ing cartridges. Carbon dioxide foam was applied but failed to reduce the temperature, and it was decided then to use water to quench the fire. This was begun at 8.55 a.m. on October 11, adequate measures having been taken to ensure the safety of the staff, and continued for 24 hours, at the end of which time the pile was cold. Although the Committee of Inquiry was unable to endorse the conclusion that the observed temperature recordings indicated the need for a second heating, it agreed that both the instrumentation in the pile and the instructions to the physicist were inadequate. The Atomic Energy Authority has accepted full responsibility for the accident and is determined to do all it can to avoid a similar occurrence elsewhere.

As to the measures taken to deal with the consequences of the accident, the committee appointed by the Medical Research Council agreed that these were essentially right, and, once they were brought fully into play, were applied decisively and were adequate to prevent ill effects. The International Commission on Radiological Protection⁶ has recommended a maximum permissible exposure for life for any fission products which may be inhaled of 10^{-9} μ C per c.c. For prolonged exposure this value should be divided by 10, but for short periods of exposure, similar to those occurring as a result of this accident, may be multiplied by 10. If 10^{-9} μ C per c.c. is considered to be one unit, then the air contamination over the factory site from the afternoon of October 10 to midday October 11 varied between 2 and 10 units. All measures necessary to safeguard the members of the emergency squad working on the damaged pile were taken, and no cases of severe excessive exposure occurred. The accepted permissible dose of radiation in any 13-week period is 3 r. For the relevant 13-week period including the accident the 3 r maximum was exceeded by only 14 workers, and the highest recorded level was 4.66 r. These findings were checked and found to be accurate by personal emergency recording equipment used during the accident. In accordance with standard practice these workmen have been removed from further radiation risk and will not resume until it is safe to do so. No worker was detained for special treatment, and in only one case was there any difficulty in decontaminating hands and heads of exposed persons. Suitable protection was provided for this workman when he returned to his home, and the decontamination was completed next day. The procedure is strict and the monitoring sensitive, so that no risk remains for this man or for the persons with whom he comes into contact.

Some anxiety was felt by members of the public who thought that the risk from inhalation of radioactive materials outside the works might be significant. Measurements made on the hair and clothing of persons who cycled in the vicinity show that, even if they neither washed nor changed their clothes in ten days, the exposure would still have been negligible. As previously stated in these columns,² the main potential hazard was from absorption of radioiodine. The report con-

⁶ *The Times*, November 11.

firms this view and states that, except for the need to check periodically the content of strontium-90 in the milk of cattle grazed on certain specified areas, no risk exists from either radiostrontium or radiocaesium as a result of the accident. Having agreed that absorption of radioiodine constituted the main hazard, the committee has presented data which indicate that no harmful effects are likely to result either to plant personnel or to members of the public. A thyroid iodine survey has been made among workers and among local inhabitants round the works. The International Commission on Radiological Protection recommended a level of $0.1 \mu\text{c}$ for safe continuous and constant activity in the adult thyroid. The highest thyroid activity recorded among the staff is $0.5 \mu\text{c}$ and among the local population $0.28 \mu\text{c}$ in a child. These levels are well within the permissible level for short exposure, which is accepted as ten times the recommended level of $0.1 \mu\text{c}$ for prolonged exposure.

The decision to suspend distribution of milk from the Windscale area was a difficult one to make. No established tolerance for radioiodine in milk exists, but a limit of $0.39 \mu\text{c}$ per litre for milk given to infants had been suggested. The first milk analyses revealed levels up to $0.8 \mu\text{c}$ per litre, and milk distribution was stopped. After consultations between the medical and physics experts it was agreed that milk from the area should not be consumed until the levels had decreased to not more than $0.1 \mu\text{c}$ per litre. Examination of water, meat, eggs, and vegetables in the area revealed that no hazard existed in relation to ingestion of these items. The committee of the Medical Research Council expressed the opinion that the delay between recognition of the accident and the institution of an extensive and rapid milk-sampling programme throughout the area of possible risk was a weakness in the organization apparent only after the event, and that the investigations had revealed certain gaps in scientific knowledge which require early attention.

The final section of the Report outlines the differences between the Windscale plant and the more modern installations already working at Calder Hall and under construction for the electricity authorities in other parts of the country. The new piles not only have better controlling equipment but operate at a higher temperature. The latter modification will allow release of much of the Wigner energy as it is formed, so that operations to release stored energy will be required less frequently. Moreover, in the newer piles failure of a fuel cartridge would be detected immediately and the amount of radioactive material which could escape into the atmosphere would be too small to constitute a hazard. In the words of Sir Edwin Plowden, chairman of the United Kingdom Atomic Energy Authority, this accident caused disturbance and anxiety to many people. No harm to any person has resulted or is likely to result from the episode, and the devotion to duty and prompt and efficient actions of all those concerned in dealing with the accident deserve the highest praise. We should be grateful, too, to the members of the various expert committees who have

produced so promptly a report which makes available to the public all the relevant facts, and interprets them for us.

LIGHTNING SHOCK

A direct hit by a lightning flash or a high-voltage electric current is almost invariably fatal. Massive holes and tears are found in the body, especially in the brain and blood vessels. But most people apparently struck by lightning seem to suffer no more than freakish damage to parts of their clothes and body. This is because the current tends to take the pathway of lowest resistance; it leaps from one low-resistance conductor to another, so that down this pathway all the energy is dissipated, leaving organs a few centimetres away unharmed. The main resistance offered by the body is in the dry skin, which is why household electric currents are so much more dangerous to the wet body. Surprisingly, the pathways followed by such currents as do traverse the body are not yet finally settled. It is thought that the energy goes mainly along blood vessels or nerves,¹ but A. W. Weeks and L. Alexander² considered that the whole body is a low-resistance, structureless gel, so that there is a steady potential drop along the shortest line between the points of entry and exit of the current, with uniform potential fields around. When the current passes from one hand to the other it traverses the lower cervical spinal cord, which may explain why the results of this accident often look like transverse myelitis or even disseminated sclerosis. Whatever the pathways taken, it is the nervous system that always seems to bear the brunt of the current, though experimentally large currents can make the heart stop or fibrillate. A condition of profound "shock" with apparent suppression of all nervous activity may last one or two hours after a heavy electrical shock, yet the persons still recover without apparent sequelae.

The precise aetiology of the massive lesions seen at necropsy in fatal cases is poorly understood. Heating effects are undoubtedly important, especially with currents such as are used for legal electrocution, in which currents of high amperage and medium voltage are applied for several minutes. Electrolysis producing gases has been suggested as causing the holes sometimes seen in the brain. Blake Pritchard³ thought they might be due to electrostatic effects bursting apart oppositely charged portions of the body, in the same way as objects held are often flung far away from the person; but this is unlikely in view of the probably uniform potential fields in the body. The wave of compressed air produced by the discharge may also have some mechanical effects.

The surprising thing is perhaps that those who survive lightning stroke do not have more permanent and striking disabilities. Minor sequelae are frequent, and headaches and paraesthesiae seem to be the commonest effects

⁵ Critchley, M., *Lancet*, 1934, 1, 69.

according to Drs. D. Shaw and M. E. York-Moore, who report in the *Journal* this week (p. 1152) on incidents at Ascot racecourse⁴ and at Aldershot. These authors did not see any spinal lesions. Most of the effects, however bizarre, could be attributed to the vagaries of the pathways taken by the current. Purely psychiatric sequelae of the traumatic neurosis type seem virtually absent, according to the authors. They point out that, though the experience is traumatic enough, it is apparently accepted as an act of God or other external event which is unconnected with any possible guilt, nor can it be the subject of compensation. Macdonald Critchley⁵ and others have thought "hysterical" symptoms were common, but it is possible that some of them had a definite though transient neuro-pathological basis.

The changes seen in the body after an electric shock depend in the first place and most importantly on the physical characteristics of the current applied, especially on voltage. Of secondary importance is the pathway of the current—its points of entry and exit—and how great a potential gradient is produced inside the body once the high resistance of the skin has been broken down. The brain seems to be the most sensitive organ, but its functions are more often temporarily suspended than destroyed or permanently modified. For this reason it has always been recommended that prolonged artificial respiration be given to those apparently dead from electric shock or lightning. However, a careful physical examination is also necessary, since other potentially fatal lesions such as skull fractures may result from the patient being hurled on to the ground or on to other hard objects by the force of the current.

OBSCURE ABDOMINAL PAIN

Most doctors, because this is rightly considered an important part of their training, are familiar with the differential diagnosis of abdominal pain. They also know, when they answer the telephone in the middle of the night, that if the patient has diarrhoea in addition to abdominal pain the condition is probably not one requiring urgent surgical treatment. Nowadays there is less delay in referring the acute abdomen to hospital, and here careful examination of the urine, rectum, and vagina together with facilities for obtaining a white blood count, a straight radiograph of the abdomen, and a test of the serum-amylase level have enhanced the accuracy of diagnosis.

There are, however, three rare conditions—essential hyperlipaemia, porphyria, and periodic disease—and two common ones—spastic colon and neurosis—which lead to diagnostic difficulties. Spastic colon and neurosis can usually be excluded by careful history-taking and detailed analysis of the characteristics of the pain after the manner outlined by J. A. Ryle.¹ Patients with spastic colon are usually women aged 17 to 40, and all too often have at least one, and usually two, abdominal scars as a result of appendicectomy and removal of a small ovarian cyst; these procedures have not influenced their recurring abdominal pain and may have given rise

to the dangerously erroneous idea that they have adhesions.² There is also the danger that the mechanically minded house-surgeon and surgical registrar may fail to explore sufficiently deeply the social and emotional background of the case. Thus, in a recent example of this type, the patient had accumulated a folder of notes comprising 60 pages, been admitted to hospital three times for a total of 33 days, had one laparotomy and was threatened with another, made 20 separate visits to out-patient departments, been seen by not fewer than five different consultants and eighteen other doctors, and received eighteen different medicines before the true nature of her disease was established by taking a detailed personal and family history in an interview lasting thirty minutes.

Essential hyperlipaemia, porphyria, and periodic disease are more difficult to diagnose, but are worth considering in the differential diagnosis of obscure abdominal pain. Essential hyperlipaemia is characterized by recurring attacks of abdominal pain, nausea, and vomiting, often suggestive of acute pancreatitis.^{3 4} Rarely there may be hepatosplenomegaly, cutaneous xanthomatosis, and lipaemia retinalis. The diagnosis is usually made by the accidental discovery of milky serum, and during the attacks there is fever, a leucocytosis, and a raised erythrocyte sedimentation rate. Hypercholesterolaemia may or may not be present, and other conditions—diabetes mellitus, nephrosis, myxoedema, von Gierke's disease, Niemann-Pick disease—which may have associated hyperlipaemia are absent. This condition responds well to a low-fat diet, which reduces the lipaemia and prevents further attacks of pain. It can, however, recur after dietary indiscretions. Acute porphyria may cause severe, colicky, abdominal pain, distension, marked constipation, but absence of guarding or peritoneal irritation. Not infrequently a laparotomy is performed, and the diagnosis not made until a specimen of urine left overnight in the sluice room is noted to have become a characteristic dark-red colour. In these cases the colourless chromogen, porphobilinogen, can be detected in the urine by the simple Ehrlich's aldehyde test,⁵ and this should be carried out in all cases of obscure colicky abdominal pain. This disease may also be characterized by nervous manifestations—peripheral neuritis, bulbar palsy, psychoses, or hysteria. Periodic disease,⁶ recently discussed in these columns,⁷ is a less well understood disorder or group of disorders and seems to be more common in people living in the Mediterranean littoral. It is characterized by recurring attacks of fever, which may be unassociated with other symptoms, or be accompanied by abdominal pain or arthralgia. Usually the fever recurs at regular intervals over some years, and despite thorough investigation no cause for it is found.⁸

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

NEW COLLEGE BUILDING

The foundation-stone of the new College building for the Royal College of Obstetricians and Gynaecologists was laid by Queen Elizabeth the Queen Mother on November 6.

The site for the building is in Regent's Park, between Hanover Gate and Clarence Gate.

Welcoming the Queen Mother, the President of the College, Professor A. M. CLAYE, recalled that 25 years ago Her Majesty, then Duchess of York, had opened the College's house in Queen Anne Street. Since then the infant had attained its majority, and on the present occasion it might not be out of place to let those whom they served know what the College stood for and in what way it could help them. The College prescribed the training for doctors specializing in obstetrics and gynaecology, and conducted examinations to test their knowledge. There were few such specialists in Britain to-day who were not members of the College, and an increasing number in the Commonwealth were also. By endowed lectures and scholarships, awarded every year, the College encouraged original work, and its members had made many contributions towards the remarkable reduction of the death rate that had taken place in recent years among mothers and newborn babies. The College also awarded diplomas to family doctors who had fulfilled certain conditions of training and passed an examination in maternity work. Those two examinations for the membership and the diploma had played an important part in raising the standard of work in this field of medicine.

Queen Mother's Address

Replying to the President, the QUEEN MOTHER said she well remembered the opening of the Queen Anne Street premises. Ever since she had watched with deep interest the development of their work. The men who founded the College, particularly Professor Blair-Bell, the first president, and Sir William Fletcher Shaw, the first secretary, were indeed men of vision. The spirit that moved them was a desire to unite the twin subjects of obstetrics and gynaecology, believing that thereby a greater service could be rendered to the women and babies of this country and the Commonwealth. It was a happy thought that a bronze relief of those two pioneers would adorn the entrance hall of the new building. How well that early ambition had been fulfilled was clear for all to see. The number of their fellow members had increased sevenfold

since the foundation of the College. It was not surprising, therefore, that they needed a new building in which to carry on their work of postgraduate education and research.

Their fellow members had contributed in some measure towards the steady fall in maternal mortality which had occurred during the last 25 years, and for that this country and the Commonwealth, and indeed the whole world, was in their debt and would be for ever grateful. But the art,

(P.A.-Reuter Photos, Ltd.)

H.M. Queen Elizabeth the Queen Mother laying the foundation-stone of the new College building.

science, and practice of medicine could never stand still. There were always new fields to conquer. It was no longer enough that a woman should escape death in childbirth; she had the right to emerge from the most momentous and wonderful experience of her life unharmed both in mind and in body and with a strong and healthy baby. She herself wished to pay personal tribute to three men who had brought great distinction to the College. First to their late president, Sir Charles Read, who must be in the thoughts of all of them—his devotion to the College had been unbounded, and his untimely death at the height of his

Architects' drawing of the future College building. The administrative block is seen on the right, and the assembly hall block on the left (Architects: Louis de Soissons, Peacock, Hodges, and Robertson.)

powers was a sad loss to his friends and to the profession which he adorned; to their former president, Sir William Gilliatt, who had cared for her daughter, the Queen, when her children were born; and to Sir Henry Simpson, whom she and thousands of his patients remembered with affectionate gratitude.

The new building with its fine museum, library, and lecture hall would do much to improve the standing of and knowledge in this particular branch of medicine, and it would be a meeting-ground in the heart of London for obstetricians and gynaecologists from every part of the Commonwealth. The Queen Mother then supervised the lowering of the foundation-stone into position, tapped it, and declared the stone well and truly laid.

Following the ceremonial laying, the honorary secretary of the College, Mr. IAN M. JACKSON, read out a list of the contents of the casket placed under the foundation-stone. Among the items were a copy of the Articles of Association of September 12, 1929; a copy of the Royal Charter of 1947 of King George VI; a copy of the first College seal; the annual report of the College for 1956; and a copy of *The Times*.

The New Building

The new building will stand on the site of the former Sussex Lodge, bounded by Sussex Place, the Outer Circle, Kent Passage, and Park Road. It is L-shaped in plan, facing the Outer Circle and Lake, and will consist of a four-storied administrative block housing the College offices, members' rooms, council chamber, committee rooms, etc., with a flat for the President and other accommodation on the fourth floor. The assembly hall block will consist of a large entrance hall and staircase leading to the assembly hall at first-floor level. The library and museum will be on the ground floor with the pathological laboratories and research rooms above on the Park Road side of the building.

The exterior has been carefully designed to harmonize with the Nash buildings of the neighbourhood, and will be in hand-made golden-brown bricks with Portland stone dressings, cornices, etc., and copper roofs. Internally the finish will be simple, with flush hardwood doors and floors. Many rooms and all corridors are to be treated acoustically to reduce noise. There will be no visible means of heating, a comprehensive system of panel heating being used. Partial plenum heating will be applied to the Council chamber, assembly hall, and main committee room. None of the fully grown trees, of which there are many on the site, will be felled as a result of the new building.

Annual Dinner

The College's annual dinner was held on the same evening, at Grosvenor House, where Professor Claye presided over a company of more than 400. The MARQUESS of SALISBURY proposed the toast of the College, to which the PRESIDENT and Professor BRUCE T. MAYES, chairman of the Australian Regional Council of the College, replied. The latter conveyed messages of greeting from the chairmen of the College's Canadian, New Zealand, and South African Regional Councils. Professor W. C. W. NIXON proposed the toast of the guests, and Mr. RICHARD THOMPSON, M.P., Parliamentary Secretary to the Ministry of Health, who was deputizing for the Minister of Health, replied.

"According to the *Madras Mail* of July 17, the Government of Madras is to subsidize private medical practitioners for performing the operation of vasectomy. This procedure has long been advocated by the Family Planning Board of Madras, and from replies to a questionnaire the Government has learnt that there is a genuine demand for it. The subsidy to be paid will be Rs.25 per operation carried out on persons earning Rs.200 (£15; \$42) a month or less. The scheme will be in force for one year and the total expenditure on subsidies has been fixed at Rs.25,000 (£1,875; \$5,250)." —*News of Population and Birth Control*, November, 1957.

ACCIDENT AT WINDSCALE

The promised White Paper on the Windscale Accident* was published on November 8. It consists of six annexes preceded by a short memorandum by the Prime Minister. The whole report runs to 26 pages. The first two annexes have been written by the Atomic Energy Authority's committee of inquiry. The first is a non-technical, "security" version of the committee's fuller report to the Authority on the cause of the accident—too early and too rapid heating during routine annealing of the graphite leading to the failure and oxidation of one or more uranium (or possibly lithium-magnesium) fuel cartridges—and the measures taken to deal with the accident. The second is the committee's report in its entirety on the measures taken to deal with the consequences of the accident. Then, as the third annex, comes a report on the health and safety aspects, prepared by a committee† appointed for the purpose by the Medical Research Council.

Conclusions of M.R.C. Committee

The conclusions of the Medical Research Council's committee are as follows:

"(i) The information available is adequate to allow an assessment to be made of the possible risks to human health and safety arising from the recent accident at Windscale.

"(ii) After examining the various possibilities, we are satisfied that it is in the highest degree unlikely that any harm has been done to the health of anybody, whether a worker in the Windscale plant or a member of the general public.

"(iii) The highest levels of radiostrontium in locally produced milk are well below those at which an appreciable hazard would arise even if such milk were consumed over a period of years: but the radiostrontium levels in some samples of grass from certain occasional pastures indicate that a watch should be kept on the milk in such places to see that contamination does not, in the future, show signs of approaching significant levels.

"(iv) Certain weaknesses in organization were apparent after the event, notably the delay between recognition of the existence of an accident which might lead to the emission of radioactive substances over the surrounding country and the institution of an extensive and rapid milk-sampling programme throughout the area of possible risk. Further, certain gaps in our scientific knowledge were revealed, and require early attention.

"(v) Despite these shortcomings the measures adopted by those responsible for the health and safety of the population in and around Windscale were essentially right, and, once these were brought fully into play, they were applied decisively and were adequate to prevent ill effects."

Remainder of the Report

Annex IV is a memorandum by Sir Edwin Plowden, chairman of the Atomic Energy Authority, in which he states that the Authority accepts full responsibility for the accident, and that it considers the root cause to have been partly "inadequacies of the instrumentation" provided at Windscale and partly errors of judgment on the part of the staff. Annex V is a note by the Atomic Energy Authority to relieve anxiety about the possibility of a similar accident occurring at Calder Hall or the nuclear power stations being built for making electricity. The final annex gives the terms of reference and composition of three committees under Sir Alexander Fleck's chairmanship, which the Prime Minister has appointed to recommend measures to remedy the deficiencies disclosed in the report. One of these committees is to review "the organization within the Authority

* *Accident at Windscale No. 1 Pile on 10th October, 1957*, Cmd. 302, 1957. H.M.S.O. Price 1s. 3d. net.

† Sir Harold Himsworth, F.R.S. (*chairman*), Sir Ernest Rock Carling, Professor A. Bradford Hill, F.R.S., Dr. J. F. Loutit, Professor W. V. Mayneord, Professor J. S. Mitchell, F.R.S., Dr. E. E. Pochin, Professor B. W. Windeyer, Dr. B. S. Lush (*secretary*), with Sir William Slater, F.R.S., secretary of the Agricultural Research Council, as an observer.

as a whole for control of health and safety." Its members, besides Sir Alexander Fleck, are Mr. C. F. Kearton, Sir William Penney, Sir George Barnett (Chief Inspector of Factories), and Dr. J. S. Carter, Ph.D. (Chief Alkali Inspector).

BRITISH ORTHOPAEDIC ASSOCIATION

AUTUMN MEETING

The autumn meeting of the British Orthopaedic Association was held in London from October 3 to 5 under the presidency of Mr. PHILIP WILES. It comprised an instructional course of four lectures, a symposium on bone, and a considerable number of short papers. Mr. NORMAN CAPENER, of Exeter, was installed as the new president. We report here two papers with especially wide implications, the first on the genetic factor in orthopaedics, the second on radioactive isotopes and bone.

Genetics and Orthopaedics

Dr. C. O. CARTER (M.R.C. clinical genetics research unit) said that orthopaedic conditions could be divided into three groups: (1) those where an abnormal genetic constitution, often a single gene mutation, was solely responsible, (2) those due only to environment, and (3) those, such as congenital dislocation of the hip, where both factors played a part. Studies of monozygous twins had proved most helpful in differentiating these groups. With the first group the twins were always concordantly affected; with the second no more often than dizygous pairs; with the third they showed notably greater concordance than dizygous pairs—for example, in congenital talipes equino-varus there was a 23% concordance in monozygous twins but only 2% in dizygous twins. Environmental diseases were becoming less common with improved public health, while largely genetic ones tended to increase in frequency. This had resulted not only from the increase in mutations due to radiation but also from better medicine leading to greater survival and hence a higher reproductive rate among those with such mutants. Herein lay a danger unless counteracted by advice to such parents on the risks to their children.

Mutations might be dominant or recessive. Family histories showed that achondroplasia and dysplasia epiphysealis multiplex were the result of dominant mutant genes, whereas Morquio's form of osteochondrodystrophy was usually dependent on a recessive mutant gene. With dominant genes prognosis was straightforward; sporadic cases would be due to fresh mutations, and later brothers and sisters were most unlikely to be affected. But the risk for the children of those affected (if they lived to reproduce), would be 50%—that is, 1 in 2. Homozygotes for recessive mutations could arise only if two clinically healthy people, each of whom was heterozygous for the same mutant gene, married and had children. There was then a 1 in 4 risk of any child being homozygous and clinically affected, a 2 in 4 risk that any child would be a carrier but clinically normal, and a 1 in 4 risk that the child would not have the recessive mutant gene at all. It followed that, once an affected child had been born, the risk for later children was 1 in 4; but the normal brothers and sisters and also the affected child, if surviving, would not have affected children unless they were unlucky enough to marry a carrier. The main hope for prevention lay in finding ways of detecting clinically normal heterozygotes, and warning them of the risks to their children if they married each other. This was now being done in Italy, for example, to reduce the frequency of the lethal blood disorder known as Cooley's anaemia.

Sex-linked Muscular Dystrophies

A special class of recessive mutations was that of the X chromosomes where heterozygous females having two X chromosomes were clinically normal, but males with the mutation on their single X chromosome were not protected by a normal gene on the Y chromosome and were affected.

Most childhood muscular dystrophies were due to such sex-linked recessive mutations. This was true of all those where the victim was severely affected and was off his feet by the age of 11 years. These patients were all boys, and their families showed a sex-linked recessive pattern of inheritance. The milder but otherwise similar cases were as often girls as boys, and were mostly due to an ordinary, not sex-linked, recessive mutant gene.

Dr. Carter mentioned spina bifida cystica, talipes equino-varus, and congenital dislocation of the hip as examples of mixed genetic and environmental origin. In congenital dislocation of the hip 6-7% of the sisters of affected children were also affected and about the same proportion of daughters; brothers and sons less often. This might well be due to a dominant mutant gene, only one-fifth to one-tenth of the females with the gene being clinically affected, and even fewer of the boys with the gene. The environmental factors concerned were not fully known. The condition was commoner after breech birth, and Record and Edwards in Birmingham had shown it to be commoner also in firstborn and in babies born in winter. To reduce the incidence of such affections, much further work was needed to pick out those with the genetic constitution for the disorder but clinically unaffected, and to identify the environmental factors which lead to the clinical manifestation of the genetic constitution.

Radioactive Isotopes and Bone

Dame JANET VAUGHAN (Oxford) said that radioactive elements from "fall-out" which entered the body were concentrated in the skeleton, where they manifested themselves by producing anaemia, changes in the bones themselves, and neoplasms. The vital factor was the radiation dosage; once the element was within the bone the important factors were the character and the energy of the radiation, the half-life of the element, and the nature of its decay products. All investigations had been complicated by the large number of variables. There were marked differences in species resistance, and other variables included the amount ingested, the route of ingestion, the diet at the time, the duration of ingestion, the site of deposition, and the pattern of subsequent bone growth. In describing experiments with radiostrontium in the rabbit, she showed how the age of the rabbit affected the pattern of deposition, which depended on the site and rate of bone growth at the time; from the point of view of tumour formation it was the local concentration of a radioactive element that was dangerous. Work on these extremely complex problems was still at a very early stage, and it was rash to assume that the behaviour of one radioactive element would prove similar to that of any other.

Motoring News

ENGINE OILS

There can be few more confusing things for the present-day motorist than the choice of oils. Publicity stunts and advertisements are for ever proclaiming new products with superb additives which do this, that, and the next thing for your engine. That there are so many different varieties of oil is in itself confusing, but, to make matters more difficult, each separate company markets its own particular brand under a different name. Many of us are content to stick to one or perhaps two types of oil year in, year out, regardless of the kind of car, simply because it saves trouble or because such and such an oil is specified in the instruction book. Since the makers may have been paid to recommend particular brands in this instruction book, there is no harm done in looking at other varieties with different characteristics.

The reason for the introduction of some of the new oils is that the old ones were not able to stand up to the demands

The Riley One-Point-Five

Some months before the announcement of this model journalists and motoring correspondents were invited to the Riley factory at Abingdon on Thames to try this latest example from the vast B.M.C. concern. The One-Point-Five, as it is called, is an attempt to provide a fast sports saloon for the enthusiastic motorist, and it is indeed both fast and fun to drive. The 1,489 c.c. engine develops 68 b.h.p. on a compression ratio of 8.3 to 1; it is coupled to the M.G.A. gearbox and fitted into the now familiar Wolseley 1,500 body. Road-holding is one of the car's good features; others are the gearbox and its short central lever. The result is that the car can be driven hard with great confidence. Top speed is in the region of 90 m.p.h., with up to 80 m.p.h. in third gear. A pleasing interior with leather seats and polished walnut dashboard and door sills give the car a quality feel. The fact that this model is for the enthusiast is shown by the presence of a revolution counter accompanying two other large round dials set in front of the driver. The only point of criticism which could be made was that the presence of a tall driver at the wheel resulted in a very small space indeed for the rear passenger behind him. Priced at £863 17s. including tax, this is one of the most interesting cars to have come from B.M.C. for some time and it should achieve considerable popularity.

IAIN GELLATLY.

The Riley One-Point-Five.

cannot be broken down. These are particularly suitable for the smaller new cars, because they give the same protection as the heavy oil yet offer less resistance. In using multigrade oils in air-cooled cars it is sometimes necessary to exercise a little care, because engines of this sort tend to run hotter than normal water-cooled engines, and, though a multigrade oil, like any other, will still protect the engine so long as it circulates, excess heat burns up oil, especially in a light grade, all of which means a loss in economy. In cars whose engine runs at about the same temperature as the normal water-cooled engines—for instance, the Volkswagen—multigrade oils are satisfactory.

Detergent oils are another addition to the ranks. These are designed for use in engines which are in good condition but have accumulated a certain amount of carbon, having perhaps been running for some time on normal oils. Draining and refilling with a detergent oil removes all the carbon deposits, scours out the engine and keeps it nice and clean. This is fine if the engine is not worn, but detergents are not to be recommended if the engine is in any way unsound, for the process of scouring out the carbon is so thorough that any worn spots underneath immediately make themselves apparent, to the detriment of the engine's performance.

It is best, then, to keep off multigrades and detergents (most multigrades contain some form of detergent anyway) if you are not too certain about the condition of your engine. But reasonably new cars, or even old cars with overhauled engines, are certainly the subjects for this treatment. A point to remember is that when changing from ordinary oils to multigrades it is necessary to drain out the oil again after 600 or 700 miles to clear the engine of the impurities which the oil has removed. A light oil or multigrade is therefore the answer for new cars and a heavier one for older models, with the sparing use of detergents when necessary.

Correspondence

Because of heavy pressure on our space correspondents are asked to keep their letters short.

Smoking Habits of Doctors

SIR,—Six years ago we asked all the doctors in Britain to tell us their smoking habits, and over 40,000 of them complied. We were thus able to study their habits in relation to the mortality from different diseases that has subsequently befallen them. In particular we observed, as readers of your columns may recall, a significant association between cigarette-smoking and lung cancer (*Journal*, 1956, 2, 1071).

We believe it would be useful to continue with this inquiry. We might learn more about some of the less common diseases that afflict us, and, more especially, we would hope to get more information about the effects of stopping smoking. But if we are to do that effectively we must bring up to date the smoking habits reported to us six years ago. We are now attempting to do so.

As a preliminary measure we wrote to some 500 doctors, representative of all those who had answered us in 1951. Their replies showed that a substantial proportion of the smokers of 1951 (current or recent "givers-up") had changed their habits. On the other hand the non-smokers had not changed. We shall therefore shortly be writing to all doctors of the former group—the smokers and ex-smokers of 1951—but not to any of the latter, the non-smokers. This explains why some doctors who answered in 1951 will receive our request for further information to-day and others not. (We would, of course, be very glad to hear from any 1951 non-smoker who has ceased to be a non-smoker.) In addition to thus bringing the information up to date we have taken the opportunity to ask two short extra questions of importance—one on inhaling and another on the previous smoking habits of pipe smokers.

In asking doctors once again to help us in this way we would stress three points. In sending out many thousands of forms we shall inevitably make a few errors—in address, title, statement of previous smoking habits, etc. Since virtue has no news value, these mistakes will stand out disproportionately. We trust we may be forgiven them. Secondly, while there is no time limit on reply an immediate

return of the form does considerably help us. Lastly, and most important of all, the more replies we get the better will be our data. *Whether or not they have changed their smoking habits since 1951*, we beg our previous helpers to be so kind as to help us again.—We are, etc.,

Infantile Fundus Lesions and Mental Capacity

SIR,—Mr. J. H. Doggart's article on this subject (*Journal*, October 19, p. 933) is very valuable, since it draws attention to a relationship which is little appreciated. It is quite a common experience for us here to admit babies who were thought to be blind but who subsequently prove to be mentally defective without gross peripheral defect. In addition to the points mentioned by Mr. Doggart, we have been interested in the relationship between mental retardation and retrolental fibroplasia,¹ having 23 cases of this condition among our mentally defective children.

Mr. Doggart considers that Gesell's opinion² is far more realistic than that expressed by one of us (B. H. K.)³ in regard to an early decision as to mental defect. Perhaps the difficulty here is partly one of terminology. "Mental deficiency" and "defective" are in this country legal terms, which imply among other things that a child is unfit to attend school. Since there is, in most cases, little to be gained by early ascertainment, it seems very unwise to inform the parents that a baby is mentally defective, still more so to take administrative action, if there is a considerable risk that the prognosis may be wrong. One may refer to the opinion of such an eminent authority as Vernon,⁴ who considers that developmental and other quotients under the age of 2½ years have virtually no predictive value. The excellent review by Jones⁵ covers the literature on this subject.

It is often possible in biology to deduce laws which have a certain statistical validity and general application. It may prove very dangerous to apply these broad generalizations to individual cases. Mr. Doggart says that in such conditions as Tay-Sachs disease, epiloia, and Schilder's disease we can emphatically advise against any future pregnancy. It is generally recognized that tuberous sclerosis (epiloia) is a condition in which affected individuals often fail to have children, that a great many cases are due to new mutation, and that, if inherited, the transmission is of the dominant type. When advising parents about future children it is therefore incorrect to dismiss this disease in one breath with other conditions which are usually transmitted in a recessive manner. So far from emphatically advising the healthy parents of a child with tuberous sclerosis against further pregnancies we can reassure them that if they have another child he is no more likely to be affected by the disease than the offspring of any other parents. It is true that there are theoretical objections to such a statement in that it does not allow for "incomplete penetrance" masking the disease in one parent or for mutation of more than one germ cell (gonadal mosaicism), but the risk of these is so remote that it can be disregarded for purposes of practical advice. Perhaps the following table showing the family background of 13 cases of tuberous sclerosis recently seen at the Fountain Hospital will illustrate the problem.

	Parents Normal	1 Parent Affected
Number of patients	10	3
" " normal siblings	22	4
" " affected	0	0
" " siblings with other defects	0	0

It will be seen that all 22 siblings born to healthy parents were normal, and that, by good fortune, so also were the four siblings born where one parent was affected.

General rules have a certain value, but in order to treat and counsel individual people it is essential not only to know the general rules but to be able to apply them to

particular cases in the light of a full knowledge of all the attendant circumstances. Recent developments in medical science only serve to emphasize the truth of Pascal's thought: "*A mesure qu'on a plus d'esprit on trouve qu'il y a plus d'hommes originaux. Les gens du commun ne trouvent pas de différence entre les hommes.*"—We are, etc.,

Anaesthesia in Dystrophia Myotonica

SIR,—Recently attention has been drawn to the dangers of giving thiopentone to patients suffering from dystrophia myotonica.¹⁻³ To date we have collected records of 20 cases of dystrophia myotonica which have had anaesthetics. Ten of these patients had some anaesthetic complications, and of these three have died. I would be grateful to receive information from any of your readers who have anaesthetized patients suffering from this disease, even though the response to anaesthesia has not been abnormal.—I am, etc.,

LEON KAUFMAN.

Acute Inversion of Uterus

SIR,—I read with interest the report of a case of acute inversion of uterus by Drs. J. T. B. Bain and B. K. Ziolkowska (*Journal*, May 11, p. 1102), and the letters from Dr. Henry FitzGibbon (*Journal*, September 7, p. 589) and Mr. Frank Stabler (*Journal*, September 21, p. 714).

I entirely agree with Dr. FitzGibbon on the aetiology and management of this most desperate obstetric emergency. The sooner the inverted uterus is reduced the better the prognosis, as illustrated in my report of a similar case.¹ The condition is relatively rare in the West as compared with Far Eastern countries, where faulty management of the third stage is the main factor in its causation.² This has been discussed in greater detail in an earlier communication from me.³ Fundal insertion of the placenta is a predisposing factor. This is apt to bring down the fundus uteri by its sheer weight, starting a process of inversion which can be completed by an expulsive effort. This was most probably what happened in the case under discussion. An oxytocic drug is also a causative factor, because the potent contraction of the uterus attempts to expel the partially inverted fundus like a foreign body, thus completing the process.

"A sudden and severe post-partum haemorrhage" occurring within a few minutes of a normal labour in an otherwise healthy woman, coupled with "an inability to palpate a definite fundus," is sufficient indication of acute inversion unless otherwise proved; quick diagnosis and immediate reduction under short and swift anaesthetic (such as chloroform "brissettes") give little time for shock to supervene. Once shock occurs the situation becomes desperate. One is then confronted with a vicious circle—inversion cannot be reduced unless shock is overcome, and shock will not pass away unless the inversion is reduced. Restitution therapy only helps the patient to rally momentarily. Here blood is by far the best restorative in a case of "3 pints (1.7 litres) being lost within a few minutes," when haemorrhagic shock is added to the already established visceral shock.

I beg to differ with Mr. Stabler's opinion on the cause of shock in acute inversion. In my view, the cause of shock and probable death in the case, quoted by him, of rabbits sharply jerked in the vertical position is actually cerebral

anoxia followed by syncope, because morphologically an erect posture is inconsistent with the habit and welfare of quadruped animals. Dr. O'Sullivan's treatment by hydraulic pressure seemed to be more interesting than practical, because its effect is more accidental than reliable in a desperate urgency.—I am, etc.,

Correlation of Human and Animal Ringworm

SIR,—In an interesting paper on the correlation of human and animal ringworm in the West of Scotland (*Journal*, September 21, p. 678) the authors, Mr. J. C. Gentles and Mr. J. G. O'Sullivan, say that I am "apparently convinced" that cattle were responsible for infection of a number of patients with *Trichophyton mentagrophytes* and cite a paper of mine¹ in support of their allegation. What I actually wrote was: "Lesions on the wrists and forearms, coupled with a history of the hand-milking of cattle known to be infected with ringworm, suggests that this fungus may be one of the causes of cattle ringworm in the Midlands," and again in the same paper "... the evidence available as to the probable animal contacts of human patients is often highly dubious, coming, as it does, from untrained and sometimes prejudiced observers." If this is evidence of "conviction," I should like to be told how I ought to express doubt.—I am, etc.,

Coroners' Criticisms

SIR,—I should like to express my whole-hearted support of the observations of Dr. N. Beattie (*Journal*, October 12, p. 885) and to make a further point. If officers of the Crown are to be free to make such criticisms, in public, and in their semi-judicial capacity, is it not high time that the considerable expenses incurred in such postgraduate education, higher examinations, etc., be recognized by the Crown as being "wholly, necessarily, etc." incurred in pursuit of our occupation, and therefore as being eligible for tax relief? I intend to bring this matter to the notice of my M.P. and hope many others may feel moved to take similar action.—I am, etc.,

London, W.8.

PATRICK J. MCQUADE.

Spontaneous Recovery in Long-term Personality Amnesia

SIR,—Most functional amnesias are circumscribed and the memory returns fairly quickly with the help of hypnosis or narcoanalysis. The case reported here is exceptional in that the amnesia involved the patient's complete past history, persisted in spite of the usual therapies, continued for a long period, and memory returned spontaneously without any known physical or emotional shock.

In December, 1949, the patient was taken to a hospital by the police, suffering from loss of memory. Three injections of thiopentone were given, but all that could be elicited was that his name was A.B.C. and that he dreamed of Ayrshire cows. He was transferred to a mental hospital. He had a sum of £53 in his possession, but no identification papers of any kind. He was not emotionally disturbed. On being questioned, whether he did not feel ill, ate and slept well. He could not give his true name, his age, his home address, his occupation, whether single or married, etc. To all questions he responded with: "I don't know. I don't remember." Attempts to regain his memory with hypnosis failed. He was fairly deeply hypnotized three times by myself, twice by Dr. B. L. Lloyd, and twice by Dr. D. E. R. Kelsey. Four sessions with intravenous thiopentone were given by Dr. H. De Silva, but the only interesting informa-

tion elicited was that "my mother is very cruel" (patient sobbed for 10 minutes), that he liked his father, and that he had worked as a herdsman on a farm. An ether abreaction by Dr. E. R. Jones failed to elicit any further information. With the patient's permission I called in the police to examine him, in case he was a missing person wanted for some offence, but he was not identified. He was discharged 11 months after admission and we lost contact with him.

In April, 1957, he wrote me a letter in the following terms: "I was at your hospital in 1950. When I left you asked me to let you know when I could remember all about myself. I now know nearly everything. I would like to seek your advice on many things." At an arranged interview he informed me that in November, 1956, his memory suddenly returned, and he realized that his real name was X.Y.Z., not A.B.C. He then proceeded to give a full account of his life history, from which the following is of interest. He was evacuated to the country in 1939 at the age of 10 for the duration of the war. He could not get on with his mother, she was psychologically cruel, so he did not rejoin his family at the end of the war. After a number of jobs at various farms as herdsman, he joined the R.A.F. He remembers having "attacks of nerves," went on leave to an aunt, and after that lost his memory.

The motive of the amnesia remains puzzling, as the R.A.F. records make no note of any possible determining stress. It may be of significance that from the age of 10 to 16 he was separated from his parents and that he lacked maternal love and security. At any rate it is interesting that Stengel¹ in his studies of fugues with the impulse to wander has noted that in the great majority of such cases the "biological process of domestication" had been disturbed.—I am, etc.,

I. ATKIN.

Basingstoke

Sulphamerazine

SIR,—In September, 1951, I reported¹ a case of sulphamerazine crystalluria in a child and recalled three other reported cases.²⁻⁴ The matter was taken up by other correspondents, notably Dr. J. Rendle-Short,⁵ who reported four cases of children admitted to hospital with anuria following the administration of sulphamerazine, and Dr. W. Brand,⁶ who reported a case of haematuria, oliguria, and abdominal pain from the same cause. Drs. S. A. Morton and R. H. Dobbs⁷ reported six cases all admitted to hospital in the previous 12 months with anuria or oliguria following the administration of this potentially dangerous drug. In his communication Dr. W. Brand posed these questions: How dangerous is sulphamerazine to children? What is the incidence of complications following its use? Should it ever be used in domiciliary practice? For a time, at least, the reported cases of sulphamerazine crystalluria ceased. But not all cases reach the medical journals. In September at least one national daily carried a report of an inquest in Wigan on a 4-year-old child who died four days after "cremomerazine" had been started for the treatment of measles. By the reported remarks on the necessity for giving plenty of fluids when taking this drug, it is obvious that crystalluria and anuria occurred in the same familiar and fatal pattern.

I hope that you will again afford the hospitality of your columns to proclaim that sulphamerazine is potentially a very dangerous drug, for which there is no legitimate reason whatever for continuing its use. Sulphadimidine has the same therapeutic effect on the same organisms, but has none of the dangers of sulphamerazine. It is claimed that sulphamerazine need be given only twice a day, that the dose is small and is therefore easy to administer. Sulphamerazine is said to be safe when given with plenty of fluids, but every general practitioner knows that some mothers cannot be counted on to follow these instructions. "The child won't take anything" is a remark we hear twenty times a week, but generally the medicine is taken nevertheless. If sulphamerazine is given to a dehydrated child who (after the

A male, aged 74 but looking much younger, had slight attacks of loss of balance in 1937. These improved and virtually stopped for three or four years, when tinnitus developed and he had occasional severe Ménière symptoms, during which "everything collapses underneath me." He had been treated by many otorhinolaryngologists, and was finally advised to have a labyrinthectomy. He was referred to me, not because of any special competence in the specialty, but because his doctor was aware that I had seen a good deal of the work of René Leriche. On December 12, 1951, I injected the left stellate ganglion with procaine: Horner's syndrome developed rapidly and persisted for over an hour. For two days the patient had no attacks, but then relapsed completely. A second infiltration was carried out on February 19, 1952, followed by an even more rapid onset of Horner's syndrome and tingling down the left arm. No further attacks occurred until August, when there was moderately severe recurrence. I carried out a third stellate infiltra-

tion; and when last I heard from the patient on February 2, 1957, he wrote, "I am happy to say that I have not had any more trouble since my last injection."

This result does support Mr. Wilmot's contention, although the stellate infiltration had no effect on the tinnitus or on the deafness. It would seem, therefore, that it is never too late to try the effect of stellate infiltration, which, by the "second method" of Leriche and Fontaine,¹ is easily carried out.—I am, etc.,

London, W.1.

The Misnamed Stethoscope

SIR,—Dr. F. R. Langmaid's letter (*Journal*, October 19, p. 943) resurrects in my mind the wonder that I experienced when I first heard that an electrocardiogram was in fact the "graph," and that the electrocardiograph was the instrument. Can anyone elucidate this one?—I am, etc.,

Wrexham.

R. P. W. KUP.

Medical Association for the Prevention of War

SIR,—Let us allow ourselves no illusions about the true nature of the Medical Association for the Prevention of War (*Journal*, October 19, p. 943). It was the ideal way for Communism to infiltrate at least one of the professions and obtain a modicum of prestige for their nefarious theories. If a Communist is told what to do he will do it—that is his particular brand of freedom—even to joining the Church. Once inside this association he will know how to act, and to the best advantages of his Muscovite masters. That is his technique; and fools and babes fall for it like leaves in autumn.

A second aspect of this association must surely be its overwhelming uselessness in preventing war. I can well imagine the Kremlin oozing with tears of regret for having started the war in the face of the association, whose members will no doubt have chartered a plane (and a gross of peace umbrellas) and thrown themselves at the feet of Khrushchev, waving their stethoscopes as the true symbols of peace upon earth. I shall give them the widest possible berth and shall continue to treat them with the gravest possible suspicion.—I am, etc.,

Kingswinford, Staffs.

W. A. O'CONNOR.

Haemorrhage and Shock

SIR,—May I comment on two letters in your issue of November 2? That by Dr. C. M. Heath (p. 1050)—how true. I was brought up with this aphorism: "There are three grades of liar: the liar, the d—liar, and the statistician."

That by Dr. M. A. Dobbin Crawford (p. 1050)—how equally true. My life was undoubtedly saved, and subsequent full recovery secured, when in the first world war I recovered consciousness in time (as the only M.O. within ten miles) to stop my orderly moving me from where my aeroplane had crashed. The injury was severe enough even then—paralysis of all four limbs, diaphragm, and lower ribs. Many hundreds of other cases owed their lives to the hours of immobility enforced by a shell casualty where haemorrhage was not a serious complicating factor. Some years later I chanced, on the Great North Road, to arrive as a car turned without warning into a small side road and thus precipitated an overtaking motor-cyclist in a head-over-heels accident. Remembering my own experience, I refused, rudely and emphatically I fear, the crude police litter and long Liston splint, and prevented any movement whatever until skilled first-aid, a Thomas splint and a motor ambulance were by the patient's side. I subsequently received a letter from my old chief, Lord Trenchard, then Commissioner of Police, thanking me and affirming that my action had probably saved the motorist from a charge of manslaughter.

