hospital, a member of the General Medical Council, and a representative of London University on the school council of his old medical school. In addition he served on the council of the Royal College of Physicians in 1932–4.

Hedley was an athlete in his younger days. In 1895 he won both the sports cup at Uppingham and the freshmen's quarter mile at Cambridge. But cricket was a more lasting

JULY 27, 1957

OBITUARY

BRITISH
MEDICAL JOURNAL 239

interest. He played in the school eleven all the while he was a student at St. Thomas's, and in 1919 became president of the cricket club until his retirement. He also served for three years as president of the amalgamated clubs.

In his own specialty he inclined towards conservatism, but his judgment was as sound as his surgery. As would be expected, his teaching followed the middle way, governed by the golden rule to practise whatever was best for his patients.

He married Kathleen, daughter of the late James Halliday, of Harrow-on-the-Hill, and had five sons and one daughter. Mrs. Hedley died in 1945.

K. B. writes: It is difficult to realize that "Jock" Hedley has died, because although he retired from the active staff of St. Thomas's some 21 years ago he always looked so much the same—a little more frail, perhaps, but always very much alive and interested in life, events, and his old hospital. Wars demarcate generations of men from one another, and Hedley in manner and characteristics took me back not merely to before 1939, but pre-1914. This is not to say that either his mind or his gynaecology remained in that era, but that in meeting him one recognized the virtues and attitudes of life of that time. For in many ways Hedley could be said to have the Horatian qualities of the golden mean, a mean which he certainly achieved whether or not he consciously aimed at it.

He came to St. Thomas's in 1899 from Cambridge, and besides taking his many professional qualifications he played cricket for the hospital all the time he was a student. Appointed to the staff in 1910, he continued to 1936. During this time he served the hospital in his characteristic, ally conscientious manner. Besides his consulting work, he took great interest in the students' activities and was president of the cricket club for some 17 years.

The balance which Hedley showed in his life was revealed also in his conservative attitude in obstetrics, his careful judgment, his plain clinical teaching, and his interest in trying to do what he considered best for each individual patient. His courteous manner usually remained unruffled, but, when aroused, a preliminary tensing of his jaw muscles gave warning that he would stand his ground.

Hedley was blessed with family, and many will have happy memories of being entertained at Cobham. Mrs. Hedley died in 1945 and he faced the disruption of his life with fortitude, refusing to allow the later phase to be any winter of discontent. As he grew older he did so, as they say in the North, "all of one piece," and his governorship of the hospital and activities on many committees brought him back into the hospital after the last war and up to his death.

A. J. MORLAND, M.D., F.R.C.P.

Dr. Andrew Morland, physician in charge of the department for diseases of the chest at University College Hospital and physician to the French Hospital, died in University College Hospital on July 13. He was 61 years of age.

Andrew John Morland was born on May 6, 1896. While at Sidcot School, in Somerset, he developed tuberculosis, for the treatment of which he went to Switzerland. When he had recovered he continued his education at the University of Lausanne and learned to ski, a sport at which he excelled and which he enjoyed almost until the time of his death. During the first world war he worked for a time with the Friends Ambulance Unit in France, until his health again gave cause for concern. He then determined to become a doctor and trained at University College Hospital Medical School, graduating M.B., B.S. (with honours and distinction in medicine) in 1923. After holding a resident post at the Brompton Hospital he went back again to post at the Brompton Hospital as medical superintendent of the Palace Sanatorium at Montana. In 1928 he joined the staff of the Mundesley Sanatorium in Norfolk, where he remained until he came to London in 1935, having been appointed physician to the French Hospital. Two years later he was elected

to the staff of University College Hospital and eventually became chief of his department there. In 1955 he was elected a Fellow of University College.

In 1930 Dr. Morland proceeded to the M.D. and took the M.R.C.P., and in 1941 he was elected to the Fellowship of the College. A recognized authority on tuberculosis, he was at one time on the editorial board of *Tubercle* and was the author of a book entitled *Pulmonary Tuberculosis in General Practice* (1932). He was a member of the council of the National Association for the Prevention of Tuberculosis and of the executive committee of the International Union against Tuberculosis.

Dr. Morland married Dorothy Saunders in 1928, and she survives him together with a son and daughter of the marriage.

H. N. writes: Andrew Morland's name is known widely because of his invention of the artificial pneumothorax needle which bears his name. He had many and varied interests outside of medicine. In his youth he was a skiing champion, and he continued to ski enthusiastically and well until 18 months or so before his death. He had a great knowledge of literature and art, and numbered many writers and artists among his patients and friends. He remembered with special pleasure his help to D. H. Lawrence in his last illness and his friendship with Mark Gertler. His interest in Switzerland, which began early, was maintained throughout his life, and for four years he worked at Montana, in the Valais. He travelled widely both in Europe and farther afield, but had a most intimate acquaintance with and devotion to France. He served the French Hospital in London for 20 years, and his appointment in 1950 as Chevalier of the Legion of Honour pleased him greatly. He had a full and interesting life, and among its more pleasant circumstances was his knowledge that his many patients regarded him as their friend.

Dr. HARLEY WILLIAMS writes: I knew Dr. Andrew Morland best as a blend of visionary and practical man. He believed wholeheartedly in exchange between countries. Speaking both French and English, he was very impressive at international meetings, and how eager he was when it became possible to send British children for treatment in Denmark. Then he directed a plan for treating other children in Switzerland. He had the same desire for exchanges of knowledge with the Far East. These ideas he worked out in a manner of his own, inspiring others, ignoring difficulties, calmly proceeding to his objective. He knew by instinct the best way of doing a thing, and I think this came out of long reflection in those silent moments when he was seemingly wrapped in himself. He was never ambitious to be well thought of, and cared little for being thanked. I believe our friend was one of those who penetrate further, who feel more, and who perceive what is not obvious to most other men. He radiated the sort of power which every doctor envies. He gave others the confidence which overcomes fear and helps people to help themselves.

I do not think Andrew Morland had a single enemy in the world. He gained his human ends by methods we should all like to emulate—he achieved them because they were right. He meditated much, and after he had reached his decision he let the event bring its own fruit. And, generally, he was not disappointed. How did our friend achieve this unusual wisdom? In this prosaic modern world he seemed to draw upon mystical resources within himself. He was one of those men who are born wise, but he got inspiration from nature and art. He enjoyed gliding down the snow slopes in the sunshine, but he had first made the arduous upward climb. He loved pictures, and liked also to help those who paint them. With Andrew, silence was a form of communication; he possessed a wordless power which inspired courage and optimism.

In the years of our friendship I remember no occasion when we differed. Yet it was not always that we thought the same: often our views were opposite. What, then, was his secret? It was that his way of looking upon life included so many sympathies. His outlook was free from

envy or malice. He had a strange power to unify antagonisms, to reconcile contradictions, to merge thought into action. These are rare gifts, and in Andrew they prevailed, like a natural force. Having seen these qualities used so well, we ought not to grieve that our friend was taken from us before the normal time. When the hour comes for us to die, we may hope to have the courage he showed when he knew his days were to be short. His family have not only irreplaceable personal memories: they will know that Andrew Morland, in the estimation of the whole world, was a good physician and a good man.

ALAN GREGG, M.D.

Dr. Alan Gregg, a former vice-president of the Rockefeller Foundation and director of its division of medical sciences for over 20 years, died at Big Sur, California, on June 19, aged 66.

Alan Gregg was born at Colorado Springs and educated at Cutler Academy and Harvard, graduating in 1911 and obtaining his M.D. in 1916. After his internship he served from 1917-19 in the Harvard medical unit attached to the Royal Army Medical Corps, and joined the international health board of the Rockefeller Foundation in 1919. Three years later he became associate director of medical education, and from 1930 to 1951 was director of the division of medical sciences. He was appointed vice-president of the Foundation in 1951, retiring in 1956. Last November he received the Lasker award from the American Public Health Association for his work on public health and medical education.

A.D. writes: The recent death of Dr. Alan Gregg, vice-president emeritus of the Rockefeller Foundation, New York, has removed a wise counsellor and devoted friend of many Britons. He paid frequent visits to this country and was familiar with all our great centres of medical and biological research and those who work in them. He entertained at the Athenaeum, where he was always welcome.

It is difficult to be the adviser and agent of a wealthy foundation with grants to dispose of without losing something of the common touch and becoming pompous and suspicious of friendly advances. Alan Gregg resisted successfully all such temptations. But the heart-burnings and twinges of conscience and doubt necessarily associated with the taking of decisions on which projects out of many should be supported are well set out in his address "The Dormant Torment" delivered before the American Public Health Association, and published in its journal in December, 1956.

Dr. Gregg was a master of English with a profound knowledge of English and American classics. He threw off epigrams and quotations from his well-loved poets as easily as rain falls from a roof, and these were received with as much welcome as rain after a long drought. One of his greatest occasions was the oration he delivered at Johns Hopkins, Baltimore, at the Welch centenary celebrations. He was always proud of his service in France with the R.A.M.C. in 1917-19. He acquired a thorough knowledge of the French language. He joined the staff of the Rockefeller Foundation in 1919, and became director of its division of medical sciences in 1930. In 1951 he was promoted to be a vice-president—a signal honour. He retired shortly after to a small village in California. It was hoped that he would enjoy there many years of happy retirement, and would incorporate in a book his mature reflections on medical education and research. Alas, his health deteriorated rapidly and he had several strokes which involved his memory and speech. He did, however, see through the press *Challenges to Contemporary Medicine*, the Bampton Lectures of Columbia University, 1953.

Many British institutions owe much to him and the Foundation he served. They include the London School of Hygiene and Tropical Medicine, the National Hospital for Nervous Diseases, Queen's Square, and the Maudsley Hospital's School of Psychiatry. The Rockefeller Foundation

does not allow its staff to accept honours or honorary degrees, but after he retired he received from the American Public Health Association a well-earned Albert Lasker award.

Alan Gregg was excellent company and a great raconteur. In appearance and dress, whether on a visit to England or receiving visitors in his office on the 54th floor of the Rockefeller Building, New York, he looked like the conventional English squire up in town for the day. One found it hard to believe that he knew more about academic institutions and how they work than any other man. He often said that his main job was "talent spotting," and that what had given him the most pleasure was to watch the careers of former Rockefeller Fellows, in whom he took a keen and fatherly interest.

He leaves a widow and four children. His youngest son has followed his father into the medical profession. It is sad that, after so many years of enforced separation while he was abroad on duty, his real home life with his family was so short.

D. R. LEWIS, M.D., F.R.C.P.Ed.

Dr. D. Rhys Lewis, a consultant dermatologist to the Welsh Regional Hospital Board, died at the Brompton Hospital, London, on July 6. He was 66 years of age.

David Rhys Lewis was of Welsh descent and had a distinguished medical career in his native land. He was trained at Edinburgh, where he graduated M.B., B.Ch. in 1920 and served as house-physician at the Royal Infirmary. Later he proceeded to the M.D., and in 1934 he became F.R.C.P. of Edinburgh. As a postgraduate he had studied also in Paris and Vienna, devoting his attention especially to dermatology. In 1922 he started in general practice at Llansamlet, a busy industrial area near Swansea; here he gained special experience in lead intoxications among the spelter workers and in skin diseases peculiar to industrial workers. Over the course of years he developed his interest in dermatology, and in 1931 was appointed a visiting physician at Swansea General Hospital with special care of patients with skin diseases. A few years later he became a referee for industrial skin diseases to the Home Office. With the coming of the National Health Service in 1948 he was appointed consultant dermatologist to the Welsh Regional Hospital Board for the South-west Wales group of hospitals.

Lewis took an active part in the medical life of Swansea, becoming chairman of the medical staff of Swansea Hospital and later (1954-5) chairman of the Swansea Division of the B.M.A. In 1950, to the great pleasure of his wide circle of friends, he was made High Sheriff of Breconshire, an office which he held with quiet dignity and modesty. He was an ardent Welshman with a strong sense of tradition, and the holding of this ancient office was a real delight to him. At this time also his learning in Welsh literature received recognition by his election to the court of governors of the National Library of Wales, and he was proud also to take part in the bicentenary celebrations in London of the Honourable Society of Cymmrodorion. To his knowledge of the language, folklore, and history of his native country he added a wide and balanced outlook on the world outside Wales, an outlook enhanced by his residence at Edinburgh and his sojourns on the Continent. He made social contacts readily and had a very wide circle of friends, and, it may fairly be said, no enemies.

David Lewis retired early this year from his Health Service post, but his hopes of a happy retirement in his home country were shattered by the onset of a grave illness, which, in spite of the most skilful care, ended his life on July 6. The affection and regard which his medical colleagues and other friends had for him was shown by the large attendance at his funeral on July 10, when he was buried in a quiet graveyard at Salem, Llangefelach, in the beautiful and still unspoiled countryside a few miles north of Swansea.

David Lewis married in 1922 Miss Jane Davies, also a native of the Swansea Valley, and she survives him together with a daughter: to them is extended the sincere sympathy of his many friends.

Medical Notes in Parliament

VIVISECTION

Lord DOWDING criticized the practice of vivisection on July 18, and asked for an inquiry with a view to repairing loopholes in the law, and thereafter an adequate system of inspection to ensure its enforcement. He admitted that the abolition of vivisection was a windmill beyond the reach of his lance; but he contended that painful experiments on animals were morally wrong, and that it was basically immoral to do evil that good might come.

There were, he said, about 2,500,000 experiments every year in about 520 laboratories, but to guard against breaches of the law there were no more than five inspectors. The law was riddled with loopholes, and the whole inspection system was a hollow sham maintained to throw dust in the eyes of the critics and to save the conscience of the apathetic. Thousands of animal lives were expended every week in the manufacture and testing of drugs. There had never been an inquiry into the details of this trade.

One flaw was the absence of any definition of what constituted an anaesthetic. A true anaesthetic caused loss of consciousness and feeling, but in the *Lancet* and the *British Medical Journal* and other professional publications operations were described which had been performed under drugs which were not true anaesthetics. They included experiments involving the tearing out of cats' eyes, smashing cats' legs, and the repeated dropping of a metal rod on the extended thighs of small rodents. One asked oneself what went on behind the closed doors of laboratories to which the public had no access. It was reasonable to suppose that the most shocking experiments occurred which never appeared in print.