Therefore, let patients R.I.P. alive.—I am, etc.,

Chipping Campden, Glos.

C. B. HEALD.

Stomatitis Associated with Streptomycin Therapy

SIR,—Belatedly—due to distance—I have just read Dr. W. C. Harris's letter (*Journal*, October 12, p. 884) drawing my attention to the paper of Beham and Perr in 1948,¹ which I had so stupidly overlooked when writing my memorandum (*Journal*, September 14, p. 628). I am delighted, and grateful, that he has done this, and I agree that the evidence presented suggests that stomatitis occurring during streptomycin therapy may be a declaration of hypersensitivity.

My slight note had, I should say, a twofold purpose; first, to point out that stomatitis can occur as an isolated clinical abnormality (and such was the case in only one of the four cases mentioned by Dr. Harris); and, secondly, that it can be associated with an impressive rise in eosinophil count. I was interested to find, on reading the paper of Beham and Perr, that relapse of stomatitis on readministering streptomycin was as rapid in their patients as in those that I reported.—I am, etc.,

New York.

RAYMOND PARKES.

Maternal Age and Foetal Oxygenation

SIR,—Dr. E. P. N. Turnbull and Professor Dugald Baird describe (*Journal*, November 2, p. 1021) a valuable reduction in perinatal mortality from anoxia achieved by inducing labour at the 42nd week in postmature primigravidae over 25 years of age. To obtain samples of cord blood they clamped the cord "immediately after delivery." While this procedure was obviously justified for the important purpose of O₂ measurement for which it was employed, one would like to be reassured that ordinarily the newborn baby will be laid a little below the level of the placenta and will be allowed to keep its umbilical cord for the few moments necessary to collect its full entitlement of foetal corpuscles. One would not wish anaemia to be added to anoxia.—I am, etc.,

London, N.9.

MAIR THOMAS.

Patent Ductus Arteriosus

SIR,—In your leading article (*Journal*, October 5, p. 810) you state that the treatment of patent ductus arteriosus with left to right shunt is ligation and division of the duct, the latter in order to prevent recanalization. My experience with over 100 cases suggests that simple ligation of the two ends of the ductus with braided silk ligatures is adequate treatment—all the cases have been followed for at least six months and no recanalization has been observed. I think most instances of recanalization which have been reported have been due to the ligatures or their knots being insufficiently tight, or to the use of absorbable or stretchable material.

Division and suture of the ductus must make a much longer and riskier operation than the simple 20-minute procedure which I find ligation to be. In the hands of those with great experience it apparently does not raise the mortality rate much, but if used generally by all who operate for patent ductus arteriosus it would almost certainly result in an appreciable increase in mortality. My experience suggests that it is unnecessary to inflict this extra risk on the patient.—I am, etc.,

Manchester.

HERBERT HAXTON.

Vaginitis

SIR,—The method of treating monilial vaginitis suggested by Dr. M. G. Good (*Journal*, March 2, p. 517) is very similar to a method which I was taught (by whom I have forgotten) and used for at least nine years. There are, however, two minor differences: (1) I use a saturated solution of NaHCO₃ to clean the vagina—not a weak solution as suggested by Dr. Good. The reason for using NaHCO₃ was originally the belief that this would help to remove mucus. (2) 1% aqueous solution of gentian violet is used instead of an

alcoholic solution of methyl violet; alcoholic solutions are unkind to the unanaesthetized patient's mucosa.

Three points have always seemed important: (1) The cleaning process must be thorough to remove all debris from the bottom of the crevices between the mucosal folds—the most prominent in the para-urethral area. It may take up to 10 minutes to achieve. (2) The vagina is thoroughly dried before applying gentian violet so as not to dilute the 1% solution. (3) The patient is entitled to treatment for this distressing complaint on the day she first reports. Treatment is admittedly unpleasant for the patient (necessitating 10–15 minutes' manipulation in the lithotomy position) and time-consuming for the doctor. But it has the following advantages: failures are very infrequent—as are recurrences; and, whether the patient be pregnant or not, relief from symptoms is immediate—as they walk out. Immediate relief from irritation has not been achieved with any self-applied drug which I have yet advised my patients to try, although I have had to use them for the occasional case which does not respond to one treatment as outlined above.—I am, etc.,

Malvern, Australia.

JAMES SMIBERT.

Snake-bite

SIR,—Mr. C. W. Greene (*Journal*, October 5, p. 825) describes the Macedonian viper as *Vipera nasicornis*, and states that it is the same as the English viper. In fact the Balkans species is the long-nosed or sand viper (*V. ammodytes*), and is quite different from the English *V. berus*. The venoms of the two are distinct, the Macedonian species having a pronounced neurotoxic factor in addition to the haemorrhagic which is prevalent in the English species. Polyvalent antivenin applicable to both species is produced by the Pasteur Institute at Garches, near Paris, and by the Behring Works, Marburg, Germany. It is true that the bite of the English viper, as a rule, is not too dangerous, and can often be controlled by local treatment (Sir Philip Manson-Bahr, *Journal*, August 24, p. 468). But in other species every case should be treated on its own merits, and antivenin should be the first line of defence. The frequency of snake-bite as such is often exaggerated, but it must be kept in mind that every bite, wherever possible, should be treated by a physician. Neglect can be fatal, as is shown by the recent tragic death of Dr. Karl P. Schmidt, of the Chicago, a leading herpetologist, who was bitten in the laboratory by a South African Boomslang (*Dispholidus typus*), and, having failed to consult a physician, died within 24 hours.—I am, etc.,

Bethesda, Maryland, U.S.A.

E. SCHWARZ.

Mongolism in a Twin

SIR,—With reference to Dr. J. V. Morris's medical memorandum (*Journal*, November 2, p. 1038), in view of the rarity of mongolism in one of twins, a further case is quoted for record purposes.

The mother, aged 43, was of average intelligence. She had had no serious illnesses, except for a pleural effusion in 1942. The twin girls were her thirteenth pregnancy—seven children from her first marriage and four from her second. She had had two miscarriages, the last in 1952 necessitating curetting on two occasions within one month and a blood transfusion. With her twelfth child in 1955 she again had a transfusion for antenatal anaemia. The birth of the twins in May, 1957, was normal except for a five-day post-in maturity. The sister was a vertex presentation weighing 6 lb. 10 oz. (3 kg.); the mongol child a breech, weighing 4 lb. 5 oz. (2 kg.). They are now nearly 6 months old, the sister's weight is 13 lb. 1 oz. (5.9 kg.) and the mongol sister's weight is 9 lb. 2 oz. (4.1 kg.). She would at one time take up to 1½ hours over 2 oz. (56 g.) of milk, and her average weekly gain has been 3–3½ oz. (85–99 g.) per week, while her sister's has been 3–8 oz. (85–227 g.) per week. Both have doubled their birth weight. The child has definite mongol features with a microcephalus which shows greater prominence of the left parietal eminence. She has had no serious illnesses and

no fits. She has responded well to oral iron for some clinical anaemia. The contrast between the two children is enormous: the sister is much bigger, chubby, happy, laughing, and observant. The mongol is smaller, thin, expressionless, and shows very little interest, although her eyes will follow for a short while a clicking of one's fingers. The only abnormality of the sister is that she is tongue-tied. All the other brothers and sisters show no obvious abnormalities.

From an aetiological point of view, the mother's blood transfusions can possibly be ruled out, as cases are reported in British literature as far back as 1876. But is it coincidence that these twins were the fifth children, exactly as occurred in the case reported by Dr. Morris?—I am, etc.,

Stenosis of the Sphincter of Oddi

SIR,—I was very glad to read the annotation on this condition (*Journal*, November 2, p. 1044). I believe, owing to lack of recognition and inadequate treatment, stenosis of the sphincter is the cause of many disappointments after cholecystectomy. Spasm of the sphincter may be inaugurated by pathological conditions of the biliary passages or of the pancreas, and will probably yield to antispasmodics. But in due course spasm leads to fibrosis, which is an irreversible condition. The resulting stenosis can almost certainly be excluded, and a cholangiograph on the operating table reveals or confirms stenosis, which yields a characteristic appearance, which I have previously described and illustrated.¹ To avoid post-operative disappointments it is imperative that the sphincter be divided. This is accomplished either by the sphincterotome devised by Doubilet and Mulholland,² or, if this instrument cannot be manipulated through the fibrosed duct, the duodenum is opened and the sphincter divided on a probe passed down the common duct. Section of the sphincter not only relieves back-pressure in the biliary passages, but, what is also of great importance, in addition it decompresses the pancreatic ducts. Causes and types of pancreatic dysfunctions are still much of a mystery, and it is probable that abnormalities of the pancreas are a not uncommon cause of "post-cholecystectomy syndromes."—I am, etc.,

Influenza Epidemic

SIR,—Like many others who have encountered influenza epidemics from time to time, I have regarded the word "Asian" as 1957 and all that, but on looking up Fagge's *Principles and Practice of Medicine*, 1886 edition,¹ I find strong support for the word "Asian." He states that during the last four centuries the influenza periods have been carefully studied, the late Dr. Parkes (in Reynold's *System*) saying there were eleven in the sixteenth century, sixteen in the seventeenth, and eighteen in the eighteenth. Between 1800 and 1850 there were no fewer than ten. There was a long lull after 1850. Fagge states that no other disease diffuses itself equally widely over the earth's surface. In some epidemics it has ranged over every quarter of the globe. He states that many observers have thought the epidemic follows a definite direction—namely, from east or the north-east towards the west or south-west. Thus the epidemic which raged in London in 1833 was believed by Hirsch to have been related to one in 1830 in China, which reached Moscow later. In 1831 it spread over Russia, Poland, Germany, France, Sweden, Italy; it appeared next in the Isle of Man and lastly in New Jersey. In 1832 it affected Spain and the U.S.A. In 1833 it reached London via Russia, Germany, and Denmark. Fagge says: "It is particularly worthy of notice that both in England and France influenza seems to occur only as an extension from other countries." Some old writers have doubted whether

it can arise in Europe, and believe that its home is some remote part of Asia, such as Chinese Tartary, and is always derived from thence. Fagge, in 1886, was convinced influenza was due to a living thing, capable of reproducing and multiplying itself once it has reached a district or country.—I am, etc.,

REFERENCE

¹ Fagge, C. H., *Principles and Practice of Medicine*, 1886. London.

SIR,—We were interested to read the experience of our neighbours, Drs. John Fry and E. M. Hume (*Journal*, November 2, p. 1057). We would largely agree with their findings, but are surprised at the considerable disparity in the incidence of influenza between their practice and ours. The two practices are evidently of comparable size, but the total number of patients actually seen by us to date has been 479, representing about 8.3% of the practice. This compares with Dr. R. E. Hope Simpson's incidence of 8.9% recorded in the same issue and contrasts with Dr. Fry's estimate of over 15%. Most working adults require certification of illness and most children with influenza give rise to sufficient anxiety to warrant consultation, if only by telephone. We would have regarded an additional 100 as a generous estimate of those who suffered from influenza but did not consult us, and, differing from Dr. Fry's estimate of 25%, we do not consider that more than 10% of our patients at risk have so far been affected. We are bemused by these statistical disparities.—We are, etc.,

Epsom College Centenary Fund

SIR,—You were good enough to publish the original letter explaining the needs of the College for many improvements and appealing to the profession for the money necessary to carry them out (*Journal*, November 27, 1954, p. 1280). Progress was reported in an interim statement, which you also kindly published (*Journal*, November 12, 1955, p. 1205); and it is now due to subscribers that they be informed of the present position. If all those who have signed covenants survive for the full seven years, we have in sight a net total of about £60,000. This includes several bequests, allocated to this fund by the council, which would, in the ordinary way, have gone to swell the endowment. It includes also generous assistance from the British Medical Association and the Medical Insurance Agency. The balance, subscribed by members of the profession and by Old Epsomians, many of whom are doctors, accounts for less than £40,000. This result, frankly, is disappointing. The needs of the College are so urgent that the council have already embarked on a new boarding house, new laboratories and classrooms, and will still be faced with rebuilding the kitchens and dining-hall. These essential projects will cost far more than the appeal has produced, and to meet the cost it will be necessary to use the whole of the endowment fund and the general purposes fund investments, a most regrettable but inevitable expedient.

The centenary fund has not been closed, and we do beg the profession to help. The new buildings are actually going up and are open to inspection at any time. Medical men and women are urged to pay a visit to satisfy themselves of the merits of the planned expenditure. Financially, the College will be hard hit when the improvements have been paid for; but the council have realized that the efficiency of the College is at stake and that their duty has been to go forward with them. We need much more help, and we do urge the 98% of the profession who have not yet responded to the appeal to contribute, whether or not they are already regular subscribers to the charitable funds administered by the College for the benefit of the widows and orphans of medical men.—We are, etc.,

Epsom College, Surrey.

Obituary

RICHARD WARREN, D.M., M.Ch., F.R.C.S.

Mr. Richard Warren, who was honorary surgeon on the staffs of the London and Brompton Hospitals before moving to Weston-super-Mare some thirty-five years ago, died at Weston-super-Mare on October 31. He was 81 years of age.

Richard Warren was born at Waltham Abbey, Essex, on February 17, 1876, the son of General Sir Charles Warren, F.R.S. From Charterhouse he entered New College, Oxford, with a scholarship, and took a first-class in the honours school of natural science in 1897. The best boxer of his day at Oxford, he competed for the heavy-weight amateur championship, but was knocked out by a policeman. From Oxford he went on to the London Hospital as a Price Scholar, and he graduated B.M., B.Ch. in 1900. Two years later he was admitted a Fellow of the Royal College of Surgeons of England, and he proceeded to the D.M. in 1905 and the M.Ch. in 1907. From 1901 to 1903 he held a Radcliffe Travelling Fellowship. After graduation he became senior dresser to out-patients at "The London," where, for a number of years afterwards, he held a variety of other appointments, including those of receiving-room officer and surgical registrar. There were then only two registrars—Otto Leyton, medical, and Warren, surgical, and the surgical registrar was not allowed to operate. Despite this, Warren performed with great success 100 major operations, most of them abdominal, at "The London" within a fortnight of being elected to the staff in 1909. He was a fine operator, and for such a big, powerful man the gentleness of his touch was remarkable. He examined in surgery for the universities of Oxford and Cambridge from 1914 to 1922, and he wrote a *Textbook of Surgery* which was published in 1915. During the first world war he served in France as a temporary major in the R.A.M.C., being at one time officer commanding a surgical division at Rouen. From 1907 to 1921 he was surgeon to the Shadwell Children's Hospital, and from 1915 to 1921 surgeon to the Brompton Hospital.

In 1921 Warren left London, resigning his hospital appointments, and settled at Weston-super-Mare, where he became surgeon to the general hospital and consulting surgeon to the West of England Sanatorium, Weston-super-Mare, and to Burnham-on-Sea Cottage Hospital. For many years one of the leading medical men in the west of England, he was chairman of the Bristol Division of the B.M.A. in 1928–9, president of the Bath, Bristol, and Somerset Branch in 1935–6, and chairman of the East Somerset Division in 1937–8. He married Miss Violet I. Jenkin in 1912 and had two sons and one daughter. Mrs. Warren died in 1941.

N. C. C. writes: Richard Warren went to Weston-super-Mare in 1921, taking over the practice of the late Dr. H. S. Ballance, including the post of an honorary surgeon to the general hospital—an appointment he held until his enforced retirement in 1950. Family reasons necessitated his leaving London, and to that fact Weston owes a great debt of thankfulness. He was a brilliant surgeon, working with absolute precision and calm, and the standard of surgery at the Weston Hospital was at once enhanced by his work there. "Dicky," as he was affectionately called by all his colleagues, was not only outstanding in his craft, but carried with him the cheerfulness, courtesy, and humility which are

Nov. 16, 1957

OBITUARY

the stamp of a really great man. He was always willing to help with his sound opinion, which was given almost apologetically. One felt that one could go to him for help and advice, receiving understanding and valuable assistance given with the wisdom born of sound knowledge and experience. He had a deep sense of humour, and his anecdotes and reminiscences, which were many, were told in a quiet voice which gave them added charm. In his leisure time he enjoyed shooting and fishing, in both of which he excelled, and was often to be seen, even in his seventies, on the mudflats at dawn or dusk looking for duck and snipe. "Dicky" was also a musician, and his knowledge and appreciation of classical music were of a high standard. In fact, he was so widely informed that there was scarcely a subject he could not discuss without obvious understanding and some authority. On retirement from the hospital work and some authority. He so loved, he still kept his interest in its progress and was always sure of a warm welcome when he occasionally visited his hospital, but increasing deafness prevented him from active participation in many social events. We shall miss his kindly presence, but will always be grateful that we were privileged to know him and work with him.

K. C. M. writes: Richard Warren is no longer with us, and the world is a poorer place for his passing. Since his retirement some years ago we have missed his long, thin figure from the hospital wards, but he was still ever ready to pass on the benefit of his vast knowledge and experience to whoever wanted it. I first met him twenty-five years ago, to whomsoever wanted it. I first met him twenty-five years ago, when, as a brash, over-confident, and ignorant young house-surgeon, I arrived at Weston-super-Mare. He treated me with a kindness and courtesy I did not deserve and was ready to listen and discuss a case as an equal. I fell under his spell in those far-off days, and as the years went by it turned to adoration as his patience, help, and encouragement made it possible for me to gain a higher degree. His pride and happiness in my achievement was the greatest compliment I could have been paid. During those years one was always being astounded by the wealth of his knowledge, and often when some new procedure was written about he would remark with a twinkle in his eye that So-and-so had written about that in 1912, quoting date and journal. He was for ever learning and was always enthusiastic about new methods and techniques. He was a brilliant diagnostician and operator, and his handling of the inflamed testine was a joy to watch. One of the last great general surgeons, he was well equipped to tackle any surgical problem in all parts of the body. Others may write about his brilliant academic career, but we who knew him were given an unforgettable chance of basking in the light of his wit, wisdom, and charm. He was a born teacher, and, although not a good speaker to a large audience, was able to pass on his knowledge and experience to anyone interested in learning. He was a kindly man, and in all the years I knew him I have never heard him say an unkind word about anyone. I think that his love of music was second only to his love for surgery, and on his retirement he began to learn and study the songs of Schubert, and he recently informed me that he now knew over 150 songs by that great master. Richard Warren was a humble man, as only a great man could be, and it was an honour to have had the privilege of knowing him, working with him, and being counted as one of his friends. With his passing we have all lost a colleague whose standards were so high both professionally and morally that all we can do is to strive humbly to follow the example he set. He was indeed the complete man.

E. L. PERRY, D.S.O., M.R.C.S., D.P.H.

Colonel E. L. Perry, who was well known in the Indian Medical Service for his work as a malaria officer, died at Sidmouth on November 4 aged 85.

Edmund Ludlow Perry was born on June 28, 1872, the son of Surgeon Major George Perry. He studied medicine at St. Thomas's Hospital, winning several prizes and qualifying M.R.C.S., L.R.C.P. in 1895. Joining the Indian Army Medical Service in the same year, he served on the North-

West Frontier, being mentioned in dispatches in 1897. After the campaign in 1901–2 he was awarded the medal, with clasp. In 1906 he took the D.P.H. of Cambridge, and in the following years he was in turn chief malaria officer in the Punjab, lecturer in hygiene at Lahore Medical College, and acting sanitary commissioner to the Punjab Government. During the first world war he served in Mesopotamia, being twice mentioned in dispatches and awarded the D.S.O., and in North Persia. After a year in Afghanistan he was appointed sanitary commissioner with the Government of Madras. His final post in the I.M.S. was that of assistant director of medical services, Calcutta. Honorary surgeon to the King from 1925 to 1927, he retired in the latter year and lived for a time at St. Malo, where he was proconsul. Later he went to live at Sidmouth, Devon, and had been medical officer of health to the urban district council for the past 21 years. Apart from his work as M.O.H. he took an active part in local affairs, having been a past-president of the Sidmouth British Legion and Sidmouth Rotary Club. Colonel Perry's wife died 18 months ago.

We are indebted to Sir RICHARD CHRISTOPHERS for the following appreciation: It was with deep regret that I heard of the death of Colonel Edmund Ludlow Perry, of the Indian Medical Service, with whom in early days in India I had many happy associations. I first knew Colonel Perry (then major) in 1910 as one of the eight senior officers of the Service specially selected as provincial malaria officers to organize and carry through malaria research and surveys in each of the Provinces of British India—the first time I suppose such a task was ever undertaken in any tropical country. I was to see more of Colonel Perry during the first world war in Mesopotamia, where he was in charge of a large military hospital of the Expeditionary Force at Basra, and again when he was sanitary commissioner of the Punjab. Always Perry was a delightful companion, breezy, cheerful, and with a natural spontaneity that was very characteristic of him, and a staunch friend. He was in many ways rather remarkable for his unexpectedly wide interests. He was, for example, an enthusiastic amateur astronomer, and in India had made his own quite large mounted telescope in which I well remember being shown the planet Jupiter. That he was no novice was shown by his being the first to see and announce his finding of a nova. Again, very characteristically, when asked by an educational authority to write a small book on health precautions for use of schoolchildren, Perry produced no formal textbook but a veritable Arabian Nights story that conveyed all that was required, was a best seller, and was translated into a number of languages. Perry was physically unusually hardy, indefatigable in what he undertook, and believed always in seeing things for himself. He was a great walker, and it is said of him that in the Jaipur Hill Tracts, one of India's most malarious and remote areas, he left behind him among local hill tribes a tradition of a lone walker to be seen at strange times and places on the hill slopes. After Perry had retired to Sidmouth it was a great pleasure to meet him again on a night when he went to the trouble to come up to London to a lecture I was due to give at the London School. He was his old self and full of vitality and interest in his work.

R. MAXWELL CHANCE, M.D.

Dr. R. Maxwell Chance, who was well known as a general practitioner in the West End of London for forty years, died in London on August 27. He was 69 years of age.

Robert Maxwell Chance was the son of a schoolmaster and received his general education at Hymers College Hall and his medical education at Aberdeen University, where he graduated M.B., Ch.B. in 1910, going on to take the M.D. with highest commendation two years later. He had a brilliant student career and was the envy of his fellow students, but still he found time for manly sports, especially in boxing and Rugby football. Four years after he had graduated came the first world war, and he volunteered

at once, going to France in 1914. He was involved in the horror at Ypres, when the Germans poured chlorine gas over the unprepared front, and his lungs were badly damaged. He was invalided, but as soon as he was able he worked in the officers' hospitals of Sister Agnes and the Freemasons in London.

A. D. W. writes: Maxwell Chance started general practice in the West End of London in 1917 and continued up till the last day but one of his life. He was probably the doyen of the doctors in the district, and his patients included some of the highest in the land. Although his practice was of the type regarded as fashionable, yet when the National Health Service came he joined with an

enthusiasm inspired by the idealism of his character, which came as a revelation to me. He was disillusioned by the Service and resigned in a sad frame of mind after a fair trial of the system and went back to his old way of life, where he was appreciated for his true and real worth.

He had the most delightful charm of manner, which was not an effort or a pose. As a diagnostician he was remarkable, and he recognized his own last illness, the bewildering symptom-complex of argenteaffinoma and

serotinaemia. Altogether admirable was his tenacity of purpose in the way he cared for his patients, and if he felt that he had not done all that he should he would take the matter terribly to heart. His practice included much hotel work, and many a tourist from abroad took away with him a life-long love and regard for Max. He found the work of National Service tribunals congenial and made an excellent chairman, well respected by the other members. He was representative of a class of medical man that may disappear under modern regimentation, but they will be missed because they were wonderful doctors, and none more so than Maxwell Chance. A few weeks before he died he told me how his wife had helped him through the years of general practice and how, when his long-drawn-out illness came, she had stood by him in his resolve to work to the last. To her and to his daughter, Maridel, whom he dearly loved, goes the sympathy of all his friends, and they are many.

R. M. ATWATER, M.D., Dr.P.H.

His many British friends have heard with profound sorrow of the death on October 18 of Dr. Reginald M. Atwater, commonly known as "Rex," the executive secretary since 1935 of the American Public Health Association. He was 65 years of age.

Reginald Myers Atwater went on from Colorado College to Harvard University, where he graduated in medicine in 1918, and five years later he took the doctorate of public health of Johns Hopkins University. In his early years he taught public health in Changsha, China, and at Harvard, and then was a county health commissioner in New York State before joining the American Public Health Association. He received many honours, including the Cuban order of Carlos J. Finlay, the Sedgwick medal of the A.P.H.A., and the honorary fellowship of the Society of Medical Officers of Health.

A. D. writes: Under Rex Atwater's shrewd and energetic guidance the A.P.H.A., with a membership of about 15,000, exercised great influence on American public health. Atwater was a first-class administrator and was always looking for new ways in which the A.P.H.A. might extend its sphere of usefulness. He travelled constantly to attend branch meetings of his association and was often accom-

panied by British visitors, included among whom have been Dr. V. M. Crosse, of Birmingham, and, this year, Sir Andrew Davidson, of Scotland. He was most hospitable both at his home in Bronxville and in New York. He was good company, with a fund of anecdotes and a lively sense of dry humour. It was good to see him doff first his coat and then his waistcoat to join in the square dances after a public-health dinner. A non-smoker and a strict teetotaler, he was an active worker at the famous Riverside Church, New York, and his charming wife, formerly Charlotte M. Penfield, was a daughter of the manse.

No appreciation of Rex would be complete without mention of his annual Christmas card. He was a devoted family man, and had 5 children and 11 grandchildren. Every year a family photograph of all of them was taken and sent to all his friends with Christmas greetings and a short description of where all the children were and what they were doing. Rex Atwater was the finest type of American, and his mark will remain on American public health for many years yet to come. He had a warm affection for those members of the British public health service who had the privilege of his friendship.

A. C. WILSON, M.R.C.S., L.R.C.P.

Dr. Ambrose Cyril Wilson, a well-known psychiatrist—or psycho-analyst, as he would have preferred to be called—died on October 7 at the age of 76 after an illness of several months.

The son of the Rev. Ambrose Wilson, D.D., who in turn was headmaster of Melbourne Grammar School, Australia, housemaster at Rugby, and headmaster of Lancing College, Cyril Wilson was born at Carlisle and received his earlier education at the same schools at which his father held masterships. Shortly after leaving Lancing, he went on the stage, playing in various touring companies for about a year, but, deciding to take up a medical career, he entered St. Bartholomew's Hospital. Qualifying in 1908, Dr. Wilson continued to follow a somewhat varied career in medicine. First he served as surgeon lieutenant in the Royal Navy for five years, resigning his commission in 1913, and then proceeded to Capetown, where he considered settling in practice. On the outbreak of war in 1914, however, he at once returned to England and joined the R.A.M.C., in which he served as a regimental medical officer at the Dardanelles—where he became seriously ill with paratyphoid and dysentery—and later in France.

On demobilization he became attracted to psychological medicine, and subsequently to psycho-analysis, in which he received his preliminary training from Dr. Ernest Jones and Dr. Melanie Klein. Throughout his subsequent career he remained a staunch Freudian and was a prominent member of the Psycho-analytical Society. In 1924 he was appointed a clinical psychologist at the West End Hospital for Nervous Diseases, London, and continued to do valuable work with that institution until 1945. In addition, he held appointments at the Psycho-analytical Clinic, the Institute for the Scientific Treatment of Delinquency (now called the Portman Clinic), and in the psychological department of St. Bartholomew's Hospital; also for a time he acted as psychiatrist to Broadmoor Mental Hospital.

C.W.D. writes: Those of us who knew Cyril Wilson intimately will miss him very much as a most loyal friend and delightful companion. He was devoted to his specialty, and at no time would he consider any treatment for psychoneuroses other than psycho-analysis; though prepared to modify his methods at out-patient clinics, he preferred to use the full Freudian technique. For this reason he was somewhat intolerant of criticism of psycho-analysis, and his outspoken comments and spirited defence of his subject occasionally offended some who otherwise would have been his close friends. Consequently one had to know him really well to appreciate his excellent qualities.

Cyril Wilson disliked intensely relinquishing the treatment of any of his patients until he considered they had reached

a condition of stability, and in private practice he continued to treat many a patient without fee, in some instances for several years. A good speaker and an excellent conversationalist, he was extremely diffident in putting his views and ideas into writing, and with his few publications he invariably asked one or more colleagues to read them and make any corrections that seemed desirable. Several excellent communications he never published.

Cyril Wilson remained unmarried, which allowed him to be a very "clubbable" man, to use the Johnsonian term, and his frequent visits to the Union Club and attendances at the Fountain Club of St. Bartholomew's Hospital gave him considerable pleasure. Cyril Wilson will be greatly missed both by his patients and by close friends.

CLIFFORD WHITE, M.D., F.R.C.P., F.R.C.S. F.R.C.O.G.

The obituary of Mr. Clifford White was printed in the *Journal* of November 2 (p. 1053).

A. W. B. writes: It was at the end of the first world war that I first began to know Clifford White as a very good friend. I was appointed to the honorary staff of one of his hospitals as I emerged from the war, like many others, debilitated by illness and with no asset but a subdued hope. Clifford soon heard of my return to civilian life and thereupon sought me as an object for his help. It was during those early months that I realized his essential kindness. It was not merely a cheery greeting and good wishes but an organized kindness which sprang from his sympathy and generosity, never overlaid by an ostentatious patronage but coolly active and real. This quality of heart, tempered by his careful thought, led him throughout his long life to notice and even watch for opportunities to identify himself with the difficulties of all those who worked with him. It inspired his consideration for his residents and nurses, his patience and forbearing with the many little short-comings of those he knew to be learning. Often I used to assist Clifford in the Samaritan theatre. Never can I remember a peevish intolerance or a sharp word if some-thing he needed was not immediately at hand. After an operation, which may have stretched him, he might quietly take an assistant or a nurse aside and almost whisper a word of help and advice.

Others have written of his professional conscience and surgical skill, but few of his friends remember him as an obstetrician at Queen Charlotte's. His less than robust health led to resignation from this hospital during the late twenties, and, so characteristic of his almost quixotic honesty, he also refused to undertake any more midwifery in private practice. As an obstetrician he practised before these modern days of antibiotics, blood transfusion, and advances in radiology, and so belonged to the "old school" of skill in vaginal manipulations and delivery which are almost unknown to the young men of to-day. But he was almost unknown to the young men of to-day. The word insight into a difficult obstetric situation. The word "honesty" reminds me further of his dealings with his private patients. Clifford was scrupulously careful always to consider that which was essential for their treatment, irrespective of any other consideration.

Sometimes he seemed to be "difficult," especially in medical committees. During a discussion he would be silent for a while, listening with his head turned to one side, and then he would speak with an acute and final criticism of some proposal which he showed to be clearly unsound. Clifford White combined all the qualities which unite to form the high ideal of the vocation of medicine, but most prominent in my memory are kindness, sympathy, and honesty.

GERTY T. CORI, M.D., Sc.D.

The obituary of Dr. Gerty Cori was printed in the *Journal* of November 2 (p. 1055).

We are indebted to Professor F. G. YOUNG for the following appreciation: Dr. Gerty Cori was a most out-

standing biochemist; in the researches carried out in collaboration with her husband she was an equal partner, while some lines she developed with junior colleagues and students alone. It was natural that when in 1947 the Nobel prize came to be awarded she and her husband were given the award jointly, sharing it with Professor B. A. Houssay.

When, in 1922, Carl and Gerty Cori moved to Buffalo, N.Y., from Prague they began their investigations on carbohydrate metabolism which brought them such distinction, Carl Cori working as a biochemist at the State Institute for the Study of Malignant Diseases in Buffalo while Gerty was at first assistant in pathology in the same Institute. At the Institute they carried out studies on the biological action of x rays, on the effects of ovariectomy on mammary tumours, and on the carbohydrate metabolism of tumours. Their interest in carbohydrate metabolism became dominant and they proceeded to study the fate of sugars ingested by the whole animal, taking up a question which Claude Bernard had first investigated many years before. Making use of the rat, they were able to show that about one-half of the glucose administered by the mouth was stored as glycogen in the liver and muscles, while some of it was converted to fat or oxidized. They then proceeded to study the influence of hormones, particularly insulin and adrenaline, on carbohydrate metabolism, and this led to their elucidation of what is now known as the Cori cycle: in the mammal, as opposed to the frog, lactic acid formed in the muscles is not reconverted to glycogen in skeletal muscle tissue but in the liver. Thus glucose formed from glycogen in the liver can be successively transformed to muscle glycogen, lactic acid, liver glycogen, and then glucose again.

The researches of those days were surveyed in an article, "Mammalian Carbohydrate Metabolism," published in *Physiological Reviews* in 1931. It was in this year that Carl and Gerty Cori moved to St. Louis, Mo., where ultimately they both became professors of biochemistry in the school of medicine of Washington University. In St. Louis they took up the investigation of isolated enzyme systems and found that under suitable conditions glycogen in a muscle extract could break down to a hitherto unknown compound of glucose and phosphoric acid which they isolated and identified as α -glucose-1-phosphate. They then showed that glucose-1-phosphate, a substance of rather special properties, was on the pathway for both the breaking down and building up of glycogen, the enzyme phosphorylase being concerned with the interconversion of glucose phosphate and polysaccharide. Later, an enzymic method was introduced for the assessment of the structure of the glycogen molecule, which is capable of significant variations with respect to the length of the various parts of the chains which constitute it (see *British Medical Journal*, 1957, 1, 1436). During the past few years Gerty Cori and her pupils have applied these enzymic methods of molecular analysis to the glycogen in the liver and muscles of patients with glycogen-storage disease. In the liver-kidney type, first described by von Gierke, only the liver and kidney are affected and the origin appears to be in a deficiency of the enzyme glucose-6-phosphatase, an essential catalytic factor in the transformation of glycogen to glucose. In generalized glycogenosis some cases were found to possess glycogen with abnormally short outer chains, and a deficiency of the debranching enzyme appeared to be responsible for the condition. In other cases no obvious enzymic reason was found for the existence of the condition. In this way several types of the disease were differentiated.

The artificial production, *in vitro*, of polysaccharide from glucose-1-phosphate (1939) was a very great achievement, and this had a tremendous influence on research all over the world. Besides sharing the Nobel prize for medicine in 1947, Gerty received many honours, including honorary degrees from Boston University, Smith College, and Yale, Columbia, and Rochester Universities. Despite a prolonged illness she carried on her researches with great fortitude.

The Coris' laboratory and home in St. Louis was a meeting-ground for investigators from all over the world, and Gerty's keen mind and kindly grace will be sorely missed by all who knew her.

Medico-Legal

PSYCHIATRIST VINDICATED

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

The difficulties which sometimes beset the doctor who is called to give expert medical evidence can be formidable. However clearly he expresses the material upon which his expert opinion is formed, he may be misunderstood. He may be the victim of wholly unmerited adverse publicity in the national press for which he has no redress.

Dr. Donald Blair, of St. Bernard's Hospital, Southall, was instructed in February, 1957, to make a psychiatric examination of Mr. Ernest Frederick Barker, of Chandos Road, Willesden Green, for the purpose of giving evidence in a divorce suit brought by Mr. Barker against his wife. The Barkers had been married in 1936. They had two children and lived together until 1956, when Mr. Barker left home. Mr. Barker's petition against his wife alleged among other things that she had been guilty of the matrimonial offence of cruelty by refusing to allow him to have sexual intercourse with her, well knowing that by reason of her refusal her husband's health was being seriously undermined.

On making his examination Dr. Blair found Mr. Barker to be suffering from a chronic anxiety state. In order to form a conclusion about his patient's health he asked a great many questions, as he was naturally bound to do. From the answers to those questions he concluded that the chronic anxiety state had lasted for a long time.

On May 29, 1957, Dr. Blair was called to give expert evidence at the hearing before Mr. Justice Wallington. He told the court about his instructions for the examination of Mr. Barker and about his questions to Mr. Barker, on the basis of the answers to which his opinion about Mr. Barker's state of health was formed, and he also said with perfect propriety that if the evidence which Mr. Barker had given at the hearing about his married life was true it would be sufficient to account for the chronic anxiety state.

Dr. Blair had accordingly, as the Court of Appeal subsequently found,¹ made his examination and formed his opinion in the way any doctor must do and had told the court, as every expert should, what the facts were on which his opinion was based as well as what his opinion was. Like all expert evidence, if the facts on which Dr. Blair's opinion was based were inaccurate, because Mr. Barker's answers to his questions during the examination were untrue, his evidence would not assist the court.

Mr. Justice Wallington came to the conclusion² after hearing Mr. Barker that his evidence was not to be relied on and that his answers to Dr. Blair on which Dr. Blair's opinion was based were untrue, and he therefore rightly said that there was no evidence which he could accept about the chronic anxiety state in relation to the parties' married life. He then went on to say—as the Court of Appeal five months later pointed out, wholly without justification—that Dr. Blair was usurping the functions of the court in the way in which he had handled the matter. The judge is reported to have used such hard words as "flouting the court" and "making himself examining magistrate." "Nobody but a psychiatrist, I suppose, would dare to enter on such an activity." He said that Dr. Blair had questioned Mr. Barker carefully about his mental health and concluded that he had been suffering from a chronic anxiety state for a number of years, and that was something a doctor had no right to do for the purpose of giving evidence.

Language of indignation from the bench is news for the headlines, and when the Court of Appeal long afterwards vindicates its victim that is not headline news. Few lawyers

¹ *The Times*, November 1, 1957.

² *Daily Telegraph*, May 30, 1957.

would blame Dr. Blair if he refused ever to give expert evidence again, and, since fair and accurate reports of judicial proceedings published in newspapers are published under the shield of privilege, the law of libel can give him no redress. That judicial indignation is rare and rarely unjustified only makes things worse.

But to administer justice the courts very often depend upon expert evidence, and this unfortunate story will at least do some good if it serves to reaffirm the proper province of the expert, to which Dr. Blair had, as the Court of Appeal confirmed, so well confined himself. It is for the expert to form his opinion on the facts put before him and to inform the court not only of his opinion but of what those facts were. It is for the court to decide whether those facts were fact or fiction.

So far the court's task is relatively easy. Sorting fact from fiction is the judge's daily stint. When from identical facts experts of equal eminence form, as they sometimes do, incompatible opinions, it is then the fun starts for the lawyers.

The Medical Defence Union instructed Messrs. Hempsons, solicitors, to act for Dr. Blair.

SALIVA CLUE

A test of saliva in the gum of an envelope flap to determine the blood group of an accused person was referred to in evidence last week. A motor dealer was charged at Birmingham with demanding money with menaces.¹ He was alleged to have sent letters to two former business associates, demanding the money, and was committed on bail for trial at Birmingham Assizes. The saliva remaining in the gum of the flap on four of the envelopes was tested and found to be group A, the same as the blood group of the accused man. About 75% of the population secrete blood group antigens in the saliva.

Medical Notes in Parliament

Consultants' Merit Awards

Mrs. LENA JEGGER (Holborn and St. Pancras, South, Lab.) asked the Minister of Health on November 11 to state the estimated annual cost of the administration of the merit award scheme, and the amounts paid annually from public funds to the chairman and other members of the committee concerned. Mr. D. WALKER-SMITH gave the figure as £4,600, including £2,100 paid to the chairman of the committee, £400 to the vice-chairman, and £30 to those members who had retired from practice.

G.P. Vacancies

Dr. DONALD JOHNSON (Carlisle, Con.) asked what were the factors taken into consideration by executive councils in choosing candidates for the filling of general practice vacancies. Mr. WALKER-SMITH told him that it would not be possible to give an exhaustive list of all the factors taken into consideration. The decision must turn on the suitability of each candidate in comparison with others for the particular vacancy.

Franks Report Proposal

Mr. N. DODDS (Erith and Crayford, Lab.) asked the Attorney-General, in view of the criticism of the qualifications of medical members on pensions appeal tribunals, what action was being taken to implement the recommendation of the Franks Committee that each tribunal should include a practitioner with recent clinical as distinct from administrative experience, and that as far as possible that experience should be directly related to the type of disability before the tribunal. The ATTORNEY-GENERAL informed him that the Lord Chancellor had this matter under consideration.

Unprofessional Conduct

Mr. V. COLLINS (Shoreditch and Finsbury, Lab.) asked the Minister of Health, as representing the Lord President

¹ *The Times*, November 9, 1957.

of the Council, if he would request the General Medical Council to include wilful and deliberate neglect of a patient in the list of matters of unprofessional conduct for which a doctor might be removed from the *Register*.

Mr. WALKER-SMITH replied that the General Medical Council already had power to remove from the *Register* any medical practitioner whom they considered to be guilty of infamous conduct in any professional respect. While it was for the Council to determine in individual cases what conduct came within this definition, the Lord President of the Council was satisfied that it was wide enough to include such a breach of duty.

Mr. COLLINS said that recently a doctor had been severely censured and fined £100 because, without taking action to ensure proper treatment, he had removed from his list a patient who was dying. Would the Minister regard that as an example of infamous conduct that merited dismissal from the Health Service? Mr. WALKER-SMITH said that he could not properly comment on individual cases which in some circumstances might come to him.

Hospital Pay-beds

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked the Minister of Health in how many hospitals he had agreed to a relatively large number of single-bedded side wards being designated as Section 5 pay-beds on the understanding that only a much smaller number of these should be used at any one time; and what steps he had taken to ensure that in such cases a patient moved to one of these small wards for urgent medical reasons would not be returned to the main ward to make room for a paying patient. Mr. WALKER-SMITH stated that he knew of only one case in which approval had been given on this basis. He saw no reason why it should have the result implied in the question.

Mr. HASTINGS said there had been two or three applications from the North-east Regional Board. Unless an inferior type of treatment was given for ordinary persons, the principal effect of pay-beds must be to get patients in at once. Mr. WALKER-SMITH said he thought the difficulty this procedure was designed to meet was that in some hospitals the demand for Section 5 beds was low, but they had to be available for the different specialties at a time when the patient wanted to go in.

Mr. HASTINGS asked him to give instructions that patients needing these beds for medical reasons would not be turned out into ordinary wards to make room for paying patients. Mr. WALKER-SMITH pointed out that a bed designated under Section 5 could be used for persons needing the accommodation urgently on medical grounds. Whether they went there and how long they stayed was a question for the doctor treating them.

Dr. EDITH SUMMERSKILL (Warrington, Lab.) said there was rather an abuse of this facility. Was it not desirable to warn hospital authorities that these beds should not be used in that manner? Mr. WALKER-SMITH said that if she meant there should be instructions that there should not be a designation of this sort at all he would want further evidence, for there were advantages outweighing the disadvantages.

Dr. SUMMERSKILL said she did not say that. She was prepared to have this designation. But if a bed was being used for a sick patient taken from a general ward, and then a patient in a position to pay asked for it, that was then a patient in a position to pay asked for it, that was grossly unfair. Mr. WALKER-SMITH said he had no reason to suppose there was any danger of such a thing happening. If there was, he would certainly consider clarifying what he understood to be the position by a circular.

Detention Certificates

Dr. DONALD JOHNSON (Carlisle, Con.) asked if the Minister was aware of the ruling of the Lord Chief Justice in his judgment in the case of *Regina v. Head* in regard to the definition of a moral defective under the Mental Deficiency Act, 1913; and whether he would order an immediate review of the certificates of all detainees in institutions that had been made under Section 1(d) of this Act

relating to moral defect with a view to ascertaining whether these were valid in accordance with the correct interpretation of the law. Mr. WALKER-SMITH replied that he was aware that the Lord Chief Justice in the case in question referred to the statutory definition of moral defectiveness in the Mental Deficiency Act, 1913, and to the necessity for strict observance of its terms. The Board of Control in consultation with the Home Office was examining certificates given in the circumstances to which the Lord Chief Justice was referring.

Caponized Chickens

Lieut.-Col. BROMLEY-DAVENPORT (Knutsford, Con.) asked if the Minister had yet received advice from the Medical Research Council on the effect upon humans of eating chickens caponized by hormone injections. Mr. WALKER-SMITH stated that the advice of the Medical Research Council was that experiments had shown that any trace of oestrogen remaining in the flesh of caponized chickens was extremely small, and that neither carcinogenic nor other undesirable effects were to be expected from the use of diethylstilboestrol. In the light of this advice, no further investigation seemed called for.

Hospital Service.—The report of Sir Noel Hall on the administrative structure of the hospital service will be published in about a fortnight.

Mental Illness.—Legislation will not be possible in the present session on the Report of the Royal Commission on Mental Illness and Deficiency, but the Minister is considering what can be done by administrative means in advance of legislation.

Vital Statistics

Influenza

The numbers of deaths from influenza and pneumonia have continued to fall except in the Republic of Ireland. In the week ending November 2 deaths from influenza reported from the great towns were as follows, with the figures for the previous week in parentheses: England and Wales 263 (399), Scotland 20 (31), Northern Ireland 8 (16), and Eire 17 (13). Towns with 10 or more deaths from influenza were as follows: London 37, Birmingham 12, Stoke-on-Trent 11, Dublin 10. The total of weekly National Insurance claims in England, Wales, and Scotland fell sharply, from about 393,000 to about 299,000; the latter total is about double the corresponding figure last year.

The accompanying graph shows numbers of deaths in the 160 great towns of England and Wales from early September to the latest date for which figures are available.

The following table shows the age distribution of deaths from influenza in the 160 great towns of England and Wales. The unusually high proportion of deaths among young and middle-aged adults is still noticeable.

% ..	1	6	5	10	33	45

The maps below show the numbers of deaths from influenza plus pneumonia as a percentage of the total deaths. These are deaths reported from the great towns for the latest two weeks for which figures are available.

Week Ending November 2

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 444, whooping-cough 401, diphtheria 5, measles 1,736, acute pneumonia 1,443, acute poliomyelitis 60, dysentery 282, paratyphoid fever 8, typhoid fever 3.

Northern Ireland in 1956

The general death rate, the infant mortality rate, and the death rate from tuberculosis were the lowest ever recorded in Northern Ireland in 1956. The death rate was 10.6 per 1,000 population. Of the total deaths 66.2% were of persons aged 65 years and upwards, the corresponding figure in 1955 being 65.9%. Since 1946 there has been an increase of 210% in male mortality from lung cancer. Deaths of women from lung cancer nearly doubled—37 in 1955 to 72 in 1956.

The infant mortality rate in 1956 was 29, while the rate for 1955 was 32 per 1,000 live births. Maternal deaths numbered 17, compared with 24 in 1955. The rate for such deaths for 1956 was 0.58 per 1,000 births, which was a decrease of 0.25 from the rate for 1955 and a decrease of 0.28 from the average rate for the five years 1951-5. Mortality from tuberculosis declined from 211 deaths in 1955 to 164 in 1956. The resultant rate for 1956 was 0.12 per 1,000 of the population, which is little more than a quarter of that recorded five years ago.

Deaths from influenza plus pneumonia as percentage of deaths from all causes in week ending October 26.

Deaths from influenza plus pneumonia as percentage of deaths from all causes in week ending November 2.

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in September was 100, compared with 98 in the previous month and 93 in September, 1956.

The numbers of cases of industrial disease in the United Kingdom reported during September, 1957, were as follows: lead poisoning 12, mercurial poisoning 1, aniline poisoning 1, compressed air illness 1, epitheliomatous ulceration 20, chrome ulceration 12; total 47. There was one death from epitheliomatous ulceration due to pitch and tar.—*Ministry of Labour Gazette*, October, 1957.

Infectious Diseases

The only large variations in the trends of infectious diseases in England and Wales during the week ending October 26 were an increase of 104 for measles, from 1,310 to 1,414, and a decrease of 383 for acute pneumonia, from 2,280 to 1,897.

The increase in the number of notifications of measles was mainly due to a rise of 190 in Lancashire, from 136 to 226. The notifications of whooping-cough numbered 349 and were 31 more than in the preceding week. The notifications of scarlet fever, 399, were 17 more than in the preceding week. Only small variations were recorded in the local returns of both whooping-cough and scarlet fever. 3 cases of diphtheria were notified, being 2 more than in the preceding week. The fall in the incidence of acute pneumonia is still mainly confined to the northern section of the country; the largest declines were 118 in Lancashire, from 241 to 123, and 72 in Yorkshire West Riding, from 196 to 124.

The notifications of acute poliomyelitis numbered 66, and these cases were 8 fewer for paralytic and 6 fewer for non-paralytic cases than in the preceding week. The largest returns were Yorkshire West Riding 8 (Rotherham C.B. 2), Kent 6 (Margate M.B. 2), and Middlesex 6 (Hendon M.B. 3). The largest centres of dysentery were Yorkshire West Riding 66 (Huddersfield C.B. 27, Leeds C.B. 18, Bradford C.B. 11), Lancashire 56 (Manchester C.B. 18, Liverpool C.B. 16), and London 20.

Nov. 16, 1957

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1948-56 are shown thus - - - -, the figures for 1957 thus ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending October 26 (No. 43) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Medical News

Royal Society Medals.—The president and the council of the Royal Society have awarded the Copley Medal to Sir HOWARD FLOREY, F.R.S., professor of pathology at Oxford, for his distinguished contributions to experimental pathology and medicine; and the Buchanan Medal to Sir NEIL HAMILTON FAIRLEY, F.R.S., for his distinguished contributions to the control of malaria.

Wellcome Research Laboratories.—The Wellcome Foundation is expanding its research resources at its Beckenham Laboratories by a £1m. development scheme. At present at Beckenham there are the Foundation's chemical research and pharmacology laboratories, the biological division's laboratories and stud (for the development and large-scale production of sera and vaccines), and the new £250,000 building for making poliomyelitis vaccine (see illustration). The new development comprises three further buildings.

The first two, both of which are already under construction and will together cost about £700,000, are for work on virology: one will be used for research on virus vaccines, the other for the production of the vaccines. These twin buildings, which are sited close to the poliomyelitis building, will provide some 75,000 sq. ft. (7,000 sq. m.) of laboratory space. The third building, which will cost nearly £300,000, is for work on veterinary biological products. The poliomyelitis building, which was begun a little over two years ago and first occupied in January this year, presented formidable problems to its designers, as most of the processing of poliomyelitis vaccine must be done under conditions of sterility as exacting as for a surgical operation. Fortunately there is little risk of infecting those who make the vaccine. To provide these sterile conditions and avoid "breaking" sterility during processing, the services to the various laboratory suites have had to be segregated to the maximum: this has been achieved by siting the plant rooms at one end of the building and running the very complicated services through special "service" floors lying between each "working" floor. Exposed pipes, ducts, and drains and other objects apt to collect dust have thus been virtually eliminated from the laboratory suites. Use has also been made of air-pressure gradients to protect sterile rooms; many rooms have filtered air which can be heated or cooled at will; and certain sterile areas have their own air-conditioning plants as an added precaution. Finally, a strict discipline is imposed on the movement of staff from one suite to another.

Mental Hospitals in 1956.—According to the latest report of the Board of Control the number of patients in mental hospitals fell by 1,193 during 1956. This is the second successive year in which there has been a drop, compared to an average increase over the previous five years of 1,223. At the end of the year there were 138,215 patients under treatment in mental hospitals. These hospitals provided accommodation for 124,218 patients (1,043 more than in

1955), but, as for various reasons 3,005 beds were not in use, they were overcrowded to the extent of 17,002 beds (931 less than in 1955). There were 83,994 admissions compared with 78,586 in 1955 and 55,856 in 1950, and there was again an increase in voluntary admissions and a fall in admissions under certificate, 78.2% of admissions being voluntary. (*Annual Report of the Board of Control to the Lord Chancellor For the Year 1956*. H.M.S.O., price 8d. net.)

Royal Society of Tropical Medicine and Hygiene.—The DUKE OF EDINBURGH was the guest of honour at the Golden Jubilee Banquet of the Royal Society of Tropical Medicine and Hygiene held at the Royal College of Surgeons on November 12. The President of the Society, Brigadier J. S. K. BOYD, F.R.S., was in the chair. In proposing the health of the guests Sir PHILIP MANSON-BAHR expressed the thanks of the Society to the Duke of Edinburgh for the privilege he had conferred on them by being present on this occasion. Among the other guests, whom he identified with epigrammatic wit, was the only surviving daughter of Sir Patrick Manson, Mrs. HOSSACKS. In response, Sir HENRY DALE, O.M., observed that among those present was the Ambassador of the Dominican Republic, Dr. LUIS THOMEN, who was professor of tropical medicine in Santo Domingo University, founded in 1538. Proposing the health of the Society, the DUKE OF EDINBURGH said that its members had made a great contribution to the relief of human suffering. It was largely due to members of the Society that he had been able to travel in other countries safe from the effects of tropical diseases: "You have at least one satisfied customer." The success of workers in tropical medicine all over the world, he continued, had been tremendous. But the control of tropical diseases had created other problems. What had emerged from this success was the problem of the healthy state of whole communities. In reply, Brigadier BOYD said that there were now 2,000 Fellows on the Roll of the Society. There was no barrier of race, creed, or nationality in the way of admission to it, and their meetings in Manson House were really gatherings of the clans of those interested in tropical medicine.

International Collegium for Neuro-Psycho-Pharmacology.—At a meeting in Zurich during the second International Congress for Psychiatry last September it was decided to found an international collegium for neuro-psycho-pharmacology. Its objects are the promotion of research, exchange of ideas, and collaboration in the fields of experimental and clinical neuro-psycho-pharmacology. These objects are to be achieved by the organization of special symposia as well as general meetings. Professor E. ROTHLIN (Switzerland) was elected president. It is hoped that the first international meeting of the Collegium will be held next year.

Royal College of Obstetricians and Gynaecologists.—At an extraordinary meeting of council on November 5 Dr. I. C. Rubin, of New York, was admitted to the College's honorary fellowship. The following were admitted to the membership:

G. Adams, N. Allan, J. P. Alvey, R. D. Atyeo, S. A. Aziz, J. D. Baeyertz, V. Benatar, G. K. Bernays, W. P. Black, W. Chew, H. D. Chomse, A. Clark, R. B. Conyngham, L. M. Dhadphale, I. P. Dunnett, P. F. M. Du Toit, A. A. Earn, L. Epsztejn, F. M. Fountain, D. Friedberg, D. M. Gratton, D. E. Gunatilleke, A. D. Hewson, B. K. Higgins, V. Hingorani, A. N. Horwitz, M. H. Hutcheon, E. G. Jonas, I. H. Kidd, D. J. Lancaster, M. E. Larg, M. Lesser, T. S. Macdonald, C. N. McFarlane, L. Mehta, H. A. Milne, B. J. Murphy, P. R. Norris, T. C. O'Connor, C. E. Parr, A. B. L. Peake, R. P. C. Perrott, P. M. Russell, A. P. Ryan, G. T. Smedley, J. H. Spurway, D. A. Thatcher, G. H. M. Wallace, J. H. Walters, M. B. Wingate, and E. C. Wood.

Christmas Cards.—The Grenfell Association is able to report this year, for the first time, a considerable drop in the tuberculosis mortality rate in Labrador and Northern Newfoundland. The funds necessary for the association's anti-tuberculosis work there are supplemented by the sale of its

Christmas cards. A leaflet illustrating the cards, which range in price from 1s. 2d. to 4d. each (with envelope), is obtainable from 66, Victoria Street, London, S.W.1, price 2½d. Calendars are also available. The International Planned Parenthood Federation's Christmas card is a reproduction of "Mother and Child" by Robert Russell. Cards (5s. per half-dozen, with envelopes) are obtainable from 69, Eccleston Square, London, S.W.1. The Deaf Children's Society has taken a detail from Michelangelo's "Holy Family" for its Christmas card. Packets of six of these cards, with six Christmas seals, may be obtained for 3s. 6d. per packet, from 1, Macklin Street, Drury Lane, London, W.C.2.

Sir Macfarlane Burnet, F.R.S., director of the Walter and Eliza Hall Medical Research Institute, Melbourne, since 1943, has been elected a member of the Royal Swedish Academy of Sciences.

Harben Lecturer.—Professor A. BRADFORD HILL, F.R.S., has been appointed Harben lecturer for 1957 by the Royal Institute of Public Health and Hygiene. He will give three lectures at the Institute next May on "The Experimental Approach in Preventive Medicine."

Professor L. P. Garrod, professor of bacteriology at St. Bartholomew's Hospital, London, gave the inaugural Becton, Dickinson lecture at Seton Hall College of Medicine and Dentistry, New Jersey, on October 16. He spoke on the sterilization of surgical equipment.

Council for the Investigation of Fertility Control.—The council held its inaugural meeting on November 6 to discuss its work in organizing tests and clinical trials of contraceptives in Britain and elsewhere. The council was set up under the Oliver Bird Trust (see this *Journal*, September 28, p. 773) to carry out work on this subject with the Family Planning Association.

COMING EVENTS

British Institute of Radiology.—Annual congress and exhibition, November 27–29, at the Royal Horticultural Halls and Napier Hall, Westminster. Details from the Institute, 32, Welbeck Street, W.1.

Royal Film Premiere.—In aid of the British Red Cross Society at the Plaza Theatre, on November 28 at 7.15 p.m., premiere of "The Ten Commandments." Tickets from the chairman, Film Premiere Committee, 14, Grosvenor Crescent, London, S.W.1.

Stephen Paget Memorial Lecture.—LORD COHEN OF BIRKENHEAD will lecture at 5.30 p.m. on November 28, at University College, London, on "Some Reflections on Animal Experiments." The annual meeting of the Research Defence Society will follow the lecture.

NEW ISSUES

SPECIALIST JOURNALS AND ABSTRACTS

All the journals listed below are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Venereal Diseases.—Issued quarterly (£3 annually). The new issue (Vol. 33, No. 3) includes:

TABES DORSALIS WITH SPECIAL REFERENCE TO PRIMARY OPTIC ATROPHY. Richard D. Hahn.
SOME UNUSUAL CASES OF NEUROSYPHILIS. Robert Lees.
TREATMENT OF NON-GONOCOCCAL URETHRITIS FROM THE POINT OF VIEW OF COST AND EFFICIENCY. G. Jelinek.
WEST INDIANS IN GREAT BRITAIN. J. St. Elmo Hall.
GUMMA OF THE PENIS. R. D. Catterall, C. D. Collins, and A. Redmond.
PROGRESSIVE BLINDNESS DUE TO POSTERIOR UVEITIS FOLLOWING ANTISYPHILITIC TREATMENT FOR INTERSTITIAL KERATITIS. W. V. Macfarlane.
SUDOMOTOR REACTION IN NEUROSYPHILIS. G. W. Csonka.
PRESENT PATTERN OF EARLY SYPHILIS IN THE MANCHESTER REGION. S. M. Laird.
SIDE-EFFECTS OF PENICILLIN TREATMENT. R. S. Morton.
STREPTOMYCIN-RESISTANT GONORRHOEA IN THE FEMALE. A. C. C. Davey.
NOVOBIOICIN, SPIRAMYCIN, AND AMINOTROZOLE IN THE TREATMENT OF NON-GONOCOCCAL URETHRITIS. R. R. Wilcox.
USE OF CONCENTRATED SOLUTION OF LECITHIN IN KAHN ANTIGEN. Elizabeth B. McDermott, Frank T. Nakamura, Mary R. Dockrill, and Reuben L. Kahn.
KINETICS OF THE TREPONEMA IMMOBILIZATION REACTION UNDER IMPROVED CONDITIONS. Oswald B. Portella and William R. Thompson.
SYMPOSIUM ON TRICHOMONAL INFESTATIONS, 1957.

British Heart Journal.—Issued quarterly (£3 annually). The new issue (Vol. 19, No. 4) includes:

WILLIAM HARVEY 1578–1657.
DOGMA AND EXPERIMENT IN HARVEY'S TIME. A. Morgan Jones.
PULMONARY HYPERTENSION IN MITRAL STENOSIS. William Evans and D. S. Short.
RELATION OF THE FIRST AND SECOND HEART SOUNDS TO EVENTS IN THE CARDIAC CYCLE. John Reinhold and Ulf Rudhe.
HEART SOUNDS AND INTRACARDIAC PRESSURES IN MITRAL STENOSIS. Desmond Julian and L. G. Davies.
THE SIZE OF THE LEFT ATRIUM IN CONDITIONS OTHER THAN MITRAL VALVE DISEASE. B. W. Cobbs, jun., J. P. Shillingford, and R. E. Steiner.
LIPOPROTEINS IN CORONARY ARTERY DISEASE. E. M. M. Besterman.
A WHOLE BLOOD OXIMETER. I. C. Roddie, J. T. Shepherd, and R. F. Whelan.
THE MECHANISM OF THE PULSUS BISFERIENS. P. R. Fleming.
THE VALSALVA MANOEUVRE IN AORTIC VALVE DISEASE. A. E. Doyle and G. H. Neilson.
PULMONARY OSSIFICATION WITH CARDIAC CALCIFICATION IN MITRAL VALVE DISEASE. H. A. Fleming and C. L. N. Robinson.
MYOCARDIAL FIBROSIS AND CALCAREOUS EMBOLI IN VALVULAR HEART DISEASE. E. D. Wigle.
ANEURYSM OF THE MITRAL VALVE IN SUBACUTE BACTERIAL ENDOCARDITIS. Neil Maclean and Mary K. Macdonald.
LIFE EXPECTATION OF PATIENTS WITH MITRAL STENOSIS WITH AND WITHOUT OPERATION. E. Donzot, R. Heim de Balsac, P. Samuel, and E. Beyda.
HAEMODYNAMIC EFFECTS OF SQUATTING DURING REPOSE. Leon Brotmacher.
HAEMODYNAMIC EFFECTS OF SQUATTING DURING RECOVERY FROM EXERTION. Leon Brotmacher.

Archives of Disease in Childhood.—Issued six times a year (£4 4s. annually). The new issue (Vol. 32, No. 165) includes:

VENO-OCCLUSIVE DISEASE OF THE LIVER AND INDIAN CHILDHOOD CIRRHOSIS. Derrick B. Jelliffe, Gerrit Bras, and Kanai L. Mukherjee.
DECIDUOUS TOOTH ERUPTION. Frank Falkner.
BLOOD OXYGEN STUDIES IN PREMATURE INFANTS. Patricia M. Russell and F. P. Hudson.
LOW OXYGEN TENSION IN THE MANAGEMENT OF NEWBORN INFANTS. Sven Sjöstedt and Gösta Rooth.
AMINO-ACIDURIA AND HYPERMETABOLISM IN PROGERIA. A. Harell Steinberg, A. Szeinberg, and B. E. Cohen.
THE APPLICATION OF SERUM LIPOPROTEIN ELECTROPHORESIS IN PAEDIATRIC PRACTICE. H. B. Salt and O. H. Wolff.
THE URINARY PHENOLSULPHONPHTHALEIN (PHENOL RED) EXCRETION TEST IN HYDROCEPHALUS. K. M. Laurence.
REDUCING SUGARS IN THE URINE AND BLOOD OF PREMATURE BABIES. J. C. Haworth and Morag S. Macdonald.
CONGENITAL IDIOPATHIC HYPOGAMMAGLOBINAEMIA. K. M. Pearce and M. S. Perinpanayagam.
CHRONIC NEUTROPENIA. Muriel M. McLean.
WHEAT GLUTEN AND COLIAC DISEASE. Claire Alvey, Charlotte M. Anderson, and Mavis Freeman.
PALPABILITY OF THE LIVER AND SPLEEN IN INFANTS AND CHILDREN. Brian McNichol.
B.C.G. TUBERCULIN. John Lorber.
THE HYPERSENSITIVITY REACTIONS TO PARA-AMINOSALICYLIC ACID (P.A.S.). Stuart Cairnc.
THE DIAGNOSIS OF PERTUSSIS WITH SUPRALARYNGEAL AND MODIFIED PERNASAL SWABS. Andrew Bordan.
THE SIGNIFICANCE OF THE C-REACTIVE PROTEIN ESTIMATION IN STREPTOCOCCAL AND ALLIED DISEASE. Sheila F. Dawson.
CEREBRAL ABSCESS AS A COMPLICATION OF NEONATAL SEPSIS. N. R. Butler.
H. Barrie, and K. W. E. Paine.
HYDATID CYST OF THE KIDNEY IN A CHILD. M. E. Broughton.
RADIAL NERVE PALSIES IN THE NEWBORN. Geoffrey V. Feldman.

British Journal of Industrial Medicine.—Issued quarterly (£3 annually). The new issue (Vol. 14, No. 4) includes:

EXPERIMENTAL STUDIES ON THE RELATIVE IMPORTANCE OF CONCENTRATION AND DURATION OF EXPOSURE TO DUST INHALATION. B. M. Wright.
THE EFFECT OF THE USE OF CALCINED ALUMINA IN CHINA BISCUIT PLACING ON THE HEALTH OF THE WORKMAN. A. Melkior and E. Posner.
AIR POLLUTION IN DIESEL BUS GARAGES. B. T. Commins, R. E. Waller, and P. J. Lawther.
OBSERVATIONS ON URINARY CADMIUM AND PROTEIN EXCRETION IN MEN EXPOSED TO CADMIUM OXIDE DUST AND FUME. J. C. Smith and J. E. Kench.
CHEMICAL AND HISTOLOGICAL POST-MORTEM STUDIES ON A WORKMAN EXPOSED FOR MANY YEARS TO CADMIUM OXIDE FUME. J. C. Smith, J. E. Kench, and J. P. Smith.
AN INVESTIGATION INTO THE ACUTE RESPIRATORY REACTION TO THE INHALATION OF TAMARIND SEED PREPARATIONS. Peter G. Tuffnell and I. Dinewall-Fordyce.
A REVIEW OF 102 CASES OF BEAT CONDITIONS OF THE KNEE. W. B. Rorntree.
VENTILATION OF IMPERMEABLE CLOTHING. G. S. Christie, J. P. Gleeson, W. G. Jowett, and A. S. Wright.
ABSENCE AND THE PHYSICAL CONDITIONS OF WORK. R. D. Shepherd and J. Walker.
AZO DYES AND HEINZ BODIES. Philip Rofe.
EXPERIENCE OF PULHEEMS IN THE 1952 ARMY INTAKE. S. Rosenbaum.
THE EFFICIENCY OF VARIOUS LIQUID IMPINGER SAMPLERS IN BACTERIAL AEROSOLS. K. R. May and G. J. Harper.

Medical and Biological Illustration.—Issued quarterly (£3 annually). The new issue (Vol. 7, No. 4) includes:

HOW JOINTS WORK. C. H. Barnett.
GLOSSARY. Sylvia Treadgold.
PARTIAL REVERSAL LINE PHOTOGRAPHY. Percy Wynn Bullock.
THE ADDITION OF SOUND TO 16-MM. FILMS. Derek Stewart.
COLOUR CORRECTION OF ELECTRONIC FLASH WITH LUMINESCENT PLASTICS. M. Walter.
A COMPACT APPARATUS FOR STEREOSCOPIC PHOTOGRAPHY. Reginald E. B. Hudson.

Annals of the Rheumatic Diseases.—Issued quarterly (£3 annually). The new issue (Vol. 16, No. 3) includes :

EMPIRE RHEUMATISM COUNCIL. MULTI-CENTRE CONTROLLED TRIAL OF CORTISONE ACETATE AND ACETYL SALICYLIC ACID IN THE LONG-TERM TREATMENT OF RHEUMATOID ARTHRITIS. RESULTS OF THREE YEARS' TREATMENT.

CONTEMPORARY RESEARCH ON THE PATHOLOGY OF RHEUMATOID DISEASE REVIEWED IN THE LIGHT OF 100 YEARS OF CELLULAR PATHOLOGY. D. H. Colling.

METABOLIC AND ANTIRHEUMATIC ACTIVITIES OF 6-METHYL-PREDNISOLONE (MEDROL). Edward W. Boland and Grant W. Liddle.

HISTOCHEMICAL INVESTIGATION OF CONNECTIVE TISSUE IN CASES OF ACUTE RHEUMATISM. A. I. Strukov and G. V. Orlovskaya.

RELATION OF HIGH MOLECULAR WEIGHT PROTEINS TO THE SEROLOGICAL REACTIONS IN RHEUMATOID ARTHRITIS. E. C. Franklin, H. G. Kunkel, J. H. Müller-Eberhard, and H. R. Holman.

EFFECTS OF PROLONGED ADRENOCORTICAL STIMULATION ON PATIENTS WITH RHEUMATOID ARTHRITIS. H. F. West.

HEREDITY IN ANKYLOSING SPONDYLITIS. Wallace Graham and Irene A. Uchida

HYPERGLOBULINAEMIA IN RHEUMATOID ARTHRITIS. L. Bonomo.

17-KETOSTEROID EXCRETION IN MEN WITH GOUT. E. R. Cook, G. D. Kersley, and M. Luscombe.

CAPILLARY RESISTANCE IN RHEUMATOID ARTHRITIS. J. L. Potter and F. W. Witzell.

EXPERIMENTAL POLYARTHRITIS IN RATS INJECTED WITH A TUMOUR EXUDATE. Gaëtan Jasmin.

OCULAR PRESENTATIONS OF STILL'S DISEASE AND THEIR TREATMENT. W. K. Smiley, E. May, and E. G. L. Bywaters.

SYMPOSIUM ON RHEUMATOID ARTHRITIS, STOCKHOLM, 1957.

Abstracts of World Medicine.—Issued in the first week of each month, this journal contains abstracts of important papers selected from the current medical literature of the world. Annual subscription £4 4s.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, November 18

BRITISH OCCUPATIONAL HYGIENE SOCIETY.—At London School of Hygiene and Tropical Medicine, 5.15 p.m., Professor T. F. Hatch (Pittsburg) Human Engineering.
GUY'S HOSPITAL.—A. Physiology Theatre, 4.45 p.m., Endocrine Demonstration of Thyroid Function Tests. Guest speaker, Professor E. E. Puchin.
HUNTERIAN SOCIETY.—At Apothecaries' Hall, Black Friars Lane, E.C.4, 8.30 p.m., discussion: Full-time State-controlled Medical Service is Contrary to the Best Interests of the Patient. For the motion, Sir Francis Wailes, F.R.S., and Mr. Douglas Woodroff. Against the motion, the Rt. Hon. the Earl Ailes, K.G., O.M., CH., and Dr. Bruce Cardew.
INSTITUTE OF NEUROLOGY.—5.30 p.m., Academician E. A. Asratyan (Moscow): Compensatory Function of the Brain.

Tuesday, November 19

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, W.C., 5.30 p.m., Dr. J. A. B. Gray: Peripheral Mechanisms Underlying Sensations.
CHADWICK TRUST.—At Royal Society of Tropical Medicine and Hygiene, 5.30 p.m., Mr. John Steven, F.Inst.P.C., F.R.S.H.: Storage, Collection, and Disposal of Refuse.
INSTITUTE OF DERMATOLOGY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. J. A. B. Gray: Peripheral Mechanisms Underlying Sensations.
LIVERPOOL UNIVERSITY: FACULTY OF MEDICINE.—At Lecture Theatre, New Medical School, 5 p.m., Centenary Address by Professor K. J. Franklin, F.R.S.: Sir Charles Scott Sherrington, O.M., F.R.S. (Born November 27, 1857).
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Mr. H. C. Edwards: Crohn's Disease and Allied Disorders.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Arnott Demonstration by Professor R. J. Last: The Pectoral Girdle.
ST. MARY'S HOSPITAL MEDICAL SCHOOL (WRIGHT-FLEMING INSTITUTE THEATRE).—6 p.m., Mr R. A. Brews: Aetiology of Carcinoma Corporis Uteri.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. B. G. Parsons-Smith: Neurological demonstration.

Wednesday, November 20

EUGENICS SOCIETY.—At Rooms of Royal Society, Burlington House, W., 5.30 p.m., symposium: Problem Families, Speakers, Mr. Paul Cadbury, Dr. M. MacGregor, and Dr. Catherine Wright.

HARVEIAN SOCIETY OF LONDON.—At 11, Chandos Street, W., 8.15 p.m. Mr. W. F. Winterton, Miss Josie Joshua, Mr. G. I. M. Swyer, and Dr. T. C. N. Gibbens: Castration as a Therapeutic Measure.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Virus Diseases.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Mr. D. S. M. Barlow: Problems Associated with the Construction of Heart-Lung Machines.

● **INSTITUTE OF NEUROLOGY.**—5.30 p.m., Mr. Harvey Jackson: Intracranial Neoplasms.

● **INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.**—3 p.m., Mr. C. W. F. Burnett: Disordered Third Stage.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. A. R. C. Higham: Enuresis.

MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 8.15 p.m., Dr. L. C. Hill, Dr. D. L. Crombie, Mr. A. G. Timbrell Fisher, and Dr. J. W. T. Patterson: Symposium on Rheumatic Pain.

OXFORD UNIVERSITY.—At Radcliffe Infirmary, 5 p.m., Litchfield Lecture by Professor William Doolin: Abraham Colles and His Contemporaries.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. J. Hardwicke: Proteinuria.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. Mary D. Sheridan: Young Deaf Child (illustrated).

Thursday, November 21

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, W.C., 5.30 p.m., Dr. J. H. Humphrey: Antibody Metabolism.

HONYMAN GILLESPIE LECTURES.—At University New Buildings, Teviot Place, Edinburgh, 5 p.m., Professor Ian Donald: Respiratory Phenomena in the Newborn.

HYPOTHERAPY GROUP.—At Royal Society of Medicine, 8 p.m., discussion to be opened by Dr. O. Garrod, Dr. A. W. Frankland, and Dr. A. Denis Leigh: Asthma.

INSTITUTE OF DERMATOLOGY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. J. H. Humphrey: Antibody Metabolism.

LIVERPOOL MEDICAL INSTITUTION.—At Liverpool Stanley Hospital, 2.30 p.m., afternoon clinical demonstration.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of London, 8.30 p.m., Dr. W. M. Levitt: Megavoltage Radiotherapy (including Cobalt Teletherapy).

MANCHESTER MEDICAL SOCIETY: SECTION OF ANAESTHETICS.—At Staff House, Manchester University, 7.45 for 8 p.m., Dr. J. P. Payne: Influence of Carbon Dioxide on the Neuromuscular Blocking Activity of Relaxant Drugs.

NORTH-EAST LONDON CLINICAL SOCIETY.—At Prince of Wales's General Hospital, Tottenham, N., 2.30 p.m., meeting.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor S. Thomson: Molluscum Scabaeum and its Surgical Significance.

ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: Normal Vision and "Refraction Patients."

ROYAL SOCIETY.—4.30 p.m., Sir Eric Rideal, F.R.S., and F. H. Taylor: On Haemolysis and Haemolytic Acceleration; D. A. T. Dick and Leah M. Lowenstein: Osmotic Equilibria in Human Erythrocytes Studied by Immersion Refractometry.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—At London School of Hygiene and Tropical Medicine, 7.30 p.m., laboratory meeting.

SURREY INTER-HOSPITAL PSYCHIATRIC ASSOCIATION.—At Long Grove Hospital, Epsom, Surrey, 7.30 p.m., clinical meeting. Papers by Dr. A. B. Monro, Dr. W. M. Ford-Robertson, and Mr. G. Preston.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—At Nurses' Recreation Hall, West London Hospital, Hammersmith, W., 8.30 p.m., address by Dr. Macdonald Critchley: Language of Gesture.

Friday, November 22

FOUNTAIN HOSPITAL.—5 for 5.30 p.m., Subject: Royal Commission on the Law Relating to Mental Deficiency. Papers by Dr. C. W. J. Ingham: Local Authority Services; Dr. J. F. MacMahon: Feeble-minded Psychopaths.

● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. T. Brain: clinical demonstration.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., clinical demonstration by Dr. J. N. Pattinson.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—2 p.m., Institute "At Home": 4.30 p.m., annual address by Miss D. Josephine Collier: Otolaryngology: A Synoptic Discipline.

MIDLAND CENTRE FOR NEUROSURGERY, Holly Lane, Smethwick, near Birmingham.—8 p.m., Mr. Murray A. Falconer: Temporal Lobe Epilepsy.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Dr. L. M. Franks: Hormones and Prostatic Growth.

● ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.—5 p.m., William Meredith Fisher: Memorial Lecture by Mr. Bethel Solomons: History of Infant Welfare.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Webb-Johnson Lecture by Sir Wilfred Fish: An Enterprise in Dental Research.

ROYAL MEDICAL SOCIETY, EDINBURGH.—8 p.m., debate with Glasgow University Medical-Chirurgical Society. The Motion: That Statistics are Vital in Medicine.

Saturday, November 23

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—11.30 a.m., Professor Dohleman: Experimental Studies on the Function of the Labyrinth. KENT PEDIATRIC AND CHILD HEALTH SOCIETY.—At Children's Department, Farnborough Hospital, 3 p.m., Dr. A. E. Claireaux: Some Problems of Prematurity. SCOTTISH OTOLARYNGOLOGICAL SOCIETY.—At Glasgow Royal Infirmary, 2 p.m., 75th meeting.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

BIRTHS

Barrell.—On October 29, 1957, at Southampton General Hospital, to Dr. Bridget A. W. (formerly Osselton), wife of James J. Barrell, L.I.B., a daughter—Helen Theonic.

Chartres.—On November 7, 1957, at Churchill Hospital, Oxford, to Mary (formerly Gaudin) and Dr. John Chartres, a sister for Roger and Diana.

Fleischl.—On October 29, 1957, at Napier, New Zealand, to Charmian (formerly Quinton), M.B., B.S., wife of Peter Fleischl, M.B., M.R.C.P., M.R.A.C.P.—a son.

Freeman.—On November 5, 1957, at the Lancaster Royal Infirmary, to Mary, wife of Granville Freeman, a second son—Gavin James.

Wilson.—On September 16, 1957, at Charing Cross Hospital, London, W.C., to Mary Wilson (formerly Beency), M.B., B.S., D.Obst. R.C.O.G., wife of Geoffrey Wilson, a sister for Sarah—Clare Alexandra Marshall.

DEATHS

DEATHS

Briggs.—On October 18, 1957, at Blue House, Eythurst Close, Kingswood, Surrey, Hugh Francis Briggs, M.B., F.R.C.S.Ed., Surgeon Captain, R.N., retired, aged 72.

Keeling.—On October 15, 1957, at Woodcote Grove House, Coulsdon, Surrey, Hugh Nevill Keeling, M.R.C.S., L.R.C.P., aged 79.

Matthews.—On October 13, 1957, at Brambleshaw, Speldhurst, Kent, Charles Edward Matthews, M.D., D.P.H., aged 96.

Orr.—On October 17, 1957, at Beaconsfield, Bucks, Vivian Bernard Orr, M.B., B.S., aged 84.

Stewart.—On October 16, 1957, at Alders, Branksome Park, Bournemouth, Hants, Pat Adam Stewart, O.B.E., M.B., Ch.B., Lieutenant-Colonel, R.A.M.C. (retired).

Struthers.—On October 13, 1957, the result of a car accident, Ronald Anderson Struthers, M.D., M.R.C.O.G., aged 37.

Watson.—On October 11, 1957, in hospital, William Hall Watson, M.C., L.M.S.S.A., of 48, High Street, Great Missenden, Bucks.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Polio Hazard of Triple Antigen

Q.—I have recently been advised by my local health authority that triple antigen carries so big a risk of predisposing to paralytic poliomyelitis that its use is probably unjustifiable even in the winter months. What is the evidence for this view, and is it sufficient to outweigh the important practical advantages of triple antigen, in that to achieve a comparable immunity by supposedly safer agents requires nine as opposed to three injections?

A.—There is no direct evidence that a mixture of pertussis vaccine and diphtheria and tetanus toxoids precipitates paralytic poliomyelitis. There is evidence, however, that a mixture of pertussis vaccine and diphtheria toxoid does so, and it is a reasonable presumption that the addition of tetanus toxoid will not lessen the risk. The evidence is contained in numerous publications since 1950, and recent observations in Great Britain have appeared in a report by a Medical Research Council committee.¹ In this report it is stated that during 1951-3 about 13% of cases of paralytic poliomyelitis in children of 6 months to 2 years of age in large centres of population were directly due to injections of diphtheria prophylactics and pertussis vaccines, alone or mixed. The risks varied with different prophylactics. In very approximate figures one case of provocation poliomyelitis occurred in every 50,000 injections of alum-precipitated diphtheria toxoid, in every million injections of formal toxoid and T.A.F., in every 170,000 injections of plain pertussis vaccine, and in every 20,000 injections of mixed diphtheria-pertussis vaccine, mixed vaccine with alum carrying more risk than mixed vaccine without alum. The committee found also that the risk of provocation poliomyelitis was as high (or higher) in April, May, and June as in July, August, and September.

Mixed antigens should therefore be used with care and forethought. In the months of December, January, February, March, provided there is little poliomyelitis about, they are reasonably safe. At other times of the year they carry a risk. In all immunization campaigns the safety of the individual child is the first consideration, and the safest agents at present are formal toxoid (F.T.), toxoid antitoxin floccules (F.T.F.), and plain pertussis vaccine. If it can be shown that previous vaccination against poliomyelitis removes the risk of provocation paralysis, and if poliomyelitis vaccine can be shown to be effective in very young children, it will be safe to return to using mixed and "triple antigens." Until that time it is difficult to justify their use all the year round.

Auto-hypnosis

Q.—By what techniques may auto-hypnosis be achieved? What is the clinical behaviour of the subject when so hypnotized, and how can he terminate the state? Does auto-hypnosis serve any useful purpose?

A.—Patients who have been hypnotized can be taught to hypnotize themselves, and this may be useful where relaxation or reinforcement of suggestion are needed when the hypnotist cannot be present. It is possible but difficult for a patient to induce the initial hypnosis himself, but occasionally analgesia during torture or dental treatment has been achieved in this way. The usual method is to induce hypnosis several times in the patient, the process becoming briefer each time until a light somnambulism can be reached.

instantly on command. He is then told to sit in a comfortable chair and fix his attention on a clock with a second hand. He is told to relax as before and as the hand reaches 60 to "let himself go off." Once he has learned to do this under supervision he can then usually achieve the same result alone. He may be told that under hypnosis he will recall suggestions previously made by the hypnotist. After some practice it is often possible for the patient to fractionate the hypnosis so that he can, for instance, suggest areas of anaesthesia and test them himself. It is well to set a definite time for return to normal consciousness, as in some patients the hypnosis becomes progressively deeper and longer with each session. Deep auto-hypnosis is of much less therapeutic value than that in which awareness and some control remain. Amnesic fugues have occurred after self-hypnosis and it is possible that the production of hysterical disabilities is afterwards facilitated. These complications should be seriously considered before advising the treatment, especially if the patient easily attains a deep amnesic somnambulism.

Self-hypnosis can be used to teach the patient to achieve relaxation before public speaking or acting, and as an aid to the treatment of tics and stammering and also of such ingrained habits as clearing the throat, unseating the dentures, or scratching an area of skin. A process resembling self-hypnosis can be used as a means of getting off to sleep, the patient relaxing and repeating to himself mentally the instructions previously given by the hypnotist. Hypnosis then turns into sleep. Fixation on an imagined scene, with the eyes closed, is a good method, and eventually sleep becomes conditioned to visualization of the scene. Successful "counting sheep" presumably works in this way. In self-hypnosis some supervision is necessary until the pattern of the hypnosis induced becomes stable. Instruction in self-hypnosis is quite often requested by introspective and pre-psychotic individuals who are really seeking to acquire or regain mental powers beyond their present capacity, so that careful selection is necessary. On the other hand it can be taught quite easily to young adults whose interest in the subject is entirely healthy.

Babies of Doubtful Sex

Q.—How should the sex of a baby be registered in cases where it is uncertain? Is there any legal definition in English or Scottish law of male and female?

A.—There appears to be no provision for the entry of sex in the register to be other than "boy" or "girl." If the original entry is subsequently shown to be wrong, it can presumably be corrected, provided the statutory requirements relating to correction of errors are met.

There does not appear to be any relevant legal definition of male and female in either English or Scottish law.

Cancer Hazard of Electrolysis for Hirsuties

Q.—Is there any known association between the frequent use of electrolysis to remove facial hair and skin cancer?

A.—Frequent use of electrolysis to remove facial hair may produce inflammatory changes and be followed by extensive scarring. In so far as malignant change may follow any chronic inflammatory or irritative process it would be expected on theoretical grounds that frequently repeated electrolysis might predispose to cancer, but such cases do not appear to have been recorded. However, if (as is sometimes done) the electrolysis is applied to hairy melanomata on the face or elsewhere, malignant melanomatous change has been observed.

Hyaluronidase Inhibitors and Oral Contraception

Q.—What is known about the use of hyaluronidase inhibitors as oral contraceptives? Have there been any trials of them in India?

A.—Sieve¹ claimed that phosphorylated hesperidin, a hyaluronidase inhibitor, was an effective oral contraceptive, but it is now generally agreed that this claim was unfounded

and that the method has no value. More recent experimental work carried out with far more effective hyaluronidase inhibitors, such as rehibin, has shown that, though when added to semen which has then been inseminated it has decreased the fertilizing capacity of the semen, when administered by mouth it has been wholly ineffective. Indeed, since hyaluronidase inhibitors (and other enzyme inhibitors) are active substances, it seems very unlikely that effective concentrations could be established at the site where they would have to act—that is, in the Fallopian tubes—if administration was by mouth.

So far as I am aware, no trials of hyaluronidase inhibitors have been conducted in India. Trials of *m*-xylohydroquinone, which Sanyal² considers to be the active anti-fertility factor in pea oil, have been carried out in India, and it is claimed³ that the injection of this substance has led to decreased fertility.

Hydrogenated Vegetable Oils and Coronary Disease

Q.—Vegetable oils rather than animal fats seem nowadays to be recommended for patients with coronary thrombosis. A patient has heard, however, that hydrogenated vegetable oils are harmful in this condition. In what form are hydrogenated vegetable oils met with in the dietary? Is there likely to be any truth in what this patient has heard said about them?

A.—Margarine is the commonest hydrogenated vegetable oil in the diet, and it is usually produced by the hydrogenation of cotton-seed oil, peanut oil, soybean oil, or other oils; whale oil is often added to margarine and hydrogenated in the process. These vegetable and marine oils contain unsaturated essential fatty acids, and during the process of hydrogenation, which converts these soft oils into hard fats, much of the essential fatty acid content is destroyed and more saturated unnatural fatty acids are formed.

Vegetable oils have been recommended for patients with coronary thrombosis because they lower the hypercholesterolaemia often associated with this condition, and this action is thought to be related directly to the lack of saturation of the essential fatty acids contained in these oils. Hydrogenated vegetable oils behave as animal fats in this respect and have no depressant action on the circulating cholesterol, but whether it is desirable to control the hypercholesterolaemia is a question which remains to be answered. Thus it is not yet possible to say whether hydrogenated vegetable oils are harmful to patients with coronary disease. The influence of various hydrogenated and unhydrogenated vegetable oils on the circulating cholesterol has recently been described by Ahrens and his associates.¹ After a careful and detailed study they concluded "that recommendations for radical changes in food habits, even by those populations most seriously threatened by atherosclerosis, should await a clearer definition of the specific food factors which control serum lipid levels."

NOTES AND COMMENTS

Progressive Myopia in a Man of 60.—Dr. D. S. McLaren (London, N.17) writes: Your expert in his answer ("Any Questions?" October 12, p. 894), is surely not suggesting that keratomalacia is to be considered as a possible cause of progressive myopia in a man of 60? This "colliquative necrosis" of the whole cornea is due to extreme vitamin-A deficiency, and still causes blindness in thousands of children in the tropics. Presbyopia is usually attributed to lens sclerosis, but progressive myopia due to an increase in the refractive index of the lens may be a feature of incipient cataract. The same phenomenon may be seen in diabetes, as an index of early involvement of the lens, but is excluded by the normal urine in this case.

Angular Stomatitis.—Dr. A. Fry (London, S.E.25) writes: The answer given in "Any Questions?" (October 26, p. 1007) that sometimes the aetiology of angular stomatitis is obscure and there is no valid explanation for its presence is, I think, a correct one. There is very seldom a satisfactory response to vitamin-B complex therapy even in large doses. May I mention a treatment which is simple and gives a quick and permanent cure? It is the use of hypnotic suggestion. A case was described by me¹ (Case No. 14) of a female, aged 43, who had angular stomatitis for over 10 years. She had massive vitamin-B complex therapy, local hydrocortisone, etc., without any effect. Three sessions of hypnotic suggestion gave her relief. The lesions completely disappeared. It is now over 2½ years since her last treatment and there has been no recurrence.

Treatment of Morphine Addiction.—Dr. J. Y. Dent (London, W.14) writes: A rather inadequate answer was given on the treatment of morphine addiction ("Any Questions?" October 5, p. 838). Admitted that it is what is given to patients in Lexington, U.S.A., but it is not treatment for addiction but merely detoxication and is very painful for most of the cases. America has an irrational phobia against the use of apomorphine. In Britain it has been found that sudden withdrawal of morphine, with the giving of alcohol and injections of apomorphine, removes all craving for morphine, heroin, or methadone in a few days with little or no deprivation symptoms, and the patient can leave the nursing-home in a week or ten days. He needs to have no psychotherapy except a few minutes' waking suggestion, and the prognosis is more than 50% that he will not relapse during the following twelve months. More can be found about this treatment in an earlier "Any Question?" (April 6, 1957, p. 839) and in various numbers of the *British Journal of Addiction*.

OUR EXPERT replies: The method of treatment I described has behind it a great wealth of clinical experience, and similar systems are used in centres other than Lexington and countries other than the U.S.A. The abstinence syndrome which results when morphine is suddenly removed is an abnormal and dangerous physical state and can be produced in animals. Adequate treatment surely includes detoxication. There are, however, many ways of treating morphine addiction, and Dr. Dent may be correct in his view that rapid withdrawal and the use of apomorphine is a rapid and effective method. I find it surprising that no subsequent supervision is thought to be necessary. Perhaps the relapse rate might have been even less than 50% if patients had been given psychotherapy after discharge from hospital.

Correction.—Messrs. Bayer Products Ltd., the makers of "monodral," the methobromate of penthiolate, which was included in the last supplement of "Approved Names" (*Journal*, October 26, p. 995), point out that the main action of penthiolate is not as a mydriatic, as we stated, but as an "antispasmodic for the treatment of peptic ulcer and allied conditions."

Collected Articles from the "British Medical Journal"

THIRTY YEARS' RESEARCH ON THE CONTROL OF CHOLERA EPIDEMICS

BY

Sir LEONARD ROGERS, K.C.S.I., M.D., F.R.S.

In 1908 to 1921 I reported on a curative treatment of cholera, based on the great loss of chlorides and alkalis from the blood revealed by biochemical estimations. These losses were counteracted by intravenous infusions of large amounts of hypertonic and alkaline salines, with the reduction of the case mortality to one-third to one-fourth of the former rate in the same hospital (Rogers, 1908, 1917, 1921).

Unfortunately the improved treatment was not practicable in the 85% of the population of India who lived in villages, with no doctors capable of administering the essential intravenous salines. It was not until 1925, after my return to England, that I was able to begin prolonged epidemiological studies in the hope of finding some method of controlling cholera epidemics, which during the half-century up to 1939 had been responsible for an average annual recorded death rate of 344,000 (Rogers, 1944) and during the nineteenth century had repeatedly spread as a pandemic over south-east Asia and Europe (see maps in *Cholera and its Treatment*, 1911, Oxford Medical Publications).

Seasonal Incidence of Cholera in Relation to Rainfall, Temperature, and Humidity

The first step was to tabulate the monthly cholera deaths in the eight provinces of India for thirty years and to chart the average rates per 100,000 population in relation to the average rainfall, temperature, and relative and absolute humidities so as to allow the seasonal incidence to be studied in relation to climatic conditions as illustrated by the *Indian Atlas of Meteorology*. This inquiry revealed the closest relationship between the monthly readings of the absolute humidity—a measure of combined heat and moisture—and the seasonal incidence of cholera in all parts of India.