Lord COHEN OF BIRKENHEAD, in a maiden speech, declared himself prepared to say without fear of contradiction that no wanton cruelty was inflicted on animals in the course of physiological, therapeutic, and bacteriological investigation.

The major advances in surgery, the construction of new parts of the heart, approach to the brain, the excision of lungs in which there was malignant disease, all owed practically everything to knowledge gained about control of infection, haemorrhage, and shock, and about anaesthesia from the animal world. Those who were prepared to proclaim that animal experiments should be banned must be prepared to allow their fellow men to suffer and succumb to disease the course of which might yield in future to animal experiments.

Man had never hesitated to become the subject of experiments to serve his fellow men. There were experiments requiring a conscious man's mind and a knowledge of how long sutures remained in the body, and Lord Webb-Johnson had carried out such experiments on himself on at least 60 occasions. Could there be any doubt that animal experimentation had led to an enormous increase in the control by man over the diseases which beset him?

Thirty years of close association with physiologists, bacteriologists, and others who sought power over nature and enused animal experiments convinced him that they were enriched by their work by love and meekness and in their service to mankind. They resented any insinuations that they were callous, indifferent to suffering, or wanton, cruel, if not sadistic, in their outlook. They respected Lord Dowding's motives; let him respect theirs. To suppose that shocking experiments were carried out behind locked doors was to impute motives to others that Lord Dowding would not have imputed to himself.

He respected Lord Dowding's view on the ethical question. But it must be remembered that the vast majority of mankind conceived that man's prime duty was towards his fellow man. They deplored as deeply as Lord Dowding cruelty to animals, including experiments that were unnecessary, irrelevant, and unjustified. Any means that could be devised

that would ensure that such experiments were not carried out would be acceptable to them. They believed that the present law satisfactorily met the problem of inflicting unnecessary pain through the methods of certification and inspection.

Lord CHESHAM, Lord-in-Waiting, speaking for the Home Office, agreed that there was the strongest feeling against any practice which caused avoidable pain to animals. The Home Office had no vested interest one way or the other in vivisection. Their duty was to see that the law was properly enforced. No one could perform an experiment on a live animal without a licence; having been given the licence, he might do nothing unless the animal was under an anaesthetic of sufficient power to prevent it from feeling pain, except in certain circumstances for which there must be certificates. The remark by Lord Dowding about the inspection system being a hollow sham did the greatest disservice to a most conscientious and hard-working body of public servants.

Asian Influenza

Mr. J. SNOW (Lichfield and Tamworth, Lab.) on July 22 asked the Minister of Health for a statement regarding the new Oriental influenza epidemic, and what precautionary action his department was taking. Mr. J. K. VAUGHAN-MORGAN stated that laboratory confirmation had now been obtained that persons suffering from the Asian type of influenza had arrived in this country. There was at present no sign of any material spread of the infection here so far.

Mr. SNOW, recalling the 1917 epidemic, asked what lessons could be learned from the records of that time, and if the Minister would consider issuing some sort of statement that would allay anxiety. Mr. VAUGHAN-MORGAN replied that he thought his answer would allay anxiety. All the evidence so far was that in Britain the epidemic was and would be of a mild nature. This and the 1917 epidemic were not comparable. There was far more international knowledge and co-operation now than then. If M.P.s were unfortunate enough to catch this influenza, he added, the best clinical advice he had received so far was to go to bed.

Caponized Cockerels

Sir JOCELYN LUCAS (Portsmouth, South, Con.) asked if the Ministry of Health would investigate the effect on human beings who eat artificially caponized chickens. Mr. VAUGHAN-MORGAN replied that no advice on this aspect of the subject had reached him from the Medical Research Council. He proposed to get in touch with them. Investigations in America had shown that ill effects were very unlikely.

Mr. HEATHCOAT AMORY, Minister of Agriculture, Fisheries, and Food, answering questions on the same subject, said he doubted whether a special investigation was necessary. It was already known that the feeding of chicken necks which contained implants of synthetic oestrogens was dangerous, and a warning was given against the practice in the Ministry's advisory leaflet. He was considering whether additional publicity—and, he added later, perhaps regulations—should be given to the warning already issued.

Snuff or Cigarettes

Mr. GRESHAM COOKE (Twickenham, Con.) asked the Minister of Health if he would consult the Medical Research Council for their advice on the taking of snuff as a safe alternative to smoking. Mr. VAUGHAN-MORGAN said he was advised that, although no relationship had been demonstrated between the taking of snuff and the incidence of lung cancer, there was insufficient evidence on the effects of this practice to justify it being recommended as a safe alternative to smoking. He added that there had been a small-scale inquiry which demonstrated that there was no connexion, but some work undertaken in South Africa had suggested a possible connexion between snuff-taking and cancer of the nose among the Bantu.

Doctors' Lists

Mr. VAUGHAN-MORGAN informed Mr. S. AWBERY (Bristol, Central, Lab.) that on July 1, 1956, the number of general medical practitioners with lists of over 1,500 was 13,582, while 8,364 had over 2,500 patients and 2,979 had over 3,500; at the same date the average list was 2,272.

Senior Registrars

Mr. KENNETH ROBINSON (St. Pancras, North, Lab.) asked what was the total number of fourth-year and fully trained senior registrars in the Health Service; and what was the number of additional consultant appointments, in terms of whole-time equivalents, made in the last 12-months period for which figures were available. Mr. VAUGHAN-MORGAN gave him the following information. At June, 1956, the number of senior registrars in England and Wales other than those in first- to third-year posts were as follows: In fourth-year training, 136. Completed four years of training and awaiting higher posts, 90. Holding fifth- and sixth-year training posts in certain specialties, 13. Holding part-time posts (most hold also other part-time posts as consultants or senior hospital medical or dental officers), 26. Holding, before July, 1948, hospital posts of unlimited tenure graded as senior registrar in July, 1948, 17. University staff holding honorary appointments in hospitals, 78. Others holding miscellaneous appointments of a kind not included above, 40. Doctors from overseas temporarily in this country and holding posts graded as senior registrar, 8. Total, 408. It was estimated that in the year ending June 30, 1956, paid consultant appointments in England and Wales increased by about 65 whole-time equivalents.

Patients in Broadmoor

Dr. DONALD JOHNSON (Carlisle, Con.) asked the Home Secretary on July 18 whether he would include the Criminal Lunatics Act, 1800, the Criminal Lunatic Asylums Act, 1860, and the Criminal Lunatics Acts of 1883 and 1884 in the revision of mental health legislation on which the Government proposed to embark. Mr. R. A. BUTLER stated that he would consider how far the principles embodied in the legislative proposals resulting from the Government's consideration of the report of the Royal Commission on Mental Health could be reflected in the practice and legislation relating to Broadmoor patients. But it would not in his view and as at present advised be appropriate to combine a revision of the law relating to Broadmoor patients with the revision of mental health legislation arising out of the Royal Commission's report.

Venereal Disease in Dominica

Mr. DAVID JONES (The Hartlepoons, Lab.) asked the Secretary of State for the Colonies on July 16 what provisions existed on the island of Dominica for health teaching about venereal diseases. Mr. J. PROFUMO, the Under Secretary, replied that health teaching about venereal diseases was undertaken within the ambit of a yaws eradication project, on which W.H.O. and Unicef were assisting. This had been in operation for some years, and a start was being made under it to control venereal diseases. The 1955 incidence per 1,000 of population for venereal diseases and yaws respectively was about 5.5 and 17 in Dominica and 9 and 0.6 in Trinidad.

Scottish Hospital Beds

Mr. J. S. MACLAY, Secretary of State for Scotland, informed Mr. W. HANNAN (Glasgow, Maryhill, Lab.) on July 16 that in 1955 there were 2,129 pay-beds in Scotland, the rate of occupancy was 97%, and the occupancy by patients paying Section 4 charges was 64%. The corresponding figures for 1956 were 2,147, 90%, and 63%. At the end of September, 1955, there were 46,727 patients on waiting-lists, and last September 46,596.

Smoking Compartments in Trains

Mr. FRANK BESWICK (Uxbridge, Lab.) asked the Minister of Transport and Civil Aviation if, in view of the new evidence regarding the danger to health of tobacco smoking, he would give a general direction to the British Transport Commission not only to set aside adequate numbers of train compartments in which smoking was prohibited, but also that these compartments should be more prominently indicated, and the prohibition enforced, with more adequate penalties for defaulters. Mr. G. R. H. NUGENT, the Parliamentary Secretary, replying on July 17, said the Government's policy was to make known the risks of smoking, leaving it to individuals to make up their own minds. If the public wanted more non-smoking compartments, the British Transport Commission was ready to provide them. The present notices seemed adequate, and the Commission was shortly submitting by-laws increasing the penalty for smoking offences. Mr. BESWICK claimed that there was a very real hardship. The extraordinary correspondence he had received showed that there was real suffering by bronchial people. Mr. NUGENT said that if any evidence was given him of the need to alter the present arrangements he would send it on to the Commission. The questioning then became a succession of contradictory opinions on whether it was the smoking or non-smoking compartments that should be labelled, with a special plea by Mr. E. SHINWELL (Easington, Lab.) that non-smokers should not be allowed to clutter up smoking compartments.

Drunk in Charge.—The number of prosecutions in England and Wales in 1955 for the offences of driving or being in charge of a motor vehicle while under the influence of drink or drugs was 3,867. The number of convictions was 3,311; sentences of imprisonment were imposed in 209 cases and fines were imposed in 3,059.

Universities and Colleges

UNIVERSITY OF ABERDEEN

At Graduation ceremonies on July 4 and 5 the following degrees were conferred:

M.D.—¹W. G. Smith, ¹D. W. Taylor, ²D. S. Munro, W. I. Cranston, M.B., Ch.B.—¹Dita M. K. Evans, ¹J. H. Wyllie, ¹D. Ogston, ²T. M. Forrester, ²J. W. Norris, G. E. Evans, ¹A. Akinkugbe, E. R. Alexander, W. S. Allan, J. T. Anderson, T. Adan, A. Akinkugbe, E. R. Alexander, F. H. Brown, G. L. Chalmers, B. A. Charles, Muriel Clarke, A. B. Coull, Nancy P. Cruickshank, D. P. Cummine, J. F. Davidson, Helen M. Dean, Margaret G. Duguid, D. Eccleston, D. R. Findlay, C. L. Forbes, Elizabeth M. J. Hamilton, G. L. Horsfall, J. McG. Imray, Jean J. Kerr, Elizabeth M. McK. Leslie, G. M. McAndrew, Deirdre C. C. MacArthur, J. S. McCracken, F. G. Macdonald, Joan Macfarquhar, R. W. McIntyre, H. N. Mackenzie, Mhairi L. Matheson, C. D. Mowat, J. A. Murray, C. J. Must, Margaret McK. Philip, D. D. Reid, Doris J. Ritchie, G. C. Shirreffs, F. R. C. Soper, G. S. Sorrie, Gillian Stephenson, R. G. Strachan, A. McL. Thomson, G. H. Vaughan, L. I. Walters, D. S. Young.

¹With honours. ²With commendation.

Diplomas in Public Health were granted to G. Cassie, G. Innes, Isabel E. James, G. T. Pollock, and W. J. W. Rae.

The following University prizes and medals have been awarded during the session 1956-7: *Anderson Gold Medal and Prize in Clinical Medicine*, D. Ogston; *proxime accessit*, J. W. Norris. *Alexander Smith Cardno Prize in Anatomy*, J. M. Leegaard. *Chanock Gold Medal in Anatomy*, Durno Prize in Anatomy, and *Lizars Gold Medal in Anatomy*, Anne M. Wyllie. *Dyce Davidson Memorial Gold Medal in Materia Medica*, G. Russell. *Matthews Duncan Gold Medal in Obstetrics*, J. H. Wyllie. *Fulton Essay Prize in Neurology*, Keith Gold Medal in Surgery, *MacQuibban Prize in Medicine*, and *Davidson Smith Prize in Diseases of Children*, D. Ogston. *Fife Jamieson Gold Medal in Anatomy*, Anne M. Wyllie; *proxime accessit*, W. M. Park. *MacQuibban Prize in Surgery*, G. S. Sorrie. *Murray Medal and Scholarship* (for the most distinguished graduate in medicine of the session) and *Shepherd Memorial Gold Medal in Surgery*, Dita M. K. Evans. *Ogston Prize in Surgery*, W. D. McKay. *Silberg Prize in Anatomy and Silberg Prize in Physiology (including Biochemistry)*, Anne Chew. *Thursfield Award (1956)*, B. H. Smith. *Venn Essay Prize (1956)*, G. M. McAndrew. *John A. Watt Prize in Preventive Medicine*, J. A. Baldwin.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending July 6 (No. 27) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1957					1956

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenzal pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications (uncorrected) in England and Wales in the week ending July 13 were as follows, with the figures for the previous week in parentheses: paralytic 68 (68), non-paralytic 65 (65), total 133 (133). Total cases in Scotland were 3 (9), Northern Ireland 10 (8), and Eire 3 (2).

The outbreak continued in Essex, from which 14 cases were reported (Ilford M.B. 4, Leyton M.B. 2). Other district notifications were as follows: Kent 16 (Maidstone M.B. 7), Lincs, Lindsey 10 (Lincoln C.B. 7), London 14 (Holborn 2, Lewisham 3, Wandsworth 2), Warwickshire 10 (Birmingham C.B. 3, Coventry C.B. 5), Glamorganshire 6 (Merthyr Tydfil C.B. 2, Rhondda M.B. 4), Monmouthshire 3 (Aber-tillery U.D. 3).

Of the 10 cases in Northern Ireland, 6 were reported from Belfast C.B.

Week Ending July 13

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 413, whooping-cough 1,661, diphtheria 3, measles 13,417, acute pneumonia 197, acute poliomyelitis 133, dysentery 465, paratyphoid fever 4, typhoid fever 2.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1948-56 are shown thus - - - - -, the figures for 1957 thus ————. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

In England and Wales during the week ending July 6 a further large fall in the notifications of measles was recorded of 1,907, from 17,417 to 15,510. Scarlet fever notifications fell by 36 from 436 to 400, and dysentery by 2 from 464 to 462, while whooping-cough rose by 77 from 1,554 to 1,631.

The largest falls of measles were Buckinghamshire 97, from 225 to 128, Durham 79, from 511 to 432, Essex 153, from 554 to 401, Lancashire 141, from 1,214 to 1,073, London 157, from 584 to 427, Middlesex 129, from 624 to 495, Southampton County 202, from 691 to 489, Staffordshire 97, from 614 to 517, Warwickshire 319, from 1,241 to 922, Worcestershire 176, from 411 to 235, Yorkshire West Riding 186, from 2,192 to 2,006, and Glamorganshire 154, from 430 to 276. Notable increases were recorded in Kent 241, from 754 to 995, Leicestershire 128, from 334 to 462, and Norfolk 67, from 542 to 609. Notifications of whooping-cough rose in Devon 25, from 15 to 40, Durham 35, from 47 to 82, and Suffolk East 23, from 8 to 31 (Deben R.D. 13, Gipping R.D. 11).

The largest returns of dysentery were Lancashire 119 (Eccles M.B. 17, Irlam U.D. 16), Shropshire 21 (Oswestry M.B. 9), Yorkshire West Riding 66 (Leeds C.B. 18), and Anglesey 15 (Valley R.D. 15).

Influenza

Five passengers on the liner *Orcades* were isolated at Port of London Isolation Hospital near Gravesend with suspected Asiatic influenza earlier this week. They comprised 3 men, a woman, and a 7-year-old girl, and all were reported to be recovering fast. Of the 828 passengers and crew, 92 were reported to have had influenza. The ship sailed from Sydney, Australia, and called at various ports of the American continent.

England and Wales in June Quarter

The highest birth rate since 1951, and the lowest infant mortality ever, for a June quarter were recorded in England and Wales for the June quarter of 1957. Live births numbered 185,390, giving a rate of 16.6 per thousand population, the same as in the June quarter of 1951. Rates for the

second quarters of 1956 and 1955 were 16.4 and 15.5. Deaths numbered 118,177, giving a rate of 10.6 per thousand population. The rates in the June quarters of 1956 and 1955 were 10.8 and 11.2. Deaths of children under 1 year of age numbered 4,031, giving a new record low rate for a June quarter of 22.2 per thousand related live births. The previous lowest rate for this quarter was 23.0 last year. In 1938 the corresponding rate was 50.3. 4,264 stillbirths were registered, giving a rate of 22.5 per thousand live and stillbirths; in the corresponding quarter of 1956 the rate was 22.8.

Medical News

Scottish Mental Hospitals.—During 1956 the number of admissions to mental hospitals in Scotland again increased, according to the Annual Report of the General Board of Control for Scotland for 1956. The number was 10,147, as compared with 9,168 during the previous year. When multiple admissions are allowed for, the number of patients admitted during the year was about 9,200. The proportion of voluntary patients again rose, being 73% of the total admissions. At the end of the year, the number of patients in mental hospitals was 20,925, or 152 more than at the end of 1955. Of the resident patients, only about 23% were voluntary. The number of mental patients boarded out in private dwellings is decreasing and at the end of 1956 was 341. During the year 8 patients in mental hospitals committed suicide and 55 had accidental deaths. Twenty-five reports were provided by the Board in actions for divorce brought on the grounds of incurable insanity. The number of mental defectives discharged was 290, an increase of 116 over the figure for the previous year. Appeals to the sheriff against the continued detention of a mental defective were made in 25 cases. One was sustained and the rest were dismissed.

Equipment for the Cripple.—A useful feature of the Seventh World Congress of the International Society for the Welfare of Cripples was the exhibition of technical aids for the disabled. The exhibition was held at the Central Hall, Westminster, during the Congress (July 22-27). There were some 60 exhibitors. Perhaps the most interesting aspect of the exhibition was the evidence it gave of progress abroad in the development of light-weight artificial limbs made from synthetic materials. In Germany the epoxy resins are used with fibreglass and cotton and nylon stockinets in a laminating technique, while in the United States polyester resins are combined with fibreglass and cotton stockinets. A Norwegian above-knee artificial limb with a suction socket was shown, made from a thermoplastic resin ("plexidur"), the knee and ankle mechanisms, with the exception of the axle in the knee, being made of a phenol formaldehyde and fabric laminate. One outstanding advantage of these synthetic materials for artificial limbs is that their manufacture does not entail the costly apparatus and specialized skill that metal does; another is that they do not corrode. On the British stands there was, regrettably, no evidence of any comparable exploitation of these new materials. Other exhibits included the British-made "sleyride" electric indoor chair—a battery-operated wheel-chair for use in the home, an artificial arm activated by bottled carbon-dioxide (from Germany), and the American hydraulic locking device for the knee-joint. Doctors wishing for further information about the appliances shown at the exhibition are invited to write to the secretary, Central Council for the Care of Cripples, 34, Eccleston Square, London, S.W.1.

Consolidated Leaflet of "Approved" Names.—The G.M.C. has issued a revised consolidated leaflet of "approved" names of drugs. "Approved" names are devised or selected by the British Pharmacopoeia Commission, the intention being that, if a drug should later be included in the *British Pharmacopoeia*, the "approved"

name should become its official title. The revised leaflet (dated June, 1957) contains all the "approved" names issued since 1948 up to May this year, together with those given earlier where the drug concerned has not been the subject of an official monograph. The "approved" names are listed alphabetically, with the corresponding chemical and other names alongside; the latter include some trade names. The leaflet may be obtained free on application to the secretary, British Pharmacopoeia Commission, General Medical Council Office, 44, Hallam Street, London, W.1.

Anaesthetics Research.—A new department of anaesthetics was opened last Tuesday at the Royal College of Surgeons by Sir HENRY DALE, O.M., F.R.S. Occupying a suite of rooms on top of the College's new building, the department is beautifully constructed and equipped for research (see photograph). It is believed to be the only anaesthetics research department in the country which is free

Research Department of Anaesthetics at Royal College of Surgeons.

from the responsibilities of providing a hospital anaesthesia service and of undergraduate teaching. But clinical work is made possible by virtue of honorary appointments which some members of the staff hold at the Whittington Hospital, and by arrangement with other hospitals in London. The department also undertakes postgraduate teaching. It is under the directorship of Dr. R. F. Woolmer; other members of the staff are Dr. G. R. Graham, first assistant; Mr. D. W. Hill, physicist; and Dr. J. F. Nunn, Leverhulme research fellow, together with ancillary workers. Laboratory facilities permit work on experimental animals to be carried out, and special apparatus can be constructed in an elaborately equipped workshop. The two main lines of investigation being undertaken at present are on hypothermia in experimental animals and on human respiration during anaesthesia. A number of generous gifts from industry have made the venture possible.

Royal College of Surgeons of Edinburgh.—At a meeting of the College on July 10 Sir WALTER MERCER, the president, conferred the honorary fellowship on Sir STANFORD CADE and Sir GEOFFREY JEFFERSON, F.R.S.

F.R.C.S.Ed.—The following were admitted fellows at the meeting of the Royal College of Surgeons of Edinburgh on July 10:

R. S. Adib, L. C. A. Ariotti, N. S. Brara, C. A. Cass, W. Cochran, J. G. Connolly, W. N. de Vos, P. L. C. Diggory, H. H. Gossman, E. J. Hargadon, J. H. Hodgson, M. Husain, G. A. Jose, E. Kreft, L. J. G. Kruger, R. I. Lindfield, S. F. Massoud, A. W. Maxwell, J. P. O'Neill, D. L. E. Paine, D. A. Peebles, G. R. G. Prendiville, Z. Rahman, T. Rangiah, A. L. Rencken, A. L. Reynolds, A. A. Robertson, J. G. Robertson.

L. N. B. Roy, P. M. Segelov, M. K. Senapati, F. Shah, K. N. Sharma, H. U. Shaw, R. A. Shearer, G. H. Tilak, M. S. Tin, D. C. Vora, J. R. Watson, R. A. Williams, R. O. Wise, and K. Wood.

Anaesthesia Prize.—The Anaesthetic Section of the Royal Society of Medicine offers a prize of £30 for the best paper submitted by a senior registrar or registrar in the National Health Service holding a clinical appointment in an anaesthetic department or hospital. The subject may be of the author's choice but must be connected with anaesthesia. Papers must be submitted by January 1, 1958. Further details from the hon. secretary, Anaesthetic Section, Royal Society of Medicine, 1, Wimpole Street, London, W.1.

College of Physicians and Surgeons of South Africa.—The College is holding this autumn its first examinations for its fellowships in medicine, in surgery, and in obstetrics and gynaecology. The examinations will be held on September 30 and October 2 and 3 in Capetown. Sir HARRY PLATT, Sir RUSSELL BRAIN, and Mr. A. J. WRIGLEY, F.R.C.O.G., have been invited to attend the examinations as observers.

Readership in Medical Parasitology.

—Dr. P. L. LE ROUX, D.Sc., M.R.C.V.S., has been appointed to the readership in medical parasitology at the London School of Hygiene and Tropical Medicine. The appointment is from October 1. After graduating at Edinburgh, Dr. le Roux spent from 1924 to 1930 in South Africa, where he was successively a veterinary research officer in the Department of Agriculture and lecturer at Transvaal University College. During 1931-46 he was engaged in veterinary research in Northern Rhodesia, and since 1947 he has been lecturer in helminthology (later senior lecturer) at the London School of Hygiene and Tropical Medicine.

Medical Octogenarians.

—Lady HUTCHISON celebrated her 80th birthday on July 17. She thus joined as an octogenarian her husband Sir ROBERT HUTCHISON, the distinguished paediatrician, who became 80 in 1951. Lady Hutchison qualified with the London M.B. in 1904, having received her medical education at Durham University College of Medicine, Newcastle upon Tyne.

Royal Society of Health.—New fellows, elected in recognition of their noteworthy work in the promotion of health, include Dr. RALPH G. BEACHLEY, director of public health, Arlington County, Virginia, U.S.A.; Dr. FRANK H. N. CRUICKSHANK, medical officer in charge of the Public Health Training Centre, Jamaica; Dr. SIDNEY E. L. FERREIRA, assistant director of medical services, Jamaica; Dr. EDWIN N. H. GRAY, medical officer of health, Runcorn Urban and Rural Districts; Professor RONALD E. LANE, professor of occupational health, Manchester University; and Dr. JAMES H. WEIR, medical officer of health, Kensington and Chelsea.

Mr. K. F. Darrell Waters retired this month after 35 years as senior surgeon to St. Stephen's Hospital, Chelsea; for the last 25 years he was also deputy medical superintendent. His consultant colleagues marked the occasion with a dinner in his honour.

Professor J. B. S. Haldane, F.R.S., has been granted the title of professor emeritus of London University on his resignation from the Weldon chair of biometry at University College.

Professor Robert Cruickshank, principal of the Wright-Fleming Institute, St. Mary's Hospital Medical School, has left by air for a month's lecture tour in Australia and New Zealand.

COMING EVENTS

Radio.—B.B.C. Third Programme, July 31, 7.30 p.m. Mr. E. J. AMBROSE, of the Chester Beatty Research Institute, will discuss "Cancer: a Problem of Cell Organization."

Bengué Memorial Lecture.—The Royal Institute of Public Health and Hygiene's Bengué Memorial Lecture will be given on October 9, at 4 p.m., by Dr. LOUIS ZIZINE (Paris). His subject will be "The Endocrine Problems of Asthma."

31st French Congress of Medicine.—Organized by the Association des Médecins de Langue Française, Paris, October 16 to 18. Details from the general secretary, 8, Rue du Pré-aux-Clercs, Paris, 7.

International Society of Angiology.—Third international congress, October 18-21, Atlantic City, New Jersey, U.S.A. Details from Dr. H. HAIMOVICI, 105, East 90th Street, New York 28.

Blood Matching.—One-day symposium on "Compatibility Tests for Hospital Use," under the aegis of the Sheffield Regional Hospital Board, October 17, at the Royal Victoria Hotel, Sheffield. All interested welcome. Details from the director, Regional Transfusion Centre, Sheffield, 10.

NEW ISSUES

British Heart Journal.—The new issue (Vol. 19, No. 3) is now available. The contents include:

AUSCULTATORY AND PHONOCARDIOGRAPHIC SIGNS OF PULMONARY STENOSIS. Aubrey Leatham and David Weitzman.
 ATRIAL SEPTAL DEFECT IN CHILDREN. Joan Warner and G. R. Graham.
 THE SMALL PULMONARY BLOOD VESSELS IN ATRIAL SEPTAL DEFECT. D. Heath and W. Whitaker.
 PROGNOSIS OF ISOLATED VENTRICULAR SEPTAL DEFECTS. E. Mannheim, D. Ikkos, and B. Jonsson.
 AORTIC ORIGIN OF THE RIGHT PULMONARY ARTERY. C. Caro, V. C. Lermenda, and H. A. Lyons.
 PULMONARY VASCULAR PATTERNS IN PULMONARY HYPERTENSION. A. E. Doyle, J. F. Goodwin, C. V. Harrison, and R. E. Steiner.
 ADDITIONAL ELECTROCARDIOGRAPHIC SIGNS OF CARDIAC PAIN. William Evans and R. K. Pillay.
 THE EFFECT OF SERPASIL IN PULMONARY HYPERTENSION. D. Halmagyi, B. Felkai, Z. Cipotti, and G. Kovács.
 NETWORKS IN THE RIGHT SIDE OF THE HEART. G. Austin Gresham.
 MALIGNANT ATRIAL ARRHYTHMIA. William Dewhurst.
 FUNCTIONAL TRICUSPID INCOMPETENCE IN RELATION TO THE VENOUS PRESSURE. Conrad Lottentbach and John Shillingford.
 THE MECHANICAL PROPERTIES OF THE LUNGS IN PATIENTS WITH PERIODIC BREATHING. David Mendel and Malcolm B. McIlroy.
 ENDOCARDIAL CUSHION DEFECTS: COMMON ATRIO-VENTRICULAR CANAL AND OSTIUM PRIMUM. Maurice Campbell and G. A. K. Missen.
 THE HAEMODYNAMICS OF MITRAL STENOSIS BEFORE AND AFTER COMMISSUROTOMY. Janet Dickens, L. Villaca, A. Woldow, and H. Goldberg.
 SINO-AURICULAR BLOCK ASSOCIATED WITH INTRATHORACIC NEW GROWTHS. Paret Davies.
 CASE REPORTS:
 CALCIFIED CARDIAC ANEURYSM. W. J. Hanbury.
 ABSENCE OF PULSE IN BOTH UPPER EXTREMITIES DUE TO AN AORTIC ARCH ANOMALY. A. C. Azevedo, R. Roubach, A. A. De Carvalho, A. N. Toledo, and W. Zaniolo.
 ABSTRACTS OF CARDIOLOGY.