The outline map (overleaf) shows the provinces of India and the endemic areas in the north-east and south-east in which cholera is prevalent at all seasons of the year, in contrast to the remaining epidemic areas in which the disease dies out completely with the fall of the absolute humidity to well below the critical minimum of 0.400. In Bihar and monthly reading of January of 0.400. In Bihar and the eastern part of the United Provinces to the west of the Bengal endemic area the disease declines to a very low level in January and February, with absolute humidities very little above the critical point, so the regular increase of the disease in this area is a recrudescence, with the March rise of that factor well above the critical point, and cholera outbreaks fur-

ther west occur as the absolute humidity rises well above the critical point in March, April, and May. The seasonal spring rise of cholera in the epidemic areas can therefore be foreseen by watching the absolute humidities, many illustrations of which will be found in my epidemiological papers of 1926 and 1928. Moreover, my conclusion that cholera does not become widely prevalent, or continue so, when the absolute humidity falls below the critical point of 0.400 has been confirmed in China and elsewhere (Rogers, 1926, 1928).

Relation of Summer South-west Monsoon Rains to Cholera Incidence in the Following Spring and Summer

A map of the thirty-year average cholera incidence of the different provinces of India, as well as of their subdivisions, with varying climatic conditions where indicated, enabled comparisons to be made with years of epidemic prevalence in the forty-five years for which cholera data of every province were available. Any marked deficiency of the rainfall during the previous year's monsoon was also recorded in view of the fact that the three most widespread epidemics had followed failures of the previous monsoon rains over large areas of India, resulting in extensive famines (Rogers, 1928).

Deficiencies of communications necessitate the concentration of the starving people in large camps, with inevitable outbreaks of cholera in such years. It is therefore of the greatest interest to note that my maps showed 41 provincial epidemics of cholera, and in no fewer than 40 of them previous monsoon rains had been greatly deficient in the epidemic regions. As deficiency or otherwise of the monsoon rains is evident by the beginning of October, or earlier, it follows that the likelihood of an epidemic arising in March to May of the following year can be foreseen five or six months ahead and any possible precautions taken.

The one exception to the rule occurred in 1894 at the twelve-yearly Kumbh Fair at Allahabad, with a million pilgrims camped on the sands of the Ganges. Although elaborate sanitary precautions had been taken, cholera broke out in the middle of January, about a month earlier than usual, and the dispersal of the pilgrims caused a widespread epidemic with one of the highest recorded death rates of the United Provinces. I found the explanation of this very exceptional occurrence in the fact that the absolute humidity had been greatly in excess during the winter months, and especially in February, when the main spread of cholera took place.

Pilgrimages and Spread of Cholera

Kumbh Fair at Hardwar.—This fair, which is held every 12 years, takes place at the site of the issue of the sacred Ganges from the Himalayas near the eastern border of the Punjab. In 1891 this large fair passed off with only the average cholera incidence of 0.49 per 1,000. The previous monsoon rains had been good and careful sanitary precautions had been taken. In 1892 the conditions were different, for the previous monsoon rains had been very deficient, and by far the worst cholera outbreak of the 86 years of which we have records took place in the Punjab, with a cholera death rate of 2.70 per 1,000; and the pandemic spread across the north-west frontier of India to overrun South-East Asia and Europe. Yet the same sanitary precautions had been taken as in 1891. The explanation is simple: the water in the sacred bathing-pool—650 by 30 feet (200 by 9 metres) in extent—in which the 70,000 pilgrims present bathed and which they drank, and bottles of which they took home to infect their households, was stagnant because of failure of the previous monsoon rains. It is recorded that "two sufferers in the last stage of cholera were taken out of the [bathing] pool and died immediately afterwards." It is a religious custom of the Hindus—with which Europeans could not interfere without incurring a risk of provoking riots—to place pilgrims dying from cholera on the banks of any sacred water, of which they must drink. The Punjab medical records also show that, of the last 23 years in my chart of the Punjab cholera incidence, in no fewer than 17 cholera was spread over that province by pilgrims returning from the Hardwar Fair (Rogers, 1928).

The Puri Pilgrimage Fair.—The Jagannath Temple at Puri, Orissa, on the east coast of India south of Calcutta, is visited yearly in March and July by many thousands of pilgrims from all parts of India. In specially sacred years 250,000 may be camped around an insanitary town of 49,000 people, their only water supply at the time I am concerned with coming from easily contaminated shallow wells and open tanks. No wonder Orissa for long has had the highest cholera death rate of any of the 200 divisions of India. Here again all the years with the highest cholera incidence had been preceded by very deficient south-west monsoon rains. The returning pilgrims spread the disease far and wide to Lower Bengal, Bihar, the Central Provinces, and North-East Madras, as indicated in the map.

The Pandarpur Pilgrimage.—Bombay Deccan lies to the east of the Western Ghats, with the Pandarpur pilgrim centre about the middle. Cholera is regularly spread by pilgrims returning to their homes from the June Fair. An exception was 1910, when there was no cholera within hundreds of miles to be spread. Here again all the more severe

epidemics followed serious deficiencies of the monsoon rain-falls of the previous year.

Pilgrimages in the Madras Presidency.—This is an important endemic area, with the highest annual incidence and rainfall in the cold weather months, and absolute humidities of well over 0.400, as well as the highest rainfall from the north-east monsoon in October to December in the most densely populated south-east area. Madras has no very large pilgrimages, yet has a total of 2,500,000 pilgrims a year, who have been repeatedly recorded to have spread cholera.

Returns from India show an average of 20 million pilgrims travelling every year to attend the major fairs, so the problem of preventing spread of cholera by them is one of great magnitude.

Forecasting Cholera Epidemics in India

The evidence summarized above convinced me that the approximate dates of the spring outbreaks of cholera can be foreseen by watching the absolute humidity data, and the probability of their reaching epidemic proportions in any given area can be estimated from the monsoon rains of the previous summer. To test the correctness of that conclusion I arranged for the necessary data to be supplied from India at the end of the south-west monsoon early in October, and was able to send my forecasts by air mail in time to be published in the *Indian Medical Gazette* before the annual spring rise of cholera incidence. They proved remarkably correct, as was noted in the annual medical reports of the Government of India (1930, 1933).

Recommendations for Control of Cholera Epidemics in India

The epidemiological inquiries summarized above convinced me that the only possible way to control cholera epidemics in India was the use of wholesale inoculation of millions of pilgrims before they reached the fairs after long journeys by road and rail, usually through cholera-infected districts. The elaborate sanitary measures for long in use at the places of pilgrimage could not prevent their infection either on their long journeys to the fairs or at the place of pilgrimage, in view of the religious customs above described at the Hardwar Fair of 1892. I therefore drew up a memorandum on the history of the repeated outbreaks of cholera at these fairs and their wide diffusion by the pilgrims, especially in unfavourable years after failure of the previous monsoon rains, together with their occasional extensions to Europe as pandemics for which India is responsible. I advised compulsory anti-cholera inoculation as the only possible way to prevent such catastrophes, but a unanimous verdict of the public health officers that my proposal was "impracticable" was endorsed by the responsible administrative authorities. It was justly pointed out that the use of compulsion

Map showing Indian provinces (before 1948), cholera endemic areas (shaded), pilgrim centres, and the January absolute humidity line of 0.400.

might provoke riots on the ground of interference with the religious customs of the people. That decision had to be accepted and more propitious conditions awaited.

Compulsory Inoculation of Pandarpur Pilgrims Successfully Carried Out

The good seed had, however, been sown, and it was not long before it came to fruition. In the meantime the provincial administrations had been handed over to Indians, and in 1936 the medical authorities of the Bombay Presidency realized that all the conditions favourable to a serious outbreak of cholera at the June Pandarpur Fair were present. They therefore had the courage to order the compulsory inoculation of all pilgrims before their admission to the fair, either before setting out on their dangerous journey, or en route by the doctors who had for years past accompanied each band of pilgrims. This was accomplished with very little difficulty, and at the end of the cholera season the medical authorities were able to report that "the spread of the disease was thus effectively prevented." Four years of the disease was thus effectively prevented. "since later the Bombay public health office recorded that "the year 1937"—that is, following the year in which compulsory inoculation was introduced at Pandarpur—"there has been no outbreak of cholera at the fair." This favourable report was confirmed by an analysis I recorded of the cholera and meteorological data of the Bombay Deccan for the six years before and seven years after introduction of the new measures (Rogers, 1944).

As the direct result of the above success the Central Advisory Board of Health in 1939 appointed a committee, which reported favourably on the Pandarpur trial; so the Board sanctioned trials of the new measure in every province of India. Moreover, an Indian member rightly pointed out that in the performance of their religious duties the pilgrims must not endanger the lives of other people by spreading cholera infection as the result of refusing to be protected by inoculation. In 1952 an Indian colleague sent me news of the remarkable success of the new system of cholera control all over India, and I recorded the information obtainable in this country at the time (Rogers, 1952).

Through the kindness of Colonel Pasricha, I.M.S., I also obtained the cholera data of the Indian State and the monsoon rainfalls from 1940 to 1951, which enabled me to complete my studies of the available records from 1866 to 1951—a period of 86 years—and recorded the results in 1953.

Extension of Compulsory Inoculation of Pilgrims Over All India

The following figures show the gradual increase of voluntary cholera inoculations of pilgrims in India during 1928–39 and of the very large increase of compulsory inoculations in 1940–51, after their use, which I had urged in 1926–8, was sanctioned in 1940.

1928–33	Average yearly inoculations	2,700,000 voluntary
1934–9	"	6,694,000 voluntary except in Bombay Deccan
1940–51	"	22,500,000 compulsory for pilgrims

As the result of the general sanction of compulsory inoculation of pilgrims in 1940 the 5,608,310 inoculations performed in that year rose to over 12,000,000 in 1941 and 1942; and in the famine years 1943 and 1944, owing to high wartime food prices, they reached 19,860,715 and 28,805,514 respectively. During 1945 and 1951 they varied between 20 and 28 million (Rogers, 1953).

The annual cholera deaths and the previous monsoon rains, and the high rates due to the famine, are dealt with in my paper of 1953, so it will suffice to mention here the following recorded effects of the unprecedentedly increased inoculations.

Results of Compulsory Inoculation of Pilgrims Attending Kumbh Fairs

I had especially urged the compulsory inoculation of the one to three million pilgrims attending the 12-yearly excep-

tionally large Kumbh Fairs at Hardwar and Allahabad, because any success under these difficult conditions would ensure the general adoption of the measure. Two such fairs took place in the decade under consideration, and Table I, from my paper of 1953, compares their cholera

TABLE I.—Cholera Deaths Per 1,000 at 12-yearly Very Large Kumbh Fairs

Allahabad Kumbh Fair Years						Hardwar Kumbh Fair Years				
Year	Bihar-Orissa Deaths per 1,000	United Provinces Deaths per 1,000	Monsoon Rains in Previous Year	Compulsory Inoculation of Pilgrims		Year	Punjab Deaths per 1,000	Monsoon Rains in Previous Year	Compulsory Inoculation of Pilgrims	
1870	(No record)	—	—	—		1867	2.4	?	Nil	
1882	3.38	2.02	Good	Nil		1879	1.4	Good	"	
1894	4.88	3.80	"	"		1891	0.49	"	"	
1906	4.06	3.14	Deficient	"		1903	0.37	"	"	
						1915	0.68	"	"	
1918	5.90	2.56	Good	"		1927	0.55	"	"	
1930	4.60	1.35	"	"		1938	0.19	"	"	
Average	4.65	2.57	"	"		Average	0.92	"	"	
1942	0.7	0.1	"	1,249,506 in Bihar and U.P.		1950	0.01	"	Over 1,000,000	
Reduction 1954	6½-fold	25-fold	Good	2,007,749		Reduction	92-fold			

mortalities with those of such fairs back to 1867. Thus, in the case of the five more fatal Allahabad Kumbh Fairs from 1882 to 1930 without compulsory inoculation, the average deaths in Bihar and Orissa of 4.65 per 1,000 were reduced to 0.7 per 1,000 in 1942; in the United Provinces the decline was 25-fold. The total saving of lives in the two provinces in 1942 I estimate at 146,200.

Likewise the introduction of compulsory inoculation of one million pilgrims attending the Kumbh Fair at Hardwar in 1950 resulted in a 92-fold reduction in the cholera mortality as compared with the average figure of the seven previous Kumbh Fairs back to 1867; but in this case the saving of life was much less because the Punjab has the lowest cholera death rate of India, owing to its being furthest removed from the north-east endemic area from which it was yearly reinfected.

In 1954 a further Allahabad Kumbh Fair took place. Compulsory inoculation of the pilgrims was again carried out, 2,007,749 inoculations having been recorded in the United Provinces that year. The cholera death rate per 1,000 in Bihar and Orissa fell to 0.12, or a 39-fold reduction of the average figures before the adoption of compulsory inoculation of pilgrims. Similar data for the United Provinces show a death rate of 0.04 per 1,000, being 69-fold reduction on the pre-inoculation days, with a considerably larger saving of life than in the similar fair of 1942.

The unprecedentedly good results of the new measures of control are borne out by the following records of the public health officers, who carried through the immense task involved in the inoculation of millions of pilgrims. Thus Dr. A. C. Banerjee (1951) recorded that "only 11 cases [of cholera] occurred in connexion with the 1950 Kumbh Fair at Hardwar; they were all imported ones, which were all detected and isolated, and no secondary ones occurred." Moreover, "no cholera outbreaks occurred from this fair in the United Provinces or in adjoining provinces," which included the Punjab.

A control to the above is furnished by the record of a pilgrim fair at Sumaria, in Bihar, "which was overlooked by the medical authorities owing to its recurring at long and irregular intervals. Consequently neither the usual sanitary precautions nor anti-cholera inoculations were carried out; with the result that a smart outbreak of cholera followed this fair."

Reduction in Cholera Mortality in India Following General Adoption of Compulsory Inoculation of Pilgrims

In 1928 I showed the great yearly variations in cholera mortality in India to be due to deficiencies of the south-west monsoon rains of June to September of the previous year. The other main factor is the spread of the infection by the one to three million pilgrims attending the 12-yearly Kumbh Fairs at Hardwar and Allahabad. Unless these potent factors are taken into account one series of years cannot safely be compared with another series. I have therefore prepared Table II to illustrate this point. Cholera

TABLE II.—Analysis of Cholera Mortality Rates of India for 75 Years

Period	Average Yearly Deaths and Rate per 1,000	Maximum Yearly Deaths and Rate per 1,000	Minimum Yearly Deaths and Rate per 1,000	Causes of High Yearly Cholera Mortalities
1880-9	291,800 1.50	1887 473,875 2.45	1880 118,532 0.65	Deficient monsoon rains in 3 years 1882. A.K. Fair spread cholera
1890-9	398,858 3.40	1892 724,384 3.40	1898 151,510 0.71	Deficient monsoon rains in 4 years 1892. Famine year. Spread over Europe 1894. A.K. Fair spread cholera
1900-09	417,962 1.91	1900 797,273 3.72	1904 192,835 0.85	1900. Famine after general failure of 1899 monsoon 1908. Widespread failure of 1907 monsoon 1906. A.K. Fair spread cholera
1910-19	386,519 1.63	1919 578,426 2.43	1917 267,002 1.12	1919. Widespread failure of 1918 monsoon 1915. A.K. Fair spread cholera
1920-9	227,438 0.94	1921 450,608 1.87	1928 73,002 0.30	1921. Widespread failure of 1920 monsoon 1928. Partial failure of 1927 monsoon
1930-9	170,512 0.65	1930 337,322 1.40	1932 67,219 0.24	No failures of previous monsoon rains 1930. A.K. Fair spread cholera 1938. H.K. " " "
1940-5	260,966 0.87	1943 459,930 1.50	1940 86,132 0.35	1942-44. Famines due to wartime high food prices 1942. A.K. Fair. Pilgrims inoculated. 25-fold reduction of cholera
1946-55	79,057 0.39	1948 162,370 0.7	1954 13,554 0.554	No widespread monsoon failures 1950. H.K. Fair. Pilgrims inoculated. 92-fold reduction of cholera 1954. A.K. Fair. Pilgrims inoculated. 69-fold reduction of cholera

data became available for greater Bengal and Assam only in 1877-8; so the table shows the data for each decade from 1880 to 1955 except for the exceptional period of 1940-5, on account of the unique famine due to a several-fold increase of food prices during the second world war.

In considering such a long period it must first be borne in mind that during the 75 years dealt with there has been a steady improvement in the sanitary conditions of the towns, but very little in the vast number of small villages, in which 85% of the population live out their lives. Secondly, there has been a great rise in the population, so the rates of cholera deaths per 1,000 are most comparable.

In each of the first five decades from 1880 to 1929 there were two or more years of very high mortalities due to failure of the monsoon rains of the previous year or to the occurrence of an Allahabad or Hardwar Kumbh Fair, or to both. It will be observed that there was no material decrease in the average cholera mortality per 1,000 in those five decades except a decline in 1920-9 to 0.94 from 1.63 in the previous decade; this is partly accounted for by the

absence of any Kumbh Fair in that decade. The steady improvement in railway communications may have helped by reducing the necessity for long marches through infected villages. On the other hand, 1930-9 is the first decade in which there had been no failure of the previous monsoon rains; so it is significant that the only years of high cholera incidence were those of Kumbh Fairs at Allahabad in 1930 and at Hardwar in 1938. Accordingly the death rate fell from 0.94 in 1920-9 to 0.65 in 1930-9, the lowest up to this time. Yet in the succeeding period of 1940-5 the figure rose once more to 0.87, due to the great rise in wartime food prices already mentioned, with a maximum cholera mortality of 459,930 or 1.50 per 1,000, and that too in spite of previous good monsoon rains and the then recently adopted compulsory inoculation of pilgrims.

Thanks to the kindness of Colonel Pasricha, I.M.S., and of the Director-General of the India State in sending me the cholera records of the last four years, 1952-5, I am able to summarize them in Table II and to give the yearly figures in Table III, in view of their great significance. It is fortunate that in the last decade (1946-55) there was no material failure of the monsoon rains and that Kumbh Fairs took place at both Allahabad and Hardwar, making it as comparable as possible as regards the cholera death rates with the decade 1930-9, just before the adoption of the new compulsory inoculation of pilgrims all over India. The total

TABLE III.—Cholera Deaths and Rates Per 1,000, 1946-55

	No. of Deaths	Rate per 1,000	Averages

deaths, however, for the last period are those of the Hindu Republic of India, and do not include those of the Moham-medan Pakistan; but as the latter area is mainly composed of the Western Punjab, with the lowest cholera mortality in the Indian peninsula, this does not materially affect the cholera death rate, so the decline of that figure from 0.65 per 1,000 in 1930-9 to only 0.39, an unprecedented decline of 40%, can only be due to the large-scale adoption of compulsory inoculation of pilgrims in the last decade.

Table III gives the yearly total cholera deaths and the rates per 1,000 population in the decade 1946-55. It is remarkable in that it shows a steady decline in the yearly cholera death rates, averaging 0.5 in the first three years, 0.3 in the next five years, followed by an unprecedented fall to 0.05 in the last two years of the decade. It should be mentioned that the recent data for 1955 are wanting for three areas, but they have been estimated on a liberal scale from the rates of neighbouring areas, so can be relied on as being approximately correct. They reveal a cholera death rate of 0.05, against one of 0.65 in the decade 1930-9. This cannot but be due to a cumulative effect of the compulsory anti-cholera inoculations of the last 15 years, which now amount to approximately 300 millions, or a considerable proportion of the Hindu population of India.

Table IV has therefore been worked out to show the relative decreases in the endemic and epidemic areas respectively in the minimum years 1954 and 1955, as compared with the average deaths per 1,000 in 1930-9, immediately before the large-scale adoption of compulsory inoculation of pilgrims—a measure which was expected to exert the

greatest preventive effect in the epidemic areas, which have been so frequently infected by the movements of pilgrims. This is confirmed by the data in the lower part of Table IV. Thus the Bombay Presidency shows a 45-fold reduction, and it was in connexion with the Pandarpur Fair that com-

TABLE IV.—Cholera Incidence Before and After General Inoculation of Pilgrims

Province	Before Inoculations 1930-9		After Inoculations 1954-5		
	Average Cholera Deaths	Rates per 1,000	Average Cholera Deaths	Rates per 1,000	Reduction to

Central Provinces	12,740	0.91	434	0.02	1/45
Total epidemic areas	43,610		3,160		
Grand total	159,220		13,554		

pulsory inoculation of pilgrims was first adopted in 1936. The Central Provinces, which also had a 45-fold reduction, are liable to infection from three sides by pilgrims from Puri, Allahabad, and Pandarpur. Moreover, in the Punjab epidemic area cholera has been eliminated in the last two years. The United Provinces—endemic area—however, show only a 12-fold reduction, but the eastern divisions are early infected from the Bengal endemic area.

On the contrary, in the endemic areas shown in the upper part of Table IV, of the rates per 1,000 in 1954 and 1955, the reductions, as compared with 1930-9, amount to from 1/13 to 1/9, with the exception of Assam, which has poor communications with Eastern Bengal, showing a figure of 1/63.

Nevertheless the reductions to an average of 1/10 in the endemic areas is greater than might have been expected; so they bear out my suggestion that cholera incidence in India as a whole is gradually being brought under control by the general adoption of compulsory inoculations of the immense numbers of the moving bands of pilgrims throughout India.

Since the above paragraph was written news of a serious failure of the north-east monsoon rains of October to December, 1956, in Ceylon, and consequently in the densely populated south-eastern districts of Madras, has been received. Cholera epidemics under such conditions have been recorded (Rogers, 1928), so it will suffice to recall that the highest cholera deaths in the Madras presidency were 148,193, or 5.08 per 1,000, in 1876, and 357,430, or 12.24 per 1,000, in 1877, immediately following serious failures of the monsoon rains in two consecutive years; against only 313 deaths, or 0.01 per 1,000, in 1874. The most serious famine of southern India also resulted from these failures of the rains. The next highest cholera mortality in Madras occurred in 1897 following a similar failure of the north-east monsoon, when the Madras Presidency recorded 180,000 deaths, or 4.38 per 1,000.

The crucial test, mentioned above, of the control of cholera epidemics by the large-scale inoculation of moving bodies of the people on pilgrimages, or in famine years in search of food, is at hand, but the greatly improved rail and road communications should much simplify the problem of feeding the people in their own villages. The public health services will doubtless see the necessity of immunizing any who have to be moved to famine camps. The results of the new control measures under the present very unfavourable conditions will be awaited with the greatest interest.

The Outlook

The remarkable decline of cholera in the last decade was favoured by the unusual absence of any material failure of the monsoon rains, which in the nature of things cannot continue much longer. The crucial test will come in a year following a widespread failure of the monsoon rains. The outlook, however, is now more favourable than in the half-century 1880-1929, illustrated in Table II, with a yearly average of 344,000 cholera deaths.

In the first place if the recent decline of cholera mortality in the endemic areas to one-tenth of the rate before the adoption of general protective inoculations of pilgrims is maintained, it will have greatly reduced the sources of infection of the large epidemic areas. Secondly, the steady improvement of railway communications has been greatly augmented by a remarkable development of motor services and construction of new roads, which will much facilitate the distribution of food to formerly remote villages. This will do away with the necessity of feeding people in large famine camps, in which cholera was rampant in earlier days. I would urge that where such camps may still be necessary all entrants should be inoculated, preferably before admission, for the people are now fully aware of its advantages. Thirdly, the successful extension of the curative treatment to the villagers by means of field hospitals and ambulances will doubtless save many lives in future.

Summary

Studies of the cholera vital statistics of the last 90 years are described which led me in 1926 to advocate the compulsory inoculation of some 20 million pilgrims yearly, as the only method of controlling cholera epidemics in India. At that time the medical and administrative officers found this suggestion to be impracticable, but in 1936 it was carried out with success in the Bombay Deccan, and as a consequence was extended all over India, with very satisfactory results. During 1941-55 some 300 million pilgrims have been inoculated against cholera in India, with satisfactory results, and the outlook for the continued success of the measures for controlling cholera epidemics are considered to be good.

The nineteenth century was characterized by the frequent spread of pandemics of cholera over Europe. They should prove to be preventable in the future.

In November, 1857, John Murray published David Livingstone's *Missionary Travels and Researches in South Africa*. In reviewing the book, the *British Medical Journal* declared that Dr. Livingstone "never would have accomplished his adventurous journey had it not been for acquaintance with the healing art. The various savage tribes whose territories he had to traverse were deaf to the voice of the missionary, but were capable of appreciating the good services of the medical man. A knowledge of the healing art is acknowledged by Dr. Livingstone to be indispensable to those who would penetrate the untrodden wilds of this vast continent; and he frankly confesses that all missionaries "... should possess a competent knowledge of medicine. This is indeed a high testimony to the benevolent and all-powerful character of our profession."

RESPIRATORY SYMPTOMS, BRONCHITIS, AND VENTILATORY CAPACITY IN RANDOM SAMPLE OF AN AGRICULTURAL POPULATION

BY

I. T. T. HIGGINS, M.D., M.R.C.P.

Medical Research Council Pneumoconiosis Research Unit,
Llandough Hospital, near Penarth

Measurement of disease in industry necessitates suitable controls. A comparison of miners and ex-miners with non-miners of similar age living in the same neighbourhood has been made (Higgins *et al.*, 1956). In that comparison it is possible that our controls may have been affected by the industrial environment of the mining community to some extent, and accordingly any deleterious effect of mining on health may have been underestimated. We have tried to assess the importance of the environment by studying an agricultural community. This paper gives an account of a survey of respiratory symptoms in a random sample of the inhabitants of the Vale of Glamorgan.

The Vale of Glamorgan is an undulating plain, about 200 feet (60 metres) above sea level, of unspoilt agricultural land lying 15 miles (24 km.) west of Cardiff, between the South Wales coalfield in the north and the Bristol Channel in the south. The rainfall is about 40 inches (1 metre) per annum and the average temperatures for January and June are 41 and 58° F. (5 and 14.4° C.) respectively. The area is exceptionally free from atmospheric pollution, and only the strip bordering the coast is subject to winter mists.

During the summer of 1955 Cochrane conducted a survey of the population living in a geographically defined area of the Vale (Cochrane *et al.*, 1956). This area was approximately 55 square miles (142 square km.), with a density of 0.5 person per acre (0.2 person per hectare) (General Register Office, 1954). A private census was taken, social and occupational details were recorded, and chest radiography of 95% of the defined population was achieved. The information obtained was transferred to punch cards. Random samples by sex and age can therefore be readily drawn from this community.

Sample, Procedure, and Methods

The present sample is shown in Table I. The original intention was to study 50 men and 50 women in each 10-year age group from 25 to 74 except in the 55-64 groups, in whom we are particularly interested, where we intended seeing 100 of each sex. It was, however, found that of the 100 men drawn in this group 31 had worked at some time in mining or other dusty occupation, and as we were anxious to exclude such men the sample was therefore increased by a further 31 who had never worked in dusty jobs.

A number of investigations had been planned for the men aged 55-64. They were therefore seen at a centre during the second half of April, 1956. Each man was visited at his house by a member of the field survey team, the purpose of the investigations explained to him, his co-operation sought, and an appointment given. Transport was offered and usually accepted. Any man who failed to attend was promptly revisited, the reason ascertained, and a new appointment given. The rest of the men and all the women were visited in their homes, the majority during

January and February, 1956. Appointments were not made before these home visits, since it was considered possible that any reluctant participant might arrange to be out at the appointed time. Instead visits were continued until a person sampled was either seen or found to have moved from the area. In this way, with the help of a driver who knew the area well, 20-25 people could be interviewed daily and the main part of the visiting was completed in six weeks. Each person interviewed was asked to co-operate in a piece of research. It was emphasized that we were not looking for a disease but trying to find out more about respiratory symptoms in normal people living in healthy surroundings.

1. Respiratory symptoms were recorded, using a questionnaire similar to that used in previous studies (Higgins *et al.*, 1956). Chest illness during the past three years, persistent cough and sputum, wheeze and tightness, and a number of possible aetiological factors such as smoking habits, previous chest illnesses, and head colds "going down on the chest" were

TABLE I.—Random Sample

Reasons for exclusion of men: One man had pulmonary tuberculosis, one man was bedridden following a stroke, and in two the sitting height and weight were omitted.

Reasons for exclusion of women: One woman was incapable, and in two the sitting height and weight were omitted.

noted. All questionnaires were completed by the observer who had completed them in the previous surveys.

2. Sitting height was recorded in inches to the nearest half-inch, a special stool fitted with a measuring-rod being used for this purpose. Weight was recorded in pounds to the nearest pound, an appropriate deduction being made for clothing.

3. An attempt was made to assess lung function, using a respiratory flow-meter designed to measure peak air flows during a maximal forced expiration (B. M. Wright, to be published). The instrument is simple and portable, and appears to give useful information about the ventilatory capacity. It was hoped that this survey would indicate its value as a rough sorting instrument for those with ventilatory insufficiency and also provide normal values for men and women living in an agricultural area.

4. In the men aged 55-64 who had never worked in dusty occupations the ventilatory capacity was also assessed from the volume of air expelled in 0.75 second during a forced expiration, using the method described previously (Carpenter *et al.*, 1956). The result is expressed as the maximum voluntary ventilation (M.V.V.) (indirect) in litres/minute by multiplying the volume by 40. In both physiological tests the mean of three results after a preliminary practice blow was taken.

5. Occupational histories and chest radiographs were available from the previous survey (Cochrane *et al.*, 1956).

Results

Table I shows what was achieved; co-operation was very good. Over 95% of those still living in the area, or 91%

of those originally drawn in the sample, were interviewed. Even in those who refused to co-operate fully it was remarkable how easily information about respiratory symptoms could be elicited. Only those who consented to the physiological test and to the measurement of their heights and weights have, however, been included in the analysis. Their mean ages and anthropometric measurements are given in Table II. In both men and women there was a progressive

	46	69.3	32.1	81.5	139.5	63.3	225

* Omitting one man with severe kyphosis.

reduction in sitting height with age. Weight, on the other hand, reached a maximum in the 35-44 age group and was followed by a moderate decline in the men but only a slight fall in the women.

Prevalence of Respiratory Symptoms and Bronchitis

Table III shows the prevalence of respiratory symptoms and "chronic bronchitis" in the men and women examined in the sample. Respiratory symptoms were common in both sexes. Less than half the sample had no symptoms at all. In the men there was a fairly steady increase in the prevalence of all symptoms with age, which is best seen in the

* Tables showing the prevalence of the individual symptoms are available from the Pneumoconiosis Research Unit.

† Grade 2 (those who are unable to keep up with people of their own age at work, on hurrying, on hills, or on stairs) and over (Fletcher, 1952).

FIG. 1.—Prevalence of "chronic bronchitis" in a random sample of the population of the Vale of Glamorgan (persistent sputum and at least one chest illness during the past three years).

case of persistent cough and sputum, wheezing, and breathlessness. In the women, on the other hand, an increase in prevalence with age is less striking. There was an upward trend from age 45; but the prevalence of cough and sputum at age 65-74 was little different from that at age 25-34.

In our previous paper we defined "chronic bronchitis" arbitrarily as the persistent production of phlegm (for at least three consecutive months in the year) and at least one chest illness with increased cough and sputum during the past three years. The prevalence of chronic bronchitis in the two sexes according to this definition is shown in Fig. 1. There was a steady rise in prevalence in the men but not in the women, leading to a well-marked sex difference in the older age groups; but under 45 the prevalence was slightly higher in the women.

Ventilatory Capacity

The scatter diagram (Fig. 2) compares the peak flow and M.V.V. (indirect) results obtained in the men aged 55-64 who had never worked in dusty occupations. There was a high correlation ($r = 0.86$) between the two sets of data. In the lower range of values, in which we are most interested, sorting of subjects would have been equally effective

FIG. 2.—Relationship between peak flow and maximum voluntary ventilation (indirect) in a random sample of males aged 55-64 who had never worked in dusty jobs.

with either instrument. It seems justifiable, therefore, to use the respiratory flow meter as a rough measure of the ventilatory capacity.

Figs. 3 and 4 show the frequency distributions of the peak flow measurements* in each 10-year age group for all the men and women studied. There was a linear fall of 6.34 ± 0.579 litres/minute in men and of 3.83 ± 0.445 litres/minute in the women for each year of life.

*The instrument used was an early model and was later found to underestimate the true peak flow, defined as one lasting 1/100 of a second or more, measured with a pneumotachograph, by about 17%. This underestimate was very consistent, and the figures given can be converted to true peak flow by multiplying them by 1.17.

Effect of Occupation

Fifty-five men in the sample, mainly over the age of 45, had worked at some period of their lives in mining or quarrying. The division of the sample by occupational dust exposure into two groups and the mean ages and measurements in each are given in Table IV. Table V shows that the prevalence of respiratory symptoms and "chronic bronchitis" was higher in those men who had worked in dust. In the 55-64 group in particular a considerably higher prevalence of chest illness and wheeze and tightness was recorded. The average peak flow in this group was significantly lower (70 litres/minute) than that of the men who had worked only in dust-free occupations ($0.02 > P > 0.01$). The differences in height and weight between the two occupational groups do not account for this finding, which is clearly associated with the higher symptom prevalence in the men exposed to dust. The difference of 37 litres/minute

FIG. 3.—Peak-flow measurements in a random sample of males aged 25-74 in the Vale of Glamorgan. Black area="chronic bronchitis." FIG. 4.—Peak-flow measurements in a random sample of females aged 25-74 in the Vale of Glamorgan. Black area="chronic bronchitis."

D=Dusty—i.e., those who had worked in mining or quarrying. ND=Non-dusty—i.e., those who had never worked in mining or quarrying. T=Total. * In two men the M.V.V. (indirect) was not measured. They have been omitted from the non-dusty group in this table and in the subsequent analysis.

in peak flow in the 65-74 group, while suggesting a similar trend, is, however, insignificant ($0.50 > P > 0.40$).

About one-third of the men in the sample were farmers, agricultural labourers, foresters, and gardeners. Mortality statistics suggest that those engaged in these occupations are less liable to bronchitis than other members of the community (Registrar-General, 1938). Although the numbers in

FIG. 4

the individual age groups are small, Table VI suggests that in the present sample this group had rather less cough and sputum and "chronic bronchitis" than the rest of the sample (Table VII).

FIG. 5.—Effect of smoking on ventilatory capacity as assessed by maximum voluntary ventilation (indirect) and peak flow in a random sample of males aged 55-64 who had never worked in dusty occupations.

A significantly higher prevalence of cough and sputum in smokers than in non-smokers was found in the women under 45 ($P < 0.01$); but over this age the difference was insignificant ($0.10 > P > 0.05$). The high prevalence of cough and sputum and wheeze in the young women was largely explicable on the basis of their smoking habits. There were, however, no striking differences in the prevalence of the other symptoms or in the peak-flow measurements between smokers and non-smokers.

Occurrence of Chest Illnesses in the Past

The prevalence of past attacks of pneumonia, pleurisy, and bronchitis (those occurring more than three years ago) is shown in Table X. In both sexes those with "chronic

TABLE X.—Influence of Previous Chest Illnesses on "Chronic Bronchitis"

		No.	Previous History of		
			Pneumonia	Pleurisy	Bronchitis
Men	All in the sample . . .	301	46 (15.3)	31 (10.3)	63 (20.9)
	Those with cough and sputum	65	13 (20.0)	7 (10.8)	25 (38.5)

	Those with cough and sputum	25	5 (20.0)	2 (8.0)	7 (28.0)
	Those with "chronic bronchitis" . .	14	6 (42.9)	2 (14.3)	8 (57.1)

bronchitis" recorded significantly more attacks of bronchitis in the past than the average for the sample (men: $P < 0.001$; women: $0.01 > P > 0.001$). The women with "chronic bronchitis" also recorded significantly more pneumonia ($0.05 > P > 0.02$); but in the men the difference was insignificant ($0.5 > P > 0.3$). No excess of pleurisy in the past was found in either sex.

The number of head colds each year and whether or not head colds usually "went down on the chest" were recorded. The overall mean number of colds was 2.0 each year for both men and women, and 31.9% of these went down on the chest in the men and 34.6% in the women. Those with "chronic bronchitis" reported more colds than the others, averaging 3.0 each year in the men and 2.7 in the women, and in this group 61.5% of the men and 87.6% of the women said that colds went to the chest. Further questions suggested that the phrase "going to the chest" usually implied a cold with cough and sputum but not necessarily frank chest illness.

These findings may be compared with those of Oswald *et al.* (1953), who found that the annual mean number of colds was higher in patients with bronchitis than in controls, and that whereas colds "went down to the chest" in only 27% of the controls, they did so in 90% of the patients.

Discussion

The results found in this survey in the men aged 55–64 who had never worked in mining or quarrying may be compared with those found for non-miners in Leigh (Lancs) (Higgins *et al.*, 1956). The comparison is shown in Table XI. There was little difference in the prevalence of wheeze and tightness and of breathlessness recorded in the two areas, and persistent cough and sputum was actually slightly commoner in the Vale. Bronchitic chest illness was only slightly more prevalent in Leigh; but if single attacks of illness are excluded it will be seen that recurrent attacks were more

than twice as common in Leigh—13% compared with 5% in the Vale. This was the most striking symptom difference between the two places, but the numbers are too small for the difference to be statistically significant ($0.10 > P > 0.05$). "Chronic bronchitis" as defined was also insignificantly commoner in Leigh—11% compared with 6%.

The similarity in the prevalence of respiratory symptoms recorded in the two places is surprising in view of the great differences in atmospheric pollution between them. The Vale is completely free from such pollution; Leigh is situated in the centre of the polluted S.E. Lancashire conurbation. There is a considerable difference in mortality rates in the 45–64 age group between the two areas (Goodman *et al.*, 1953) and a difference in respiratory symptomatology would certainly have been expected. One possibility is that there are regional differences in the way people answer questions about respiratory symptoms. A cough and sputum that might be ignored in the industrial north may be recorded as being present in South Wales. Every effort in questioning was made to avoid introducing a bias of this kind, and the physiological measurements do not suggest that it was likely. Fig. 6 compares the ventilation capacity measurements in the two areas. The mean M.V.V. (indirect) in the men who had never worked in dusty jobs in the Vale was 89 litres/minute compared with 85 litres/minute in the non-miners in Leigh. The difference of 4 litres/minute is quite insignificant.

FIG. 6.—Frequency distributions of maximum voluntary ventilation (indirect) in random samples of non-mining males aged 55–64 in the Vale of Glamorgan and Leigh (Lancs). Black area = bronchitics.

TABLE XI.—Comparison of Prevalence of Respiratory Symptoms and "Chronic Bronchitis" in the Vale of Glamorgan and Leigh (Lancs). Non-miners aged 55–64

Random Sample	No.	Cough and Sputum	Wheeze and Tightness	Breathlessness		Bronchitic Chest Illness		"Chronic Bronchitis"
				Grade 2 and Over	Grade 3* and Over	Once Only	More than Once	
Vale of Glamorgan	86	22 (25.6)	21 (24.4)	21 (24.4)	7 (7.9)	10 (11.6)	4 (4.7)	5 (5.8)
Leigh (Lancs)	84	15 (17.9)	19 (22.6)	19 (22.6)	6 (7.2)	4 (4.8)	11 (13.1)	9 (10.7)

* Grade 3 are those unable to keep up with other people of their own age walking on the level, but able to walk a mile or so at their own speed (Fletcher, 1952).

A more probable explanation is that smoking is a more important cause of respiratory symptoms and reduction in ventilatory capacity than atmospheric pollution. The importance of smoking as a cause of bronchitis has often been stressed (Oswald *et al.*, 1953; Waldbott, 1953; Joules, 1954; Palmer, 1954; Oswald and Medvei, 1955; Phillips *et al.*, 1956; Clifton, 1956; Leese, 1956; Edwards, 1957; Ogilvie and Newell, 1957). In the present comparison the smoking and habits of the non-miners in the two areas were similar, and this may account for similar prevalence of symptoms and of ventilatory capacity. It seems probable that the effect of smoking may overshadow any effect attributable to atmospheric pollution, so that one would have to study non-smokers to demonstrate it.

The importance of standardizing for smoking habits in considering chronic cough has recently been stressed by Phillips *et al.* (1956). The greater frequency of recurrent chest illness in Leigh suggests, however, that once the respiratory tract has been damaged those subjected to an industrial environment, including polluted atmospheres, may be more likely to become ill, and to become ill more frequently. The results point to the importance of obtaining information about exacerbations of chest illness in evaluating the effect of atmospheric pollution. Despite the apparently increased liability to illness of those living in the polluted town there was less evidence of the deleterious effect of the atmosphere than might have been anticipated. One might expect that increased exacerbations would lead to greater breathlessness, but in fact this was not so. Nor do the ventilatory capacity measurements support the belief that respiratory symptoms were more severe in Leigh than in the Vale.

A further factor that must be considered is mortality. Death rates from bronchitis are higher in towns than in the country, and consequently our rural sample may contain a higher proportion of survivors with respiratory symptoms than did our sample at Leigh. Prevalence and mortality rates are, however, of such different orders of magnitude that it is unlikely that the factor of survival could be large.

This comparison between the unpolluted Vale and the grossly polluted Lancashire town has been restricted to men who have never worked in mining. Miners and ex-miners have been shown to have significantly more respiratory symptoms and chronic bronchitis than other industrial workers (Pemberton, 1956; Higgins *et al.*, 1956), and they also have a significantly lower ventilatory capacity than non-miners of comparable age living in the same area (Carpenter *et al.*, 1956). The proportion of miners and ex-miners in the Vale and Leigh is very different. Thus in miners in the Vale and Leigh 55–64 worked or had worked for some time in mining, whereas in the Vale ex-miners comprised slightly less than one-third. A comparison between the two areas which ignored occupation would therefore have shown a higher prevalence of bronchitis in the town. This excess would, however, have been explicable on the basis of occupation rather than urban environment and atmospheric pollution.

There is a great need for a simple test of lung function that could be used in the home. The peak respiratory flow meter used in the present investigation is a useful instrument that might perhaps fulfil this need. Its main disadvantage is that compared with the M.V.V. (indirect) it requires more co-operation from the subject to obtain a repeatable result. The practical advantage of adding objective measurement to the subjective information obtained in this type of survey, however, outweighs this objection.

Summary and Conclusions

A survey of respiratory symptoms and ventilatory capacity in over 90% of a random sample of 331 men and 300 women aged 25–74 living in the Vale of Glamorgan has been carried out.

The prevalence of "chronic bronchitis," defined as persistent sputum and at least one chest illness during the past three years, rose in the men from 2.2% in the 25–34

age group to 15.6% in the 65–74 group. In the women, on the other hand, the prevalence fell from 6.4% in the 25–34 group to a minimum of 2.1% at age 45–54 and then rose to 8.7% in the 65–74 group.

In both sexes smokers recorded a significantly higher prevalence of persistent cough and sputum than non-smokers, and in the men smokers also appeared more liable to chest illnesses and breathlessness. The influence of occupation, head colds, and previous chest illnesses is also considered.

The results obtained in the men aged 55–64 who had never worked in mining or quarrying are compared with those found previously in a comparable group of non-miners living in an industrial town. The town dwellers appeared more liable to recurrent chest illnesses and they also had slightly more "chronic bronchitis." The overall prevalence of respiratory symptoms and of ventilatory capacity, measured by the M.V.V. (indirect), was, however, surprisingly similar in the two groups. This is discussed in the light of their smoking habits; and stress is laid on the necessity for standardizing for smoking habits in studies designed to evaluate the importance of atmospheric pollution as a cause of respiratory disease.

While confirmation of these findings in different areas and over a wider age range is needed, the similarity in the pattern of respiratory symptoms and disability in non-miners in Leigh and in the Vale suggests that the industrial environment exerted a smaller effect on the general population than might have been anticipated. In assessing the importance of occupational factors as a cause of respiratory disease in a particular industry, therefore, a control group, such as we have used previously, of men of comparable age who have never worked in the industry but who live in the same neighbourhood may justifiably be employed provided there are no great differences in the smoking habits of the two groups.

A respiratory flow meter, designed to record peak expiratory flow, was used. Although still in a developmental stage the correlation ($r = 0.86$) with the M.V.V. (indirect) in the men aged 55–64 appeared to justify the use of this instrument to measure the ventilatory capacity, and normal values for the men and women in the sample are given for each 10-year age group.

I am grateful to my colleagues at the Pneumoconiosis Research Unit for their helpful advice and criticism, particularly to Dr. J. C. Gilson, Director of the Unit, Dr. A. L. Cochrane, epidemiologist, and Mr. P. D. Oldham, for statistical help, and to my invariably cheerful and determined driver and companion, Mr. Hugh Bates. The diagrams were drawn by Mr. F. Moore.

THE ADVANTAGES OF GLOSSOPHARYNGEAL BREATHING

BY

J. R. HARRIES, M.D., M.R.C.P., D.C.H.

Respiratory Unit, King George VI Hospital, Nairobi, Kenya

The advantages of glossopharyngeal breathing (G.P.B.), or "frog breathing," are widely known in the U.S.A. from the writings of Dail *et al.* (1955), and have recently been reported by Kelleher and Parida (1957).

A year ago one of our patients was taught G.P.B. after he had been in the respiratory unit for 10 months. The improvement in his general and psychological condition has been so striking that we thought it might be of interest to readers elsewhere.

The patient, a youth of 18, is totally paralysed from the neck down as a result of anterior poliomyelitis. Before he learned the technique he was pale-faced, thin, despondent, and limited to spending his days in a tank respirator, with a few minutes each day on a rocking bed. After mastering G.P.B. he could go home for six-hour periods, visit the cinema, travel by car many miles over the countryside at altitudes of nearly 7,000 ft. (2,130 m.), visit his friends, and lead a reasonably full social life. He is now a plump, sunburnt, healthy youngster who has learned to live with his physical handicap, though there has been no change in the degree of paralysis.