Issued quarterly; annual subscription, £2 2s.; single copy, 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Medical and Biological Illustration.—The new issue (Vol. 7, No. 3) is now available. The contents include:

FRONTISPIECE.
 PRESSURES BENEATH THE FOOT RECORDED BY KINEMATOGRAPHY. A. L. Wooding and C. H. Barnett.
 LEAFLETS. John Burton.
 A TECHNIQUE OF RETINAL PAINTING. T. R. Tarrant.
 A NEW STEREO CAMERA FOR EYE PHOTOGRAPHY. H. M. Dekking.
 THE IDEAL LECTURE THEATRE—II. INSTALLATIONS AND FITTINGS. Peter Hudson and Allan Low.
 LOGELECTRONICS. Dwin R. Craig.
 THE FILM ARCHIVES OF THE GERMAN SCIENTIFIC FILM INSTITUTE. W. Hirsch.
 EQUIPMENT AND METHODS:
 PULSED XENON ARC UNIT
 ILFORD 100-WATT PORTABLE PROJECTOR.
 FILM EDITING AID.
 COOLING UNITS FOR RADIOGRAPHIC PROCESSING IN THE TROPICS.
 ABSTRACTS.
 BOOK REVIEWS.
 MOTION PICTURES.
 REPORTS FROM SOCIETIES.

Issued quarterly; annual subscription, £2 2s.; single copy, 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Ophthalmology.—The new issue (Vol. 41, No. 7) is now available. The contents include:

AEIOLOGY OF UVEITIS. A. Stanworth and H. McIntyre.
 CORNEAL RADIUS IN PRIMARY ACUTE GLAUCOMA. Ragnar Törnquist.
 PHOTOGRAPHIC METHOD OF MEASURING THE ANGLE OF SQUINT. P. A. Graham and E. J. Naylor.
 UNILATERAL EXOPHTHALMOS RESULTING FROM SCLEROSIS OF THE SPHENOID BONE. J. W. E. Cory.
 MULTIPLE MYELOMATOSIS AFFECTING THE ORBIT. Doris Rose and Clifford Taylor.
 COMPLETE RETROFLEXION OF THE IRIS WITH RETENTION OF THE NORMAL VISION. A. J. Orgz.
 TRANSIENT CYST FORMATION IN THE ANTERIOR CAPSULE OF THE LENS. A. Hagedoorn.
 CONGENITAL TOTAL CATARACT—POSSIBLY RECESSIVE. Ruby Joseph.
 ANTERIOR DISLOCATION OF THE LENS IN MARFAN'S SYNDROME. D. P. Choyce.
 BOOK REVIEW.

Issued monthly; annual subscription, £4 4s.; single copy, 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Venereal Diseases.—The new issue (Vol. 33, No. 2) is now available. The contents include:

EDITORIAL.
 EPIDEMIOLOGY OF GONORRHOEA IN FINLAND IN 1953 TO 1955. A. S. Härö and R. Pääliä.
 PROBLEMS OF VENEREAL DISEASE CONTROL IN POLAND. Józef Towpik.
 EPIDEMIOLOGY OF INFECTIONS WITH TRICHOMONAS VAGINALIS IN THE LIGHT OF IMPROVED DIAGNOSTIC METHODS. M. Joan Whittington.
 SYPHILOPHOBIA. Ida Macalpine.
 TREATMENT OF NON-GONOCOCCAL URETHRITIS. J. Oliver Doyle, A. J. Gill, and S. M. Laird.
 VENEREAL DISEASE IN WOMEN PRISONERS. Elizabeth Keighley.
 INFECTION AND RE-INFECTION IN EARLY SYPHILIS. E. E. Prebble.
 INTERSTITIAL KERATITIS AFTER ADEQUATE PENICILLIN THERAPY. Arvo Oksala.
 TREATMENT OF VAGINAL TRICHOMONIASIS WITH 2-ACETYLAMINO-5-NITRO-THIAZOLE (AMINOTROZOLE) GIVEN ORALLY. R. R. Wilcox.
 EFFICACY OF VITAMIN B₁₂ IN THE ALLEVIATION OF THE LIGHTNING PAINS OF TABES DORSALIS. Aidan Redmond.
 EVALUATION OF PRICE'S PRECIPITATION REACTION IN THE SERO-DIAGNOSIS OF SYPHILIS. M. R. Darekar and H. I. Jhala.
 OBITUARY:
 JULIUS WAGNER VON JAUREGG, M.D., 1857-1940. W. D. Nicol.
 JOHN FRIEND MAHONEY, M.D.
 BOOK REVIEW.
 INTERNATIONAL UNION AGAINST THE VENEREAL DISEASES AND TREPONEMATOSIS.
 ABSTRACTS.

Issued quarterly; annual subscription, £2 2s.; single copy, 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Saturday, July 27

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—At B.M.A. House, Tavistock Square, London, W.C., 2.15 p.m., 36th annual general meeting.

Friday, August 2

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. N. C. Oswald: clinical demonstration.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Begg.—On July 21, 1957, at the Jersey Maternity Hospital, to Christine, wife of Dr. Douglas Begg, a son—Andrew Philip.
 Crossing.—On July 20, 1957, at Robroyston Hospital, Glasgow, to Margaret (formerly Abdy), wife of Frank Crossing, F.R.C.S., a son.
 Kenyon.—On June 7, 1957, at University College Hospital, London, W.C., to Nuala (formerly Gilmore), M.B., B.Ch., and W. Islay Kenyon, M.R.C.P., a second son—Niall Vincent.
 Schofield.—On July 8, 1957, to Anne Davies, M.B., Ch.B., wife of Graham Schofield, M.B., F.R.C.S., 9, Lomondside Avenue, Clarkston, Glasgow, a second daughter—Katherine Anne.
 Stowe.—On July 13, 1957, to Jessica (formerly Brabbits), wife of Sidney Stowe, M.B., Ch.B., of 213, Newhampton Road East, Wolverhampton, a second child—a son.

DEATHS

Bennett.—On July 8, 1957, at 21, Lonsdale Road, Bournemouth, Norman Bennett, M.D.
 Bolton.—On July 8, 1957, in hospital, Norman William Bolton, F.R.C.S. Cunningham.—On July 2, 1957, at his home in Wellington, New Zealand, John Keith Cunningham, M.B., F.R.C.S.
 Hermon.—On July 9, 1957, at 9, Pollard's Hill, South Norbury, London, S.W., Irvine Kemp Hermon, M.D., aged 79.
 Lewis.—On July 6, 1957, at Brompton Hospital, London, S.W., David Rhys Lewis, M.D., F.R.C.P., of Tredilion, Uplands, Swansea.
 Morland.—On July 13, 1957, at University College Hospital, London, W.C., Andrew John Morland, M.D., F.R.C.P., of 1, East Heath Road, Hampstead, London, N.W., and 135, Harley Street, London, W., aged 61.
 Shrubbsall.—On July 7, 1957, in an Oxford nursing-home, Jane Reid Foulds Shrubbsall, M.D., D.P.H. R.C.P.S. (formerly Gilmour), aged 78.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Survival in Prostatic Cancer

Q.—What is the survival rate in cases of cancer of the prostate treated (1) by stilboestrol only, and (2) by operation and stilboestrol?

A.—The latest figures on the survival rate of cases of prostatic cancer treated by stilboestrol alone, by orchidectomy alone, and by orchidectomy together with dectomy alone, were published by Nesbit and Baum in 1950¹ stilboestrol were published by Nesbit and Baum in 1950¹ from a very big survey. Graphs based on their figures were prepared by Pyrah and included in his recent paper on the use of hormones in the treatment of cancer of the breast and prostate.² The graphs are reproduced here and show that the best results in prostatic cancer, both with and without metastases, were obtained by combining stilboestrol therapy with orchidectomy.

Five-year survival of patients with cancer of the prostate (A) without metastases, and (B) with metastases. The graphs, which are from the paper by Pyrah² in the *British Journal of Surgery*, are based on 1,000 cases of cancer of the prostate collected by Nesbit and Baum.¹

If your questioner, in referring to operation, means radical removal of early cancer of the prostate, then there are no published British figures available, because I do not know of any surgeon who has operated on a big series, most people believing that when the disease comes to clinical

diagnosis it is inoperable. A few American urologists, however, believe that prostates containing the small hard nodules which are sometimes found even in youngish subjects, and which are microscopically malignant, should all be submitted to radical prostatectomy. Most British urologists and pathologists believe that these nodules are very often latent carcinomas which would not necessarily give rise to clinical symptoms, and they do not, therefore, advocate radical prostatectomy. Hence any reference to an American series of cases where radical removal has been done must be viewed in the light of this difference in approach.

Apnoeic Infants

Q.—Is it true that nikethamide and lobeline are equally effective in stimulating breathing when injected into the umbilical vein of a newborn infant? Is lobeline less likely than nikethamide to cause a convulsion?

A.—There would probably be general agreement that lobeline is preferable to nikethamide for the purpose of stimulating breathing in an apnoeic newborn infant. It is probably the more effective respiratory stimulant of the two, and less likely to provoke a convulsion: in fact, if a dose of 1/20 gr. (3.2 mg.) is not exceeded this danger need not be feared. The best method of administration is to inject the dose into the umbilical vein at a distance of some inches from the anterior abdominal wall, and then to "milk" the cord towards the baby. Great care must be taken to avoid accidental injection into an umbilical artery, since this may give rise to widespread thrombosis, extending into the femoral artery and its branches.¹

The usefulness, in practice, of these chemical respiratory stimulants, however, is much more debatable, and the whole question has been well reviewed by Gairdner.² Probably the main indication for the use of lobeline would be the persistence of apnoea for five minutes or more after birth, in circumstances where it was impossible safely to administer oxygen either into the trachea or into the stomach, or after failure of such methods. If the delay in onset of respirations was due to a drug such as morphine or pethidine, however, the more logical and effective treatment would be to inject nalorphine 1 mg. intravenously.

Chronic Cyanide Poisoning

Q.—What are the symptoms, treatment, and prognosis of chronic cyanide poisoning? A woman of 31 with symptoms suggestive of disseminated sclerosis was working with cyanides for six months before the appearance of her first symptoms. She had retrobulbar neuritis with bilateral partial optic atrophy, and paraesthesiae and motor symptoms in upper and lower limbs which have improved but not disappeared in the year following their onset. Could this clinical picture have been due to cyanide intoxication? If so, what are the possible portals of entry?

A.—The only long-term effect attributed to exposure to cyanide fumes is enlargement of the thyroid. Hardy, Jeffries, Wassermann, and Waddell¹ report two cases in which changes in the thyroid gland occurred in persons exposed to cyanide fumes from a case-hardening process. They suggest that this is a thiocyanate effect, comparable to that observed during the treatment of hypertension with thiocyanates, since the cyanide ion is converted rapidly in the body to thiocyanate. It is most unlikely that the symptoms described by the inquirer were due to cyanide poisoning.

Cyanides are absorbed mainly by inhalation or ingestion, but they may penetrate the skin.

Anterior Fusion in Spondylolisthesis

Q.—What are the principles of the operation of anterior fusion of the vertebrae for the treatment of spondylolisthesis of the lumbar spine? Is the operation recommended in such cases?

A.—Anterior fusion for spondylolisthesis was first devised because of the distraction inherent in placing a posterior graft in spondylolisthesis. Burns¹ described the placing of a graft in a drill hole in the bodies of the fifth lumbar and first sacral vertebrae. Mercer^{2,3} described the application of an anterior graft to the fifth lumbar and first sacral vertebral bodies. Merle d'Aubigne⁴ modified this by placing a metal strut instead of a graft in a drill hole.

The results have been extremely disappointing, because the graft crossing the disk space always disappears. The operative mortality has been high, and it is a method of fusion which has, I think, now been completely abandoned. If undertaken it requires exceptional technical skill to avoid fatality.

Attempted Abortion and Foetal Malformation

Q.—Is there any evidence that attempts to induce abortion by douching with toxic substances, such as disinfectants, result in an increased likelihood of congenital abnormality? In one case I know of a woman douched herself with a disinfectant early in her pregnancy, experiencing at the time pain and shock but no haemorrhage, and was later delivered of a full-term stillborn anencephalic.

A.—It is questionable whether any form of vaginal douching has any effect on a pregnancy unless air or fluid enters the uterus through the cervix. It may then kill the foetus by interfering with its implantation. If it does not interrupt the pregnancy, however, there is no evidence that it can interfere with foetal development, and certainly not to cause malformation. Indeed, the results of an inquiry published by Whitehouse and McKeown¹ indicate that attempted induction of abortion by any method is not a significant cause of anencephaly. In the case of a gross malformation such as anencephaly, the adverse factor (the nature of which is unknown) presumably has to operate within the first few weeks, probably before the woman has experienced amenorrhoea or other symptoms leading her to believe that she is pregnant.

NOTES AND COMMENTS

Timing of Intravenous Ergometrine.—Dr. B. J. BOUCHÉ (London, S.W.19) writes: Answering a question about the timing of intravenous ergometrine in parturition ("Any Questions?" June 15, p. 1429), your expert's reply takes no notice of the letter by Dr. Keith Vartan (*Journal*, May 16, 1953, p. 1108). In his letter Dr. Vartan states that in an experience with 1,130 patients at the British Hospital for Mothers and Babies, where alternate cases were used as controls and 1 mg. of ergometrine or "methergin" (methyl ergometrine) was given intravenously when the shoulders were born, the manual removal rate of the placenta "was more than twice as great"—i.e., it rose from 1.6% to 3.7%. The letter ends by saying: "In short, they [their figures] exactly confirm the important work carried out at University College Hospital by Martin and Dumoulin."¹ The work quoted was undertaken primarily to ascertain the value of intravenous ergometrine in preventing post-partum haemorrhage, but the conclusion drawn on the need for manual removal of the placenta in such cases was also very important, and surely it cannot be set aside or ignored as of no consequence.

REFERENCE

- ¹ Martin, J. D., and Dumoulin, J. G., *British Medical Journal*, 1953, 1, 643.