Mechanism of Frog Breathing

Frog breathing is a mode of breathing used by people with respiratory paralysis and sometimes by normal people to augment their vital capacity in underwater swimming (Dail *et al.*, 1955). The tongue is the main organ of breathing. It is thought that the following steps constitute G.P.B. (Zumwalt *et al.*, 1956). The lips are opened, the floor of the mouth is depressed, the palate elevated to close the nasopharynx, the larynx closed, and the oesophageal orifice shut. This enables a maximum amount of air to be accommodated in the buccal cavity. The lips are then closed: a small amount of air is lost during this manoeuvre, and the air is trapped. The tongue is then pushed upwards and backwards, forcing the air into the pharynx. At this moment the larynx is opened and the air passes into the trachea, where it is trapped by closure of the larynx. This is the mechanism of each "stroke." About ten strokes are taken for each breath, and at the end of this breath the larynx is opened and the air expelled passively.

Each stroke takes in approximately 60 ml. of air, each breath being about 600 ml. There are, of course, individual variations in frequency and stroke volume, though it is thought that the volume of each stroke should be at least 1% of the expected vital capacity. Some patients use, in addition, a sucking mechanism to get air into the mouth and pharynx. This is especially so when the nose is used to frog-breathe while the mouth is kept closed. The detailed technique for teaching G.P.B. can be found in the *Manual of Instruction* published by the National Foundation for Infantile Paralysis.

The advantages of G.P.B. may be divided into two main groups: physical and psychological.

Physical Advantages

The various advantages of frog breathing have been described fully by Dail *et al.* (1955) and by Zumwalt *et al.* (1956). Briefly, G.P.B. improves the vital capacity, which in these severely paralysed patients equals the inspiratory capacity; the coughing power is augmented, as evidenced by an increase in the maximum expiratory flow rate (M.E.F.); G.P.B. is a useful method, possibly the only effective method of chest stretching (Plum, 1957); physiotherapy, such as hydrotherapy and the use of tilt boards, is made more feasible, and, of course, long periods can be spent without any form of respiratory aid.

G.P.B. cannot be taught in the presence of paralytic involvement of the tongue and pharyngeal muscles or concurrent disease of the heart or lungs. The patient must have a desire to learn or much effort will be wasted. It can be learnt even if a tracheotomy tube has been inserted: the tube must be corked tightly, as the pressure developed in the trachea may blow the cork out.

There are a few theoretical disadvantages to G.P.B. Air inhaled through the mouth is dry and irritating. This can be overcome by pulling in air through the nose. Our patient has mastered this technique. It may take a long time to learn, and after the method is learnt it may take weeks before any appreciable "breathing" time is acquired. Our patient took three weeks to learn, and it was two months before he could breathe two hours, but in a further two months this was increased to six hours. Although drinking is possible during G.P.B., eating should not be attempted in case a choking attack occurs, which may render the patient helpless. Theoretically, the increased intrathoracic pressure may interfere with the venous filling of the right side of the heart (Dail *et al.*, 1955), but we have noticed no alteration in pulse rate or blood pressure in our patient. This interference with venous filling is more likely to apply during maximum G.P.B., which, in any case, is carried out only a few times daily.

During the 10-months period of observation our patient's vital capacity remained at 200 ml. His G.P.B. vital capacity is now 2,700 ml. and his M.E.F. 109 litres a minute.

To illustrate the usefulness of the cough-augmenting power of G.P.B., our patient, while out for a ride, partially occluded his right bronchus with a plug of mucus. On his hurried return he was put in a tank, and with the help of maximum G.P.B. and positive pressure in the tank he was soon able to cough up the offending plug.

Chest Stretching.—Before being taught to frog-breathe, our patient could spend only about five minutes on a rocking bed because of insufficient ventilation. He was rocked in the position of maximum efficiency, the rock being from the horizontal to the head-up position, the angle of the rock being about 40 degrees. By means of an inflatable belt applied to the abdomen below the umbilicus and timed to inflate as the head was reaching the horizontal, sufficient ventilation was obtained. This was the position until he learned to frog-breathe. After this he was able to spend several hours on the bed without other aid. His ventilation was adequate. This was calculated by means of the Radford nomogram and measured on a Benedict-Roth spirometer, using a nose-clip and a mouthpiece. The patient was instructed not to frog-breathe—this could be detected by observing the spirogram. We feel that the explanation of this increased ventilation was due to the fact that G.P.B. had stretched his lungs, so improving their compliance, though no actual measurements of compliance were made.

Psychological Advantages

Perhaps the most striking improvement in this patient was the change in his psychological outlook. The fear of dying from asphyxiation must constantly loom large upon the horizon of patients whose respiratory muscles are

SPIROGRAPHIC STUDIES IN GLOSSOPHARYNGEAL BREATHING

BY

Physician

Respiratory Unit, King George VI Hospital, Nairobi, Kenya

Glossopharyngeal breathing (G.P.B.) has been used in the U.S.A. and in Scandinavia as a substitute for the normal respiratory mechanism in patients with gross paralysis of the respiratory muscles and to augment the remaining ventilatory ability. It may also be used to improve the compliance of the lungs and chest and to aid the coughing power.

This investigation was carried out to estimate the speed of air flow during expiration, which is important in coughing; to estimate the effect of different positions on the efficacy of the method; and to attempt to elucidate the peculiar characteristic features of the spirographic pattern.

The subject of these tests was an 18-year-old European male who had complete paralysis of all spinal muscles except those of his neck and the right upper rectus abdominis. He had been taught to use G.P.B. after he had been paralysed for nine months. The tests were performed over a period of 10 months, beginning some six weeks after he had learned G.P.B.

During the period of observation there was no improvement in the degree of paralysis, the vital capacity remaining at 200 ml. throughout this time.

Methods

Spirographs were obtained, using (1) the Sandborn metalulator or a Benedict-Roth spirometer at slow speeds, and (2) a high-speed kymograph (20 cm. in 10 seconds) with a spirometer similar to that described by Bernstein *et al.* (1952). Recordings were made in the semi-sitting and in the supine position both during spontaneous respiration and during G.P.B.

During the tests the patient held the mouthpiece between his teeth, the nose being clipped. The spirometers were filled with a mixture of approximately 50% air and 50% oxygen.

All the results are at ambient pressure and temperature, and saturated. The average atmospheric pressure was 625 mm. Hg and the temperature 23–25° C.

Measurements were made of the minute-volume, the vital capacity, the number of strokes per breath, the number of breaths per minute, and the speed of each stroke. The

Results

	Spontaneous Respiration	Glossopharyngeal Breathing
Vital capacity	200 ml.	Supine, 2,464 ml. Semi-sitting, 2,016 ml.
Maximum expiratory flow	Over 100 ml./min.	Over 1 litre/min. (a) Normal G.P.B., 86 l./min. (b) Maximum G.P.B. effort: Sitting, 109 l./min. Supine, 85.7 "
Stroke volume	60 ml. approx.	60 ml. approx.
No. of strokes per breath	10–12	Variable: 0.40–0.55 sec.
Respiratory rate	24/min.	6–8/min.
Tidal volume	200 ml.	600–660 ml.
Minute-volume	4,800 "	4,800–5,200 ml.

All volumes are at ambient temperature and pressure saturated.

paralysed. This is always in evidence if mechanical failures of respiratory apparatus develop or if the power fails. It can also be seen when using positive pressure through a face-mask when the tank has to be opened for the first time, and when weaning from respiratory aids is started. By learning frog breathing it might be said that the patient has taught himself to live and is no longer beset by fears of dying. After the initial psychological improvement due to removal of these fears further improvement develops through the sense of achievement from learning the technique and in acquiring further breathing-time. Other factors are the sense of freedom from respiratory aids and the ability to lead a fairly full social life. It is possible that some of the psychological improvement in our patient could be put down to the eventual acceptance of his position, but we feel that the dramatic coincidence with the ability to frog-breathe is against this.

Chronic respiratory cripples confined to an institution live a far more circumscribed life than can be imagined by normal people. They have little interest beyond the four walls of their ward and at times show a remarkable ability to be petty and "take it out" of their attendants. Jealousies of attention given to other patients become a prominent feature of their reaction to their environment. This hostility reaction is, of course, not uncommon in many disabling diseases. It is of greatest importance to enlarge the small unchanging scene before them. In patients "fixed" to a ward, social interests are confined to daily visits by friends and relatives, to routine talks, to cinema shows, and to occupational therapy. However, the main drawback to this existence is that they themselves are static, and it must be obvious to them that their own interests are due to be artificial stimuli, dependent upon others. On the other hand, a patient who is independent of fixed respiratory aids becomes able to enjoy an ever-changing source of stimulation from outings in a wheelchair, car rides, etc. He now feels that although he is physically unable to move he is no longer utterly dependent upon the visitations of others to obtain the stimuli necessary for normal expression.

Before learning G.P.B. our patient had frequent fits of depression with episodes of weeping several times a day. He was difficult to amuse, because his interests flitted from one thing to another. He had evidence of withdrawal, and as a rule did not encourage visitors other than his and close family circle. He was thin, ate indifferently, and always had pains here and there. Since mastering the technique the weeping fits are a thing of the past. He spends considerable time reading, typing with a mouthstick, and playing chess, and doing jigsaw puzzles, also with a mouthstick. He is much less hostile and does not try to put "a spanner in the works," except very occasionally. He is now pleased to see any visitors who might wish to see him. He eats well, rarely complains, and is plump and sunburnt.

G.P.B. has so many advantages that we believe that the teaching of this technique is one of the most important advances made in the treatment of respiratory poliomyelitis in recent years.

Summary

A description of the mechanism of glossopharyngeal breathing is given. The disadvantages are briefly outlined and a description of some of the physical and psychological advantages is given.

speed of maximum expiratory air flow was measured during expiration following a "normal" glossopharyngeal breath and following a maximum glossopharyngeal effort.

The results are given in the accompanying Table.

Discussion

Pattern of the Spirograph.—The presence of a mouth-piece and of a nose-clip and the resistance of the spirometer interfered to some extent, and the figures shown therefore probably do not represent the true performance. Previous spirographic recordings of G.P.B. on a Sandborn metabulator (Dail *et al.*, 1955; Zumwalt *et al.*, 1956) show

FIG. 1.—Spirogram of G.P.B. in the supine position showing, from left to right, "normal" G.P.B., a maximum G.P.B., and spontaneous respiration.

FIG. 2.—High-speed spirogram (20 cm. per sec.) showing the characteristic pattern of G.P.B.

gulp. A thread held in front of the mouth during G.P.B. shows that some air is expelled just before the lips are closed.

Vital Capacity.—The predicted vital capacity for the patient—height 5 ft. 10 in. (178 cm.), weight 130 lb. (59 kg.)—based on West's (1920) normal values, is approximately 4,350 ml. The patient's vital capacity when breathing spontaneously is less than 5% of this. If the maximum glossopharyngeal effort can be compared with the vital capacity, then G.P.B. in the supine position increases the figure to more than 50% of the predicted normal. In normal subjects the vital capacity is greater when sitting than when recumbent. In our patient the glossopharyngeal "vital capacity" in the supine position was some 400 ml. more than in the semi-sitting position. We feel that this apparent paradox is explained by the fact that in these

respiratory cripples only the inspiratory fraction of the vital capacity is present, as can be seen from Fig. 1. The inspiratory capacity in normal people is reduced when the position is changed from sitting to lying. Whitfield *et al.* (1950) found this reduction to be some 319 ml. in normal adults. The patient's explanation was that "his abdomen got in the way" in the semi-sitting position. Kaltreider *et al.* (1938), examining 50 normal males aged 18–30, found an inspiratory capacity ranging from 2,410 to 4,930 ml., with a mean of 3,790 ml., at 37° C. saturated in the recumbent position. The figures given by our patient would suggest that G.P.B. had almost restored the patient's inspiratory capacity to normal.

Maximum Expiratory Flow.—During spontaneous respiration the maximum expiratory flow could be measured only over 100 ml., but this flow was much less than the expiratory flow rate during a normal respiration, and was only 3.75% of the mean maximum expiratory flow of a normal adult. This serves to illustrate the handicap from which these patients suffer during coughing. During G.P.B. the maximum expiratory flow improved considerably—that is, 109 l./min. in the sitting position—though this is much less than the normal (400 l./min.). As the effectiveness of a cough is partially dependent upon the maximum expiratory flow the advantage of a respiratory cripple's ability to perform G.P.B. is evident. The maximum expiratory flow was greater when sitting. The vital capacity, as had been noted, was reduced in this position.

Stroke Volume and Duration of Stroke.—Dail *et al.* (1955) suggest that G.P.B. requires a stroke of volume of at least 1% of the predicted vital capacity and that the efficacy of this method is increased when less time is taken to complete each stroke. The time for each stroke in their patients was in the range 0.3 to 1 second. The stroke volume for our patient was 1.38% of the predicted vital capacity, each stroke being accomplished within a period varying from 0.4 to 0.55 second.

Tidal Volume, Minute-Volume, and Respiratory Rate.—Our patient is unable to breathe spontaneously for more than a few minutes at a time. The ventilation required during spontaneous respiration calculated from the Radford nomogram (Radford *et al.*, 1954) at this altitude (5,260 ft., 1,585 m.) at a respiratory rate of 24 would be 8,232 ml./min.; as can be seen from the Table, he is unable to do much more than 50% of this. At respiratory rates of 6 and 8 the required minute-volumes are 5,100 ml. and 5,880 ml. respectively. During G.P.B. he can provide himself with minute-volumes of approximately 4,800 to 5,200 ml. at these slower respiratory rates. The lower figures recorded by us might partly be due to the increased resistance of the mouthpiece and of the spirometer, coupled with the fact that the patient normally performs G.P.B. through his nose and mouth, whereas during the recordings he was able to breathe only through his mouth. This improvement of ventilation is amplified by the fact that he can breathe without an aid for some six hours at a time and has travelled by car for short periods at altitudes of 6,400 ft. (1,950 m.).

Summary

Spirographic recordings of glossopharyngeal breathing on slow and fast recording kymographs are presented. The improvement of the vital capacity and of the maximum expiratory flow rate due to glossopharyngeal breathing is demonstrated.

SEROLOGICAL RESPONSE OF CHILDREN TO A THIRD DOSE OF POLIOMYELITIS VACCINE

A REPORT TO THE MEDICAL RESEARCH
COUNCIL*

In 1956 a study was made of the antigenic activity of British poliomyelitis vaccine in a group of 196 children who, at the time of their first dose of vaccine, had no detectable antibodies to any of the three types of poliomyelitis virus (Medical Research Council, 1957). Three batches of vaccine, Nos. 4, 5, and 6, prepared by the Glaxo Laboratories, were used in the study. The children were given two doses, each of 1 ml., separated by an interval of four weeks, and sera were taken on the average two weeks after the second dose. All the children, except two, produced neutralizing antibodies to all three types of poliomyelitis virus.

A further study has now been made, with some of the children from the same group, to determine the antibody decline after primary immunization and the antibody response to a third injection of poliomyelitis vaccine given eight to eleven months after the second dose.

Methods

Vaccines.—Two batches of vaccine, Nos. 7 and 10, prepared by the Glaxo Laboratories were used for the third injection, approximately the same number of children being injected with each batch. Both batches were tested in injected with each batch. Both batches were tested in rhesus monkeys by the routine method (Biological Standards Control Laboratory, 1957) and shown to have similar antigenic activities and of the same order as those used for the primary course of immunization.

Schedule.—Of the 196 children taking part in the previous study, 107 were given a third dose of vaccine: 15 from London, 18 from Manchester, 37 from Central Scotland, 18 from Sheffield, and 19 from Southend-on-Sea. Each child had a sample of blood taken eight to eleven months after the primary course of immunization and on the same day 1 ml. of vaccine was injected into the left deltoid muscle. Two to three weeks later another blood sample was taken.

Titration of Sera.—Sera, which were inactivated at 56° C. for 30 minutes and stored at –10° C., were titrated by the method already described (Medical Research Council, 1957). For each subject the sera taken before and after the third dose were titrated in the same test together with the serum taken after the second dose. In this way it was possible to make a valid comparison of antibody levels at various stages of immunization. The values obtained from the repeat titrations of the sera taken after the second dose were similar to those obtained previously. It was also possible to re-titrate 58 of the 107 sera taken before the first injection of vaccine. These sera were originally titrated at a dilution of 1/8, and those showing no neutralization at this level for all three types of virus were considered "triple negative." It has been suggested that titration at such a level might not exclude all children devoid of a basal immunity and that higher concentrations of sera should have been tested. The 58 sera were therefore retested by mixing undiluted serum with virus suspension—that is, at a dilution of 1/2. With

*Children were immunized and sera collected by Dr. A. M. Peach and Dr. R. H. R. White (London); Dr. P. B. Stones and the medical staff of the Health Department (Manchester); Dr. J. D. Finlayson, Dr. W. M. Jamieson, Dr. R. C. McLeod, and Dr. B. R. Nisbet (Scotland); Dr. J. Rendle-Short (Sheffield); Dr. J. Stevenson Logan, Dr. A. D. Macrae, and Dr. Gladys Neill (Southend-on-Sea). Laboratory investigations were made by Miss A. J. Ferguson, Dr. F. T. Perkins, Mrs. K. Russell, Dr. J. O'H. Tobin, and Miss R. Yetts, of the Biological Standards Control Laboratory, Hampstead. The results were analysed and the report prepared by Dr. F. T. Perkins.

only three sera was neutralization found to occur at this dilution, and in each case neutralization was with one virus type only which, it was found, was not neutralized with a serum dilution of 1/4. With none of these three children was the response to the initial immunization more than the mean value for the group. We therefore feel justified in regarding the children used in the study as being originally "triple negative."

Results

Of the 107 children who were given the third dose of vaccine, seven were excluded from the analysis, since their antibody level to a particular type at this time was much greater than after the second dose, indicating infection by poliomyelitis virus during the period between these doses. Of these children, two showed an increase in type 1 titre from 64 and 256 to >8,192, one an increase in type 2 from 128 to >8,192, and four an increase in type 3 from 16, 16, 32, and 1,024 to 2,048, 2,048, >8,192, and >8,192 respectively. Thus, in the final analysis the results from 100 children were used.

Fig. 1 shows the individual titres for each type at the three different stages during immunization. It is evident that the decline in antibody titres during the period between the second and third doses was least with type 2 in which the geometric mean titre for the whole group fell from 283 to 166, a 1.7-fold decrease, and only one serum had a titre of less than 4 at the time of the third dose. With type 1 the geometric mean titre fell from 78 to 14, a 5.6-fold decrease, and 31 children gave titres of 4 or less at the time of the third dose, including seven who had titres of 4 after the second dose. With type 3 the geometric mean titre fell from 113 to 19, a sixfold decrease, and 20 children gave titres of 4 or less at the time of the third dose.

It is also evident from Fig. 1, considering the group as a whole, that the third injection of vaccine gave a substantial antibody response to each of the three types. The increase in mean antibody titres for type 1 was from 14 to 1,886, for type 2 it was from 166 to 27,560, and for type 3 it was from 19 to 7,080.

A more detailed analysis of the effect of the third dose is shown in Fig. 2, which gives for each child the antibody titres before and after the third dose of vaccine. All children except three gave an antibody response to all three types, although the degree of response varied considerably with the individual child. Of the three exceptions each responded to

Serological Responses of Children to Two and Three Doses of Poliomyelitis Vaccine

Batch of Vaccine Used for Primary Immunization	No. of Sera*	Virus Type	Geometric Mean Antibody Titre of Sera taken:		
			After Second Dose	Before Third Dose	After Third Dose
4	37	1	62	12	1,146
		2	314	128	22,940
		3	91	14	3,520
5	27	1	67	13	1,998
		2	229	214	17,370
		3	107	19	8,870
6	33	1	145	18	2,928
		2	278	148	29,480
		3	155	25	15,300

* Three of the 100 children were excluded from this analysis, as they received different batches for their first and second injections.

all but one type for which they already had a high antibody level. There was also considerable variation in the antibody levels reached after the third dose; for type 2 no child gave a titre of less than 256, whereas for types 1 and 3 there were 13 and 3 respectively giving titres of less than 256. It is interesting to note that of these poor responders to types 1 and 3 there was one child who gave the lowest titre to types 1 and 3—namely, 4 and 32—and also the lowest titre of 256 to type 2. Of the remaining poor responders to types 1 and 3, all responded well to the other components.

An analysis was made to determine whether the three different batches of vaccine used for the primary immunization differed in their ability to produce a basal immunity which might be reflected in the degree of response to the third injection. It was possible to do this, even though two different batches of vaccine were used for the third injection, as they were evenly distributed between the groups of children receiving the three batches for the primary course. The results of this analysis are given in the accompanying Table, and indicate that there were no striking differences

in antigenic activity between the three batches, although there is some indication that batch 6 might have been slightly more potent in all three components than the others.

Conclusions

It is evident from the results of this study that a third injection of poliomyelitis vaccine given to children eight to eleven months after the primary course produced a substantial antibody response to all three components of the vaccine. The responses in many of the children were as good

FIG. 1

FIG. 1.—Antibody levels in children after two and three doses of poliomyelitis vaccine.

FIG. 2

FIG. 2.—Individual antibody responses of children to a third dose of poliomyelitis vaccine.

as those which occur in children as a result of infection with poliomyelitis virus. These findings are similar to those already reported from America by Salk (1956) and Brown and Smith (1956).

It should be noted, however, that during the period between the primary course of immunization and the third injection a decline in antibody level occurred which was especially marked in the case of types 1 and 3, resulting in a high proportion of children with titres of 4 or less at the time of the third dose. In some of these children the response to the third dose of vaccine was poor, especially with type 1, and it is proposed to study, with those children in the original group who did not receive the third injection, the question of whether the chance of a poor response is increased the longer one waits before giving a third dose.

It is also intended to follow up those children who have already received the third dose, to determine to what extent their antibody levels are maintained over the next few years.

Summary

A study was made in a group of 100 children who initially had no detectable poliomyelitis antibodies, to determine the decline in antibody level after immunization with two doses of poliomyelitis vaccine, and the response to a third dose of vaccine given eight to eleven months after the second dose.

The decline in antibody level was greatest with types 1 and 3, resulting in a high proportion of children with low titres at the time of the third injection.

In the majority of children a substantial antibody response to all three types was obtained to the third injection of vaccine.

Those responsible for this study are grateful to the parents who consented to allow their children to take part and also thank the Ministry of Health for the supply of poliomyelitis vaccine.

UNHERALDED PULMONARY EMBOLISM

BY

H. COHEN, M.B., M.R.C.P.

Senior Medical Registrar, Royal Hospital, Sheffield

AND

J. J. DALY, M.B., M.R.C.P.

Medical Registrar, Royal Hospital, Sheffield

Pulmonary embolism is a common disease which accounts for 2 to 3% of all deaths in hospital (Brooks, 1952). It is suspected when a patient has acute chest symptoms either post-operatively or after prolonged bed rest. It can, however, occur in patients who appear to be fit, are active, and have no signs of venous thrombosis (Hampton *et al.*, 1945), and in these patients diagnosis is difficult, as the clinical picture frequently resembles pneumonia.

The object of this report is to describe 10 cases, eight of which had unheralded pulmonary embolism as described above. The remaining two patients had no signs of venous thrombosis when first seen, but had been at rest in bed for about a week before they developed chest symptoms. Such a short period of bed rest is not generally associated with venous thrombosis.

Case 1

A woman aged 21, who worked as a machinist, was admitted to hospital on November 23, 1955, with a history of left-sided chest pain for eight days. One month previously she had a similar pain on the right side of her chest for three days. Fever was present on both occasions and there was no history of haemoptysis. A day before admission she complained of a dry cough. Her weight had been steady. At the onset of the last attack penicillin was given. She had been working between the two episodes of pleurisy. Her past health had been good and there was no history of chest illness in the family.

Physical examination revealed a pale girl, not distressed, with a temperature of 100° F. (37.8° C.). There was no evidence of phlebitis in her legs. Examination of the chest disclosed signs of collapse at the left base. The cardiovascular system appeared normal with a blood pressure of 110/80. Treatment was started with analgesics and intramuscular penicillin.

Investigations.—Chest x-ray examination showed elevated left leaf of diaphragm. Blood count: Haemoglobin, 50%; red cells, 4,290,000 per c.mm.; white cells, 7,000 per c.mm. (normal differential); E.S.R. (Westergren), 98 mm. in one hour. Mantoux positive at 1/10,000. Specimens of gastric juice were collected for examination for tubercle bacilli.

The pain subsided but the fever continued. On November 27 there were signs of a left pleural effusion. The fluid was turbid, contained polymorphs and lymphocytes, and culture was sterile. Streptomycin, 5 g. twice daily, and isoniazid, 200 mg. twice daily, in divided doses, were substituted for penicillin. On December 3 she called for a bed-pan, complained of feeling faint, collapsed, and died.

Necropsy Findings.—There was a left pleural effusion of 1,200 ml. This was yellow but mixed with blood. Straddling the bifurcation of the pulmonary artery was a coiled mass of ante-mortem thrombus showing branching. Further down the right pulmonary artery a small thrombus was noted adherent to the vessel wall. A yellowish-brown firmly adherent clot was seen in the left pulmonary artery. Both were associated with established infarcts. Extensive dissection of the leg veins revealed no ante-mortem thrombus.

Comment.—This case illustrates several important features. The patient had been active before the onset of her symptoms. Between the episodes of pleurisy she was working. At no time was there any clinical evidence of phlebitis. Her cough had never been productive and there appeared to be no response to antibiotics. At necropsy the appearance of the ante-mortem clot suggested an embolus, and there was no evidence of thrombosis in the calf veins.

Case 2

A miner aged 54 was admitted to hospital on May 5, 1955, with a history of intermittent chest pain for one year. The first attack was right-sided and lasted three days. He then remained well until March, 1956, when one night he awoke with severe retrosternal pain radiating to the left and associated with breathlessness and tightness in his chest. Three weeks later he experienced pleural pain on the left side. The next incident, 11 days later, was right-sided and accompanied by haemoptysis. Two days before admission he experienced right-sided chest pain, again with haemoptysis. During the five weeks before admission he was breathless on moderate exertion. At no time was cough a prominent feature. During each illness he was febrile, and with the last three attacks he had been given penicillin, oxytetracycline, and streptomycin. There was no family history of chest illness, and his general health in the past had been good.

Examination revealed an ill, cyanosed, breathless man, in pain and with a temperature of 101° F. (38.3° C.). Movement was diminished and rales were heard over both lung bases. There was no evidence of heart failure and the blood pressure was 120/70. Examination of his legs revealed no evidence of thrombophlebitis.

Investigations.—Chest x-ray report (Dr. N. A. Lewtas) was as follows: "Lung fields: There are bilateral pleural effusions. There is an opacity lying peripherally in the left mid-zone which does not appear to be of segmental distribution and is very suggestive of an infarct." The E.C.G. was normal. Blood count: Haemoglobin, 96%; white cells, 12,000 per c.mm., with normal differential; E.S.R. (Westergren), 90 mm. in one hour.

Treatment was started with anticoagulants, penicillin, and streptomycin. The patient improved over the course of a week and became afebrile. Prior to discharge on June 15 he was up and about and symptom-free. Chest x-ray examination at that time revealed a small residual shadow at the left costophrenic angle.

Comment.—This patient had five acute attacks of chest pain in a year. Between attacks he was well apart from breathlessness on moderate exertion just before admission. He had never had clinical evidence of venous thrombosis. His sputum was not purulent on any occasion. There appeared to be no response to antibiotics, and it was not until he was given anticoagulants that his condition improved and no further attacks occurred.

Case 3

A man aged 76 was admitted to hospital on May 30, 1955, complaining of sudden onset of abdominal pain 12 hours previously. The pain was generalized, but was more severe in the left loin and worse on breathing. Two weeks previously he had experienced a similar attack. Prior to this his health had been good.

Physical examination revealed an ill man with a temperature of 100° F. (37.8° C.). Moist sounds were present at both bases. The blood pressure was 190/90. There were no abnormal signs in his abdomen and no evidence of venous thrombosis in his legs. Pleurisy was diagnosed and the X-ray examination of the chest showed shadowing at both bases and evidence of an effusion in the region of the horizontal fissure.

The patient continued to experience pain, which had spread to his left shoulder. An intermittent fever was present. On June 13 he collapsed and died.

Necropsy Findings.—There were fibrinous adhesions over the lower lobe of the right lung. Both pulmonary arteries contained coiled pieces of ante-mortem thrombi. An infarct was present in the upper part of the right middle lobe. There was congestion at both bases. No evidence of thrombosis was found in the legs.

Comment.—This patient's illness consisted of two attacks of pleurisy associated with persistent fever. Abdominal pain was the presenting feature. There was no response to chemotherapy. No evidence of venous thrombosis was found at necropsy.

Case 4

A man aged 43 was admitted to the Royal Infirmary, Sheffield, on April 30, 1952. He had been well until two weeks previously, when pain developed in the left side of his chest and in his left loin. He had recurrent attacks of pain and haemoptysis during these two weeks. The past history was not recorded.

Physical examination revealed that he was shocked. B.P. 90/70. There were no signs of heart failure. He was febrile—temperature 100° F. (37.8° C.). The breath sounds were diminished at the left base. There was no tenderness of the calves or swelling of the legs. An E.C.G. showed a Q wave and an inverted T wave in standard lead III. He collapsed and died shortly after admission.

Necropsy Findings.—The right ventricle was dilated. At the bifurcation of the pulmonary artery, and extending for a short distance into the right branch and for a long way into the left branch and its subdivisions, lay a greyish-red, firm, coiled pulmonary embolus completely occluding the vascular lumen. There was ante-mortem thrombus in the

left femoral vein. At the base of the left lung there was a dark-red, friable haemorrhagic infarct. Both pleural cavities appeared normal.

Comment.—The clinical picture, consisting of peripheral circulatory failure, chest pain, and an electrocardiographic abnormality in a man of 43 who was active until the onset of his illness, was suggestive of coronary thrombosis, and quite unlike that usually associated with pulmonary embolism.

Case 5

A male clerk aged 56, previously fit, developed pain in his left groin, radiating to the right groin, and shooting down his right leg. His left testicle became swollen, but not his legs. He was admitted to the surgical wards of another hospital on July 20, 1956, and a diagnosis of acute epididymo-orchitis was made. *Staphylococcus aureus* was grown on culture of his urine, and he was treated with chloramphenicol. He remained in bed in hospital for one week and was discharged on July 28, the pain and testicular swelling having gone. However, treatment with chloramphenicol was continued. At home, he stayed in bed for about half the day and for the remainder rested in an armchair. Four days after discharge from hospital he developed a severe pleural pain in the left side of his chest. The onset was not dramatically sudden: it was about four hours before the pain became severe. He had a slight cough and produced a small quantity of tenacious blood-stained sputum. He was seen by his general practitioner, who diagnosed pneumonia and treated him with oxytetracycline. He improved, but four days later had another attack of pain in the left side of his chest, this time associated with breathlessness and signs of consolidation in the left lower lobe. Following this attack the antibiotic was changed to erythromycin and he again improved. Three days later he had an attack of pleural pain in his right side: he became breathless, cyanosed, and collapsed, and was admitted to hospital on August 9.

Inquiry revealed that four years previously he had had an operation on varicose veins in his left thigh. There was no history of previous respiratory disease or other illness.

Physical examination on admission revealed a thin cyanosed man whose breathing was rapid, shallow, and painful. He was febrile—temperature 101° F. (38.3° C.). The pulse was regular, rapid (130 a minute), and the blood pressure 160/110. Jugular venous pressure was raised about 2 cm. above the sternal angle. There was no oedema of the legs or sacral pad. The heart was not clinically enlarged, but there was a sternal heave. The pulmonary second sound was split. There were no murmurs. Dullness to percussion was present over both lung bases with crepitations in these areas and bronchial breathing over the right lower lobe posteriorly between the eighth and tenth ribs. The legs were not tender and there were no visibly inflamed veins. Homan's sign was negative. There were no other abnormal physical signs.

He was treated with phenindione, penicillin, 500,000 units six-hourly, and streptomycin, 0.5 g. twice daily.

Investigations.—Chest x-ray examination (August 10) showed bilateral pleural effusions and patchy inflammatory changes at both bases. The final x-ray examination, on August 21, showed, in the left lateral film, fluid or pleural thickening along the posterior chest wall and linear atelectasis just above the diaphragm. The conclusion was that the appearances could be due to embolism, inflammatory change, or possibly pleural thickening. Blood count: Haemoglobin, 92% (14.1 g./100 ml.); red cells, 5,030,000; white cells, 11,000 (polymorphs 66%, lymphocytes 30%, monocytes 4%); E.S.R. (Westergren) 92 mm. in one hour. E.C.G. showed no abnormality other than tachycardia and no evidence of acute cor pulmonale.

The patient improved greatly, but 10 days after admission, while still on anticoagulants, he developed thrombophlebitis of the left femoral vein in the femoral canal. The left leg became swollen, tender, and painful. Anticoagulant therapy was continued for four weeks, by which time his

leg had returned to normal except for a little oedema round the ankle. Before he was discharged from hospital he had recovered and showed no signs of pulmonary hypertension.

Comment.—Unlike the others, this patient was not active up to the time when he first had chest symptoms. Thrombosis of a pelvic vein may have followed epididymo-orchitis. Alternatively, epididymo-orchitis might have been mimicked by thrombophlebitis in the pampiniform plexus. The history of recurrent attacks of pleurisy not responding to treatment with antibiotics was characteristic of pulmonary embolism. In this case signs of pulmonary hypertension were an aid to diagnosis.

Case 6

A storekeeper aged 59 was in good health and at work when he had an attack of shivering. He had a non-productive cough, with a fever, and went to bed for eight days. He was active but convalescent, when, almost three weeks after the start of his first illness, he had a sudden severe stabbing pain in the left side of his chest posteriorly. He was breathless, and the pain was worse on coughing or deep breathing. He was admitted to hospital on March 3, 1952, two days after the onset of this pleuritic pain. There were no other symptoms, and, apart from bronchopneumonia in 1949, no past illness of note.

Physical examination revealed that he was breathless at rest but not cyanosed. He was febrile—temperature 100.4° F. (38° C.). He had clubbing of the fingers and toes. Chest expansion was poor and there were signs of consolidation at the left base. There were no signs of heart failure or of peripheral venous thrombosis. The blood pressure was 135/90.

Lobar pneumonia was diagnosed and penicillin, 240,000 units six-hourly, was given. On the day after admission to hospital he had a haemoptysis, and this persisted for four days. He was improving generally and the signs of consolidation were diminishing, when on March 10 he had a solidation were diminishing, when on March 10 he had a recurrence of pain in the left side of his chest. He improved again, becoming afebrile, but on March 22 his temperature rose.

Treatment with penicillin was stopped, and instead he was given chloramphenicol, 0.5 g. six-hourly. On March 23 he developed pleuritic pain in the right side of his chest and there were rales at both lung bases.

It was not until March 31 that he had pain in his right leg, with some swelling, but still without tenderness. Anticoagulant therapy was started on that day and he slowly improved, but still had swelling of his right leg on discharge from hospital.

Investigations.—The sputum was mucoid and no pathogen was grown from it. Chest x-ray films, which were repeated, showed shadowing (inflammatory changes) at both lung bases, with, on April 4, a shadow at the left base suggestive of segmental collapse. Blood count on March 5 showed: Hb, 83%; white cells 8,000, with 65% polymorphs. E.S.R. (Westergren), 47 mm. in one hour.

Comment.—Again in this case the symptoms and signs of pulmonary embolism appeared well before the signs of venous thrombosis.

In the cases so far described a definite diagnosis could be made because of the post-mortem findings, the radiological findings, or the later development of venous thrombosis. In the following four cases the diagnosis could not be proved, but the clinical picture presented by each patient was that which we have come to associate with pulmonary embolism and each recovered after treatment with anticoagulants and antibiotics.

Case 7

A sales manager aged 36 was well and at work, when he developed a "head cold." The next day he had pleural pain in the left side of his chest and produced grey sputum streaked with blood. He went to bed and was treated by his general practitioner with sulphonamides and penicillin.

The haemoptysis continued. Six days after the start of his illness he had pleural pain in the right side of his chest. There was a past history of a football injury to his right leg with subsequent swelling and tenderness in the calf. This had occurred 10 years previously and he had been well since.

He was admitted to hospital on December 17, 1956, nine days after the start of his illness. He was afebrile. Physical examination revealed a pleural rub at the right lung base and signs of collapse at the left base. There were no signs of peripheral venous thrombosis. X-ray examination showed a small effusion in the left costophrenic angle. No pathogen was grown from the sputum, which contained blood for the first week that he was in hospital. The E.C.G. was normal. He was treated with anticoagulants and penicillin and made a rapid recovery.

Comment.—The occurrence of a second attack of pleurisy while the patient was being treated with penicillin and the persistent haemoptysis suggested a diagnosis of pulmonary embolism, possibly from the site of old thrombophlebitis.

Case 8

A mine-worker aged 53 was recovering from an operation for arthrodesis of his right hip performed six months previously for osteoarthritis. He was well and had been walking one to two miles a day for over a month. Two days before admission to hospital on February 23, 1957, he had a sudden sharp pain in the right side of his chest. He had difficulty in breathing because of the pain, which was pleural in character. He had no cough or haemoptysis. Six months previously whilst in hospital following his operation he had two similar attacks of pleural pain. Except for a history of injury to his right hip there was nothing of note in the past history.

Physical examination revealed that he was hypertensive (blood pressure 145/105). There were no signs of heart failure. The percussion note was impaired at the right lung base, in which area the breath sounds were diminished and there were a few crepitations. There was no evidence of peripheral venous thrombosis. He was febrile on admission, temperature 100.5° F. (38.1° C.). He produced no sputum. Chest x-ray examination showed that the right diaphragm was raised and there was some ill-defined shadowing at the right base. The blood count and E.C.G. were normal. He was treated with penicillin and anticoagulants, and made a satisfactory recovery.

Comment.—The previous attacks of pleural pain and the sudden onset of the illness described above suggest pulmonary embolism. He may have had phlebotrombosis in his pelvis following the operation on his hip.

Case 9

A miner aged 56 was admitted from the casualty department as an emergency case on March 15, 1957. He had collapsed at work, having had a sudden pain in his back and the left side of his chest. The pain was worse on deep respiration. One year previously he had been treated for a papilloma of the bladder; this had been removed by diathermy. A cystoscopy had been performed on February 5, 1957.

Physical examination revealed that respiration was shallow, being restricted because of pain. The percussion note was impaired at the left lung base and there were crepitations at both bases. He was not shocked (blood pressure 150/80). His temperature was normal on admission but rose to 101° F. (38.3° C.) on the fourth day. There were no signs of venous thrombosis. The E.C.G. and blood count were normal. The sputum was mucopurulent, and on culture a moderate growth of *H. influenzae* was obtained. Chest x-ray examination showed elevation of the right diaphragm with segmental shadows in both lower zones. The shadows one week later had cleared, leaving the well-defined markings of linear collapse.

Because of the nature of the sputum he was treated at first with penicillin and streptomycin, but not with anti-

coagulants. He did not improve, and three days after admission the sputum became stained with bright blood, and at times was pure blood. A diagnosis of pulmonary embolism was made. He was treated with anticoagulants and slowly improved.

Comment.—The sudden onset of the symptoms and the lack of response to antibiotics suggest a diagnosis of pulmonary embolism. In this case pelvic veins, thrombosed during diathermy of a bladder papilloma, were a probable source of the embolus.

Case 10

A lorry driver aged 38 was admitted to hospital on February 1, 1957, with a history of pleuritic pain on the left side of his chest with shortness of breath for one week. He had complained of a dry cough for three days. Two weeks before admission he had abdominal pain, colicky in nature, situated in the hypogastrium, together with diarrhoea which persisted for 48 hours. The stools were of normal colour and were not blood-stained.

In 1944, while in the Army, he had recurrent attacks of diarrhoea lasting nine months in all, for which he had been fully investigated at a military hospital in Germany. The diarrhoea settled completely on return to this country.

Physical examination revealed a breathless man in pain, with a temperature of 101° F. (38.3° C.). Respiratory system: Diminished movement; dullness to percussion and reduced breath sounds, with rales at the right lung base. The pulse rate was 100 a minute, regular. B.P. 120/80. Heart sounds normal. No evidence of cardiac failure. The central nervous system was normal in all respects. There was no abdominal tenderness; the spleen and liver were not palpable.

Investigations.—Urine contained no albumin or sugar. X-ray examination of the chest initially showed a triangular shadow in the right lower zone consistent with consolidation. Haemoglobin, 14.8 g./100 ml.; white cells, 8,000 per c.mm. (normal differential). E.S.R., 51 mm. in one hour. Sputum: No pus cells, no pathogens grown; culture for acid-fast bacilli was sterile.

Forty-eight hours after admission he experienced a similar attack of pain on the left side of his chest. Physical examination revealed a pleural rub with rales at the right lung base. Following this he coughed up a small quantity of bright red blood. Three days later there was a recurrence of pleurisy on the right side. A second chest x-ray examination showed a triangular opacity at the left base.

He was treated with penicillin and anticoagulants and made an uninterrupted recovery. Radiological resolution of both shadows at the lung bases had occurred three weeks after admission. A bronchogram at that time was normal.

Comment.—In view of the repeated attacks of pleurisy, the absence of purulent sputum, plus the haemoptysis, this man was regarded as having had pulmonary emboli although at no time was there evidence of venous thrombosis.

Discussion

Thrombosis of the calf veins may not produce pain or tenderness. The severity of the symptoms may be related to the extent of the clot (Marks *et al.*, 1954). Thrombosis may occur intra-abdominally, and Marks *et al.* noted that in 12 out of 70 fatal cases pulmonary emboli originated from sites other than the calf. Thus the absence of physical signs does not exclude the diagnosis of deep venous thrombosis, and indeed Grundersen (1955) observed that clinical evidence of venous thrombosis was present in less than 10% of 119 cases of pulmonary embolism. Of these 119 patients, 7 were ambulant and in good health just before they had a pulmonary embolus. Hampton *et al.* (1954) described 10 cases of pulmonary embolism in which no signs of peripheral venous thrombosis were found clinically, although thrombosis in deep veins of the leg was later demonstrated by

venography in three patients, and another patient had a thrombosed haemorrhoid. All 10 patients were at work and had no heart disease when they developed chest symptoms. Renner (1949) reported a similar case. This patient presented with the features of a myocardial infarction. The electrocardiographic changes were interpreted as those of auricular flutter with marked right axis deviation. Later, clinical and radiological signs suggestive of pulmonary embolism became evident. A well-documented case of pulmonary embolism occurring in a fit and active man has also been described (Hollister and Cull, 1956, Case I).

In cases where embolism cannot be proved it is possible that occlusion of the pulmonary artery is due to thrombosis. Pulmonary embolism cannot always be distinguished pathologically from autochthonous pulmonary-artery thrombosis, particularly as thrombus may form around an embolus. The appearances are difficult to interpret if the patient died of cor pulmonale a long time after the embolism occurred. The common experience is that peripheral venous thrombosis precedes occlusion of the pulmonary artery, and pulmonary embolism is thought to be much commoner than thrombosis of the pulmonary artery. As peripheral venous thrombosis may be "silent" it is sometimes clinically impossible to distinguish between pulmonary embolism and thrombosis. It is our intention to emphasize the clinical syndrome; for the exact differentiation is not important, the treatment for both conditions being the same.

None of the cases we have described had signs of venous thrombosis when first seen, and eight of these patients had been well and active up to the time when they first developed symptoms. Almost all had recurrent attacks of pleurisy which did not respond to treatment with antibiotics, although temporary improvement after each acute attack was attributed to the antibiotic given at the time. An important feature was the absence of purulent sputum. The patients treated with anticoagulants recovered and have not developed cor pulmonale.

As anticoagulant treatment is sometimes effective, the diagnosis of pulmonary embolism is important. It should be considered in cases of recurrent pleurisy or pneumonia not responding to antibiotic therapy, particularly if symptoms and signs are bilateral, even in the absence of signs of venous thrombosis.

Summary

Ten cases of pulmonary embolism are described. None of the patients had signs of peripheral venous thrombosis when first seen, and eight had been active until they developed chest symptoms. Pulmonary embolism occurring in patients who appear to be fit, are active, and have no signs of venous thrombosis has been termed "unheralded pulmonary embolism." The three patients treated with anticoagulant recovered. Three patients died, and the necropsy findings are reported.

In nine of the cases the clinical picture was that of recurrent attacks of pleurisy which did not respond to treatment with antibiotics. The sputum was blood-stained but not purulent—an important aid to diagnosis.

Reference is made to similar cases that have been reported.

We wish to thank Dr. T. E. Gumpert, Dr. H. P. Brody, and Professor C. H. Stuart-Harris for permission to use the records of cases under their care, and Dr. J. L. Edwards for his help and advice.

COMBINED PROPHYLACTICS VARIATIONS IN RESPONSE, IN CHILDREN, TO DIPHTHERIA TOXOID PRODUCED BY ADDITION OF TETANUS TOXOID AND H. PERTUSSIS VACCINE

BY

GUY BOUSFIELD, M.D.

Immunization Specialist to London and Middlesex County
Councils

AND

L. B. HOLT, D.Sc.

Wright-Fleming Institute, St. Mary's Hospital Medical
School, London, W.2

There are three recognized ways in which the immunological response to a primary dose or course of an antigen may possibly be reduced (Parish, 1955). These are: (1) the presence of passive immunity, as in the case of maternally bestowed specific antibody in very young infants; (2) the giving of a primary stimulus of one antigen simultaneously with a secondary dose of another antigen; and (3) an imbalance of antigens in a similar antigen; and (3) an imbalance of antigens in a similar antigen—for example, in animals an excess of tetanus toxoid may seriously reduce the response to the diphtheria toxoid component of a mixture (Barr and Llewellyn-Jones, 1953) while an excess of pertussis vaccine depresses the diphtheria antitoxin response as compared with a maximum obtained from a mixture containing less vaccine when a fixed dose of fluid diphtheria toxoid is employed (Barnes and Holt, 1955). On the other hand, the response to a primary dose or course of fluid toxoid may be significantly increased by admixture with a vaccine—for example, pertussis vaccine and diphtheria toxoid, or typhoid vaccine and tetanus toxoid. More-over, Ungar (1956) found that the addition of diphtheria and tetanus toxoids to pertussis vaccine had no adverse effect on the immunity response of mice to injections of the mixture as compared with results obtained when the plain vaccine was used.

Little is known of the effect on the response to the diphtheria toxoid of variations in the ratio of vaccine to toxoid in children, and even less in respect of triple mixtures.

The primary purpose of the present work was to observe, in children, the effect on the response to a fixed amount of purified fluid diphtheria toxoid (30 Lf), of the addition of different quantities of (1) *H. pertussis* vaccine, and (2) purified tetanus toxoid. The criterion adopted was the conversion rate obtained by the Schick test (S.C.R.) measured one month after one dose. All children used in this work were under 2 years of age, originally Schick-positive, and each group was carefully sub-balanced for age. All injections were given by the sub-cutaneous route, and all Schick tests were performed with Wellcome toxin and control. It should perhaps be mentioned that the work reported in this paper progressed over a period of time exceeding two years, which accounts for the use of different primary reagents at various stages. Each investigation in which comparisons are made, however, involved the use of identical antigens and, of equal importance, were self-contained.

First Investigation

Part 1

This embraced the use of varying doses of *H. pertussis* vaccine in combination with a single sample of purified diphtheria toxoid (Batch No. E. 3977; 1,900 Lf/mg. P.N.). The results (Table I) show most clearly that the adjuvant

action of the vaccine increases progressively with increase of dose of vaccine, and with no hint of an optimum ratio of vaccine to toxoid, up to the maximum of *H. pertussis* vaccine dosage used—that is, 20,000 million.

TABLE I.—Effect of Varying Pertussis Dosage with 30 Lf of Diphtheria Toxoid on S.C.R., One Month After One Dose. All Children Under 2 Years of Age, Originally Schick-positive

Diphtheria Toxoid Dosage	<i>H. pertussis</i> Organisms	No. of Cases	Post-Schick		S.C.R.
			Positive	Negative	
30 Lf (control)	None	124	62	62	50.0%
30 Lf ..	5,000 mil.	101	30	71	70.3%
30 Lf ..	10,000 "	109	24	85	78.0%
30 Lf ..	20,000 "	101	5	96	95.0%

Part 2

This was to ascertain to what extent, if any, the addition of different doses of purified tetanus toxoid altered the response to the fixed dose of diphtheria toxoid. A purified tetanus toxoid (Batch No. C.T. 87/142; 1,100 Lf/mg. N.) was used for these mixtures. The groups of children tested were in every way comparable to those in Table I. The results (Table II) show that in these children the purified

TABLE II.—Effect of Varying the Dose of Tetanus Toxoid Added to 30 Lf of Diphtheria Toxoid, on S.C.R., One Month After One Dose

Diphtheria Toxoid Dosage	Tetanus Toxoid Dosage	No. of Cases	Post-Schick		S.C.R.
			Positive	Negative	
(1) 30 Lf (control)	None	124	62	62	50.0%
(2) 30 Lf	3 Lf	105	53	52	49.5%
(3) 30 Lf	6 Lf	111	51	60	54.1%
(4) 30 Lf	12 Lf	111	40	71	64.0%
(5) 30 Lf	25 Lf	111	53	58	52.3%

χ^2 mixture 4/control = 4.66, d.f. = 1, $P=0.05$.

tetanus toxoid had a significant adjuvant effect in the ratio of 12 Lf tetanus toxoid to 30 Lf diphtheria toxoid, but when the dose of tetanus toxoid was increased to 25 Lf the response to the diphtheria toxoid component was only approximately equal to the control—that is, 30 Lf plain diphtheria toxoid.

From the results shown in Table II it appears that the addition of purified tetanus toxoid improved the diphtheria antigenicity of the mixture up to a point. Without a series of cases in which the dose of tetanus toxoid lies between 12 and 25 Lf it is not possible to infer exactly at what dose the response diminishes. However, on account of considerations mentioned below, this point is of no more than theoretical interest. The important point is that the dose of tetanus toxoid should not be too high relative to that of diphtheria toxoid.

Part 3

Having shown (Tables I and II) that both pertussis vaccine and tetanus toxoid independently increased the antigenicity of diphtheria toxoid, it was decided to investigate the further series of comparable infants inoculated with a mixture corresponding to the current-issue composition of triple prophylactic. The same primary reagents were used and the tests were performed as before, one month after a single injection. For the sake of comparison, certain results have been taken out of the other two tables and set forth again, these being the mixtures which approximate most closely to those employed in the triple prophylactic.

The results (Table III) show that both pertussis vaccine and tetanus toxoid, when added to diphtheria toxoid separately and used as dual prophylactics, tended to improve the behaviour of the diphtheria toxoid, but when both were added together and used as a triple antigen the S.C.R. fell from 95% in the case of the diphtheria-pertussis mixture to 83.6% for the triple antigen.

It seemed possible that the improvement in the diphtheria toxoid antigenicity produced by the addition of pertussis vaccine was due to adsorption of some of the toxoid on to

TABLE III.—Comparative Efficiency of 30 Lf of Diphtheria Toxoid Alone and Combined with Pertussis Vaccine and Tetanus Toxoid. S.C.R. One Month After One Dose

Material	Diph. Toxoid	<i>H. pertussis</i> Organisms	Tetanus Toxoid	No. of Cases	Post-Schick		S.C.R.
					Pos.	Neg.	
1. F.T. control	30 Lf	None	None	124	62	62	50.0%
2. Diph. and tet.	30 Lf	"	6 Lf	111	51	60	54.1%
3. Diph. and pert.	30 Lf	20,000 mil.	None	101	5	96	95.0%
4. Diph., pert., and tetanus	30 Lf	20,000 mil.	5 Lf	110	18	92	83.6%

χ^2 mixture 3/mixture 4=7.05, d.f.=1, P=0.01.

the vaccine despite the failure to demonstrate any adsorption, employing ordinary laboratory procedures to measure toxoid.

In the routine preparation of triple antigen, the diphtheria and tetanus toxoids are mixed before addition to the vaccine. If the tetanus toxoid was more readily adsorbed on to the vaccine than the diphtheria toxoid, the latter might be left at an antigenic disadvantage. To obtain further information on this point it was therefore decided to prepare triple prophylactic in three different ways.

Second Investigation

For these mixtures a fresh lot of primary reagents was used (diphtheria toxoid Batch No. B.P. 51/53, 2,050 Lf/mg. P.N., and tetanus toxoid B.P.T. 3, 1,130 Lf/mg. T.N., and a fresh stock of *H. pertussis* vaccine). The mixtures were made in the following three different ways, but always giving a final product containing per ml. (one dose): 30 Lf of purified diphtheria toxoid, 5 Lf of purified tetanus toxoid, and 20,000 million *H. pertussis* organisms.

Sample A.—Diphtheria toxoid was added to half the volume of *H. pertussis* vaccine. Tetanus toxoid was added to the other half-volume of vaccine. After three days the two lots were mixed and bottled.

Sample B.—Tetanus toxoid was added to the *H. pertussis* vaccine. After three days the diphtheria toxoid was added, and the mixture bottled.

Sample C.—Diphtheria toxoid was added to *H. pertussis* vaccine. After three days the tetanus toxoid was added and the mixture bottled.

These three mixtures were tested as before, the results being shown in Table IV.

TABLE IV.—Results of Post-Schick Tests One Month After a Single Injection of Triple Prophylactic Prepared in Three Different Ways

Mixture	No. of Cases	Post-Schick		S.C.R.
		Pos.	Neg.	
A. (F.T. + $\frac{1}{2}$ vacc.) + (T.T. + $\frac{1}{2}$ vacc.)	150	25	125	83.3%
B. (T.T. + vacc.) + F.T.	166	33	133	80.0%
C. (F.T. + vacc.) + T.T.	145	26	119	82.0%

It will be seen that the S.C.R. from the mixture made nearest to the "normal" way (mixture A) is almost exactly that found with the previous set of primary reagents. There is no significant difference between mixture A and the other two: these findings therefore show that the method of preparing the triple prophylactic does not affect the immunological response to it, but they endorse the conclusion that the addition of 5 Lf of tetanus toxoid to a mixture of 30 Lf of diphtheria toxoid and 20,000 million *H. pertussis* produces a significant reduction in the S.C.R.

Third Investigation

From the preceding results it can be inferred that the addition of 5 Lf of tetanus toxoid in some way militates against the most effective diphtheria response. One explanation of

this could be that the triple antigen constitutes a stimulus which is beyond the capacity of the local antibody-forming tissues to handle adequately.

An attempt to solve this problem was made by utilizing different sites for different antigens. The diphtheria toxoid mixed with 20,000 million *H. pertussis* organisms had already given an excellent result. Thus it seemed reasonable to inject this into the left arm, and, at the same time, to administer the appropriate dose of tetanus toxoid separately into the right arm. On a further group precisely the same materials were mixed as a triple antigen and given in one arm. Finally, a third, or control, group was necessary, consisting of children inoculated with the same mixture of diphtheria toxoid and *H. pertussis* vaccine but without any administration of tetanus toxoid.

If the method in which separate arms are used for the diphtheria-pertussis mixture on the one hand and tetanus toxoid on the other gives an S.C.R. which approximates to that obtained from the diphtheria-pertussis mixture alone, it seems logical to assume that the lower S.C.R. following the use of triple antigen is due to overloading of the local immunity mechanism. If, however, the result from administration into separate arms is still poor, it could then be inferred that one is asking too much of the whole body defensive mechanism at one time. The primary reagents used in this third investigation were (1) purified diphtheria toxoid Batch No. B.P. 51/53 as before, (2) purified tetanus toxoid Batch No. C.T./5, 1,150 Lf/mg. N., and (3) a fresh batch of pertussis vaccine common to all the mixtures. The results of this investigation are shown in Table V.

TABLE V.—Effect of Administering Diphtheria Pertussis Prophylactic Into One Arm and Tetanus Toxoid Into the Other, Controlled by a Group in Which the Triple Prophylactic is Given Into One Arm. S.C.R. One Month After One Dose

Group	Left Arm	Right Arm	No. of Cases	Post-Schick		S.C.R.
				Pos.	Neg.	
A	30 Lf diphtheria toxoid plus 20,000 mil. <i>H. pertussis</i>	Nil	120	15	105	87.5%
B	30 Lf diphtheria toxoid plus 20,000 mil. <i>H. pertussis</i>	5 Lf tetanus toxoid	128	17	111	86.7%
C	30 Lf diphtheria toxoid plus 20,000 mil. <i>H. pertussis</i> plus 5 Lf tetanus toxoid	Nil	138	31	107	77.5%

χ^2 Group C/Group A=4.34, d.f.=1, P=0.05.
 χ^2 Group C/Group A+B=5.97, d.f.=1, P=0.02.

Comment

Two points arise from these results: The first is that, although different primary reagents were employed in the first and second investigations, the results from the two triple prophylactics were virtually identical. On the other hand, in the third investigation the result from the triple mixture (Table V, Group C) was significantly lower at 77.5%, and similarly with the double mixtures from 95% in the first investigation to 87.5% in the third. The most probable reason for these differences is thought to be due to variations, from batch to batch, in the adjuvant properties of the pertussis vaccine. The second point is the finding that there is no significant difference between the diphtheria responses in children receiving (1) diphtheria-pertussis mixture in one arm and tetanus toxoid in the other, and (2) those receiving the diphtheria-pertussis mixture only. But the diphtheria responses from those children receiving the triple prophylactic are significantly lower—77.5% against 87.5%.

Although the third investigation was designed to show whether or not the giving of a triple prophylactic constituted an overloading of the local immunity mechanism of the child, the findings do not enable us to arrive at a definite conclusion, despite the fact that the addition of 5 Lf of tetanus toxoid to the diphtheria-pertussis mixture does cause a significant fall in the S.C.R. Since one triple prophylactic mixture gave rise to an S.C.R. of 83.6% and another, of simi-

lar composition, to only 77.5% we must concede that 83.6% is at least attainable. When, therefore, we do not obtain 83.6% we must blame the preparation and not the immunity mechanism of the child. And yet with both triple prophylactic mixtures the omission of the tetanus toxoid component resulted in a significantly greater S.C.R. It would seem possible that the triple prophylactic does not overload the immunity mechanism but that the adjuvant action of the vaccine is shared by two toxoids, of which one, the tetanus toxoid, is apparently a more potent antigen than the other. Utilizing an equation relating geometric mean titre to % S.C.R. (Holt, 1955), it is calculated that the addition of 20,000 million *H. pertussis* organisms to the 30 Lf of diphtheria toxoid increases the mean antitoxin response some 14 times and that the further addition of 5 Lf of tetanus toxoid reduces the increment to about fivefold. It may be that the answer to this difficulty will be to reduce the tetanus toxoid to 2 Lf per dose.

Discussion

Immunization against whooping-cough cannot reasonably be withheld in the very early months of life, because it is then that pertussis is most dangerous to the child, and this then that pertussis outweighs the very small risk of producing paralytic poliomyelitis (Bousfield, 1951). The measure of the increase in risk entailed by adding fluid toxoid to the vaccine is still not by any means precisely known, but the long-term risk in a severe falling off in the immunization rate against diphtheria is one to be taken very seriously.

It would seem that in the case of very young infants the procedure which would incur the absolute minimum risk of causing post-inoculation poliomyelitis would be to inoculate them in one arm with plain pertussis vaccine and fluid toxoid in the other on each of three visits. This would keep to a minimum the number of clinic attendances and would very materially help to preserve a high immunization rate against diphtheria. The reduction in efficiency of immunization against diphtheria by adopting such a procedure would, in comparison with two doses of P.T.A.P., be marked, but a high percentage of the child population would be no immunized well. Furthermore, there would seem to be no reason for not using mixed fluid tetanus and diphtheria toxoids in place of diphtheria toxoid only. In our opinion, every effort should be made to encourage immunization of children against tetanus in order to avoid the several disadvantages attending the use of tetanus antitoxin.

In view of the importance of primary immunization of infants against diphtheria, and the necessity for protection against whooping-cough during the first year of life, the only reason for withholding inoculations on the lines suggested would appear to be the existence of a local epidemic of poliomyelitis.

In respect of booster doses the problem is very much less complicated, in that there is no urgency, and one can choose the time of year. The period of minimum risk is, of course, during the winter, and, since the poliomyelitis provocation risk is then usually very low, some freedom in the choice of reagent is possible. Clinical experience lasting over several years and involving considerable numbers of children has shown that a subcutaneous injection of P.T.A.P. diluted 1 in 5 in 0.5-ml. dosage causes negligible allergic reactions, whatever may be the materials used for primary immunization.

The reason for the relative freedom from allergic reactions when using this diluted P.T.A.P. would seem to be that in P.T.A.P. the toxoid is adsorbed on to aluminium phosphate, and is only partly liberated after injection; when diphtheria toxoid is employed for boosting, all the toxoid is immediately available for the production of allergic manifestations in a sensitive subject. We have seen one or two most disturbing reactions following the use of diphtheria toxoid for boosting. The use of adrenaline has twice been most necessary. The 0.5-ml. dose of 1 in 5 P.T.A.P. (equal to 0.1 ml. of P.T.A.P.) has proved adequate to restore the Schick-negative state in every child of pre-school age who had relapsed to positive.

Although many may feel attracted by the idea of a multiple prophylactic incorporating diphtheria toxoid, pertussis vaccine, and poliovirus vaccine, with or without the addition of tetanus toxoid, it is clear from the findings in this present communication that precise exploratory field trials are necessary in order to determine the best balance of antigens in any new mixture to be used in man. The complete answer to the problem of post-inoculation paralysis would be to immunize against poliomyelitis before 3 months of age, provided such a procedure is shown to be efficient.

Summary

This study is concerned with the field efficiency of mixed antigens where the point of reference was the diphtheria response in children receiving one dose of 30 Lf of purified diphtheria toxoid measured one month after one inoculation.

It was found that the addition of *H. pertussis* vaccine to the 30 Lf of diphtheria toxoid enhanced the Schick conversion rate progressively with increase of dose of vaccine—from 50% conversion rate with no vaccine to 95% with 20,000 million *H. pertussis* microbes. There was no evidence of excess of vaccine although there is evidence that different batches of vaccine may have different toxoid-adjuvant properties.

The addition of purified tetanus toxoid to the constant amount of diphtheria toxoid also increased the S.C.R. up to an optimum of about 12 Lf of tetanus toxoid/30 Lf of diphtheria toxoid. The addition of 25 Lf of tetanus toxoid resulted, however, in a Schick conversion rate only equal to that from the diphtheria toxoid alone. The adjuvant action of the tetanus toxoid was less marked than that of *H. pertussis* vaccine.

The addition of 5 Lf of tetanus toxoid to a diphtheria toxoid/pertussis mixture resulted in a significantly lower S.C.R. than that obtained without the presence of the tetanus toxoid. It is calculated that the addition of *H. pertussis* vaccine (20,000 million organisms) increases the antitoxin response to the diphtheria toxoid some 14 times, and that the further addition of 5 Lf of tetanus toxoid to the mixture reduces that increment to about fivefold.

The inoculation of tetanus toxoid separately into one arm and the diphtheria-pertussis mixture into the other produced an S.C.R. identical to that obtained when the diphtheria-pertussis mixture was administered without any tetanus toxoid.

The order of mixing the components of the triple prophylactic produced no difference in the conversion rate.

The findings and their practical application are discussed; possible explanations of some of the phenomena observed are offered.

Thanks are due to Dr. J. A. Scott, County Medical Officer, London; Dr. A. C. T. Perkins, County Medical Officer, Middlesex; Dr. A. Anderson (M.O., No. 9 Middlesex Area); Dr. V. Russell and Dr. B. E. A. Sharpe (past and present D.M.O.s, No. 1 London Division); Dr. H. D. Chalke and Dr. A. Mower-White (past and present D.M.O.s, No. 7 London Division); and Dr. W. H. S. Wallace (No. 8 London Division) for many facilities in connexion with the foregoing work; also to Dr. Joan M. Barnes, of the Wright-Fleming Institute, for the preparation of all the various mixtures of antigens employed in this considerable experimental series.

Foetal distress	1 (8%)	—	—	1 (0.8%)
Secondary P.P.H.	—	1 (1.1%)	—	1 (0.8%)
Malpresentation	—	1 (1.1%)	—	1 (0.8%)

the antenatal period (Table II). These consisted of nine cases of toxæmia (including two primigravidae with unfixed head, two cases of anaemia, and one case of malpresentation), three cases of ante-partum haemorrhage, three cases of multiple pregnancy, and two abortions.

For convenience, toxæmia of pregnancy is classified into four grades: Grade 1, or mild toxæmia: a persistent blood pressure of 135/90 or over. Grade 2, or moderate toxæmia: blood pressure 135/90 or over, together with oedema or

increased weight; or persistent blood pressure of 145/95 or over. Grade 3, or severe toxæmia: the above signs more marked and/or occurrence of albuminuria. Grade 4, or imminent eclampsia: the above signs increasing and/or reduction of urinary output. If a patient progresses to grade 2 at any stage in pregnancy she is considered unsuitable for home confinement whether or not she later responds to treatment.

As previously stated, eight cases had a history of mild toxæmia in one previous pregnancy, and it seemed reasonable to book them. Six subsequently developed toxæmia (three of moderate severity), one aborted, and one was normal. From this it would appear that a previous history of toxæmia, even if mild, is a contraindication to confinement at home.

Because of the high mortality rate of the second twin, the greater incidence of toxæmia and post-partum haemorrhage, and the possibility of premature infants, all cases of multiple pregnancy are referred to hospital as soon as their condition is discovered.

Ante-partum haemorrhage, however slight, is regarded with great suspicion, and these cases are referred to hospital with little effort, apart from abdominal palpation, being made to establish the cause.

Anaemia was present in 24.8% of the cases. In addition to the two cases shown in Table II, seven others were referred to hospital for a course of treatment. Three of these also

EXCRETION OF MECAMYLAMINE AFTER INTRAVENOUS AND ORAL ADMINISTRATION

BY

K. D. ALLANBY, M.D., M.R.C.P.

AND

J. R. TROUNCE, M.D., M.R.C.P.

From the Department of Medicine, Guy's Hospital, London

Abnormalities of Labour

A reasonably light space and sufficient table room for instruments are regarded as safety factors in the conduct of labour. A sterile drum containing cap, mask, gown, gloves, and instruments for suturing forms part of the equipment. This is re-sterilized as necessary by kind co-operation of the local hospital. A sterile intravenous giving-set, together with dextran or plasma, is also considered essential.

Of the 94 cases eventually confined at home complications of labour occurred in four: one of foetal distress (a primigravida), one of uterine inertia (a para-14), and two cases of post-partum haemorrhage. One case of post-partum haemorrhage was slight, and was controlled by ergometrine. The other three cases were admitted to hospital (Table II, Cases 18-20).

Because of lack of facilities operative procedure is avoided in the home whenever possible. An appendicectomy on the kitchen table might well be fraught with less danger and complications than a difficult forceps upstairs. Where the hospital is reasonably close, transport does not usually present great difficulties.

Two cases were transferred to hospital in labour. It was felt that the primigravida with foetal distress (Case 18) might need forceps in order to save the baby. It was also possible that the baby might have needed resuscitation measures requiring facilities not available in the home. Fortunately these were unnecessary. The baby was born spontaneously in hospital after a comparatively short second stage.

In Case 19 the os was dilated about two fingerbreadths. The patient had vague pains off and on, and had never properly started. She was tired and anxious. Although originally she could not be persuaded to book with the hospital, she needed little persuasion at this stage.

Case 20 had a sudden post-partum haemorrhage of 3 pints (1.7 litres) after the placenta had been delivered. She collapsed and her blood pressure fell to 80/?. Ergometrine controlled the haemorrhage and intravenous dextran was started immediately. Her condition improved enough to enable her to be transported to hospital; the drip was kept going on the way. Her condition rapidly improved in hospital following blood transfusion.

Post-partum haemorrhage is unforeseeable. It is the greatest enemy of all concerned with domiciliary midwifery. Of the accepted methods of prevention and treatment, estimation of the haemoglobin during the antenatal period, with routine administration of intramuscular ergometrine to the mother at the time of delivery of the anterior shoulder of the infant, and the rapid administration of intravenous therapy are the most powerful weapons we possess in reducing the incidence and minimizing its effects. The patient may then be enabled to survive long enough until blood and other life-saving measures become available, or restored sufficiently to enable transport to hospital to be undertaken in safety. If blood is sent for cross-matching as soon as the diagnosis is made, valuable time, perhaps a life, may be saved.

Summary

The following points are considered important in achieving a high degree of safety in domiciliary midwifery: suitable home conditions; a system of antenatal care involving the use of a record chart and close co-operation with the midwives; a strict selection of cases for home confinement; avoidance where possible of all operative procedures in the home; and special measures for preventing and dealing with post-partum haemorrhage.

Ganglion-blocking compounds have been widely used in the treatment of hypertension since the introduction of hexamethonium, and in many cases satisfactory control of the blood pressure can be obtained with one of these substances alone, although the best results are probably achieved in combination with the rauwolfia alkaloids. Their use has greatly improved the prognosis in malignant and non-malignant hypertension (Doyle and Smirk, 1955; McMichael and Murphy, 1955; McQueen and Smirk, 1956). Although entirely effective when administered parenterally, hexamethonium is often unsatisfactory when used orally. Harington (1953) showed that hexamethonium was poorly absorbed from the intestine, only 5% or less of the dose being recovered from the urine, and its effect was short-lived, thus making frequent large doses a necessity. Furthermore, its absorption is greatly influenced by the taking of food, and increasing amounts may be absorbed as intestinal stasis occurs, leading to bouts of unpredictable hypotension. For these reasons oral hexamethonium has been replaced by pentolinium and chlorisondamine chloride, though pentolinium itself is not free from similar drawbacks when employed orally.

Freis (1955) and Ford, Madison, and Moyer (1956) have reported that mecamlamine ("inversine"), a substance with ganglion-blocking properties, is well absorbed from the alimentary tract. Mecamlamine is 3-methylaminoisocamphane and is a secondary amine, a type of compound not hitherto used for its ganglion-blocking effect. Encouraging reports of its use have already been published by Doyle, Murphy, and Neilson (1956) in this country, in addition to those of Freis and of Ford *et al.* in the United States.

The present report is concerned with the excretion of mecamlamine, following intravenous and oral administration, in hypertensive subjects without renal failure.

Methods

All subjects investigated were hospital in-patients suffering from essential hypertension. In addition to a complete history and physical examination, a 6-foot (1.8 m.) chest radiograph and a 12-lead electrocardiogram were obtained in all patients. Renal function was assessed by estimation of the blood urea and by concentration and dilution tests: no patient showed impaired renal function as judged by these methods.

Before administration of mecamlamine, each subject had been at rest in bed for at least one week, without any treatment apart from mild sedation. The blood pressure was measured lying and standing at least four times daily in all patients.

The method described by Brodie and Udenfriend (1945) was used to estimate the urinary concentration of mecamlamine. The drug is extracted from alkalinized

urine by shaking with ethylene dichloride, and when mixed with methyl orange forms a chromagen which may be measured colorimetrically. It was found that infected urines might give false results, and to prevent bacterial growth all specimens were treated with 5% thymol and stored at 4° C.

Since normal urines contain small amounts of a substance which forms a similar chromagen with methyl orange (usually equivalent to 50–100 µg. mecamylamine per 100 ml.) it is necessary to allow for this in patients receiving mecamylamine. The nature of this substance was not determined, but it appeared to be excreted at a constant rate, and the amount excreted per 24 hours varied little in each individual. The total excretion of the non-specific chromagen in 24 hours was determined in each patient before giving mecamylamine, and the appropriate fraction was subtracted from individual estimations.

Urinary pH was estimated with Gurr's universal indicator.

Urinary Secretion after Single Oral and Intravenous Doses

Fig. 1 illustrates the urinary excretion of mecamylamine after single oral and intravenous doses in three subjects. During the first 24 hours the amount recovered was approxi-

FIG. 1.—Rate of urinary excretion of mecamylamine following oral and intravenous administration of the drug to three subjects.

FIG. 2.—Comparison of rate of urinary excretion of mecamylamine with its hypotensive action following oral administration in two subjects.

mately 10–20% less after oral administration than after intravenous injection. During the next 24 hours the difference increases to 20–30%. The total recovery after a single dose intravenously was between 80 and 98%; after an oral dose it was approximately 65%.

Hypotensive Effect of Mecamylamine Compared with Urinary Excretion

Fig. 2 compares the amount of mecamylamine excreted in the urine with the effect on the blood pressure following an oral dose. The fall in blood pressure has been further compared with the percentage of the total amount recovered from the urine. It can be seen that there is a significant fall of pressure within 30 minutes of administration, but the maximum effect does not occur until after one to two hours.

The fall in blood pressure may last up to 12 or more hours, and the duration of effect appears to be related largely to the speed of excretion. Figs. 1 and 2 furthermore show that mecamylamine is excreted slowly in subjects with normal renal function, and that only 50% or less of the total amount excreted after a single oral dose is recovered in the first 12 hours. This agrees with the clinical observations of Ford *et al.* (1956), Doyle *et al.* (1956), and Smirk and McQueen (1957) regarding the duration of hypotensive effect after mecamylamine.

Effect of Urinary pH upon Excretion of Mecamylamine

Baer *et al.* (1956) have demonstrated the remarkable effect of urinary pH on the renal clearance of mecamylamine in dogs. They found that the drug was freely secreted by the renal tubules when the urine was acid, but that reabsorption occurred if the urine became alkaline.

Fig. 3 shows the effect of urinary pH upon the excretion of mecamylamine. Alkaline urines were produced by giving 2 g. (30 gr.) each of sodium bicarbonate and potassium citrate four-hourly, and 2 g. (30 gr.) of ammonium chloride four-hourly was used to ensure an acid urine. It will be seen that the excretion of mecamylamine is extremely low in an alkaline urine, but that over 50% of an oral dose is

24 hours varied between 46 and 86% of the oral dose, the average being 65%. During these observations no measurements of the urinary pH were made, but no patients received alkalis or acetazolamide whilst being treated with mecamylamine. In view of the fact that human urine is usually acid in reaction, it is not thought that the variations observed were due to any alterations in pH. If it can be assumed that the excretion of mecamylamine reflects its absorption, then these findings suggest that it is fairly consistently and reliably absorbed during continued oral administration.

FIG. 3.—Effect of urinary pH on excretion of mecamylamine following a single intravenous dose in two subjects.

FIG. 4.—Effect of urinary pH on excretion of mecamylamine and duration of hypotension following a single oral dose of 20 mg.

FIG. 5.—Urinary excretion of mecamylamine shown as mg. per 24 hours and as percentage of the daily oral dose in three subjects followed from beginning of treatment.

Conclusions

These observations upon the excretion and duration of effect of mecamylamine suggest that it possesses at least some of the pharmacological properties desirable in a hypotensive agent for oral administration. Unlike hexamethonium and pentolinium, a large proportion, between 55 and 75%, of an oral dose may be recovered from

the urine, which seems to indicate satisfactory absorption from the alimentary tract. Excretion is steady and prolonged, approximately 50% or less of the total amount recovered after a single dose appearing in the urine during the first 12 hours after administration. Likewise, there is a smooth and sustained fall of blood pressure following an oral dose. Daily excretion studies have suggested that mecamylamine is consistently and reliably absorbed within reasonably narrow limits. In the light of these findings blood-pressure controls should be obtained with relatively infrequent oral dosage and the blood pressure should not be subject to the fluctuation which has made treatment with other ganglion-blocking agents somewhat unsatisfactory. Doyle *et al.* (1956) have already published a report on the use of mecamylamine in 45 patients, and state that adequate control may be achieved with two doses daily. If the urine is alkaline, excretion of mecamylamine is almost entirely prevented, and it is likely that administration of acetazolamide had a similar effect. In either circumstance accumulation of the drug may occur and a prolonged fall of blood pressure will result.

We should like to thank Dr. K. S. MacLean, assistant director of the department of medicine, Guy's Hospital, for his helpful advice and encouragement, and for allowing us to make observations upon his patients. We are indebted to Messrs. Merck, Sharp and Dohme for generous supplies of mecamylamine (inversine).

Medical Memoranda

T. violaceum Infection of the Scalp

Trichophyton violaceum infections are uncommon in this country. Walker (1950), in an account of the cultural findings of 2,015 cases of tinea capitis seen in the U.K. over a three-year period, mentions three children all of whom caught the infection abroad. There were also two adult cases of tinea circinata. Whittle (1956) adds another case, and again the child was infected abroad. Recently, however, more cases have occurred, although unreported in the literature (Walker, 1956, personal communication).

Sagher (1947), in Jerusalem, found that 56% of cultures from infected hairs were *T. violaceum*. He quotes figures showing that the disease is common in Hungary, Italy, Russia, and Japan, but rare in Western Europe. Miedzinski and Lipski (1956) also showed that 42% of Polish scalp ringworm was due to this fungus. In America the infection appears to be commoner in Texas (Lehmann, Pipkin, and Resmann, 1950) than in New York, where Franks and Taschdjian (1956) isolated it only 9 times in 2,800 cultures.

Most clinical accounts—for example, Berlin and Meyrovitz (1955)—are those of "black dot" ringworm, but Walker (1950) mentions kerion formation. The following cases are therefore of interest because of the diversity of the clinical findings and the mode of infection.

CASE REPORTS

Case 1.—In June, 1956, I was asked to see the 8-year-old daughter of a local minister. She had a crusted eruption of the vertex of the scalp of five weeks' duration, and also a small vesicular lesion on the back of the right hand.

Microscopical examination of the scrapings from the hand revealed fungi, but unfortunately no attempt at culture was made. When the crusts had been removed several kerion lesions the size of a shilling were seen and a diagnosis of "cattle ringworm" was made, although there was no apparent source of infection. The kerion phase settled down, but was followed by the appearance of yellowish perifollicular crusts found to contain masses of fungi. The picture was that of favus, but there was no fluorescence under Wood's light. Culture at this stage produced a colony which was identified as *T. violaceum*. In view of this finding x-ray epilation was carried out, and appears to have been completely successful. Inquiry into a possible source of infection brought to light an Indian school friend, who was persuaded to attend for examination. She has subsequently been proved to be suffering from *T. violaceum* infection (Case 2) and was the apparent cause of infection.

Case 2.—A 10-year-old Indian girl had come to this country six years previously. On examination all that was found were five or six small scars, and a little fine scaling over the vertex of the scalp. There were no broken hairs, no crusts, and no fluorescence under Wood's light. The scaling, however, was in definite patches and was not quite typical of dandruff. Microscopical examination of scales and hairs on three occasions failed to show any fungi, but eventually one of numerous cultures made produced a typical colony of *T. violaceum*. Mother, father, and baby brother were examined without any abnormality of the scalp being discovered. The question of treatment is still undecided at the time of writing because of various racial problems.

Comment.—*T. violaceum* infections of the scalp apparently present themselves in very varied clinical appearances. The Indian girl showed lesions of superficial scaling of a degree which might have passed unnoticed, whilst the British girl developed favus and kerion-like lesions. I think it can be assumed that the British girl was infected by the Indian, and it seems probable, in view of the fact that other members of the Indian family were not infected, that she herself was infected in India.

I would like to thank Dr. Jaqueline Walker, of the Mycological Reference Laboratory, for her work on the identification of the cultures.

Foreign Body in the Hand

The importance of the retained foreign body as a cause of chronic inflammation of the hand has been stressed by many authors. Bunnell (1944) gives prominence to such lesions; Lake (1955) describes the case of a patient who presented with a rubber ring embedded in granulations at the base of a finger.

The following case illustrates the reaction of living tissue to the presence of a foreign body, and the nature of the foreign body renders it of unusual interest.

CASE REPORT

The patient, a married woman of 74, first attended hospital in June, 1955. At that time she had noticed the development of swelling of the left ring-finger distal to her gold wedding-ring, which she admits was "rather tight." The ring was removed, and it was noted that there was an abrasion of the skin surface beneath the ring. Following removal of the ring the swelling of the finger subsided and the skin healed—taking four weeks to do so, however.

In October, 1955, she returned to hospital with inflammation of the affected finger and a thin purulent discharge

at the site of the previous abrasion, on the dorsum of the proximal phalanx. The lesion failed to heal with conservative treatment, and culture of the pus yielded a growth of *Staph. pyogenes* sensitive to penicillin and oxytetracycline. No antibiotic had been given previously, and a course of systemic penicillin was therefore begun. X-ray examination of the digit showed some osteoarthritic changes in the metacarpo-phalangeal joint, but no evidence of bony erosion or of a radio-opaque foreign body.

The finger continued to discharge intermittently, and when seen in January, 1956, there was slight swelling over the proximal phalanx, with superficial granulations on the dorsum, surmounting a groove at the level of the proximal skin crease of the finger. A small amount of thin purulent discharge could be expressed at one point on the lateral aspect. It was decided to explore the finger, and this was done on January 23.

Under general anaesthesia the superficial granulations were excised, and on deepening the incision through the groove a foreign body was identified about $\frac{1}{4}$ in. (3 mm.) below the surface. The incision was continued around the finger and an intact elastic band was exposed below the skin surface. There was no granulation tissue on the palmar aspect of the digit. The band was removed and the remaining granulations were curetted. Two weeks from the date of operation healing was complete and there was no swelling of the finger.

The accompanying photograph shows the state of the finger one day after operation, together with the elastic band.

COMMENT

Upon further questioning the patient supplied the information that at one time her work involved the handling of small elastic bands, used for securing small parcels. She had been in the habit of slipping the bands on to her fingers. It is presumed that the band in question had lain beneath the wedding-ring for a considerable period of time, before coming embedded by a process of pressure necrosis. It is interesting that the area subjected to pressure necrosis by the elastic band was not apparent at the time that the wedding-ring was removed from the finger, the only evidence of trauma then being the small abrasion on the dorsum of the finger. The elastic band had become completely submerged beneath the skin surface, and healing around the circumference of the finger, superficial to the foreign body, was almost complete.

We thank Mr. J. B. Hume for permission to publish this case. The department of medical photography at St. Bartholomew's Hospital was responsible for taking the photograph.

Reviews

1911 AND ALL THAT

Lloyd George's Ambulance Wagon. Being the Memoirs of William J. Braithwaite, 1911-1912. Edited, with an Introduction, by Sir Henry N. Bunbury, K.C.B., and with a commentary by Richard Titmuss. (Pp. 350; illustrated. 30s.) London: Methuen and Co. Ltd. 1957.

This interesting book gives the inside history of the preparation and passage through Parliament of the National Insurance Bill, 1911. Mr. Braithwaite wrote his memoirs, mainly from his personal diary, 20 years after the Act had been passed and when he was in the relatively secluded position of a Special Commissioner of Income Tax. Though he and Mr. John Bradbury, later Lord Bradbury—the "busy B.s." as Lloyd George called them—worked all round the clock to keep up with the demands of the Chancellor, and though it had been confidently expected by almost everyone that Braithwaite would carry the main responsibility for bringing the Act into operation, he was cast aside and never attained his ambition. When he wrote the memoirs he was still smarting under the injustice of his treatment. They have been well edited, and to some extent expurgated, by Sir Henry Bunbury, who was engaged in the early days with the administration of the scheme, and there is an essay of 16 pages by Professor Titmuss on the theory and practice of national insurance.

Braithwaite was "one of that brilliant band of young men who entered the Higher Civil Service by open competition, mostly from Oxford, around the turn of the last century." The story opens with his visit to Germany in 1910 at the request of Lloyd George to find out "all about" the German national insurance scheme. Subsequent chapters recount the complex story of the drafting of the Bill and the immense opposition it encountered, not least from the doctors, as it was passing through Parliament. Though Braithwaite was principally concerned with approved societies, collecting and what contributions should be paid by casual societies, and other lowly paid workers, there are many mentions of the medical controversy, and he "sat in" when deputations were received from the British Medical Association. Incidentally he favoured payment of the doctors per case treated rather than by capitation. It was an unhappy period for the profession. On December 21, 1912, a B.M.A. Representative Meeting passed by an overwhelming majority a resolution calling on all practitioners to refrain from placing their names on any panel. A very large proportion of the doctors of the country had already signed terms had been agreed by the Association. Nevertheless, on January 2, 1913, two weeks before medical benefit was due to begin, the Government announced that nearly 10,000 doctors were available to take service under the Act, and on January 17, 1913, the Representative Body met again and released members from their pledges. Those still alive who remember those days will recall the bitterness of feeling which divided the profession into two camps: those who had stuck to their pledge and refused to join the panel, and those who had unilaterally released themselves from their undertaking. In those distant days ladies were "at home" once a month, but "panel" wives were never to be found at the homes of "non-panel" doctors or vice-versa. Normal social life among doctors and their families was violently disrupted, and it was years before harmony was restored.

The place which Braithwaite had hoped to fill in the administration was given to Sir Robert Morant. Braithwaite alleges that Morant did not like the scheme and wanted a salaried medical service. Morant and Braithwaite were soon at loggerheads, and the memoirs give Braithwaite's version of the story. The dynamic personality and driving force of Lloyd George are clearly pictured, as is

the way he "charmed, coaxed and bludgeoned" the Bill through Parliament. The work was done from the Treasury Office. The Local Government Board under John Burns was indifferent or even hostile. The newspapers, especially those controlled by Harmsworth, were actively hostile. Many prominent politicians and distinguished civil servants figure in the pages. The book illustrates the almost superhuman task required of Braithwaite and others in preparing briefs, waiting about to catch a politician, and being present when deputations were being received and when the House of Commons was considering the Bill. It will be a revelation to many to see what goes on behind the scenes when contentious legislation is before Parliament. To those interested in how the country is governed and in the beginnings of our National Health Service the book will be fascinating.

ALLEN DALEY.

PHYSIOLOGY OF NERVE CELLS

The Physiology of Nerve Cells. By John Carew Eccles. (Pp. 270+ix; illustrated. 30s.) Baltimore: Johns Hopkins Press. London: Oxford University Press. 1957.

This book is based on a series of lectures given at Johns Hopkins University in the autumn of 1955, but incorporates some more recent findings. The description of the nerve cell depends to a large extent on the recording of electrical changes in motor neurones by means of intracellular electrodes, in which field Professor Eccles holds a dominating position. An opening account of the properties of the individual neurone, when unaffected by other neurones, is followed by several chapters on the alterations produced by the activity of excitatory and inhibitory synapses and their influence in determining the possibility of discharge of the neurone. The experiments are described which demonstrate that the fundamental alteration produced by each type of synaptic action is an increase in the permeability of the neuronal surface membrane towards certain ions, which are thus enabled to move more readily across the membrane, driven by their concentrations inside and outside and by an electric potential difference. The resultant changes in electric potential, as they are observed to occur in the cell body, determine the possibility of discharge, inhibitory synapses exerting a contrary action to excitatory ones owing to a difference in the species of ions whose ability to penetrate the membrane is increased. The book concludes with a description of some of the simpler multineuronal pathways in the central nervous system, consideration being given to the different substances, mainly unidentified, which are presumed to mediate at the several synapses in each pathway. Some more highly speculative material on the relation of structure and function is also included. The work on the alterations of the electrical properties of the motor neurone by synaptic action and on the role of ions in this process, which forms the core of this book, has appeared in the physiological literature. The less specialized reader is now presented with the conclusions of this work without the strain of following the details of the original investigations. A profusion of illustrations does nevertheless provide evidence for each point as it is raised, and consideration is given for experimental procedure at various places in the text where this is required for an appreciation of the limitations of intracellular techniques.

LEFT-HANDEDNESS

Left-handedness: Laterality Characteristics and Their Educational Implications. By Margaret M. Clark, M.A., Ed.B., Ph.D. (Pp. 214+xvii. 15s.) London: University of London Press Ltd. 1957.

This is mainly an investigation into the laterality of a group of 330 Scottish schoolchildren of about 11 years of age. The author soon found that no one easy test of sidedness exists and that it is a relatively difficult matter to decide upon questions of manual preference, footedness, eyedness, and even earedness. Eventually a battery of 18

straightforward procedures was chosen suitable for use in the case of children. One or two of the testing procedures entailed the act of writing, and it was found, when the ratio of ability of the writing hand with the non-writing hand was calculated, that in the left-hand writers there was a tendency for the two hands to be closer in ability than were those of the right-hand writers. This was more noticeable in boys than in girls. The author utilized the van Piper tests within her battery, but for various reasons she was rather critical of their utility. Like so many other investigators, Dr. Clark was led to the conclusion that handedness is not a completely straightforward problem and that sinistrality is by no means a simple deviation of a normal state of affairs. Thus, a group of left-handed writers among the schoolchildren showed, on analysis of their preference tests, that they were not so uniform in their preference for the left hand as were many right-handers in their preference for the right hand. The author's conclusions as to general ability and handedness are relatively tentative, but they are suggestive as regards future research. Thus it appeared that, though left-hand writers are not less rich in scholastic achievement than right-handers, right-handed writers with left-handed tendencies may be poorer in scholastic attainment. This indication, should it be proved, would have an important bearing on the vexed question whether a left-handed child should be made to use his right hand. From all her investigations Dr. Clark came to the sober conclusion that no essential difference was apparent between left-handers and right-handers, except for their use of a different hand.

The first half of this book deals in an orthodox fashion with the problems of laterality and cerebral dominance as it stands to-day. Some important names are missing, however, such as Conrad, Subirana, and Zangwill, especially as it would appear that in the end the neurologist has the last word on the identification of the dominant half of the brain. Thus, if we may follow the author's example in quoting Nielsen (whose name, incidentally, she misspells with maddening consistency), "It is impossible to state certainly whether a given person is right- or left-handed until a cerebral lesion with aphasia occurs."

MACDONALD CRITCHLEY.

MENTAL HEALTH OF THE CHILD

The Child and the Outside World: Studies in Developing Relationships. By D. W. Winnicott. Edited by Janet Hardenberg. (Pp. 189. 16s.) London: Tavistock Publications. 1957.

There was a time in the mid-Victorian period when any text dealing with the upbringing and management of children was expected at suitable intervals to refer to the development of the child as a manifestation of the omniscient Creator and the wonder of His plan for mankind therein exemplified. Within this sincere convention it was possible to expound the current practice of the time. In these days it is in some quarters thought necessary, when giving practical advice on how to deal with everyday problems of child care, to make acknowledgment to the myth of Oedipus and the way in which the infant's developing love can in retrospect be found to re-experience the emotions of the son and murderer of Laius. The theory has changed, but the children continue to offer the same problems and often to overcome them with, and in spite of, the treatment given. The present author is both a paediatrician and a psycho-analyst, and his book, which is to some extent a sequel to *The Child and the Family*, consists of a series of essays mainly addressed to those who are professionally concerned with children, such as children's officers, teachers, and case-workers. There are sections on the psychological needs of the child, on shyness, adoption, maternal deprivation, play, stealing and other forms of delinquency, and a variety of other matters on which a child psychiatrist may be expected to have something to say. Mental health, says the author, depends on a good start with plenty of mother love, and not too much frustra-

tion or contact with abnormal children. Everything depends on a happy emergence from the Oedipus phase, for by then the die is cast. "This central theme . . . remains to-day a central fact, infinitely elaborated and modified but inescapable." For the deprived, the illegitimate, the orphan it can never be the same, for they are "unlikely to come through without scars, perhaps ugly ones." But in his chapter on sex education in schools we learn that "in free schools, where there is practically no ban on sex, the illegitimate child is surprisingly rare, and when pregnancies do occur, it is usual to find that one at least of the partners is a psychiatric case." The offspring of these unions can only add themselves to the army of the deprived who appear to be the poor heathen, so far as Dr. Winnicott's rather exclusive kirk is concerned. There is much sound sense and fine writing in this book, but it may not be very safe in the hands of those workers in the field of child welfare who are apt to take their psychology books too seriously and too literally.