OUR EXPERT replies: There are of course many reports on the use of ergometrine and other oxytocics at the end of the second

stage of labour, and the results are not always identical if only because of differences in technique, working conditions, selection of cases, and control of the experiment. Even when ergometrine is not used the incidence of manual removal of the placenta varies widely from obstetrician to obstetrician and from time to time in the same hospital. The findings of Martin and Dumoulin in regard to the need for the manual removal of the placenta after the intravenous injection of ergometrine are exceptional to the general experience—as will be seen from the table which these authors published showing the results of other writers. Moreover, they point out that, in one-quarter of their cases of retained placenta in their "ergometrine series," the injection was given too late—i.e., when the foetal trunk had already left the uterus. It is of some importance too to note that except for forceps extractions the deliveries which they were reporting were mostly conducted by medical students; even the oxytocic was injected by a student, a house-surgeon not being called unless the placenta had not been delivered within 15 minutes. This arrangement is in marked contrast to that obtaining in the series reported by Lister (see below) in which the deliveries in both the control and treated series were conducted only by senior registrars and consultant obstetricians with another qualified medical person present to administer the injection. Martin and Dumoulin in their very fair report comment further to the effect that had cord traction been applied, and if vaginal exploration without anaesthesia had been practised, some of the manual removal operations might well have been avoided. Two other major controlled investigations carried out in this country and reported in full detail are those by Ursula M. Lister¹ and L. Snaith.² Neither of these writers found the need for manual removal of the placenta to be increased. It is of interest to note, however, that subsequent to the conclusion of his controlled study Snaith continued to use ergometrine only in cases in which there was reason to expect complications in the third stage of labour; he then found the need for manual removal of the placenta to be increased. This again shows the effect of selection of cases. Taking a wide view of the literature from this country and abroad, I still maintain that the evidence so far available indicates that the incidence of manual removal of the placenta is not increased by a properly timed intravenous injection of ergometrine at the end of the second stage of labour. This conclusion is confirmed by routine use of the method in my own practice during the last ten years. The fear of imprisonment of the placenta should therefore not deter anyone from using ergometrine provided that he is working in circumstances which ensure that an expert attendant is at hand to give the injection at the right moment and to give the whole of the injection into the vein. This proviso was emphasized in the original reply, as was the fact that opinion and practice on the giving of ergometrine still vary.

THE AUTONOMIC NERVOUS SYSTEM IN ITS RELATION TO SOME FORMS OF HEART AND LUNG DISEASE***II. LUNG DISEASE**

BY

RAYMOND DALEY, M.D., F.R.C.P.*Physician to the Cardiac Department, St. Thomas's Hospital; Consulting Physician to the Chelsea Group of Hospitals*

In this lecture the significance of the autonomic nerve supply to the lung vasculature is discussed. As in my first lecture, I believe that it is appropriate to begin with a description of the anatomy. For this I am indebted to the excellent monograph by Mitchell (1956).

The lung vessels are supplied by sympathetic and parasympathetic fibres which are woven into plexuses and carry efferent and afferent fibres. The sympathetic fibres arise in the second to the fifth or sixth thoracic ganglia. They run mainly to the posterior pulmonary plexus, which lies in the posterior part of the hilar regions and also contains vagal fibres which are distributed to the vessels, bronchi, and glands of the lungs. This sympathetic supply contains afferent and efferent fibres. The preganglionic fibres are the axons of the cells in the lateral columns of grey matter. They form synapses in the corresponding sympathetic ganglia or in the stellate ganglion. The post-ganglionic fibres are the axons of the ganglionic cells. The afferent fibres have their cell stations in the dorsal root ganglia of the upper five or six thoracic spinal nerves.

Preganglionic vagal fibres arise in the dorsal vagal nuclei. Afferent vagal fibres have their cell stations in the inferior vagal ganglia. Above the lung roots each vagus nerve divides and surrounds the root, forming a large posterior and a smaller anterior plexus. Below the roots there is union with sympathetic fibres from the oesophageal plexus and with vagal fibres from the opposite side. The lung vasculature is mainly supplied via the posterior pulmonary plexus which receives direct or indirect contributions from the upper thoracic sympathetic ganglia.

The autonomic nervous supply to the various lung vessels varies greatly in its richness. It is probable that the small bronchial arteries have the best supply, the pulmonary arteries are less well supplied, and the pulmonary veins are very poorly innervated. It has been remarked by many authors how generally poor the whole pulmonary vessel innervation is, especially when compared with the autonomic supply to the systemic vasculature.

There is no marked plexus formation round the pulmonary vessels, the nerves only winding round them and giving off branches at irregular intervals. Cookson

(1953) has demonstrated frequent intercommunication by small bundles of fibres between the perivascular and peribronchial nerves, and he also showed, by special silver and methylene-blue stains, that there are comparatively few fibres around pulmonary capillaries.

Pulmonary Vasomotor Responses

Study of pulmonary vasomotor responses has been intense, producing at times definite results of great interest and at others results which are conflicting and confusing. Much of the work has been carried out on animals which are often in a most unphysiological state when anaesthetized, with bilateral thoracotomies or even as isolated heart-lung preparations. The translation of the results of such experiments to human behaviour may be most misleading. Another difficulty is the lack of appreciation of the important difference between nerve stimulation and ablation procedures. However, much fundamental knowledge has arisen from these experiments, and great credit must be given to the perfection of cardiac and pulmonary vascular catheterization by Cournand and Ranges in 1941 and the following years. It is hardly out of place to stress again the difference between the high-pressure systemic vascular system and the low-pressure pulmonary circulation with its relatively poor nervous supply. The interdependence of one circulation upon the other is becoming increasingly obvious, and stresses the importance of knowing the blood flow, pressure, heart rate, and the blood oxygen and carbon dioxide tensions before drawing firm conclusions.

The evidence which has been collected concerning these problems involves a discussion of the control of pulmonary arteriolar resistance, the control of pulmonary capillary permeability, and the effects of drugs on the pulmonary circulation. The action of various agents and procedures may be directly on the pulmonary circulation (the so-called active effect); it may be secondary to changes in the systemic circulation (the passive effect); or changes in the composition of inspired air or bronchomotor tone may influence pressure and flow in the pulmonary circulation.

Pulmonary Embolism

From time to time there have been a few reports of improvement in the condition of patients suffering from pulmonary embolism by various autonomic-nerve-blocking procedures. In the investigative field reports have covered investigations in several species of animals, in various normal and abnormal conditions. The results have been conflicting. On the one hand, Daly *et al.* (1948) in a series of scrupulous experiments in perfused lungs, has shown that stimulation of the middle cervical ganglion and the stellate and upper thoracic

*The second Goulstonian Lecture, delivered at the Royal College of Physicians of London on January 22, 1957. The first lecture was printed in last week's issue (p. 173).

sympathetic ganglia increased pulmonary arterial blood pressure by vasoconstriction. He took particular care to preserve the bronchial arterial supply, and stressed the importance and difference of his preparations from those of others. On the other hand, in intact animals and man it is generally believed that mechanical rather than autonomic factors play a far more significant part in the control of pulmonary blood flow and pulmonary arterial pressure.

Is there a Generalized Pulmonary Vasoconstriction Following Localized Pulmonary Embolism ?

Six dogs were anaesthetized. In each dog two cardiac catheters were passed, one into the main pulmonary artery, and the other into a pulmonary end-artery. Pressures were transduced by strain gauges and optically recorded on oscillograph Hathaway galvanometers. Then 20 ml. of a 1% suspension of lycopodium spores was injected into the distal catheter. Pressures were again recorded in both catheters. There was an immediate rise in main pulmonary artery pressure. When the catheter used for injection was wedged into a distal artery the rise in pulmonary artery pressure was at first believed to be due to a generalized pulmonary vasoconstriction, but on histological section lycopodium spores were seen in the lobes into which the catheter had not been placed. It was obvious that there had been a reflux past the catheter and the spores had been generally distributed through the lung.

In two dogs the above experiments were repeated, but, using positive-pressure anaesthesia, the chest was opened on the side where the catheter was wedged into an end-artery and a ligature was placed around this artery. The chest was closed and the intratracheal tube was withdrawn. *Lycopodium* spores were then injected into this catheter and normal pressures were recorded from the pulmonary artery. There is therefore no generalized vascular constriction consequent upon local embolism.

The absence of lycopodium spores in the blood leaving the lungs precluded any possibility of further arteriolar blocking by recirculation of blood. This is interesting, as the dimensions of these spores are only 27μ by 25.5μ . The discrepancy between these results and those of Prinzmetal *et al.* (1948), who found that lungs *in situ* were capable of transmitting glass beads of up to 300μ in diameter, may be related to the different surfaces of these two materials. Certainly when in a separate experiment lycopodium spores were injected into the superior mesenteric artery of a living dog and their fate in the mesentery was observed through a microscope the spores appeared to cling to the vessel walls before finally occluding arterioles.

Haemodynamics of Pulmonary Hypertension Resulting from Pulmonary Embolism and Effect of Autonomic Nerve Section

To assess the effect of nerve section three dogs were anaesthetized and a catheter was placed in the pulmonary artery. Pulmonary hypertension was produced by injection of lycopodium spores through the catheter as before. Main pulmonary artery pressures and pulmonary capillary pressures were recorded. The saphenous-artery pressure in the leg was also recorded and the cardiac output measured. At the height of the hypertension the vagus nerves which had been previously exposed in the neck were severed and all the above measurements repeated. It was therefore possible to calculate the pulmonary arteriolar resistance before and after vagotomy. Similar experiments were carried out in two other dogs, but this time the anterior nerve roots from T1 to T8, which had previously been exposed, were severed, the vagi being left intact.

A single dog was sympathectomized from T1 to T7 by a transthoracic approach in two stages a week apart. Four days after the last operation the dog was anaesthetized and catheterized, and lycopodium spores were injected into the main pulmonary artery. The main pulmonary and end-artery pressures were recorded before and after the injection.

When lycopodium spores were injected into the main pulmonary artery of dogs there was an invariable rise of pressure in the artery. After one injection the rise was not sustained, and fell to near control levels in from two to ten minutes. When the pressure in the pulmonary artery rose to above one-third of the control value, breathing usually became deeper and more rapid. The saphenous-artery pressure and the cardiac output showed no consistent response to the injection of lycopodium spores. With two exceptions the pulmonary arteriolar resistance rose.

Both vagotomy and anterior rhizotomy had no influence on pulmonary arteriolar resistance. After anterior rhizotomy the pulmonary artery pressure was a little lower than before operation. This was probably due to the time interval between injection and observation. In one dog which was injected with lycopodium spores after anterior rhizotomy the pressure again rose in the pulmonary artery.

In the sympathetomized dog injection of lycopodium spores was followed by a rise in pulmonary artery pressure from 24/12 to 50/20 mm. Hg. There was no difference in the response of this dog from the response of dogs that had not been sympathetomized.

Despite common clinical belief that a small pulmonary embolus is capable of causing a generalized pulmonary arterial constriction, it does not seem that, in the anaesthetized dog, localized lycopodium spore emboli cause such a sequence of events.

The results of these experiments are interpreted as suggesting that rises in pulmonary artery pressure following lycopodium-spore embolism are due to mechanical vascular obstruction. The degree of obstruction necessary to raise the pulmonary pressure is not clear, but multiple histological sections showed spores in the majority of large arterioles.

In this form of pulmonary hypertension produced in the animals of this series, no alteration in haemodynamics resulted from vagotomy or severance of the sympathetic efferent fibres; previous sympathectomy offered no protection against a rise in pulmonary artery pressure. Holden *et al.* (1949) produced pulmonary embolism in dogs by means of thrombi released from the iliac veins. They found that the right atrial pressure rose transiently and the systemic pressure dropped temporarily. Section of the cervical vagi, together with the sympathetic chain T1 to T4 inclusive, did not alter the pattern at all.

Mechanical blockage of pulmonary arterioles therefore causes pulmonary hypertension which is probably dependent upon the degree of blockage and is uninfluenced by the activity of known nervous pathways.

These findings are quite consistent with pulmonary embolism in man. In the absence of other heart or lung disease I have never seen a fatal pulmonary embolus which did not render ineffective more than one lung and usually about one and a half lungs; that is, an embolus which becomes impacted at the bifurcation of the main pulmonary artery. This, of course, may not be the case when pulmonary hypertension and increased pulmonary blood volume already exist. Then a comparatively small embolus can raise the pulmonary artery pressure just enough to cause acute right heart failure. The therapeutic implication is that stellate or other ganglia blockade is useless. Ganglionic blocking agents are not only useless but are also dangerous, as they lead to systemic vasodilation, and a limited cardiac output fed into a dilated systemic circuit may lead to a fatal drop in blood pressure.

Apart from defaecation associated with pulmonary embolism, which is discussed later, the only reflex mechanism involved is dyspnoea. This is mediated by the vagus. Atropine diminishes the dyspnoea and bilateral vagotomy abolishes it.

Occasionally pulmonary oedema complicates pulmonary embolism in man and animal. In the latter this occurs when the cardiac output is maintained. This normal right ventricular output then has to reach the left heart by passing

through a very limited pulmonary vascular bed. Presumably when the limit of pulmonary capillary distensibility has been reached the pressure will rise until it exceeds that of the osmotic pressure of plasma proteins and pulmonary oedema results. A comparable mechanism in man can be supposed.

Pulmonary Oedema

The mechanism of pulmonary oedema has interested clinicians for a long time. Why do pulmonary capillaries leak, either acutely or chronically? And has the autonomic nervous system any control over capillary permeability?

It is now established that in the majority of forms of pulmonary oedema transudation occurs when the blood pressure within the capillary exceeds the osmotic pressure of plasma proteins—that is, when it is above 25 to 30 mm. Hg—taking into account, of course, the usual minor pressure changes reflected from the intrapleural respiratory pressure swings. Excessive pulmonary capillary pressure accounts for the pulmonary oedema of mitral or aortic valvular lesions and left ventricular failure due to coronary artery disease or hypertension. Whether such oedema is sudden and catastrophic or chronic depends upon the thickness of tissue between the capillary and internal surface of the alveolar wall. In chronic pulmonary oedema this thickness is considerable and oedema fluid is carried away by the lymphatics, which are seen as horizontal streaks on x-ray plates. When for any reason, especially exercise, the capillary pressure rises further, cardiac asthma is more common than pulmonary oedema. When the so-called capillary alveolar gradient is as thin as normal a sudden rise in capillary pressure is likely to cause acute pulmonary oedema, and this is typically seen some hours after a myocardial infarction. Once pulmonary oedema has occurred there is alveolar anoxia and a fall in blood-oxygen saturation which leads to a further rise in capillary pressure, as is described below, and probably increases capillary permeability.