ALEXANDER KENNEDY.

AMERICAN TEXTBOOK OF PATHOLOGY

Textbook of Pathology: With Clinical Applications. By Stanley L. Robbins, M.D. (Pp. 1,351+x; illustrated. £6 6s.) Philadelphia and London: W. B. Saunders Company. 1957.

This textbook is designed on ambitious lines. It has over 1,300 pages with nearly 1,000 illustrations, and is almost half as heavy again as the seventh edition of MacCallum's textbook. At this bulk and irrespective of its contents it is very likely—indeed, almost inevitable—that Dr. Robbins' book will be used by the student as a work of reference rather than a companion during his study of pathology. This is regrettable, because the author has made a commendable effort to arouse the interest of his undergraduate readers by skilfully arranging his subject-matter in logical sequence and by taking every opportunity to simplify its complexities by patient explanation. He has in addition devoted a good deal of space and effort to the correlation of the structural and biochemical changes produced by disease with their clinical manifestations. It may well be, therefore, that if this single weighty volume were published in a short series of separate fascicles it would more successfully arouse the student's interest. The emphasis placed on clinico-pathological correlation is obviously due to the popularity of the clinico-pathological conference in the hospitals of the United States. We are slow to adopt this discipline in this country, and those who may be doubtful of its educational value will be able to see its effects on the outlook of a pathologist who has clearly spent a great deal of time on its perfection. Dr. Robbins' book is a comprehensive exposition of general and special pathology, although many British pathologists would have welcomed a more generous treatment of the general principles of pathology. The illustrations are of high quality, the outlook is modern, physiological principles are not neglected, and the text is remarkably easy to read and to follow.

GEOFFREY HADFIELD.

FLUID AND ELECTROLYTES

Fluid and Electrolytes in Practice. By Harry Statland, M.D. Second edition. (Pp. 229+xv. 45s.) London: Pitman Medical Publishing Co. Ltd. 1957.

Dr. Statland's book has enjoyed a rapid success as a popular introduction to a complex subject. An important function of this kind of introduction is to teach the language of the subject, and it does this well. The book has been revised for the new edition. It provides the student with a simple and consistent story, even if it is longer than need be for its purpose and not always accurate in detail. Contrary to what the reader of the book might be led to believe, he should be warned that in practice he will usually derive more help from the records of intakes and outputs than from the laboratory determinations, and that often the oral route is to be preferred to the intravenous.

PAUL FOURMAN.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 23 1957

EVIDENCE TO THE ROYAL COMMISSION

The British Medical Association has sent a preliminary memorandum of evidence to the Royal Commission on Doctors' and Dentists' Remuneration. It is published in full in this week's *Supplement*, and the Association intends to follow this up with evidence on specific points. Other medical organizations have already sent in their evidence, and it may be assumed that, in spite of differences of approach and of emphasis, they would converge on the central feature of the profession's agreement with the Government when it entered the Health Service in 1948—the two Spens Reports. In its preliminary memorandum the Council states that the evidence is being given "without prejudice to its [the profession's] right to press for the fulfilment of the Government's clear moral obligation to honour the promises made to the profession when it entered the National Health Service on the appointed day." The B.M.A.'s memorandum usefully recapitulates the main facts of the dispute between Government and profession over its remuneration since July, 1948. Unfortunately, it is necessary to go on repeating *ad nauseam* what these facts are, because a long succession of Ministers of Health under different Governments have done their best to ignore them, and the appointment of the Royal Commission after nine years of the N.H.S. seems directed to replacing the Spens recommendations with something else. If this something else should prove to be a more workable alternative—and acceptable to the profession as a whole—then possibly the promised consultations could result in a new charter for the profession. But no doubt our representatives will, in their subsequent evidence and negotiations, make it perfectly clear that they will not accept an inferior substitute.

As has been said many times before, when the medical profession agreed, with a bare majority, to enter the National Health Service in 1948, it accepted the then Government's word that its terms of service would be in line with the Spens recommendations for general practitioners and for consultants and specialists. These recommendations were governed by a factor of overriding significance—the guarantee of a

certain standard of living to one of the great professions about to take part in a comprehensive State-provided medical service. Since the appointed day in July, 1948, few publicists and politicians have shown any realization of what a tremendous step this was for the profession to take or what hostages to fortune it was giving by such an abrupt transition from one way of life to another. Since 1948 the profession's relations with the Government have been punctuated by a series of disputes over remuneration, all based on the simple fact that Governments have refused to put the Spens recommendations into effect. Late in the day the remuneration of general practitioners was submitted to arbitration "in order to give effect to the recommendations of the Spens Committee, having regard to the change in the value of money since 1939, to the increases which have taken place in incomes in other professions, and to all other relevant factors." When Mr. Justice Danckwerts made his adjudication public the Government of the day got a severe shock, and almost immediately made it obvious that it would not take the results of this adjudication as a model for the future. It was one thing to promise to fulfil the Spens recommendations, but the reality of fulfilment was too painful. When, therefore, the consultants and specialists in 1954 sought to have their remuneration correspondingly adjusted, they found themselves compelled to accept a settlement that bore little relation to the Spens recommendations. When, subsequently, consultants and general practitioners jointly put in a claim, the Government reacted by setting up the Royal Commission which is now sitting.

The two Spens Committees based their recommendations on what had been the normal financial expectations in the past and on the desirability of maintaining the future social and economic status of the profession and its power thereby to attract suitable recruits. Both Committees gave details of the salaries and incomes they thought different categories of consultants and general practitioners should earn in terms of the 1939 value of money, and stressed that others would have to translate these in accordance with changes in the value of money and with increases in the incomes of other professions. The Royal Commission's terms of reference have obviously been drawn up with a view to getting a different basis for the payment of doctors working in the Health Service. It makes no reference to past expectations and no reference to the changing value of money. It lays all its stress on a comparison between the present earnings of doctors and those of other professions and "connected occupations"; and it will "in the light of all this and any other relevant evidence recommend such 'current levels of remuneration' as

appear to the Commission to be justified." The Commission will not be concerned with schemes of distribution.

If the profession may have appeared at times to lay undue stress on the altered value of money, this did at least provide a basis on which the statisticians and the economists could give it exact guidance. It has not laid so much emphasis on the "increases" in other professions, in many of which exact figures are hard to get or incomplete, and for comparison are often misleading. But the Royal Commission is stressing comparison of medical earnings with the earnings of others to-day. It will be some time yet before it can make recommendations, and it is not improbable that they will be made after the life of the present Government has come to an end. The award of 10% increase to junior hospital staff, and of 5% to other hospital staff and to general practitioners, was tardily given by a Government that had already said "No" several times. At the outset of the present dispute we described the matter as a "crisis of confidence" between profession and Government. The crisis still exists. The National Health Service is in urgent need of reform. But a necessary prerequisite is the establishment of confidence between Government and profession so that together they can provide the country with an efficient Health Service staffed by contented men and women. The Minister of Health has not far to look for evidence of discontent.

FATE OF ADRENALINE IN THE BODY

The pathway of the breakdown of adrenaline and of noradrenaline in the body has received much attention in recent years, since precise knowledge of this is likely to be of great help in solving the problem of hypertension. The two channels of inactivation which have hitherto been investigated are conversion to adrenochrome and removal of the amino group from the side chain. No actual evidence has ever been obtained of conversion to adrenochrome, and the evidence of deamination by the enzyme amine oxidase has been for various reasons unsatisfactory. Now we learn of a new step in inactivation which has been discovered because of the observation of K. N. F. Shaw, A. McMillan, and M. D. Armstrong¹ that homovanillic acid is a normal constituent of human and of rabbit urine, and that the administration of dopamine (hydroxytyramine), which is a precursor of noradrenaline, increases the amount of homovanillic acid excreted.

If noradrenaline and adrenaline followed a pathway similar to that followed by dopamine in becoming

homovanillic acid, then 3-methoxy-4-hydroxymandelic acid should be present in the urine. M. D. Armstrong, and A. McMillan² have now found this substance in urine and have observed that adults excrete 2 to 4 mg. per day. Further, they showed that the excretion rose when noradrenaline was administered, the extra amount corresponding to 30% of the noradrenaline given. They also studied two patients with adrenal medullary tumours and found a greatly increased excretion: when the tumours were removed the excretion fell to normal. They recommend determination of 3-methoxy-4-hydroxymandelic acid in the urine as a method of diagnosing the presence of a pheochromocytoma.

In the formation of this compound from noradrenaline or adrenaline there are two essential steps: one is the conversion of the 3-hydroxy- group to 3-methoxy-, and the other is the deamination of the side chain by amine oxidase.

An enzyme which effects the methylation of the -OH group has now been found by J. Axelrod.³ Demonstrable in rat liver, this enzyme, when methionine and adenosine triphosphate were present, caused the disappearance of adrenaline and the appearance in its place of methoxyadrenaline. He used methionine and adenosine triphosphate because G. L. Cantoni⁴ had shown that they form an active methylating combination for nicotinamide. Axelrod identified the product formed, first, by comparing it with synthesized methoxyadrenaline, making comparisons by chromatography and by fluorescence measurements; and, secondly, by treating the product with amine oxidase and showing by chromatography that 3-methoxy-4-hydroxymandelic acid was formed. Thus adrenaline and noradrenaline undergo two changes. One is methylation of an -OH group in the ring, the other is deamination in the side chain. What remains to be decided is which process occurs first. It is clearly important to know whether methoxyadrenaline, or methoxynoradrenaline, if they are formed first, are pressor substances.

Before this new work there was much doubt about the part played by amine oxidase in the breakdown of adrenaline and noradrenaline. Among the reasons for this uncertainty was the failure of some amine-

¹ Shaw, K. N. F., McMillan, A., and Armstrong, M. D., *Fed. Proc.*, 1956, 15, 353.

² Armstrong, M. D., and McMillan, A., *ibid.*, 1957, 16, 146.

³ Axelrod, J., *Science*, 1957, 126, 400.

⁴ Cantoni, G. L., *J. Biol. Chem.*, 1951, 189, 203.

⁵ Udenfriend, S., Weissbach, H., and Bogdanski, D. F., *J. Pharmacol. exp. Ther.*, 1957, 120, 255.

oxidase inhibitors to modify the action of adrenaline in the body. However, S. Udenfriend, H. Weissbach, and D. F. Bogdanski⁵ have recently shown that when iproniazid ("marsilid") was administered to rats, and when liver slices from these rats were incubated with hydroxytryptamine the destruction of the hydroxytryptamine proceeded just as quickly as when liver slices were taken from normal rats. There was no inhibition by the iproniazid. But, when the liver cells were destroyed and homogenates prepared, the amine oxidase in the homogenates was completely inhibited by the iproniazid. The authors conclude from this and other evidence that iproniazid does not enter the cells of the liver or of the peripheral tissues, though, interestingly enough, it works in the brain. It must be said that the question of the part played by iproniazid in the body is not yet finally settled, since other observations suggest that it can have some inhibitory effect. Fresh progress, however, has now been made in the investigation of the breakdown of adrenaline, and the way to further advances has been indicated.

For students of the brain this new work also has importance. Axelrod found his enzyme which methylates adrenaline to be present in the brain. Mescaline, which gives rise to hallucinations, has three methoxy groups in the ring. Is it possible that mescaline inhibits the methylation of noradrenaline in the brain and so raises its concentration? There are other questions, too, that might be asked. Does iproniazid produce euphoria by raising the concentration of noradrenaline in the brain? Does reserpine cause depression by lowering the concentration of noradrenaline in the brain? Does chlorpromazine tranquillize by antagonizing noradrenaline in the brain? After a period during which great attention has been paid to hydroxytryptamine, a return to the study of the part played by noradrenaline might now be rewarding.

TOO MANY DOCTORS?

The departmental committee¹ appointed in February, 1955, with Sir Henry Willink as chairman, to examine the medical manpower question, has now reported.² It was asked "to estimate, on a long-term basis . . . the number of medical practitioners likely to be engaged in all branches of the profession in the future, and the consequential intake of medical students required." This remit was the outcome of a growing feeling by many, including the Representative Body of the B.M.A. and the Conference of Local Medical Committees, that perhaps too many doctors were being trained for too few openings in the future and

that a surplus during the next few years was inevitable. The feeling was accentuated by the difficulties of promotion being experienced by hospital junior staff and the lack of openings for general practice in some parts of the country. But whether these problems were due to overcrowding in the profession or to other factors was not clear, and it was the Willink Committee's task to find out the facts.

Its conclusions give the lie to fears of any serious overcrowding in the profession. Up to the present it finds that medical schools in Great Britain have not been producing too many doctors. Nor are there any signs that the limits of expansion of the medical profession have been reached. Deficiencies of varying size remain to be filled in most branches of medicine. After 1961, however—that is, the earliest date for which any measures can be effective—the Committee thinks that a reduced output of doctors will suffice and that this will be met by a reduction in the student intake by about 10% from as early a date as possible. This reduction is called for mainly because the armed Forces will need about a thousand fewer doctors from 1962 onwards. A decline in medical "exports" is also foreseen, whereas the number of those from overseas, principally Eire and the Commonwealth, who settle in this country is likely to remain the same. From 1975 more doctors are likely to be needed in civilian practice to offset death and retirement and changes in the size and age distribution of the population, and therefore the student intake will have to be raised from about 1970. This last conclusion is speculative, however, and it is suggested that the situation should be reviewed again in ten years' time.

The output of all medical schools, 27 in number, in Great Britain and Northern Ireland at present and in the near future is expected to average 1,885 per annum. During the period mid-1955 to mid-1962 inclusive, the number of new doctors beginning to practise will therefore have amounted to about 13,000, and these, together with the doctors made available by the planned reduction in the armed Forces, will meet not only the Committee's estimate of needs during that period but also a deficiency of about 800 which it found to exist in mid-1955, mainly in general practice. The average annual output required, from 1962 to 1971, from medical schools in Great Britain is estimated at 1,655. This requirement would be met

¹ The members of the Willink Committee were: Sir Henry Willink (Chairman), Dr. J. T. Baldwin, Sir Harold Boldero, Sir John Charles, Lord Cohen, Sir Andrew Davidson, Dr. A. B. Davies, Mr. J. P. Dodds, Professor Sir Geoffrey Jefferson, Mr. L. G. K. Starke, Mr. A. B. Taylor.

² Report of the Committee to Consider the Future Numbers of Medical Practitioners and the Appropriate Intake of Medical Students, 1957. H.M.S.O. London. Price 2s. 6d. net.

³ Supplement, 1956, 2, 151.

therefore by a reduction in the current annual output of about 170, and to supply this reduced number the intake to medical schools from 1957 onwards should average about 1,760—or a cut of 10% as proposed. This cut does not include colonial or overseas students who train in Great Britain and then return to their own countries to practise. The Committee estimates that the number of doctors likely to be engaged in civilian practice in Great Britain by 1971 is about 60,000 as against 53,260 in 1955. In addition there will be about 1,800 employed in the armed Forces.

In reaching its conclusions the Committee emphasizes that precise estimates of future requirements of doctors are impossible. This indeed is obvious. Quite apart from uncertainties—future losses from death and retirement, for instance—such things as changes in medical techniques and therapeutic methods, as well as changes in the incidence of disease, are so unpredictable as to make allowance for them impossible. Changes in the organization of the nation's health services are another imponderable cited by the Committee, and it adds that the numbers employed in the National Health Service "must depend on its size and scope and so, ultimately, on the amount of the country's resources allocated to it." More bluntly, one might say on what the country is prepared to spend on it. All in all, the impression gained from the Willink Committee's report is that almost every aspect of the subject is, as the B.M.A. Scottish Committee put it,³ "fraught with prognostic difficulty" and that "nothing short of efficient crystal-gazing could give the answer."

ACUTE RESPIRATORY DISEASES IN YOUNG CHILDREN

There is a well-known seasonal incidence of acute respiratory disease in young children each autumn and winter, and this high incidence reached epidemic levels in London in late 1953. The Ministry of Health was interested in the epidemiological aspects of these diseases, and to augment its usual sources of information asked nine paediatricians in London and four in the provinces to provide information relating to hospital admission of children under 5 years of age during the last thirteen weeks of the years 1953–5 and the first thirteen weeks of the years 1954–6.¹ The diseases studied were acute bronchitis, acute bronchiolitis, bronchopneumonia, and laryngo-tracheo-bronchitis. The uncommonly high incidence of these diseases in London in November, 1953, was confirmed, though there was no corresponding epidemic in the provincial centres; no satisfactory explanation was available either for the London epidemic

or its absence elsewhere. Generally, every winter there was a big rise in hospital admissions of young children suffering from one of these diseases, and at every centre and every year there were more admissions of boys than girls. This last feature also remains unexplained.

This investigation, so far as it went, poses more problems than it answers. The vast majority of cases of acute respiratory disease in children are not sent to hospital and are not seen by paediatricians, but are treated by family physicians. It is surely they who are in the best position to provide the answers to many problems by a detailed and systematic study of their cases, including the taking of full notes. From these definite patterns of disease complexes may eventually be distinguished, and precipitating factors, such as family infections, dietary habits, and social and economic conditions, be identified. Liaison may be established between the family doctors and the hospitals and public health laboratories, including the increasing number of these which are equipped for the investigation of virus diseases. The collection of specimens as near as possible to the onset of the disease, and again in the convalescent stage, requires careful organization.

We know very little about the value, if any, of chemoprophylaxis or other methods of the prevention of these illnesses, and not much more about the best treatment. We shall make little progress until we know more about their aetiology. All these aspects seem to deserve careful and concerted study, perhaps by the College of General Practitioners in conjunction with their hospital colleagues by methods that have already met with success.² The very size of the problems and the high mortality rate which is still attached to these diseases in the very young should be an impetus to tackle it as an emergency.

THE BRITISH COUNCIL AND MEDICINE

Ever since it established a Medical Department early in the war the British Council has played a great, but little appreciated, part in securing recognition in other countries of the advances made by British medicine. As it states in its Annual Report, just published,¹ it is upon the pure and applied sciences that much of Britain's prestige, prosperity, and existence as a leading nation depends. The work of the Medical Department is under the general direction of the Council's Medical Panel, whose chairman is Dr. E. A. Carmichael. Each year doctors from other countries come to Britain under the Council's auspices to take part in specially arranged courses or to pursue special lines of study as Council scholars. The Council also arranges for visits to other countries of individual lecturers and special teams of experts. In the present Report it mentions, for example, the great success attending the visit to South American countries of a team consisting of a chest surgeon, a cardiologist, and an anaesthetist. "The subjects for operation," the Report states, "were selected by members of the medical profession in each country [Brazil,

Chile, Colombia, and Uruguay], who thereby gained an opportunity of observing British methods of diagnosis, operative techniques, and the administration of anaesthetics. The immediate impact which this team made was undoubtedly great, and further results are now appearing in the form of visits from surgeons and cardiologists whose interest in British methods has been aroused and who are coming here to inquire further." And the British Council quietly notes that many of these visitors will come with authority from their universities or Governments to buy British apparatus and instruments. Then there is the Council's publication the *British Medical Bulletin*, which has achieved a reputation second to none among those periodicals which review advances in medical knowledge. When other countries ask the Council for medical films it takes great care to recommend only those which its Film Panel reviews. The libraries maintained by the Council in foreign cities are well stocked with British medical textbooks and periodicals, and its representatives play an invaluable part in making it possible for doctors to buy British medical books and journals in those countries where currency restrictions make such purchases difficult. Anyone who has seen the work of the Council at first hand can have only one regret, and that is that a niggardly budget makes it impossible for it to do more.

POLIO VACCINE DOSAGE

Children inoculated with the poliomyelitis vaccine in Great Britain have so far received two doses of it. Now that more is to be made available from a second British manufacturer and from Canada and the U.S.A., the question of giving a third dose needs to be considered. Evidence from field studies carried out by the Medical Research Council¹ showed that two doses of the British vaccine gave about 80% protection against the paralytic disease. The children studied had been inoculated in the early part of 1956 and were exposed to the risk of infection in the small outbreak of the disease in the summer of that year. Consequently, though the protection against the disease was probably high during the summer and autumn, it may have begun to wane towards the end of the year. If a third injection is given about seven months or more after the first two, it seems likely that protection can be heightened and prolonged.

A report to the Medical Research Council, published in the *Journal* this week at page 1207, provides evidence that a third dose is desirable. Analysis of data from 100 children showed that the antibody level produced by two doses declined after some months, and that a third injection, given eight to eleven months after the first two, caused responses in many of the children which were as good as those resulting from infection with the virus. These conclusions agree with

those reached in the U.S.A. and Canada. G. C. Brown and D. C. Smith² studied the effects of various inoculation schedules on infants and young children, and found that those receiving three doses had a better antibody response than those receiving two or one. Salk³ considers that the first two doses should preferably be given four to six weeks apart, and the third be given seven or more months later. R. D. Defries,⁴ of the Connaught Research Laboratories, Toronto University, gives the same advice. The schedule of two doses recommended in Great Britain presumably reflects the shortage of vaccine here, and no change of policy is to be found in the communications sent from the Ministry of Health to local health authorities this week.⁵ Sufficient vaccine is to be imported to offer vaccination before next summer to all children under 15, to pregnant women, to members of the medical profession specially exposed to risk, to ambulance staffs, and to the families of these last two groups. This apparently means two doses. But there may well be a case for also offering inoculation next spring to those children who have already received two doses.

CANDIDA NAPKIN RASHES

The clinical diagnosis of most diseases due to fungi is not only difficult but also unreliable unless supported by microscopical evidence and, in some cases, also by cultural evidence. This is no less true of cutaneous disorders of the napkin area, in which yeast-like organisms may play a part. Indeed, the necessity for these aids is apparent on reading often widely differing clinical descriptions of the lesions in textbooks and periodicals. This lack of uniformity in clinical description does not reflect insufficient observation on the part of authors, but rather the variety inherent in the clinical picture itself. In considering the differential diagnosis, a variable cutaneous "soil" which is under the influence of an equally variable microclimate has to be taken into account. A fairly large area is subjected to the deleterious action of frequent inundations of warm urine and less frequent but no less deleterious action of warm faeces. The ill effects of this vary in severity with different standards of hygiene. As clinical entities they have been repeatedly described; such are intertrigo, ammonia dermatitis, napkin dermatitis, and rash due to faeces. The feature common to them all is erythema, and in the main its relative distribution is the criterion by which they are distinguished.⁶ On the warm, moist cutaneous soil of the napkin area both pathogenic and non-pathogenic micro-organisms thrive and multiply inversely with the number of napkin changes. Occasionally some of the pathogenic forms succeed in establishing themselves in the saturated substrate, and the result may be infection such as impetigo (due to staphylococci or streptococci) or candidiasis (due chiefly to *Candida albicans*).

⁷ Holzel, A., *Arch. Dis. Childh.*, 1953, 28, 412.

⁸ Robinson, R. C. V., *J. Pediat.*, 1957, 50, 721.

In primary candida infection of the skin in this area small dull red macules⁶ are present at first, or reddish-brown papules.⁷ These desquamate in due course, so that usually small denuded patches result, each surrounded by a white overlapping fringe of epithelium. Vesicles may also be seen, and, when they rupture, also leave a denuded surface surrounded by a white fringe of epithelium. Whatever form the lesions assume at first, they may, if close together, coalesce to form much larger lesions, in which also the peripheral epithelial fringe may be observed. Unfortunately, the clinical picture is frequently indefinite and atypical, being conditioned to a greater or less extent by the idiopathic alteration already mentioned. Thus an extensively erythematous, macerated, and partly excoriated cutaneous surface may be clinically diagnosable as a severe degree of ammonia dermatitis or a napkin dermatitis, which in fact it probably is, especially if no epithelial fringes are seen; but candida infection may also be present, though not clinically discernible, in a secondary role. Likewise, it is difficult to detect it clinically when it is secondary to seborrhoeic dermatitis or infantile eczema in the napkin area.⁸ To the experienced dermatologist or paediatrician characteristic lesions outside this area may reveal the primary condition and even the nature of the secondary infection, but these may be absent.

In such cases not even the most careful clinical examination equals in value the irrefutable evidence which can be provided by the microscopical examination of a small quantity of epithelial debris taken from the lesion. The procedure required is simple and expeditious. It consists in mounting on a microscopical slide, in a small drop of 10% caustic potash solution, a scraping of macerated epithelium preferably from the edge of a lesion. In such a preparation, which should be warmed, the yeast-like organisms, when present, can be observed by examination with the aid of the usual dry objective lenses 2/3 in. (16 mm.) and 1/6 in. (4 mm.) combined with a $\times 10$ ocular. In these lesions they occur as rounded or oval budding cells (blastospores) associated with more or less thread-like growth (pseudomycelium). When oily preparations have been used to treat the lesions, epithelial debris, after being mounted directly on the slide, should be rinsed several times in ether before being immersed in the caustic potash solution, for otherwise oil drops will make definition difficult and may themselves even be mistaken for blastospores.

Treatment should follow on positive findings without delay. Superimposed infection is best eliminated first, since otherwise treatment of the primary condition will not be satisfactory. Besides correcting any errors in the napkin regimen such as insufficient rinsing or lack of ventilation due to the wearing of plastic or rubber pants, specific preparations of proved efficacy may be used. For example, 1% aqueous gentian violet or "nystatin" ointment (100,000 units per gramme) applied three times a day locally may be prescribed. If oral thrush is also present, it can be treated effectively by oral nystatin aqueous suspension (100,000 units nystatin per ml.) administered in drops directly or in the feed,

1 ml. four times a day. Candidiasis in the napkin area responds rapidly to nystatin therapy, some cases clearing in a few days. More severe cases may require longer treatment, up to two weeks or more. J. P. Bound⁶ claimed satisfactory results, usually within two weeks, from topical applications of 0.1% aqueous solution of merthiolate followed by titanium oxide paste. However, irrespective of the treatment, relapses are apt to occur, especially if treatment is stopped too soon, and reinfection also, if due care is not taken to guard against all possible sources of infection, both exogenous and endogenous.

TROPICAL JUBILEE

It is fifty years ago since the Royal Society of Tropical Medicine and Hygiene was founded, and, as the Duke of Edinburgh said at its golden jubilee banquet¹ last week, members of the Society have made a great contribution to the relief of human suffering. Foremost among this distinguished band of pioneers is Sir Leonard Rogers, F.R.S., now approaching his ninetieth year, one of the four original fellows still living. In the opening pages of this week's *Journal* he describes how he traced the conditions leading to the great epidemics of cholera in India. The outcome of this work was the present method of control by mass immunization—a method which, Sir Leonard estimates, had saved nearly 150,000 lives in two Indian provinces by 1942.

The first meeting of the Society was held on June 26, 1907. Its aims were to be "specially directed to the stimulation of inquiry and research into the cause, treatment, and prevention of human and animal diseases in warm climates, by facilitating the publication and discussion of original contributions and reports, by supplying necessary information to fellows, and by promoting social intercourse among scientific workers in all parts of the tropical world." In all these it has been remarkably successful, for from its inception the Society has attracted to its ranks the leading workers in tropical medicine. Sir Patrick Manson, who played an important part in inaugurating the Society, was its first president, and he was followed in the early years by, among others, Sir Ronald Ross, Sir William Leishman, Sir David Bruce, and Sir Andrew Balfour. The Society's *Transactions* have been published regularly since 1907, and to-day, under the editorship of Sir William MacArthur, occupy a leading place among journals devoted to tropical medicine. Speaking at the jubilee dinner, Brigadier J. S. K. Boyd, the present president of the Society, said that there was no barrier of race, creed, or nationality in the way of admission to it—a claim to be proud of in the present state of the world. If, as the Duke of Edinburgh said, the control of tropical diseases has created other problems, then members of the Society may be expected to play the same part in solving them as their predecessors did in unravelling the complex causes of the parasitic, bacterial, and metabolic disorders which have for so long threatened the health and welfare of tropical peoples.

CHANGING PATTERN OF EPISTAXIS DURING THE PAST 45 YEARS

A STATISTICAL INVESTIGATION OF 4,473 CASES AND A CRITICAL REVIEW OF THE LAST 1,000 CASES*

BY

J. P. STEWART, M.D., F.R.C.S.Ed.

Surgeon-in-charge, Ear, Nose, and Throat Department,
Royal Infirmary, Edinburgh

Though epistaxis is a rather time-worn matter for dis-course it is of considerable importance, and I hope to show its changing pattern under present-day conditions. It is impossible here to cover adequately all the ground pertaining to epistaxis, and my remarks are limited to some of the more salient features which have emerged from my analysis of a series of cases.

Present Series

I have taken for a critical review 1,000 cases of epistaxis referred to my department at the Royal Infirmary, Edinburgh, during the past five years. In order to obtain a more comprehensive record the department's complete figures dating from 1912

FIG. 1.—Number of out-patients with epistaxis.

FIG. 2.—Number of epistaxis cases admitted to hospital.

Causes of Increase

What can we deduce from these figures? The two main possibilities are either that epistaxis is on the increase or that

*Read in the Section of Oto-rhino-laryngology at the Annual Meeting of the British Medical Association, Newcastle upon Tyne, 1957.

cases are now being referred to hospital which in the past were treated at home. That the incidence of epistaxis is becoming more common is confirmed by the steadily increasing number of cases attending hospital; but it must be considered carefully whether this is a real or a false conclusion, and, if real, then what factors are at work which would produce it? Is the rate at which we now live a possible cause? No one will deny that worries and uncertainties have increased and are still increasing, despite higher standards of living for the masses, or because of their growing responsibilities and the relative fall in the standards of life for other sections of the community. Another factor may be the greater expectation of life and the fact that age is outrunning the normal wear and tear of the body tissues; the ages of those admitted to hospital would certainly lend some support to this. The increase of cardiovascular conditions may also contribute to the growing incidence of epistaxis. Cigarette smoking does not have much effect in this respect, but the ever-increasing habit of blowing smoke down the nose makes for a dry and congested nasal mucosa and therefore creates a condition in which nose bleeding is more likely to occur. The local application of decongestive nasal medicaments which are so popular and fashionable may in the course of time and with frequent abuse have a decidedly injurious effect on the nasal mucosa, causing chronic congestion and having a paralysing effect on the ciliary action with consequent proneness to bleeding.

The other possibility, that more cases are being referred to hospital, is the more likely one. The greatest increase in the hospital incidence occurred after the inception of the National Health Service. Frankly, epistaxis can be a considerable nuisance to the practitioner, and often is time-consuming. He never knows when he will be called out to deal with a case, and an enforced sudden absence just when he has embarked on a particularly long consulting session might result in a condition approaching chaos. Some hold that these cases are more efficiently dealt with in hospital, and that, in any event, they would probably have to attend there in the immediate future for cauterization of the bleeding area, so why waste time? Others deal with the epistaxis and then leave a letter addressed to the hospital with instructions to the patient that if the bleeding continues he is to report to hospital with the letter. This seems a more satisfactory line of treatment. The patient's point of view might be summed up by a portion of a letter written to the *Edinburgh Evening News* (April 11, 1957, p. 8): "Since the present Health Scheme came into force, I have noticed a distinct falling off in the interest shown to the patient by the average G.P., who now seems to consider his surgery a clearing station for the hospitals, etc." Taken all in all, there appears to be a tendency nowadays and under the present conditions in practice to refer to hospital more cases of epistaxis, and only the minority of cases are dealt with in the home. So long as practitioners are paid according to numbers of patients and not for their medical skill and art there is little incentive for the latter, and this attitude of *laissez-faire* must be accepted.

Social Strata and Locality

The social status of those attending hospital has altered little throughout the years. In the present series the patients were made up of 30.8% manual workers, 22.3% black-coated workers, 21.3% housewives, 11.9% retired persons, and 13.7% children. It may be assumed that manual and heavy industrial workers would be more prone to epistaxis because of the physical effort entailed in their labours, and they form the largest group. Housewives, however, are high on the list, and they ought to be considered in the group of manual workers. An additional factor in this latter group may be the almost permanent anxiety state from constantly rising living expenses and that very doubtful blessing "hire purchase." In regard to children, epistaxis in the past has often been associated with the presence of tonsils and adenoids, and the figures shown would seem to support this, as 39% of this group had been operated upon for tonsils and adenoids, while 61% still had their tonsils and adenoids intact.

Another factor that emerged was the locality from which these patients were drawn: 68.8% lived within the boundaries of Edinburgh, while 31.2% were sent from rural areas. One would expect a larger percentage to be admitted from a more densely populated area, but, on the other hand, remembering the great increase of patients in recent years it is tempting to think that hospitals are used because of their proximity. Maybe the country practitioner has more time to deal with his cases and delays sending them immediately to hospital; but this is dangerous ground, and it is safer not to pursue such theories.

Aetiology

The cause of the epistaxis was definitely ascertained in 383 cases. When a case is admitted to hospital without a previous medical history it is sometimes difficult to discover the true cause for the bleeding. In 219 cases the patients suffered from hypertension—this is probably an underestimate, for it is impossible to assess the usual blood pressure of a patient who has suffered a severe blood loss. The blood pressure of all patients admitted to the ward is, of course, taken as a routine, along with an estimate of their haemoglobin and in many cases a complete blood-cell examination. Trauma of the nose accounted for only 19 cases, which is somewhat surprising, while in 116 cases there were other local nasal causes. These latter cases were associated mainly with atrophic rhinitis, acute coryza, sinusitis, perforation of nasal septum, nasal polypi, and tonsils and adenoids. Among 25 cases which occurred during a systemic disease, cardiac and blood conditions formed the bulk. Four cases arose during normal pregnancy, and in this connexion should be mentioned the work of Karpow (1929), who established through animal experiments that the inferior turbinate contained a substance which had a specific action on the nerve-muscle system of the uterus. Such an action may possibly be reversible—for example, rhinorrhoea as a symptom in premenstrual tension states—and might explain the occurrence of epistaxis in those cases.

Age Incidence.—The greatest number occurred in age group 11–20 years (25.6%), while the next highest was between the ages of 61 and 70 (15.9%).

Sex Ratio.—The male sex predominated, but not to such a marked extent as one would think. The figures were 57.2% males and 42.8% females.

Previous History.—Of the cases under review 38.9% were seen during their first attack and 61.1% had had previous bleedings. Only two cases gave a family history of epistaxis.

Site of Bleeding.—In 82.5% the haemorrhage was located on the anterior part of the septum from the usual site known as Little's area. In 17.5% the bleeding occurred either from the anterior or middle turbinates or from an area farther back in the nose.

Degree of Bleeding

The severity of the bleeding may be judged from the number of patients who required admission to hospital: of the 1,000 cases, 19.2% were admitted to the wards (roughly 1 in 5). The total number of admissions in the last 45 years was 521, and 319 of them were admitted during the period of the National Health Service (practically 60%). It has always been the practice to admit severe cases of epistaxis, and the marked rise in the admission rate in recent years is one argument in favour of the possibility that epistaxis is becoming more common. Another important factor is the age of the patients admitted. It was ascertained that most of the males were aged 50–70 years and most of the females 60–80 years. They constituted 60.7% and 56% respectively of the 319 cases admitted since the inauguration of the N.H.S. Many of the older patients lived alone; some were looked after by an equally old or infirm partner, and others by intolerant and disinterested relatives who were either incapable or unwilling to undertake responsibility.

On the other hand, one would suppose that more of the admitted cases would be treated at home because of the convenience of domiciliary treatment and its freedom from per-

sonal expense to the patient. In the past, when the patient had to pay for such services, a specialist was often called on to help arrest a nose-bleed in the home, but the number of such calls has gradually dwindled so that specialists are now rarely called out. It is fortunate that we live in the antibiotic era, as these admissions would have put a very severe burden on the bed accommodation were it not for the balancing factor of a proportionate decrease, thanks to modern methods of treatment, in the admission of cases of acute infections.

Treatment

It is of interest to assess the effectiveness and the rationale of the methods of treating epistaxis used in the past. One of the earliest that I have come across was the one devised by William Buchan (1769). He started in life by studying divinity at Edinburgh University, but gave up this calling for the more lucrative one of medicine. He described his treatment of epistaxis in the following words: "If the genitals be immersed for some time in cold water, it will generally stop a bleeding of the nose," and went on to say, "I have seldom known this fail." I have no experience of this form of treatment, but have no doubt that it proved efficacious. What was the rationale for this success? It certainly had a scientific basis, and we are indebted to Spiesman (1933) for an explanation. He found that when a circumscribed cold stimulus was applied to the skin it caused a lowering of the temperature of the nasal mucous membrane with a consequent vasoconstriction, and that would certainly help to explain the good results obtained by Buchan.

In my young days it was the custom to place a large cold metal key (generally the front-door key, which in those days was of considerable size) on the nape of the neck in order to deal with a nose-bleed. It was a household remedy and enjoyed a measure of success. The cold metal was presumably placed over the cervical sympathetic ganglion in the neck, thereby inducing, by its thermal stimulation of the pressor fibres, a vasoconstrictive action on the nasal vessels. There were other methods, too numerous to mention here; but these pioneers did undoubtedly get their results, although from the scientific point of view they reaped but did not sow.

Modern treatments of epistaxis are many and diverse. Let us first consider the case which is actively bleeding. My early impressions of such cases (and many of us must have encountered similar circumstances) were of the patient slumped in his bed with a blood-stained bath towel draped round his neck and shoulders, or with his head dependent over the side coughing and spluttering blood into some homely receptacle. The room was probably packed with anxious members of his family ably assisted by neighbourly neighbours, all doing their best to help and give advice, and the scene would not be complete if one omitted the old crone sitting in her corner oftly repeating that she "smelt death." Copious and frequent libations from a bottle of brandy or some other spirit were pressed on the patient to keep his strength up, along with exhortations to fight the good fight, and at times the set-up might resemble Dante's inferno.

The first act in treatment is to clear the room of relatives and all helpers, open the window, sit the patient up, and instruct him to blow his nose vigorously in order to expel all the blood clots. If convenient a very hot or ice-cold saline douche, given by means of a Higginson syringe, is more satisfactory for the expulsion of the clots, and this will often stop the bleeding. He is then instructed to inhale through his nose and to exhale through the mouth. If sufficient time is allowed for this the bleeding often stops spontaneously, possibly from the vasoconstrictive action of the cold air, but should the bleeding continue unabated some form of pressure on the bleeding-point must be exerted. It is useful first to spray the nose with a 5% solution of cocaine, as this makes it so much easier both for the patient and for the operator. A useful gadget for this is a Rose-Cooper inflatable rubber bag, or, if such is not available, an ordinary finger-stall attached firmly at its open end

to the beak of a rubber catheter so that it is airtight. After introduction into the nose the lubricated bag is inflated and the inlet tube clamped. In most cases this effectively deals with the haemorrhage. Selvedged ribbon gauze, 1 in. (2.5 cm.) wide, is often employed for packing purposes, and some 3 to 4 ft. (900 to 1,200 cm.) can be contained in each nasal cavity. It should be soaked in a haemostatic such as hydrogen peroxide and then firmly wrung out, as an excess of H_2O_2 can be very messy. Posterior packing is rarely necessary, and if employed a penicillin cover should always be given.

If the bleeding is not severe but is more of an ooze a suitable pack is provided by oxidized cellulose. This, besides having haemostatic properties, swells with moisture so that, apart from its initial pressure on the bleeding area, it develops even more pressure shortly after being placed in the nose. Also, in cases of this type fibrin foam soaked in liquid thrombin (500 units of thrombin in 5 ml. of diluent isotonic saline) has proved of great value. Of course there are other medicated materials of which good use can be made, but they are too numerous to mention here.

In general, cauterization gives disappointing results in an active epistaxis, although if one single bleeding-point is seen this treatment often gives decisive results. It is used more often for those cases which constantly recur, and which are a nuisance to the patient, than for actual blood loss.

Thermal cauterization is extremely satisfactory provided a dull red heat is used. The bleeding area is first ringed by the cautery point and then the actual vessels are coagulated under light pressure of the cautery. If the pressure is too firm bleeding may ensue and too much of the vessel-bed tissue be destroyed, with the possibility of destruction of the coating of the septal cartilage and a consequent perforation.

Instead of heat cauterization the vessels may be sealed off by the application of some form of caustic. A fused bead of chromic acid gives excellent results provided care is taken to pack off the surrounding tissues with cotton-wool so that the flow of mucus cannot carry the chromic acid to other parts of the nose. I have seen cases where the chromic acid was carried into the pharynx. Crystals of trichloroacetic acid are extremely brittle and liable to fragmentation, so that this substance should never be employed as a cauterizing agent. A stick of silver nitrate is handy and convenient for chemical cauterization, and can be used without any previous preparation.

Thirty cases were treated by deep x-ray therapy, and this method has proved its worth in very severe cases of epistaxis that were difficult to control with ordinary methods and likely to endanger life (Stewart and Sammon, 1954). The bleeding was generally controlled completely within 48 hours of starting treatment. The dosage was a minimum central dose of 2,000 r in one week, comprising five daily treatments to each directly opposed field of 6 by 6 cm., which included the central nasal cavity. In only 13 cases was blood transfusion considered necessary to compensate extreme loss of blood.

It has been stated elsewhere that ligation of the external carotid artery has had to be undertaken in order to control bleeding and to save life; but in no case in the present series was such a heroic form of treatment carried out, and one can only think that in such circumstances an operator had been stampeded into doing what must be considered an unnecessary and uncalled-for procedure.

Finally, it is imperative that the patient who is weak through loss of blood, and consequently more than ever nervous of himself, should be given a sedative; the one recommended for this is morphine by injection, which not only has its usual action but also appears to exert some influence on the cessation of the bleeding. It is no good using amounts which have only an exciting effect; it is important to give good measure, and I recommend $\frac{1}{2}$ -gr. (30-mg.) doses for an adult, which may be repeated.

In an analysis of the treatment carried out in the present series of 1,000 cases 78.2% were dealt with by some form

of cauterization, 18.8% required to have the nose packed, and 3% were treated by deep x-ray local irradiation.

No deaths directly due to epistaxis *per se* are recorded in this series of 1,000 cases.

Summary

A thousand cases of epistaxis seen during the last five years at the E.N.T. department of the Royal Infirmary, Edinburgh, are critically reviewed, and the 4,473 cases of epistaxis treated in the department over the last 45 years are analysed statistically.

Almost half the number of cases have occurred since the inception of the National Health Service.

Two possibilities arise: that epistaxis is on the increase, and that more cases are now being referred to hospital.

Domiciliary treatment is not being fully utilized so as to lighten the burden of hospital bed accommodation.

Treatment, both present and in the past, is commented upon. Most cases (78.2%) were relieved by some form of cauterization.

No deaths due to epistaxis occurred in the series reviewed.

I am indebted to Dr. J. H. Campbell for the immense amount of time and trouble he has taken in the preparation of the material for this paper.

COLLEGE OF GENERAL PRACTITIONERS

The fifth annual general meeting of the College of General Practitioners was held at B.M.A. House on November 16. Some 200 members and associates attended. Earlier in the day Dr. D. M. HUGHES, of St. Clears, Carmarthen, had delivered the College's fourth James Mackenzie lecture.

ANNUAL MEETING

With the president of the College, Dr. I. D. GRANT, in the chair, Dr. F. M. ROSE, chairman of council, presented the annual report. He described the year's expansion. More than 700 new members and associates had been enrolled, bringing the total membership to over 4,500. Three new overseas faculties had been founded—in Victoria (Melbourne), in Tasmania (Hobart), and in New Zealand (Wellington). There were now 35 faculties in all, 13 of them overseas. A New Zealand council had been formed to co-ordinate the work of the faculties there, as did the Australian council so successfully with the five faculties in that country. The New South Wales faculty had made a special contribution to undergraduate education by arranging for students to visit general-practitioner hospitals, for week-end student-attachment to doctors' practices, for students to visit patients' homes with district nurses, and for residential vacation-training of students at 17 general-practitioner country hospitals, all the vacancies for which had been booked a year in advance. With 610 members and associates in Australia the time was approaching for the foundation of an autonomous Australian College of General Practitioners. As its parent, the College in Britain would wish it well. The College's Scottish council had submitted evidence to the committee of the Scottish Health Services Council inquiring into the provision of maternity services in Scotland, and it had been invited by the Scottish council of the B.M.A. to nominate a member to that body.

The College owed much to the boards of its faculties, many of which were publishing their own faculty journals. The obstetric survey of the South-west England faculty—

an analysis of over 4,000 confinements in domiciliary practice—had been well received, and the College had presented a memorandum of evidence to the Cranbrook Committee on the Maternity Services.

Education and Research

Under Dr. Richard Scott's direction an undergraduate teaching register had been compiled of 1,400 members of the College who were willing to take medical students into their practices. The council's postgraduate education committee (Dr. George Swift, chairman) had administered the £960 Pfizer postgraduate grant for furthering the continuing education of family doctors, and it had carefully considered possible criteria for continuing membership of the College. The work of the council's research committee (Dr. R. J. F. H. Pinsent, chairman) had increased in scope and complexity. The research register now included more than 550 general practitioners. Forty-seven faculty-sponsored research projects were being undertaken, together with seven College-sponsored investigations which included the National Morbidity Survey (in co-operation with the General Register Office), the coding and checking of the material for which had been completed. The Nuffield Provincial Hospitals Trust had given a grant of £4,450 towards the expenses of the Chronic Bronchitis Study. The *Research Newsletter* (Dr. R. M. S. McConaghey, editor) had outgrown its original form, and, by the breadth and variety of its published matter, was becoming the journal of the College. A College records unit was being developed and College archives collected. The council's practice equipment and premises committee (Dr. J. C. T. Sanctuary, chairman) had begun its work.

Plans for the proposed new building in Lincoln's Inn Fields were progressing satisfactorily with the help and full co-operation of the president and council of the Royal College of Surgeons. Temporary premises had been presented to the College at 41, Cadogan Gardens, Sloane Square, London, S.W.3.