This sequence of events is comparatively easy to understand, but it has often been thought that the mechanism of pulmonary oedema complicating head injury or bulbar poliomyelitis had a different aetiology, and that nervous influences lead to increased pulmonary capillary permeability. Sarnoff and Sarnoff (1952), in a series of ingenious animal experiments, have shown that cerebral disturbances can produce pulmonary oedema by raising the pulmonary capillary pressure above that of the plasma protein osmotic pressure. They injected fibrin into the cisterna magna of dogs and found that there was a rise in systemic pressure, an increased pulmonary blood volume presumably due to systemic venous constriction, and a consequent substantial rise in pulmonary capillary pressure. Previous adequate sympathetic denervation of the lung did not prevent the oedema occurring. Ganglionic blocking agents, however, if given before the fibrin injection, prevented the onset of oedema, or, if given when oedema had already happened, promptly relieved it. They believed that blocking agents reduced systemic arterial and venous tone and hence secondarily reduced pulmonary blood volume and pulmonary capillary pressure—the inference being that blocking agents relieve pulmonary oedema indirectly by their action on the systemic circulation and that the sympathetic supply of the pulmonary capillaries does not control their permeability.

These experimental findings are compatible with clinical experience in, for example, pulmonary oedema complicating hypertension. I, like others, have found in occasional nervous hypertensive patients, when one records the blood pressure for the second and third time, that instead of a fall there is a rise in pressure. When such vasoconstriction occurs it is wise to auscultate the lung bases, when increasing crepitations will be heard and frothy sputum may be expectorated. Also, treatment of pulmonary oedema by ganglionic blocking agents can be as effective as morphine, and that is high praise for their efficacy.

Is there any form of pulmonary oedema which is not due to a rise in pulmonary capillary pressure? In human experi-

ence war gases, especially phosgene, are probably the only examples. Experimentally there is one substance which has rather remarkable properties, and I shall describe some experiments which McMillan and I carried out with it.

Richter (1952) has shown that the intraperitoneal injection of alphanaphthylthiourea (antu) is consistently followed by the production of massive pulmonary oedema and pleural effusions. He has also demonstrated in the dog that this form of pulmonary oedema is accompanied by negligible changes in pulmonary artery pressures. The present investigation was undertaken in order to find out if the production of such pulmonary oedema in the dog could be influenced by sympathetic denervation.

Twenty-four dogs were anaesthetized with pentobarbitone sodium; 14 of them acted as controls, and eight had bilateral sympathectomies from the stellate ganglion to the eighth or tenth thoracic ganglion, two to six weeks before the injection of antu. Antu in olive oil was injected intraperitoneally into all dogs, and haematocrit readings were taken every 30 minutes.

In one dog a sympathectomy from T 8 to L 2 was carried out in order to assess the effect of low sympathectomy on peritoneal absorption. In two dogs which had intraperitoneal injections of antu, four and five hours later respectively, the ganglionic blocking agent trimetaphan camphorsulphonate ("arfonad") (Sarnoff and Sarnoff 1952) was injected through a catheter into the pulmonary artery. In three the pulmonary artery pressure was repeatedly recorded during the experiment with a mercury manometer.

Of four dogs which received 50 mg. of antu per kg. after sympathectomy, three died, whereas of seven control dogs (not sympathectomized) all died after receiving the same dose of antu. Four dogs received 25 mg. of antu per kg. after sympathectomy, and all died. Similarly, four control dogs died after receiving the same dose. One control dog died after 15 mg. of antu per kg. and one survived, while one dog which received only 10 mg. per kg. survived. It seems, therefore, that the minimum lethal dose of antu is about 20 mg. per kg.

The injection of 0.5 mg. of trimetaphan into one dog with a systolic pressure of 130 mm. Hg produced a catastrophic fall in pressure in three minutes and death within fifteen minutes. In a second dog trimetaphan was used to lower the systemic pressure from 110 to 55 mm. Hg by repeated doses, and maintained there. The initial dose required to produce the fall was 0.05 mg. and the final dose to maintain it was 2.5 mg. Owing to this large increase in the amount of trimetaphan required, its use was abandoned after two hours, during which time the haematocrit had risen 8%. Two hours later the animal died. Both these dogs had gross pulmonary oedema.

In five dogs in which the pulmonary artery pressure was recorded during the development of pulmonary oedema there was no change in mean pressure while the haematocrit was rising, even in one followed through to death.

The period of survival after antu injection appeared to be independent of the dosage, provided it was above the minimum dose, and both this and the rise in haematocrit were not significantly influenced by sympathectomy.

Post-mortem examination in all dogs dying after antu injections revealed gross pulmonary oedema confirmed by microscopy, and bilateral pleural effusions.

As the pulmonary artery pressure does not rise in this form of acute pulmonary oedema it is assumed that the pulmonary capillary pressure does not exceed the osmotic pressure of plasma proteins. Hence pulmonary oedema produced by antu is due to increased capillary permeability, and Richter (1952) has found such oedema fluid to have the composition of plasma.

In these experiments it has been confirmed that ablation of the pulmonary autonomic supply does not affect pulmonary oedema due to increased capillary permeability, nor certainly in two dogs did the ganglionic blocking agent trimetaphan influence the oedema. Therefore it must be

concluded that in no form of pulmonary oedema yet investigated does the pulmonary autonomic supply play a direct part.

Action of Drugs on the Pulmonary Circulation

A number of drugs have been stated to have a direct action on the pulmonary vascular resistance, and some have been used in attempts to lower pulmonary vascular resistance in the hope that they might prove beneficial in such conditions as primary pulmonary hypertension. With the object of assessing whether any drug had a direct effect on the pulmonary arterioles McMillan and I have again conducted a series of animal experiments. The technical procedure was the same in them all. Two cardiac catheters were passed via the jugular veins into the pulmonary artery. The first was used for injection of the drug and the second for measuring continuous pressures. A needle was inserted into each saphenous artery—one for drug injection and the other for measuring systemic pressure. The electrocardiogram was recorded continuously.

Injection of 5 minims (0.3 ml.) of 1 in 1,000 adrenaline solution into the pulmonary artery caused a rise of pulmonary artery pressure of about 10 mm. Hg between seven and eight beats after its introduction. There was also speeding of the heart rate at this time.

Injection of 5 mg. of noradrenaline into the pulmonary artery caused a rise in pulmonary artery pressure and slowing of the heart rate also after seven to eight beats.

Injection of 2 mg. of acetylcholine into the pulmonary artery caused asystole and consequent considerable lowering of pulmonary artery pressure, again after seven or eight beats. Why the pressure did not fall to zero is an interesting matter, for the electrocardiogram showed no myocardial electrical activity. It is thought that this continued evidence of pulsatile flow in the pulmonary artery is due to the pumping action of the lungs; for all this time the apex beat was palpable and it is inconceivable that myocardial contraction could be present with absent electrical activity.

The same dose of acetylcholine, when injected into a femoral artery, caused asystole in 21 to 23 beats.

These facts are interpreted as meaning that none of these drugs have any effect on the normal pulmonary circulation and that the effect is purely secondary and dependent upon their entry at least into the aortic root. The considerable delay in noticeable action of acetylcholine when injected into the saphenous artery suggests that its arrival in the coronary artery is necessary for asystole to occur.

Another drug used in the same way was "dibenyline" (N-phenoxyisopropyl-N-benzyloxyethylamine). It is described as an "adrenomotor antagonist," and is regarded as acting against the motor effects of circulating adrenaline, noradrenaline, 5-hydroxytryptamine, and most sympathomimetic amines. It does not interfere with ganglionic transmission or prevent the liberation of peripheral transmitter substances. As it is widely used in the treatment of peripheral vascular disease and the control of hypertension in phaeochromocytoma, the study of its action on the pulmonary circulation appeared to be of interest. When injected into the pulmonary or femoral artery even in doses up to 20 mg., it had no effect on pressure pulses. However, a dose as small as 2 mg., when injected into the pulmonary artery in the same syringe as adrenaline or noradrenaline, completely abolished their hypertensive responses. As might have been expected, it was quite ineffectual against acetylcholine. Dibenyline therefore lived up to its reputation as an effective blockade against adrenaline and noradrenaline.

In order to see if acetylcholine or dibenyline might be of any therapeutic use in pulmonary embolism, talc powder was injected into the pulmonary artery, and when the expected rise in pulmonary artery pressure occurred each drug, in separate experiments, was introduced into the pulmonary catheter. Acetylcholine produced the usual fall in pulmonary artery pressure after seven beats when asystole had occurred, but otherwise was without effect. Small and large

doses of dibenyline also were ineffectual in altering the induced pulmonary hypertension.

These observations are naturally very unfortunate when one is trying to discover some useful therapy for pulmonary embolism, but they do agree with the lack of evidence for mass pulmonary arteriolar vasoconstriction consequent upon pulmonary embolism, and suggest that the advent of a pulmonary embolus does not cause excessive liberation of adrenaline or noradrenaline. They do not, of course, contradict Wood's (1956) work on the effect of small doses of acetylcholine injected through a cardiac catheter on the pulmonary arteriolar resistance of patients suffering from mitral stenosis. He is considering increased arteriolar resistance in left heart valvular lesions. I am considering experimental pulmonary embolism.

Harris *et al.* (1956), working in Courmand's laboratory, infused acetylcholine into the main pulmonary artery of man and observed that it caused a slight fall in pulmonary arterial pressure when the subject breathed ambient air but a greater fall in pressure after pulmonary hypertension had been produced by hypoxia. The fall in pressure was associated with either a constant or an increased cardiac output. There was no alteration in the heart rate, the brachial artery pressure, the arterial saturation, or the ventilation. This is taken as evidence that acetylcholine causes vasodilatation in the lungs and that this action is largely dependent upon the pre-existing tone of the pulmonary vessels. It is a most difficult experiment to understand, and after studying his diagram there is considerable delay between the giving of the acetylcholine and the measurement of its response. To give sufficient acetylcholine to alter pulmonary arteriolar resistance without altering the heart rate is a possibility I find very hard to comprehend.

An interesting side-effect of producing experimental pulmonary embolism is that the dogs usually defaecate as the pulmonary artery pressure is rising. I have often wondered about the "call for the bedpan" story which is so often said to precede by a few seconds the arrival of the embolus, and have conjectured upon some message from above that the embolus was on its way. It must be that it has occurred by the time the bedpan is demanded and is a vagal reaction unconnected with the non-release of sympathetico-mimetic drugs and uninhibited by dibenyline.

The results of investigating the effect of ganglionic blocking agents on the pulmonary circulation have been somewhat equivocal. Storstein (personal communication, 1956) reported his results, using hexamethonium bromide, in 14 patients suffering from various forms of heart disease. He found a statistically significant decrease in cardiac output, systemic blood pressure, and pulmonary artery and pulmonary capillary pressures, while there was no significant change in heart rate or resistances in the systemic and pulmonary circulation. The pressure fall was roughly parallel in the systemic artery, the pulmonary artery, and the pulmonary capillary. He interpreted the pressure fall in the pulmonary circulation to be due to a dilatation of the systemic blood vessels with consequent pooling of blood and reduction of the venous return. In our own experiments in dogs injection of the ganglionic blocking agent trimetaphan into the pulmonary artery did not lower pulmonary artery pressure until it had reduced the systemic pressure. When trimetaphan was injected simultaneously with a pulmonary embolizing material the drop in systemic pressure was greater than if it had not been given, and the induced pulmonary hypertension was unaltered.

The action of ganglionic blocking agents has been investigated by several workers in mitral stenosis, and one of the most complete of these investigations is by Davies *et al.* (1954). As already mentioned, the increased pulmonary arteriolar resistance in mitral stenosis is not comparable to the increased resistance in many other conditions in which there is obstruction in either the lumen or the wall of the vessel. Certainly in many patients suffering from mitral stenosis there are structural proliferative lesions of the pulmonary arterioles, but the dramatic fall in resistance after successful valvotomy indicates an altering functional state.

Davies *et al.* administered hexamethonium via cardiac catheter placed in the pulmonary artery to 12 patients with mitral stenosis and found it produced a sharp fall in pulmonary arterial pressure without a fall in cardiac output. They believed that such a reduction of total pulmonary vascular resistance was probably, although not certainly, due to arteriolar dilatation consequent upon autonomic blockade. They write that they were careful to gauge the dose of hexamethonium so that the drop in systemic pressure was not too profound. Their argument of a primary action of this drug on pulmonary vascular resistance is good but not convincing, because the main fall in pulmonary artery pressure was systolic and in some patients the cardiac output and rate were changing. It is not quite enough to believe that because the change in pulmonary artery pressure is more profound than in the systemic the action of the drug must be on the pulmonary circuit. There are, of course, several drugs which will lower the pulmonary and systemic arterial pressures in patients with mitral stenosis as well as in normal people. An example of this is chlorpromazine. In these types of reaction a shift of blood from the lungs to the periphery may occur. However, the uncertainty of the site of action of these drugs does not detract from their value in lessening the dyspnoea of some patients suffering from mitral stenosis with high pulmonary artery pressure.

Other experiments relevant to this discussion have been carried out with ganglionic blocking agents in patients not suffering from mitral stenosis. Gilmore *et al.* (1952) showed (although hardly conclusively) that in patients with systemic hypertension hexamethonium prevented the normal pulmonary vasoconstriction which occurs on assuming the upright position. Greene and Bunnell (1950) produced a fall in net pulmonary arterial pressure in man following continuous intravenous infusion of tetraethylammonium chloride and thought that the accompanying fall in cardiac output did not fully account for the fall in pulmonary arterial pressure. They also showed that tetraethylammonium chloride abolished the "overshoot" in the pulmonary artery at the end of a Valsalva manoeuvre. They concluded that these results indicated the presence of reflex pulmonary activity. Lee *et al.* (1954) not only were unable to confirm the abolition of the pulmonary artery "overshoot" but also employed the Valsalva manoeuvre to demonstrate the absence of any striking reflex vasomotor changes in the pulmonary arterial system.

At the end of the "blow" in the Valsalva manoeuvre the systemic pressure rises and there is a simultaneous rise in venous net pulmonary arterial pressure due to an increase in venous return. There are almost identical changes in the net pulmonary capillary pressure. It is thought that the rapid increase in right ventricular filling pressure following the Valsalva manoeuvre causes a rapid increase in stroke output and hence a rise in pulmonary artery pressure. In the experiments of Lee *et al.* there was no rise in pulmonary artery pressure independent of pulmonary capillary pressure. As they say: "This strongly suggests that no pulmonary capillary constriction has taken place, and there is further evidence to the same effect when the pulmonary and brachial arterial tracings obtained during the prolonged Valsalva manoeuvre are compared. During this period venous return is restricted and stroke output reduced; reflex vasoconstriction occurs in the systemic arterial system, indicated by a rise in mean pressure, and later Traube waves appear. These indications of alteration in vasomotor tone do not occur in the pulmonary arterial pressure."

Use of Drugs in Primary Pulmonary Hypertension

Wade and Ball (1956) believe that there are at least three mechanisms operating in different patients classified as suffering from primary pulmonary hypertension: (1) functional narrowing of muscular vessels with or without thrombotic occlusions; (2) primary pulmonary arteritis; and (3) bronchial and pulmonary communications through abnormal persistent ductus arteriosus. I have also seen a young woman

patient who died of right heart failure due to pulmonary hypertension but with histologically normal pulmonary arterioles, somewhat analogous to the early stages of essential systemic hypertension. This case is important because it suggests severe functional arteriolar constriction. Unfortunately, ganglionic blocking agents were not available when the patient was alive. However, hexamethonium bromide has been used in a number of cases of primary pulmonary hypertension. Wade and Ball report no relief. When I have used it the systemic vasoconstriction was released and the low fixed cardiac output was frequently inadequate to perfuse the brain, causing most troublesome effort syncope. One of my patients explained, "I do feel a great deal better just before the next injection is due." She actually had attacks of blindness on effort with extreme retinal blanching. This, of course, is what one would expect in view of the failure of the drug to lower pulmonary artery pressure in experimental pulmonary embolism.

The results of operative autonomic denervation are unfortunately conflicting. One author saw no effect of thoracic sympathectomy and plexotomy in a child with this disease, whereas another denervated the left lung in a man with primary pulmonary hypertension and reported that the pulmonary artery pressure became normal in a following three-year observation period.

Wade and Ball also state that in one patient pulmonary hindrance was apparently reduced by tolazoline hydrochloride (prisol). This has not been my experience in one patient whom I recatheterized while on tolazoline hydrochloride. In dogs tolazoline hydrochloride is not active in the pulmonary circulation either when normal or with pulmonary hypertension due to embolism.

Of the numerous other drugs which have been used for primary pulmonary hypertension none has been effective so far as I am aware.

The evidence, therefore, for a primary action of any drug on the pulmonary circulation is extremely slender, and I personally remain unconvinced that there is any such action. The therapeutic implications are negligible.

Hypoxic Reaction

Von Euler and Liljestrand demonstrated in 1946 that anoxia induces a pressure rise in the pulmonary artery of a cat. Since then similar observations have been made on normal man (Westcott *et al.*, 1951; Doyle *et al.*, 1952). In most normal subjects, when hypoxia is produced by breathing low concentrations of oxygen the pulmonary artery pressure rises significantly, the cardiac output increases or does not change, the heart rate increases, and the pulmonary "capillary" pressure remains the same. Thus total pulmonary and pulmonary vascular resistance increases. The systemic artery pressure and peripheral vascular resistance vary in response. They may rise or fall. Storstein (personal communication, 1956) stated that in most investigations with experimental anoxia there is at the same time an increase in blood flow and pulmonary artery pressure, but that there are some patients showing at the same time a fall in cardiac output and a rise in pulmonary artery pressure. He thinks that this finding is in favour of a direct vasomotor action on the pulmonary blood vessels consequent upon changes in oxygen concentration of inspired air. Yu *et al.* (1956) have found the same type of response in patients suffering from mitral stenosis with an already high pulmonary vascular resistance when breathing low oxygen began. In most instances the resistance rose.

In patients with chronic pulmonary disease the hypoxic reaction is much less marked (Fishman *et al.*, 1952). The difference in response may be due to acclimatization of such patients to chronic hypoxia, insensitivity of chronically hypoxic oxygen receptors, or the fact that maximal vasoconstriction has already occurred with chronic hypoxia and a further acute response is impossible. It is of interest in this connection that I am told that in the hills of Mexico pulmonary hypertension in association with persistent ductus arteriosus is commonplace. Ligation of such so-called high-pressure

ductuses is not the disastrous procedure that it usually is in this country. It may be that the rarefied atmosphere of Mexico produces a functional pulmonary vasoconstriction and that by the time operation is considered in Great Britain structural narrowing has already occurred in the pulmonary arterioles.

Why does hypoxia lead to an increase in pulmonary vascular resistance? Doyle *et al.* (1952) favour the idea that hypoxia has a direct effect on precapillary pulmonary vessels as a result of low oxygen tension in mixed venous blood. On the contrary, Yu *et al.* (1956) found in their mitral stenotic patients that the reduction in oxygen saturation of arterial and mixed venous blood was not statistically related to the magnitude per cent. changes in pulmonary flow, pressures, or resistances. Fishman *et al.* (1952) suggest that acute bilateral hypoxia may cause a shift of blood into the lungs because of peripheral vasoconstriction. This suggestion is based on their experiments in which they administered 10% or 12% oxygen to one lung of patients suffering from minimal pulmonary disease. To the other lung they administered 25% to 30% oxygen in nitrogen, which prevented marked anoxia of arterial or mixed venous blood. There was no rise in pulmonary artery pressure or shift of blood from the anoxic to the hyperoxic lung, indicating that local alveolar anoxia does not cause pulmonary vasoconstriction when arterial and venous oxygen saturation is maintained.

Helen Duke (1954) showed that inhalation of gas mixtures containing 5% to 10% oxygen in nitrogen instead of atmospheric air caused a rise in left pulmonary arterial pressure in the living animal during perfusion of the left lung at constant volume inflow with blood from the right auricle. The response was not dependent upon changes in left auricular pressure, tidal air, or systemic blood pressure. It was found that it was similar in duration and latency to that occurring in isolated lungs perfused at constant volume inflow. She states:

"The tests on cross-perfused and back-perfused isolated lungs were carried out to help identify the vessels which respond to anoxia. It has already been found (Duke, 1951) that ventilation of isolated lungs with nitrogen to produce an approximately 60% oxygen saturation of the pulmonary arterial and venous blood causes a rise of pulmonary arterial pressure. The present experiments show that, in lungs ventilated with air, perfusion through the artery with blood which is approximately 60% saturated with oxygen does not cause a pulmonary arterial pressor response, but that ventilation of the lungs with nitrogen during perfusion with partially deoxygenated blood does produce an increase of pulmonary arterial pressure. Provided gas exchange only takes place in the alveolar capillaries, these findings would indicate that the site in the pulmonary vascular bed sensitive to oxygen lack is in the capillaries or veins. When perfusion was made through the vein and the lungs were ventilated with nitrogen a pulmonary arterial pressor response occurred which was very similar to that obtained during perfusion of the lungs through the artery. It would therefore appear that the alveolar capillaries are the site sensitive to anoxia."

I have repeatedly produced a rise in pulmonary pressure in anaesthetized dogs when they are breathing 10% oxygen in nitrogen. The pressure begins to rise in about one minute and continues until normal ventilation is introduced. There is usually no change in systemic pressure. This reaction is not due to carbon dioxide retention, because it occurs in exactly the same way whether or not there is a carbon dioxide absorber in the circuit. Also, breathing 5% carbon dioxide for one and a half minutes does not have any appreciable effect on the pulmonary artery, pulmonary capillary, or femoral artery pressure. There appears to be a direct correlation between the rise in pulmonary artery pressure and the fall in the oxygen saturation of mixed venous blood. In order to decide whether or not this was a reflex pressure rise, trimetaphan was infused into the pulmonary artery by a cardiac catheter during the inhalation of 10% oxygen. Pulmonary hypertension developed just as before. There was, of course, a precipitous fall in systemic arterial pressure. Thus pulmonary hypertension due to breathing 10% oxygen is a direct response of the pulmonary

vasculature probably due to a falling venous oxygen saturation and not to a nervous reflex mechanism.

Clinically it is my impression that right ventricular failure due to pulmonary hypertension in emphysema is related more to arterial and venous oxygen unsaturation than to other measurable change such as arterial carbon dioxide tension. There are occasional contrasting emphysematous patients in one of whom carbon dioxide retention with venous dilatation and papilloedema is marked, whereas in the other hypoxia and right ventricular failure predominate.

In mitral stenosis there is good correlation between the height of the pulmonary arteriolar resistance and the fall in the oxygen saturation of mixed venous blood (Holling and Venner, 1956).

In atrial septal defect, once reversal of the shunt has occurred, there is arterial oxygen unsaturation, and with normal oxygen extraction by the tissues there is a decrease in venous oxygen saturation. It is therefore hardly surprising that pulmonary hypertension is a progressive disability. The production of an atrial septal defect in dogs is usually accompanied by an initial small right-to-left shunt. This is followed by pulmonary hypertension, which may become marked. Closure of the defect relieves the hypertension.

These facts have considerable therapeutic implication. In cor pulmonale due to emphysema, treatment with thiouracil will reduce tissue oxygen consumption and hence cause a rise in oxygen content of mixed venous blood. This should progressively reduce pulmonary hypertension.

In atrial septal defect once pulmonary hypertension is initiated it is likely to be progressive, and early operation should probably be advised. Experiments are now proceeding in order to try to see if the introduction of better-oxygenated blood into the right heart may lower pulmonary arteriolar resistance and reduce right ventricular work.

Bronchomotor Tone

Rodbard (1953) suggests that changes in bronchomotor tone may influence blood pressure and flow relationships in the pulmonary circulation. Vagal stimulation, by decreasing the calibre of bronchi, reduces the alveolar capillary surface and causes increased resistance to the passage of blood. Sympathetic stimulation has the opposite effect. This idea is attractive and might explain the mechanism whereby blood is shunted away from collapsed and consolidated areas of lung. It would, of course, also explain in part the pulmonary hypertension of asthma.

Summary

I hope that I have shown that pulmonary embolism is unaccompanied by generalized pulmonary vasoconstriction; that clinical pulmonary oedema is a secondary phenomenon to changes in the systemic circulation, albeit facilitated by pre-existing disturbed pulmonary haemodynamics; that the hypoxic reaction is a direct response of the smaller vessels of the pulmonary circulation to blood unsaturated with oxygen; and that drugs known to influence the autonomic nervous system play little part in the vascular economic adjustments of the lungs.

I began by saying that the lung vasculature was poorly endowed with sympathetic and parasympathetic nervous supply and have ended by concluding that the function of even this small supply is far from clear. The lesser circulation appears to have been well named, and I can only hope that my successors will raise the status of a much-investigated and highly controversial field of endeavour.

My thanks are due to Mr. I. K. R. McMillan, who has done so much of this work, and especially for his surgical skill, which was essential; to Dr. W. Boake, who produced many ideas; to Miss Stewart and Mr. Schofield, our technicians, who have made such experiments possible; and to Miss Fairbrace, my secretary, for her kind organization.

PROLONGED ANTIBIOTIC TREATMENT OF SEVERE BRONCHIECTASIS

A REPORT BY A SUBCOMMITTEE* OF THE
ANTIBIOTICS CLINICAL TRIALS (NON-
TUBERCULOUS) COMMITTEE OF THE MEDICAL
RESEARCH COUNCIL

Experience with penicillin and later with other antibiotics has shown that these drugs are effective in the treatment of many acute respiratory infections. The management of chronic bronchial infections, particularly in patients with bronchiectasis, has proved more difficult. Although an initial response may be obtained in individual patients, especially during acute episodes, cessation of treatment is usually followed by an early relapse and the re-establishment of infection.

The therapeutic trial reported in detail below was designed to study the effect of prolonged antibiotic therapy in severe cases of bronchiectasis characterized by abundant purulent or mucopurulent sputum. Since the study was concerned with long-term therapy, patients were treated entirely at home unless some intercurrent infection necessitated admission to hospital. Patients were accepted only if they were able to attend regularly at a special out-patient clinic. As will be seen, the criteria of severity were stringent, and it was surprising how few patients satisfied them.

Since the patient assesses his illness in terms of general health, the amount and character of sputum, and his ability to work and enjoy a full life, the observations

*The members of the subcommittee were: Dr. J. G. Scadding (chairman), Professor J. W. Crofton, Drs. T. Anderson, A. C. C. Hughes, J. Knowelden, A. G. Ogilvie, W. S. Sutton, M. Telling, K. Zinneman, and C. S. Darke (secretary).
The present report was prepared for the subcommittee by Dr. C. S. Darke and Dr. J. Knowelden.

recorded at each attendance were designed to evaluate these criteria. Because of the normal fluctuation in the symptoms of this disease with the change of season, patients were observed over a consecutive period of 52 weeks whilst they received the appropriate drug under a uniform scheme.

The difficulties inherent in a trial of this character will be appreciated, not least of them being the subjective improvement which might be expected when more intense interest is shown. This difficulty was met by introducing a control medicament, lactose, and making the trial a "blind" one in which neither the clinician nor the patient knew which drug was being given. The nature of the trial was explained to the patients beforehand, and all were volunteers. The results of the study, which have been analysed in the various tables, are an attempt to obtain an objective assessment of a number of symptoms and signs common to most patients with infected bronchiectasis.

Plan of Trial

The trial was conducted on out-patients at seven centres—Chester, Edinburgh, Glasgow, Leeds, Liverpool, Newcastle, and Sheffield. Patients had to be between 15 and 55 years of age and to have had symptoms for at least three months. It was required that the bronchogram should show frank bronchiectasis affecting at least two lung segments. Before admission to the trial the patient had to be observed on four visits at weekly intervals, on each occasion bringing a 24-hour specimen of sputum; the total quantity of the four specimens, which had to be either purulent or mucopurulent, had to be at least 150 ml., and the last had to measure at least 25 ml. Patients with tuberculosis were excluded. Patients who had been receiving antibiotics or sulphonamides could be admitted only after a period of at least a month without such treatment.

During the pre-treatment period of four weeks observations were made on cough, haemoptysis, dyspnoea, and disability, as well as on sputum measurement. A postero-anterior film of the chest was taken. On the fourth visit the weight, haemoglobin, red-cell count, and degree of clubbing were recorded and the patient's general condition was assessed. If he satisfied the criteria for admission he was allocated at random, according to a centrally held list, to one of the three treatment groups—penicillin, oxytetracycline, or lactose. The drugs were provided in 0.25-g. capsules which were indistinguishable, and the supply for each patient was issued in bottles which were identified only by the patient's allocation number. As the allocation and supply of drugs was controlled centrally neither the patient nor his physician was aware of the treatment given. The patients were instructed to take two capsules four times a day on two days a week—for example, on Wednesday and Saturday—making a total dose of 2 g. each day or 4 g. a week.

Treatment was continued for a year, and during this time regular visits were made to the out-patient department, at first weekly for a month and thereafter at four-weekly intervals. On each attendance the patient brought a 24-hour specimen of sputum, and observations on the severity of cough, dyspnoea, haemoptysis, and disability were made as on the pre-treatment visits. At the completion of one year's treatment additional observations were made on clubbing, weight, general assessment of progress, and the patient's own assessment of his response to treatment. During the year's treatment it was provided that any acute episode might be treated according to the discretion of the clinician, including, if necessary, penicillin by injection or other antibiotics. All such additional treatment was to be recorded. Provision was made for the routine reporting of any presumed toxic reactions to treatment. In all groups treatment by postural drainage was conducted in accordance with the practice of the physicians in clinical charge of individual patients.

Initial Comparability of Treatment Groups

Between January, 1953, and March, 1954, 122 patients were admitted to the trial. Of these, 38 were allocated to penicillin, 44 to oxytetracycline, and 40 to lactose. The age and sex distribution of the groups were comparable. In each the male patients formed a majority, 58% of the penicillin group, 70% of the oxytetracycline, and 60% of the lactose. The average ages of the patients in these treatment groups were 34.3, 32.3, and 32.6 years respectively, and rather more than 50% of those allocated to each treatment were in the 15-34 year age group. No patient had had symptoms for less than two years, the average duration being about 20 years for each group.

Table I compares various characteristics of the three treatment groups such as their past medical history, and shows that in most respects they were alike initially. The largest

number of patients were admitted in the months of January to March, as the winter months of both years, 1953 and 1954, contributed to the total number. Nearly half the patients in each group had the first symptoms of their disease earlier than the fifth birthday. On the average the bronchograms showed eight to nine segments involved, principally with both cystic and cylindrical types. About 40% showed no collapse in any segment, while complete collapse of at least one segment was present in about 20%. Few patients had had asthma or empyema, but nearly 70% had had bronchitis, while pneumonia and pleurisy were common. About three-quarters had some degree of haemoptysis, but principally streaks only. About a half showed some degree of clubbing.

Results

Deaths.—During the year's treatment three patients died, one in each treatment group. The patient given penicillin, a woman aged 54, completed 42 weeks' treatment, defaulted,

and on inquiry was found to have died in another hospital six weeks later. No necropsy was performed and the cause of death was given as coronary artery disease, the pulmonary condition being unmentioned. A boy aged 15 had shown signs of slight improvement when last seen after eight weeks' treatment with oxytetracycline. He died suddenly while waiting in a bus queue a week later, and the cause of death confirmed by necropsy was cor pulmonale. The fatality in the lactose group occurred in a man aged 26, who had attended only two weeks from the start of treatment. He became suddenly ill and died of "pneumonia" in a few days. He had not been admitted to hospital and there was no necropsy.

Defaulters.—Four patients defaulted, two on oxytetracycline and two on lactose, before six months' treatment had been completed.

Unable to Continue Treatment.—Two patients complained that they could not take the treatment allocated, one being given penicillin and the other oxytetracycline. The former had a history of duodenal ulcer and stopped treatment after only 12 capsules of penicillin, which he said caused severe burning pain. The other complained of vomiting one hour after taking the capsules and stopped treatment after 16 weeks.

Change in Diagnosis.—One patient aged 15 originally allocated to lactose continued to receive treatment for 44 weeks and was then taken out of the trial and treated with oxytetracycline for an intercurrent illness. She improved temporarily, but died three months later (more than 12 months after starting treatment in the trial), and at necropsy was found to have fibrocystic disease of the pancreas.

All the 10 patients listed above—two from the penicillin group and four each from the oxytetracycline and lactose groups—were excluded from the remaining analysis, which is therefore confined to 112 patients (36 on penicillin, 40 on oxytetracycline, and 36 on lactose).

In addition to the four defaulters excluded from the remaining analysis, one penicillin patient defaulted at the 36th week of treatment, and one on oxytetracycline was taken off the trial at the 44th week suffering from an intercurrent illness. The observations on these two patients up to these dates have been included in the analysis. Sulphonamides or antibiotics, other than the trial capsules, were administered for a pulmonary condition to six patients in the penicillin group, to three in the oxytetracycline group, and to five in the lactose group. Nearly all this additional treatment was given by general practitioners, and since these patients remained in the trial they have been included in the analysis.

In the analysis of the observations made routinely on each visit, the four pre-treatment readings have been taken as one group. The observations in the treatment period have also been amalgamated in four groups of four consecutive readings each: (a) weeks 1, 2, 3, and 4; (b) weeks 8, 12, 16, and 20; (c) weeks 24, 28, 32, and 36; and (d) weeks 40, 44, 48, and 52 from the start of treatment.

Sputum

At each visit the patient brought in a flask specially provided a specimen of all sputum coughed up in the previous 24 hours (8 a.m. to 8 a.m.). The odour was noted, and recorded as "foul" or "not foul." The flask was then kept for 72 hours, by which time separation into layers of mucus and pus had usually taken place. The total volume, and that of each fraction, were then recorded. In some specimens separation was incomplete. These have been excluded from the averages of total volumes. Table II shows the average weekly volumes in the pre-treatment and treatment periods for each treatment group, and in the second part expresses the volumes at different parts of the treatment period as percentages of the average of the four pre-treatment readings.

Initially the average 24-hour specimen had a total volume of 96.7 ml. in the penicillin group, 76.7 ml. in the oxytetra-

TABLE II.—Average 24-Hour Sputum Measured (a) by Volume in ml. and (b) as Percentage of Pre-treatment Volume

	{ Total	100	89	84	79	76

cycline group, and 104.4 ml. in the lactose group. In each the mucus fraction was about 55% of the total. In the penicillin group the total volume fell to 89% of its original level in weeks 1-4 after starting treatment, to 74% in weeks 8-20, to 70% in weeks 24-36, and was again 74% in the final weeks (40-52). The oxytetracycline group experienced a greater relative decline in total volume, and this was seen early in treatment, the proportions in the successive periods being 66, 54, 57, and 64% of the initial level. The corresponding proportions in the lactose group, 89, 84, 79, and 76% show less change from the initial level than the other treatment groups, especially in the earlier part of the trial. In the oxytetracycline group in particular the greatest change took place in the pus fraction of the sputum, which rapidly reached and stayed at about 50% of its original volume, but, unlike the other two groups, there was little evidence of further improvement beyond the 8-20 weeks after starting treatment.

In the pre-treatment period the proportion of specimens recorded as "foul" was 29% in the penicillin, 23% in the oxytetracycline, and 37% in the lactose group. In each group these proportions fell during the year, the foul specimens forming 8, 6, and 15% of those submitted in the final four visits. This fall was gradual in the penicillin and lactose groups, but immediate in the oxytetracycline group, where in the first four weeks of treatment only 6% of specimens were foul, compared with 24% in the penicillin group and 32% in the lactose group.

Cough

At each visit the cough was graded, according to the patient's statement, as 0="none" 1="morning only"; 2="more than 1 and less than 3"; and 3="night and day." Table III shows the proportions of readings in each day, falling into these four grades. The initial distribu-

TABLE III.—Percentage of Patients Exhibiting Cough of Grade 0 to 3*

	Grade	Pre-treatment (Weeks 1-4)	Treatment Period (Weeks from Start)

	3	37	24	23	24	29

* For definitions of grades see text.

tion of grades in the three groups was not closely alike, but in each during treatment there was a subjective improvement in this symptom with a reduction in the proportion with grade 3 and slight increase in the proportion with no cough. The grading was difficult to apply, but "night and day" cough, a great disturbance to the patient, was considered to be better defined than grades 1 and 2. In the penicillin group the initial proportion of 40% with this most severe grade fell to about 20% during treatment. In the oxytetracycline group the initial proportion of 34% fell more strikingly to about 10%, while in the lactose group there was relatively less change from an initial proportion of 37% to about 25%.

Haemoptysis

The occurrence of episodes of haemoptysis since the previous visit was recorded as "none," "streaks," "clots," or "frank." At some time in the treatment period 25 (69%) of the 36 patients on penicillin reported one or more episodes of haemoptysis compared with 16 (40%) of the 40 patients on oxytetracycline and 22 (61%) of the 36 on lactose (Table IV). In each treatment group the

TABLE IV.—Haemoptysis—Number of Patients with Haemoptysis in Treatment Period

	Penicillin	Oxytetracycline	Lactose
One episode only ..	12	12	4
Two or more episodes ..	13	4	18
No haemoptysis ..	11	24	14
Total ..	36	40	36

majority of these episodes were streaks, and frank haemoptysis was rare. About half the patients treated with penicillin who reported haemoptysis had only one episode during the year. Single episodes formed the majority of those reported by the oxytetracycline group, while repeated episodes were the commonest among lactose-treated patients.

Dyspnoea

Dyspnoea at the time of each examination was recorded in five grades (Table V): (1) patient does not become more breathless than other men/women of his/her own age and build at work or walking, and on climbing hills and stairs; (2) patient is able to walk with normal men/women of his/her own age and build on the level but is unable to keep up on hills or stairs; (3) patient is unable to keep up with normal men/women on the level, but is able to walk a mile or more at his/her own speed; (4) patient is unable to walk more than about 50 yards on the level without a rest; and (5) patient is breathless on talking or undressing, or unable to leave his/her house because of breathlessness. Initially about a quarter of each group were in grade 1, about the same in grade 2, about 40% in grade 3, and a small proportion in grade 4. No patient was initially so breathless as grade 5, and on only one occasion subsequently did a patient on penicillin have this degree of dyspnoea. In each treatment group there was some improvement with a shift down the scale of grading, but no clear difference emerged between the treatments. Table V summarizes this pattern by showing the proportion of patients in grades 1 and 2 combined and in grades 3, 4, and 5 combined in each of the four consecutive readings.

TABLE V.—Percentage of Patients Exhibiting Dyspnoea of Grades 1 and 2, or 3, 4, and 5

	Grade	Pre-treatment (Weeks 1-4)	Treatment Period (Weeks from Start)			
			1-4	8-20	24-36	40-52

	3+	41	38	35	35	32

Disability Since Last Visit

At each visit episodes of known fever, the number of days confined to bed, and the number of days off work due to a respiratory illness since the previous attendance were recorded (Table VI). During treatment the penicillin

TABLE VI.—Disability as Measured by (a) Episodes of Known Fever, (b) Days Confined to Bed, and (c) Days Off Work

	Pre-treatment (Weeks 1-4)	Treatment Period (Weeks from Start)			
		1-4	8-20	24-36	40-52
Episodes of known fever:					
Penicillin (36 patients)	3	1	4	7	13
Oxytetracycline (40 patients)	4	5	6	9	8
Lactose (36 patients)	1	1	6	12	17
Days confined to bed:					
Penicillin	16	6	89	107	179
Oxytetracycline	14	7	20	57	34
Lactose	3	5	88	153	200
Days off work and proportion of time off work:					
Penicillin	246 (24%)	240 (24%)	813 (20%)	818 (20%)	796 (21%)
Oxytetracycline	273 (24%)	247 (23%)	619 (14%)	605 (14%)	793 (19%)
Lactose	241 (24%)	224 (22%)	1,033 (26%)	1,021 (25%)	981 (25%)

group reported 25 episodes, the oxytetracycline group 28, and the lactose group 36. The total number of days confined to bed were 381 for the penicillin, 118 for the oxytetracycline, and 446 for the lactose group. On the average, therefore, the patients in the three groups spent 2.95, 0.84, and 3.45% respectively of the treatment year confined to bed. The total days off work were 2,667 for those given penicillin, 2,264 for those given oxytetracycline, and 3,259 for those given lactose—that is, they spent 20.7, 16.1, and 25.0% respectively of the year off work. Much of this time off work was contributed by patients who were not at work for the whole of their time in the trial. If these are excluded the total days off work become 477, 804, and 1,069 for penicillin, oxytetracycline, and lactose groups respectively, with corresponding proportions of 3.7, 5.7, and 8.2% of the total time.

This result gives a less favourable picture for oxytetracycline, as fewer patients were excluded from this group because they did not work at any time in the year than from the two other treatment groups. However, this difference may be due to the oxytetracycline-treated patients not previously at work having a better chance of improving sufficiently to take up a job during the year. This is suggested by the fact that there were eight patients in the penicillin group, nine in the oxytetracycline group, and eight in the lactose group who did not work at all in the pre-treatment period. Subsequently five oxytetracycline-treated patients returned to work at some time in the year compared with only two in each of the other treatment groups.

Final Assessment

At the final visit, apart from the routine measurements, records were made of the weight, the degree of clubbing, and of the patient's and the physician's assessments of response to treatment. In each treatment group more patients gained than lost weight over the year, the corresponding average gain per patient being 0.76 lb. (348 g.) for penicillin, 3.38 lb. (1,533 g.) for oxytetracycline, and 0.63 lb. (286 g.) for lactose. Estimates of the degree of clubbing changed very little in any group.

Most of the patients thought they had improved during the year—78% of those given penicillin, 78% of the oxytetracycline group, and 61% of the lactose group. Nearly all the remainder considered they had not changed, only four patients—three given penicillin and one given oxytetracycline—saying they were worse at the end of the year. The physician's assessments were more conservative, record-

ing 42% of the penicillin, 60% of the oxytetracycline, and 28% of the lactose group as improved, though much of the improvement was attributed to regular postural drainage. Only two patients, both given penicillin, were worse at the end of the year in the physician's opinion.

Drug Toxicity