Elections and Presentations

Dr. Grant was unanimously elected president for 1957-8. Dr. W. N. Pickles received a past president's gold badge. Dr. A. Fraser-Darling (Grantham, Lincs) was awarded the Butterworth gold medal for 1956-7 for an essay on "The Science and Art of Prognosis in General Practice." The subject for the 1957-8 Butterworth gold medal and award will be "Second Opinions"; essays should be submitted to the chairman of the awards committee not later than September 20, 1958.

Fifteen Upjohn Travelling Fellowships (£200 each) were presented to: J. F. Burdon (Paignton, Devon), D. L. Crombie (Birmingham), R. S. C. Fergusson (Lochinver, Sutherland), S. Freeman (Manchester), J. C. Graves (Writtle, Essex), W. G. Keane (Dartmouth, Devon), C. W. Kidd (Belfast), A. U. MacKinnon (Leeds), E. G. L. Mark (Macclesfield), R. A. O'Shea (Pinxton, Notts), O. Plowright (London), W. G. Tait (Reading), C. A. H. Watts (Ibstock, Leicestershire), W. T. Westwood (Stretford, Lancashire), and D. G. Wilson (Bushey, Herts). Six Public Welfare Foundation prizes (£40 each) for final-year medical students were presented to: E. T. L. Davies (St. Mary's Hospital Medical School, London), G. H. Farrington (University of Leeds Medical School), Florence McCallum (University of Edinburgh Medical School), Lilian Orba (University of Edinburgh Medical School), D. A. R. Robertson (University of Edinburgh Medical School), and R. N. Smith (University of Birmingham Medical School).

The following faculty representatives were appointed to the fifth College council (1957-8): L. W. Batten (North London faculty), H. H. A. Elder (South London), E. A. W. Marien (East London), R. Cove-Smith (West London), George Swift (South-east England), J. C. T. Sanctuary (Northern Home Counties), W. G. Tait (Thames Valley), D. Scott Napier (East Anglia), R. M. S. McConaghey (South-west England), D. L. Crombie (Midland), K. M. Foster (North Midlands), R. A. Murray Scott (Yorkshire), S. Freeman (North-west England), R. Harkness (North-east England), R. J. Minnitt (Merseyside and North Wales), J. N. M. Parry (Welsh faculty), Richard Scott (South-east Scotland), W. S. Gardner (West of Scotland), J. M. Hender-

son (East Scotland), George Swapp (North-east Scotland), G. H. Clement (North Scotland), J. Campbell Young (Northern Ireland), V. G. Doyle (East of Ireland), J. P. J. Little (West Ireland), J. C. Walsh (South Ireland), W. A. Conolly (New South Wales), W. J. Hamilton (Queensland), H. E. H. Ferguson (Western Australia), G. D. McDonald (Victoria), the Hon. R. J. D. Turnbull (Tasmania), A. Barrett Jameson (Auckland), C. L. E. L. Sheppard (Canterbury), H. E. M. Williams (Otago), L. Myers (Wellington), G. E. Peters (Kenya). Four elected members of council, to replace those retiring, were appointed by ballot: Annis C. Gillie (West London), W. V. Howells (Welsh faculty), J. H. Hunt (South London), A. Talbot Rogers (South-east England).

Criteria for Membership

Dr. ROSE took the chair for the business part of the meeting, during which amendments were made to the College by-laws and a resolution was passed requesting council to draw up new criteria for admission to membership. The chairman thanked the B.M.A. for its generosity in allowing the College to use its Hall once again, and Dr. G. F. ABERCROMBIE moved a vote of thanks to Dr. Rose, which was carried with acclamation.

At a meeting of the new council held later, Dr. F. M. Rose was appointed chairman, Dr. Annis Gillie vice-chairman, Dr. H. L. Glyn Hughes hon. treasurer, and Dr. J. H. Hunt hon. secretary. Dr. J. M. Hunter (Northern Ireland) was appointed an additional member of council.

JAMES MACKENZIE LECTURE

Dr. DAVID HUGHES's subject for the fourth James Mackenzie lecture was "Twenty-five Years in Country Practice."

Country Practice in Years Past

"When I left hospital nearly a quarter of a century ago in the presulphonamide era and went to the country, I seemed also to be moving back a whole generation," Dr. Hughes said. He had joined an old doctor of 83 years of age, living in the dignified manner of another era. In contrast to the dignity and comfort of the home, the surgery accommodation was depressing and entirely lacking in the amenities that would now be thought essential. The walls of the surgery were distempered in a dirty dark red, the floor was of bare boards, and the room ill lit by a small gas jet. There was no examination couch and no washbasin. The contrast between the surgery and the home was difficult to understand, and yet the old patients adored the doctor. They gladly waited for hours, half a day or longer if necessary, sitting on a stone bench around the pump in the yard if the weather was fine, or on the chairs in the surgery if wet—for the doctor whom they had known all their lives.

The doctor had seen and known Lister at the London Hospital; he remembered the filthy stained frock-coats of the doubting surgeons hanging up in the surgeons' rooms; and he could recall changes as remarkable as those he himself would describe. The doctor had lived and practised from the same house for 58 years. He never discussed the condition of a patient with anyone, never gave a diagnosis, and no one would dare ask. He had the reputation for infallibility. That was the background to Dr. Hughes's new home.

When he arrived, agriculture was at a very low ebb and there was great poverty amongst the farming community; yet their families were private patients. The response to the yearly bills was invariably disappointing and payments were rare, but that did not seem to matter then. Daily mileages of 50-60 miles were routine; the nearest hospital was 10 miles away; and until 1948 almost all the acute surgery was done by general-practitioner surgeons, for the nearest consultants were then 35 miles away.

In those days midwifery dominated one's life. The one outstanding quality necessary for its successful practice was sound judgment—knowing when to leave things alone and knowing when to intervene: the use of forceps grew less as experience increased. The delivery of each baby by the family doctor in the patient's home forged a link with that family which bound the family doctor into their lives. "This is something that we are beginning to miss to-day."

Heavy Burden of Anxiety

In those days anxiety weighed heavily upon the family doctor. How difficult it had been to preserve that equanimity which Osler stressed so strongly. "I think it fair to say that the younger generation are unaware of the constant worries and anxieties which never seemed to leave us." The work and the anxiety attendant upon cases of lobar pneumonia was a vivid memory. How difficult were some of these situations for a young doctor, when all the family listened to the assessment of the case. A bad prognosis upset the household and a guarded one often gave rise to doubts of one's ability, as did a request for a second opinion. "In the course of time I have seen so much unpessimistic prognosis due to a doctor's desire to be on the safe side. I think it our duty as family doctors to carry our anxieties in our own hearts, and not needlessly transfer our fears to those less equipped to bear them."

Truthfully, his resources had not differed much from those of his predecessor and his black bag had been almost as bare.

Sulphonamides Arrive

Such was the state of general practice when, suddenly in 1935, the dramatic news came from Germany that Domagk had discovered a chemical called "prontosil." It was unbelievable that a drug had been found which would cure puerperal sepsis. That to him and to others of his generation had been a miracle, and on reflection he still thought it the great divide in therapeutics, the turning-point in the treatment of infectious disease. From 1934 to 1944 the deaths from pneumonia were reduced by half. This was a period that brought great joy to them.

With the sulphonamides, the greatest boon to them had been the establishment in 1940 of the Emergency Public Health Laboratory Service. It gave them the greatest help. The director of the laboratory had encouraged visits to discuss their cases. They had become alive to their new responsibilities in investigating isolated outbreaks of diarrhoea which were so often Sonne dysentery. They were taught that in future the swab and the specimen bottle were essential equipment for their bags, and they quickly realized that it was more profitable to take the specimens to the laboratory than to send them. "I have no doubt that the coming of the laboratory into our midst helped us to become better doctors."

To-day's N.H.S. Practice

Dr. Hughes then turned to the period of the National Health Service. It soon became obvious that their practice would need reorganizing to meet the increased demands upon their time and energy. He and his partners built a new surgery in the centre of the village, employing their own patients for the job. The accommodation included a waiting-room, an office, two consulting-rooms, a minor surgical theatre, and a small dispensary and cloakroom. From this well-equipped surgery they had derived the greatest pleasure and satisfaction in clinical co-operation and consultation, and they believed that the standard of their work had been improved.

What was the state of general practice to-day? Half a dozen doctors would give half a dozen different opinions, but Dr. Hughes hoped that any half-dozen members of the College of General Practitioners would give the same opinion—that general practice was still very much worth while, and that they themselves must assume the responsibility for creating the pattern and maintaining the traditional human relationship. To-day they could give a child an injection of penicillin which would start the process of recovery imme-

diately, and they had a wealth of other drugs and diagnostic aids. The need for the continuous bedside vigil hardly existed. But herein lay a danger to family doctoring. Science had given with one hand, but might she be indirectly taking something away with the other? Were patient and doctor becoming more remote from each other?

Statements suggesting that general practice was deteriorating and attributing this largely to the National Health scheme were, in his opinion, false. That general practitioners to-day may appear less attentive to their patients than their predecessors might be true. But, if so, it was for reasons linked neither with the National Health Service nor with the method of remuneration. It was owing to the confidence given by the newer antibiotics and the certainty that treatment would be effective. But this of itself was a danger. They must never allow their services to become a matter of mechanically prescribing chemical substances, forgetting their art. They must still try to spend more time at the bedside—the biggest event in the patient's day—and they must still consider prognosis, however much altered. If they discounted what they had learnt in their training and emphasized only the therapeutic advances they denied their patients the real purpose of their work. Patients would forgive anything except casual treatment.

BIRMINGHAM MEDICAL INSTITUTE'S NEW HOUSE

ADDRESS BY PROFESSOR ROBERT PLATT, P.R.C.P.

On November 14 the President of the Royal College of Physicians, Professor ROBERT PLATT, opened the Birmingham Medical Institute's new house at 36, Harborne Road, Edgbaston. This is the third house the Institute has possessed since its foundation in 1874. Its first, opened in 1880, was in Edmund Street and provided a commodious library and conference hall. In 1923 this building was sold, and the Institute bought a disused warehouse in Great Charles Street which, after reconstruction, made it adequate and convenient quarters. The Institute's third and present house, which with the necessary rebuilding cost £42,000, is illustrated below. The architects were Messrs. S. T. Walker and Partners, of Birmingham.

The president of the Institute, Dr. H. W. FEATHERSTONE, welcomed the guests. Professor PLATT then surveyed the present revolution in medical science and its attendant new responsibilities. He drew attention to the divergence between general practice and hospital medicine; and finally he restated the role of the Royal College of Physicians in its modern context.

Never a Greater Need for Postgraduate Education

The need for postgraduate education in medicine was greater to-day than at any time since the days of Hippocrates, said Professor Platt. This had nothing whatever to do with the advent of the Health Service, but was the result of the revolution in medical science which had been taking place

[Birmingham Post and Mail]

during the last thirty or forty years. While it was, of course, the therapeutic advances—both in medicine and in surgery—which were the most gratifying, in the same period methods of diagnosis, and indeed the whole application of medical science at the bedside, had been so transformed that a physician of thirty years ago would hardly recognize our language. Specialization had become more and more inevitable and important; but yet old boundaries had been broken down—the distinction between what is medical and what is surgical was less to-day than ever in our history, and the techniques we used brought the biochemist, the physicist, the physician, the surgeon, the psychiatrist, the pathologist, and many others, closer together than ever they were before.

Each new medical discovery, especially a therapeutic discovery, brought with it a new responsibility. So long as a disorder remained intractable its diagnosis was of comparatively little importance; but, once a powerful remedy was in our hands, we had a great responsibility to see that it was used wherever it was needed, that diagnosis was prompt and accurate, and that the remedy was not misused.

Outlook for General Practice

In this new era of medical science it might be thought that the art of medicine was no longer important and that the role of the general practitioner was diminishing in consequence. Both inferences would be entirely wrong. No method of science yet invented helped elicit a medical history or the fears and anxieties in the mind of another human being; nor would science help in explaining to him the investigation and treatment he must undergo for his relief. "I believe that the exciting days of general practice are only just beginning," continued Professor Platt. The next ten years would show more clearly the true role of the practitioner, and the skills he needed. Thirty years ago what the general practitioner did at home was an imitation of what his physician-teachers had been doing in hospital when he was a medical student. To-day we realized—though perhaps some did not realize it enough—that these two branches of medicine had now diverged. It was becoming clear that general practice was a subject in its own right, with its own techniques which were to some extent independent of, or at least complementary to, those of hospital medicine. The physician could still teach the principles and methods of medicine, but was becoming less well equipped to train students for the special role of general practice. "Many teachers I know will deny this, and will claim that general practice is simply an application of medicine and surgery to patients treated in their homes. To an extent this is true, but the same kind of objections could well be raised against the special study of paediatrics and of any other branch of medicine. Yet we do not exclude the paediatrician or the neurologist from our teaching staff."

The present was an interim period until leaders emerged who, besides conducting research in general practice, would set universally recognized standards of practice and education in that subject. There were of course plenty of favourable signs that this was already happening. But the attitude of mind which made the National Health Service the scapegoat for long-existing imperfections in medical practice helped not at all. The responsibility for showing what good general practice could achieve and what part it should play in the new medicine was a professional responsibility. Though this was not to say that the Government had no responsibility in the matter: it had a very big one. Sooner or later the Government must learn that, if the Health Service was to be efficient and first-rate, its cost was likely to rise as the years went on. Medicine had been costing more and more for hundreds of years, and, quite apart from inflation, it would be very peculiar if the plateau of cost had suddenly been reached in 1957.

Royal College of Physicians

Finally, Professor Platt spoke of the Royal College of Physicians. "In my role as president, I am proud to be

the head of an institution which like yours exists for the raising and maintenance of standards of medical practice," he told his audience. That was why the Royal College of Physicians was founded, and why it still existed to-day. That was its only role, its only *raison d'être*.

Dr. ROBERT AITKEN, Vice-Chancellor of Birmingham University, proposed the vote of thanks.

Nova et Vetera

NELSON'S VISITS TO R.C.S.

The latter half of the eighteenth century brought into prominence a curious function of the Company (later Royal College) of Surgeons. "This was to examine the wounds or other disabilities received by members of the Royal Navy and Merchant Service to assess the amount of pension to which the individuals concerned were entitled and to approve the amount spent on surgical treatment." Discussing this in his Thomas Vicary lecture delivered last week,¹ Sir Cecil Wakeley said that the examination was made by members of the Court of Examiners and the reports were sent to the commissioners for sick and hurt seamen. One of the stalwarts examined was Captain John Harvey of the *Brunswick*, who quite early in the battle of the glorious first of June in 1794 had his hand shattered by a musket ball. He bound up his wound in his handkerchief and concealed it from the crew; but soon afterwards he received a splinter from a cannon ball in the small of the back, and his right elbow was also smashed. He was forced to go below, but gave orders that the colours were never to be struck. The French ship attacking the *Brunswick* sank with all on board; but the casualties on the *Brunswick* were no fewer than 150. Harvey died in hospital at Portsmouth a month later; and the sum of £72 4s. 7d. was approved by the examiners for the expenses incurred. A monument to him and to Captain Hutt of the *Queen* was erected at national expense in Westminster Abbey.

Another hero of the first of June, said Sir Cecil Wakeley, was Sir Thomas Pasley of the *Bellerophon*, who lost a leg in the action. The examiners approved an amount of £103 2s. 10d. for surgical expenses. An interesting sequel to this was that a Mr. Davidson, an apothecary of Queen Ann Street East, who attended Sir Thomas Pasley, was summoned before the Court of Examiners on May 7, 1795, for practising without the approval of the Company of Surgeons.

But by far the most outstanding name in the procession of heroes that the College had entertained was that of Lord Nelson. There were records of two visits by him to the Company's premises there in Lincoln's Inn Fields, and these related to the two wounds that he received, to his eye and to his arm.

Nelson received the injury to his eye at the siege of Calvi on July 12, 1794. A shot struck a battery beside him, and sand and stones thrown up bruised his face, especially round the right eye. This possibly caused detachment of the retina, for Nelson lost the sight of this eye, although no injury to the globe was apparent. The loss of his arm was the result of a musket shot through the right elbow, sustained at the siege of Santa Cruz on the night of July 24–25, 1797. Amputation by the circular method was carried out immediately on his return to his flagship *Theseus*. The ship surgeon, Thomas Eshelby, performed the operation and accompanied his patient home to Portsmouth, where they arrived on September 1.

It was about six weeks later, on October 12, that Nelson appeared before a private Court of Examiners at their new

¹ "Surgeons and the Navy," Thomas Vicary lecture delivered at the Royal College of Surgeons on November 14 and published in full in *Ann. roy. Coll. Surg. Engl.*, 1957, 21, 267.

premises in Lincoln's Inn Fields. Nelson had by no means recovered his full health after the amputation, for he wrote to request an appointment at an earlier hour than that suggested, and this possibly accounted for the fact that a special court was held. He apparently did not know that the applicant had to pay a fee of a guinea, for he came without any money at all and was obliged to borrow a guinea from the secretary, Okey Belfour. Incidentally the guinea was repaid and was accompanied by a handsome china tea service. The report of the Examiners was that "the injury received is fully equal to the loss of an eye." No claim for expenses seems to have been made.

Nelson's second visit was on March 1, 1798, for the purpose of gaining approval for the expenses incurred in the "cure" of his arm. Recently there had been found among the manuscripts at the National Maritime Museum the list of these expenses. The first two items on the list proved that it was indeed Thomas Eshelby who performed the operation, a fact that had been assumed but never proved beyond doubt. It showed also that a special consultation was held at which three leading surgeons were present. Two of these, Sir James Earle and Thomas Keate, both served as Masters of the Surgeons' Company, and they were paid a guinea each for their advice on Nelson's injury.

Preparations and Appliances

READING PERISCOPE FOR "IRON LUNG" PATIENTS

Messrs. THEODORE HAMBLIN Ltd. (London, W.1) write: The structure of a Drinker respirator and the necessary attitude of a patient in it preclude him from making direct use of a mechanical page-turner. Recumbent spectacles do not overcome the difficulty. Reading matter for such a patient has thus been restricted almost entirely to that available on microfilm, to be projected on a screen. To permit a page-turner to be used indirectly, we have devised a periscope which is very simple to make from readily available materials. A satisfactory periscope of this kind can most economically be produced by the local handyman, for whose guidance the following notes are submitted.

The diagram shows the basic features: constructional minutiae have deliberately been omitted, as they will be governed by the local choice of materials and by the dimensions of the particular page-turner to be incorporated. There are, however, certain important theoretical considerations.

In theory, surface-silvered mirrors are desirable; but they are expensive and very easily damaged. In practice, ordinary plane mirrors of good quality have been found satisfactory. The two mirrors should be fixed in planes at right angles to each other; the plane of the larger should make an angle of 45 degrees with the plane of the book-bearing surface of the page-turner. These angles should be set with fair accuracy. The other measurements are not critical; those given allow the necessary clearances for the largest book which a page-turner will accommodate. In order to maintain the angles the periscope should be attached either direct to the page-turner or to a framework holding the page-turner. The entire assembly forms a unit, to be placed on a table behind the patient's head.

Because of the folding of the light path, the book must be placed with the top of the page towards the patient's head and inclined with the bottom of the page at the higher level. The position of the page-turner is, of course, dictated by the position of the book. The book-stop must therefore be replaced by a new one, to prevent the book sliding off the opposite edge of the page-turner. The correct slope of the book is achieved by sloping the entire unit, which is therefore hinged to a baseboard. A wing-nut and bolt provide control.

In use, the unit is placed with the small mirror above the patient's nose, about 3 in. (7.5 cm.) from his eyes and comfortably tilted. In order that he may from time to time relax his accommodation, and so that he shall not develop claustrophobic symptoms, the patient should be able to look between the periscope mirrors into the mirror normally attached to the respirator. When reading he will thus adopt an easy, slightly depressed, line of gaze.

FIG. 1

FIG. 2

Although the effective reading distance, about 23 in. (58 cm.), is rather longer than that usually adopted, it nevertheless permits a person with normal visual acuity to read ordinary print in comfort.

The photographs show a reading periscope, made according to the above principles. In this instance, a round mirror, which was to hand, was employed; an oblong one would have been preferable. The arm carrying the small mirror can be pivot upwards on its bolt, a refinement which allows it to swing away from the patient's face if the unit is accidentally knocked.

The Ministry of Pensions and National Insurance has issued another volume of statistics about sickness and injury among the insured working population. It is *Digest of Statistics of Incapacity, 1954–5*. Earlier collections of statistics related to 1950, 1951–2, and 1953–4, the latter being circulated in November, 1955. The statistics are based on medical certificates sent to the Ministry with claims to benefit. They do not include illnesses of two or three days for which no claims are lodged, or sickness in certain persons not eligible to claim. Thus as a measure of the incapacitating sickness of the working population they are incomplete. The introduction to the *Digest* provides such essential information as is necessary to understand the tables.

(as in a case of pheochromocytoma) may be poured into the circulation and pass into the tissues, exerting their activity there, before the kidneys are reached. Under these circumstances the urinary output of aldosterone seems to me to be a very poor measure not only of the adrenal activity but of the whole condition, because the greatest part of the aldosterone and noradrenaline present in the adrenals has been produced some time before and is hoarded in the gland until some acute crisis. This is proved by chemical analysis of Conn's tumour (7,000 μ g.) and pheochromocytoma.

Studies with amphenone by Mach and Muller² in cases of oedema with hyperaldosteronuria have proved that amphenone inhibits the production of aldosterone immediately; in these cases sodium diuresis follows amphenone treatment, while the urinary output of aldosterone diminishes. If the amphenone treatment is stopped, then aldosterone output rises again, sodium retention increases, and oedema reappears. The same thing has been described by Wolfe and co-workers.³ In this way the primary role of aldosterone in sodium and water retention has been firmly established. There is no reason to search for another mechanism. Conditions in pregnancy are complicated by the fact that, while the aldosterone activity of the adrenals is much greater during pregnancy than under conditions of non-pregnancy, the greater part of the product of the adrenal glands is hoarded in those glands and only poured into the circulation during an acute crisis.—I am, etc.,

Amsterdam.

Infants' Feeding-bottles

SIR,—I am writing to express my disapproval of the manner in which increasing numbers of infants are being bottle-fed. It seems that the upright, non-valve bottle is gaining in popularity at the expense of the boat-shaped feeding-bottle. This is resulting in more babies having increasing difficulty in sucking against the growing vacuum as the feed proceeds, which often results in a completely collapsed teat with the rubber sides in fast apposition, with no milk flow at all.

In some shops it is impossible to purchase any feeding-bottle other than the kind I condemn. While on this subject, I am at a loss to understand why the teat manufacturers sell their products with an almost non-existent hole. The dangers of too slow bottle-feeding are incomparably greater than any hypothetical disadvantages of the other extreme. Frustration comes to all of us far too soon in life without its having to be thrust on us in infancy.—I am, etc.,

London, S.W.3.

DAVID J. THOMAS.

Influenza Epidemic

SIR,—Writing as just another general practitioner in the north-west London area, I have been particularly struck by one clinical syndrome which was mentioned only by Dr. R. E. Hope Simpson (*Journal*, November 2, p. 1057). A sore throat due to pharyngitis has been a very striking symptom in this area, especially among the children and adolescents. This has been characterized by no great redness of the tonsils or faucial pillars, but rather by marked hypertrophy of the lymphoid tissue of the posterior pharyngeal wall and almost always associated with a shotty enlargement of the glands along the posterior border of the sternomastoid, often with tenderness and some pain on moving the neck. The adolescents have complained of an intensely sore throat, and say that it is "very low down" and point to the front of their necks behind the thyroid cartilage. This has been one of the common causes of a continued pyrexia, but has usually reacted promptly to penicillin—e.g., penicillin V by mouth. Occasionally they have been hoarse, with an irritable tracheal type of cough. Many have said that

gargling did not help, as it felt "lower down." I have not met this particular syndrome in previous influenza epidemics.

I am sure that the series of reports by general practitioners on their experience of the influenza epidemic have been most helpful and greatly appreciated.—I am, etc.,

Hatch End, Middlesex.

MARTIN STRATFORD.

Mongolism in a Twin

SIR,—I was interested in "Mongolism in a Twin" (*Journal*, November 2, p. 1038), as I had a similar case in 1949.

The parents, who came from healthy country families, were of good average intelligence and in their late twenties. They had a normal daughter in 1947 and again in 1948. In December, 1949, twins were born to them—a normal girl and a boy who was an obvious mongol. The diagnosis was confirmed by the professor of paediatrics at the nearest teaching hospital four months later. When the twins were nearly a year old, all the children in the family developed measles. The girls made an uninterrupted recovery, but the little boy died. Since then the couple have had a further normal daughter.—I am, etc.,

Baddesley Ensor, Warwick.

E. JEAN HIGGIE.

Nylon for the Destructive

SIR,—In mental and mental deficiency hospitals one of the problems is the destruction of clothing by disturbed and overactive patients. Such patients have therefore been clothed in ticking or canvas material. Both these are unsightly and heavy, and ticking loses its efficacy in course of time. The unsightliness and unpleasant associations of these materials leads some patients to regard them as a form of punishment. Their weight is considerable—a canvas suit may weigh over 4 lb. (2 kg.) and a girl's ticking dress over 2 lb. (1 kg.)—and it is likely that their resulting encumbrance may increase or even initiate the destructive efforts of their wearers. Finally, the frequent laundering often necessary restricts the useful life of a ticking dress to under a year in some cases.

With female patients these disadvantages may be overcome by the use of nylon. In St. Lawrence's Hospital two nylon dresses have been made for a patient aged 10 who has persistently torn her clothing to such an extent that even a ticking dress has lasted her less than a day. The nylon dresses have been very satisfactory. They are pleasant in appearance, light, warm, and after two months of use show no signs of wear. The patient has made little if any attempt to tear them, perhaps because of their lightness and lack of encumbrance, and their laundering is simple. The actual material used was dark blue industrial nylon fabric of Y. 1960 quality and manufactured by Courtaulds, Ltd. As it is relatively impervious to water vapour the neckline was made wider than usual, the sleeves short and wide, and with a loosely approximated slit at the upper back. One dress other has a single-layered skirt. The material is not inflammable.—I am, etc.,

Coulston, Surrey.

A. W. GRIFFITHS.

Dislocation of the Jaw

SIR,—Unilateral forward dislocation of the jaw as a result of yawning cannot be a very common occurrence in general practice. When a man phoned me at 2.30 a.m. recently to tell me that he thought his wife had done just this, I was frankly sceptical. I became even more so when he went on to say that his wife had often feared this happening when yawning, even though it had never actually happened to her. This combination of circumstances, I feel sure, must be even more unusual.

On my arrival I found a woman of 30 who had undoubtedly dislocated the right side of her jaw. The dislocation was reduced fairly easily with an audible click and to the instant delight of both patient and doctor. The method

used was the usual one of inserting the thumb into the mouth as far as the angle of the jaw and with the patient in a reclining position. Then pressure was exerted with the thumb in a downward and backward direction while at the same time raising the chin with the fingers of both hands. Over a cup of tea, she confirmed the fact that she had always dreaded dislocating her jaw with yawning since she had been a girl of 17, when she had an uncomfortable feeling of nearly having done it. She had dreaded having teeth extracted, and had been regarded at home, and subsequently by her husband, as rather a crank, as she would often sleep with her jaw tied up with a head-scarf. No doubt now she will be justified in continuing to do so in future.—I am, etc.,

Hull.

M. S. SANDERS.

Patients Seen in Casualty Department

SIR,—The analysis of symptoms and diagnosis among patients attending a casualty department reported by Dr. P. Mestitz (*Journal*, November 9, p. 1108) is interesting and valuable. It adds yet another study to our knowledge of the patterns of illness in various population groups. His figures show that some 27% of the patients coming up to a casualty department for help suffer from a stress disorder. This proportion is rather higher than that for urban general practice,¹ but lower than has been found in a large industrial office.² Dr. Mestitz comments that relatively fewer patients complained of symptoms in the psychiatric sphere, such as depression and irritability, than in Pougher's³ series; this difference may be due to the cultural characteristics of the group under review. In general, it seems to be true that stress tends to manifest itself by psychiatric symptoms in the more intelligent and sophisticated, and by physical symptoms in the less articulate.

The author underlines the importance of pain as a presenting symptom. In a survey by Morris and myself of a random sample of women attending a gynaecological outpatient clinic, the largest single division (about one-third) gave pain as a leading symptom, and of these only a few had any "organic" disorder. The rest showed the clinical picture of tension pain,⁴ and I agree with Dr. Mestitz that its treatment is difficult and unsatisfactory. This is probably because many patients with tension pain utilize their illness in one way or another. I am in process of collecting data on the varying incidence of stress disorder in our society. May I say, Sir, through your columns, that I should be most grateful to have a note of any observations which other workers in this field may have made?—I am, etc.,

Detention of Voluntary Patients

SIR,—Dr. W. Lindesay Neustatter, I believe, is correct in assuming (*Journal*, October 19, p. 944) that a contract of service and care is established whenever a voluntary patient signs one of the statutory forms, whereby it can be argued that, if the signatory patient be not detained 72 hours after having given his notice to leave hospital and thereafter is the subject of an untoward incident, the patient or next of kin might be in a position to bring an action for damages against the psychiatrist concerned. The psychiatrist would presumably claim in his defence that he was applying common sense in not affronting the patient, and had shown skill in allowing the patient to depart. I imagine that it is no use trying to make something which is absurd sound, sensible, and of course the present statute is utterly absurd. Dr. Neustatter's fastidious coroner should try the effect of forcing patients to remain 72 hours in hospital. Were he ever to be in this unenviable position would he not in

turn be exposed to a different type of assault at law, whereby others might seek to prove that by detaining the patient harm had been done to the mental state of the patient?

I would suggest that one way out of the present absurd position is to alter the statutory form so that the patient applies to the secretary of the management committee to enter the hospital concerned. The management committee could then take the full responsibility of the matter, and when the patient decides he wishes to leave his notice of discharge should be sent to the management committee for further consideration, pending which the psychiatrist could exercise his undoubted ethical and, I suggest, legal right to do what he thought was best for his patient under the particular circumstances. All absurdities are based on false premises, which in this instance is the assumption that any patient is likely, truly, to volunteer to be locked up and detained for 72 hours after having expressed a desire to leave. In spite, therefore, of the undoubted good which this clause in the Mental Treatment Act procured for sick people, it is based on illogicality, and, more important still, insincerity.

I very much fear that Dr. Neustatter and his fastidious coroner could be a source of very grave embarrassment to management committees in having given publicity to this matter.—I am, etc.,

St. Albans.

HAROLD PALMER.

Chlorpromazine Jaundice

SIR,—With reference to the letter from Dr. T. A. Lambo (*Journal*, November 2, p. 1048), I have used chlorpromazine in the treatment of mental patients in Malaya for approximately three years but have not seen a case of jaundice attributable to this drug. The nationalities of the patients were Chinese, Malay, Indian, and Eurasian, and the total number treated was approximately 600. No case of jaundice has been seen in patients treated by other doctors in the two mental hospitals in Malaya, and physicians whom I asked about the incidence of jaundice due to chlorpromazine stated that they had never seen a case in a non-European, although they had used it for such widely differing conditions as pain due to inoperable carcinoma and hyperemesis gravidarum. So far as I was able to ascertain, up to the end of 1956 there had not been any cases of chlorpromazine jaundice in non-Europeans in Malaya, although the number treated must have run into several thousands. This would seem to support the suggestion that there is a racial difference in sensitivity to chlorpromazine.—I am, etc.,

Bristol, 6.

V. O. G. SMYTH.

"Hypercapnoea"

SIR,—This spelling mistake, which can lead to confusion, occurs frequently in the literature of anaesthesia and respiration. All the words ending in "pnoea" describe kinds of breathing, as hyperpnoea, tachypnoea, apnoea. Numerous other words which end in "ia" describe conditions existing in the blood or tissues, as hypoxia, asphyxia, anaemia. Among these is hypercapnia.—I am, etc.,

Cambridge.

H. R. YOUNGMAN.

Poliomyelitis in West Africa

SIR,—I would suggest that a "priority" class for poliomyelitis vaccination is persons going to West Africa, and probably other tropical areas. I cannot recall that actual epidemics of poliomyelitis have been recorded in West Africa, but in any hospital or large private practice there has always been a steady trickle of cases; and in any big city market dozens of old poliomyelitis paralyses and deformities at all ages may be seen. Recently, during two months' relieving in a Kumasi practice, I passed on four probable cases to the hospital.

Before the war I do not remember hearing of any European deaths: we of that era grew up in filth, as it were,

and were probably immune. But during the later years of the war, and subsequently, they have frequently been reported. A very recent example was Dr. Pointon Dick, tuberculosis specialist, Ghana, whose obituary was published in your columns (*Journal*, August 4, 1956, p. 305). Poliomyelitis would now seem to be a greater danger than any other single disease: more so than would be yellow fever (which used to spread such terror), even in the absence of vaccination.—I am, etc.,

Bristol, 8.

GEORGE L. ALEXANDER.

Prognosis of Intermittent Claudication

SIR,—It is interesting to compare the results of a recent follow-up of Professor A. Kekwick's series of patients suffering from intermittent claudication with those published by Dr. R. L. Richards (*Journal*, November 9, p. 1091). Definite information was obtained about 103 of the 125 patients originally seen on the medical unit of the Middlesex Hospital during the years 1948–52. Thirty-seven deaths had occurred, 17 from cardiovascular disease (coronary thrombosis or presumed coronary thrombosis 13, cerebral thrombosis 1, mesenteric thrombosis 1, dissecting aneurysm 1, hypertensive cardiac failure 1), 10 from other causes, and 10 from causes unknown.

Age at Onset of Intermittent Claudication	125 Patients	Satisfactory Follow-up (103 Patients)	No. of Cardiovascular Deaths (17 Patients)	Total No. of Deaths (37 Patients)	(Average) Age at Cardiovascular Death
25–29 ..	3	2	0	0	—
30–34 ..	4	3	1	1	52
35–39 ..	1	1	1	1	42
40–44 ..	8	6	0	0	—
45–49 ..	9	9	0	2	—
50–54 ..	20	19	8	9	56.5
55–59 ..	26	20	1	8	64
60–64 ..	28	23	2	7	66.5
65–69 ..	17	13	4	6	71
70–74 ..	7	6	0	3	—
75 and over ..	2	1	0	0	—

It can be seen that, although the peak incidence of the onset of the disease in these patients falls in the 60–64 age group, the greatest proportion of cardiovascular deaths occurs in those whose symptoms first appear in the early fifties. Claudication was originally unilateral in 9, and hypertension was present in 5 of those subsequently dying from cardiovascular disease. The mean duration of claudication in the surviving 66 patients was 7.9 years.—I am, etc.,

London, W.1.

H. E. D. LLOYD.

Intratracheal Intubation in Newborn

SIR,—Although it is common practice to administer oxygen into the stomach of newborn infants in an attempt to relieve anoxia, we are not at all impressed that it does any good. We feel that any success derived from this method stems from the regurgitation of oxygen into the pharynx and its subsequent uptake by the lungs, and that the same result could be more easily achieved by the use of an oxygen tent or nasal catheter.

So firmly has the intragastric route established itself that the much more reasonable intratracheal route is sometimes neglected—indeed, many deprecate tracheal insufflation except as a last resort, when it may well be too late to restore the infant. We believe that skilfully employed intratracheal intubation, combined with oxygen under intermittent positive pressure using a Seward valve, which ensures that dangerous inflationary pressures are not exceeded, and the use of suction, to be a very valuable method of resuscitation in severe cases of white asphyxia. This we regard as the method of choice for the severely asphyxiated child, and contend that the use of intragastric oxygen for these cases merely wastes valuable time.—We are etc.,

E. ARTHUR WILLIAMS.
DEREK PRYER.

Oxford.

Tabulating Data

SIR,—Like Dr. B. Lennox (*Journal*, September 28, p. 766), we too read with interest the article by Dr. C. N. Smyth and Mr. M. N. Bainbridge (*Journal*, September 14, p. 619), because a table such as they describe could be adapted to various uses. We are not statisticians, and therefore expected to have difficulty with the section on “statistical test” (p. 622); but we feel impelled to protest against the unworthy devices whereby the appropriate complexity of this section was ultimately achieved. One can (almost) admire the playful manner in which the authors, having carefully drawn attention to a 2×2 table containing a notation restricted to “b, not b, d, not d,” suddenly produce without further explanation an equation wherein apparently “a” has been substituted for “b” throughout; but we cannot so readily excuse the crude method adopted to ensure that their equation defies comprehension. If “Na” had to be given two different values in the one equation ($\frac{Nb}{Na} - \frac{Nb}{N}$ in one column = $\frac{2}{213} - \frac{33}{2324}$ in the next) surely this little modification might have been concealed more skilfully from the vulgar gaze?

The authors give two 2×2 tables in close proximity, which we consider could justifiably be combined thus:

	Forceps (d)	Not Forceps (not d)	Total
Stillbirths (b)	2 (Nbd)	31	33 (Nb)
Not stillbirths (not b)	211	2,080	2,291
Total	213 (Nd)	2,111	2,324 (N)

If we assume, as we must to retain our sanity, that in their equation “a” has somehow become substituted for “b,” and if we write the equation as we feel that it might have been written:

$$U = \frac{\frac{Nb}{Nb} - \frac{Nb}{N}}{\sqrt{\frac{Nb}{N} \left(1 - \frac{Nb}{N}\right) \left(\frac{1}{Nb} - \frac{1}{N}\right)}}$$

Then, replacing these letters by the corresponding figures from the table:

$$U = \frac{\frac{2}{33} - \frac{33}{2324}}{\sqrt{\frac{2}{2324} \left(1 - \frac{2}{2324}\right) \left(\frac{1}{33} - \frac{1}{2324}\right)}}$$

These fractions are very different from those actually given by the authors, and derived from the same 2×2 tables, which were:

$$U = \frac{\frac{2}{213} - \frac{33}{2324}}{\sqrt{\frac{33}{2324} \left(1 - \frac{33}{2324}\right) \left(\frac{1}{213} - \frac{1}{2324}\right)}}$$

A careful reading of the text reveals that the numerator of the equation probably should be written

$$\frac{Nb}{Nd} - \frac{Nb}{N} = \left(\frac{2}{213} - \frac{33}{2324}\right)$$

but speculation on the proper notation of the denominator is beyond us. We can but suggest that the punishment should fit the crime, and that the authors should be made to explain what the correct version really is.—We are, etc.,

T. WILSON.

A. T. H. MARSDEN.

Kuala Lumpur.

Misnamed Stethoscope

SIR,—I feel sure that somewhere there is a frock-coated ghost longing for a word to be written in defence of his quite correct, and most elegant, brain-child, the word “stethoscope.” Liddell and Scott¹ have nearly a column of erudition under the heading *σχορῶω*, and near the beginning of it is the translation “to contemplate, to examine”; so why try to improve on this excellent descriptive term for an instrument for the examination of the chest?

While on the subject, may I also put in a plea to have nothing to do with the (incorrect) odious Americanism

Obituary

RONALD S. PATON, M.B., Ch.B.

Dr. Ronald S. Paton, one of Perth's best-known general practitioners, died on October 22 at the age of 58.

The son of a general practitioner in the city, Ronald Stewart Paton was born at Perth on February 19, 1899, and was educated at Perth Academy, where he was dux of his year. At the age of 16, having gained a high place in the entrance bursary competition, he matriculated at St. Andrews University, where he took the M.A. in 1918 and the M.B., Ch.B., with distinction, in 1921. His first post was as a physiology department of the university under Professor P. T. Herring. Thereafter he held resident posts at Perth Royal Infirmary and the National Hospital, Queen Square, London. Following a voyage to the Far East as a ship surgeon, he returned to Perth, where he settled in practice with his father, Dr. E. L. Paton, who died in 1933. Dr. Ronald Paton was clinical pathologist to Perth Royal Infirmary for over thirty years, and honorary physician to the infirmary from 1933 to 1946. He was also medical officer to Perth Prison; deputy medical superintendent, later superintendent, of the Criminal Lunatic Department, Perth; medical officer to the Perth Hunt; and medical officer, Perth centre of the Blood Transfusion Service. From the start of his career he was keenly interested in local medical affairs. He served for many years on the council of the Perth Branch of the British Medical Association, of which he was president in 1936–7, and which he represented at the Annual Representative Meeting for six years. A member of the local medical and panel committee for many years, he was an original member of the local medical committee and of the executive council.

J. K. writes: “Ronnie,” as Ronald Paton was universally known to friends and patients alike, was a cultured man of wide interests. He was extremely well read, in both classical and medical literature, and interested in the theatre, particularly drama. His work was influenced by his training in physiology, and he was a keen exponent of physical fitness. In his early days he was a good tennis player, and throughout his life was an enthusiastic if somewhat unpredictable golfer. His attractive and colourful personality appealed to a wide range of patients, in whose service he was cheerfully unsparing of himself. He was a very human man, of great understanding and with a great sense of humour. At meetings he could hold firmly to his opinions, not infrequently as a “champion of lost causes,” but withal he was kindly, generous, and of wise counsel. His death has left a gap in the ranks of the profession in the area which it will be hard to fill. He is survived by his widow, a daughter, and a son recently qualified in medicine and now on National Service.

F. DOUGLAS TURNER, C.B.E., M.B.

Dr. F. Douglas Turner, formerly medical superintendent of the Royal Eastern Counties Institution, Colchester, died on November 1. He was 86 years of age.

Born at Colchester on October 7, 1871, Frank Douglas Turner was educated at the Colchester Royal Grammar School and at the Moravian School at Neuwied, in Germany. He studied medicine at Guy's Hospital, qualifying M.R.C.S., L.R.C.P. in 1899, taking the London M.B. in the following year. After qualification he held a number of house appointments at Guy's Hospital, and then, for a few years, was in general practice at Huddersfield. He returned to Colchester in 1905 to take up the appointment of medical officer at the Royal Eastern Counties Institution, which was then a private institution for mental defectives under the superintendence of his father, John J. C. Turner, and

“appendectomy” as opposed to the correct original form “appendicectomy”? Our professional forerunners of the nineteenth century may have been shaky on “scientific” medicine as we understand it to-day, but their classical learning was pretty sound, and I think that if we start criticizing it at the present time we are very liable to run into trouble.—I am, etc.,

J. N. FELL.

Colchester.

Drug Firm Representatives

SIR,—Have you ever estimated how many firms send representatives to G.P.s? What would you guess—a dozen, perhaps a score? I have this week had occasion to congratulate the representative from an American firm on being the fortieth to visit me on one or more occasions in less than two years. Perhaps I am over-cynical, but who has benefited from these interviews (of varying length)? Surely the firms concerned, since they pay their employees for doing the work. I find I learn very little myself, as I read their notices in the press and the mail, and proprietary therapeutics is a very small part of my general practice. On the other hand, I have lost a lot in time, during which I might catch up with some unbiased reading, or finish my surgery earlier, or even relax. I have sometimes been a worse doctor due to my suppressed annoyance.

Some people (myself included) now insist on a 'phoned appointment, whereas others have a charity box on the desk (does the “rep” or the firm pay?). The Americans expect a private consultation fee—this might sugar the pill over here. What do other doctors think?—I am, etc.,

D. J. ADDERLEY.

London, S.E.13.

Royal College of Surgeons Annual Meeting

SIR,—I would like to bring to the attention of your readers the programme for the annual meeting of the Royal College of Surgeons of England to be held in the College on Wednesday, December 11. Last year the Council was very gratified by the interest which was shown in the annual meeting, and it is hoped that there will be a similar response this year.

The scientific programme is designed to be of special interest to the general practitioner as well as to the surgeon, and a cordial invitation is extended to any member of the profession to attend the scientific films and demonstrations and the lectures, including the Bradshaw Lecture. The programme, a detailed copy of which may be obtained from the secretary of the College, includes two lectures which form part of the postgraduate course in the basic medical sciences (a lecture on the pelvis from 9.30 a.m.–10.15 a.m., and a lecture on the physiology of pain from 11.30 a.m.–12.15 p.m.): a programme of short scientific films of general interest (10.15 a.m.–10.45 a.m., and 12.15 p.m.–2.15 p.m.): demonstrations of the current research work in the College departments of pharmacology, pathology, physiology, anatomy, ophthalmology, dental science, and anaesthetics (from 10 a.m.–11.30 a.m., 12.30 p.m.–2.30 p.m., and 4.30 p.m.–5.30 p.m.) and the Bradshaw Lecture by Sir Russell Brock on “The Present Position of Cardiac Surgery” from 2.30 p.m.–3.30 p.m. In addition, fellows and members will hear an account of the activities of the College at the statutory annual meeting of fellows and members at 3.30 p.m. and will have the opportunity to discuss these and submit motions to the meeting. The day's events will end with a monthly subscription dinner at 7.30 p.m., for which tickets may be purchased from the deputy secretary.

I hope that as many as possible of your readers will join us in the College on December 11, and we can promise them a warm welcome and something of interest to every one of them. Next year the annual meeting will be held in Cardiff on September 27.—I am, etc.,

J. PATERSON ROSS,

President.

Royal College of Surgeons of England.

London, W.C.2.

entirely dependent on voluntary contributions. On the death of his father in 1914 he succeeded him as medical superintendent.

E. B. writes: Frank Douglas Turner devoted his whole energies to the care of the mentally defective of all grades and ages. Over a period of years he expanded the original institution and developed several branches and schools, increasing the number of beds from 200 to 1,800. His guiding principle was "the patient always first," and nothing was allowed to override that golden rule. No effort was too great, and everything was directed to that one goal—the welfare of the patient.

Turner was the first doctor in the British Isles to devise a programme of training defectives with a view to their full rehabilitation as useful members of the community. The institution was no longer to be a "stagnant pool," a place where patients were "put away"; instead it became a hive of industry and a training centre for the educationally subnormal and the high-grade defective. Turner instituted a system of licensing patients out to work under sheltered conditions, and as conduct improved and self-respect was gained licence was terminated and patients were re-established in the community, to lead active lives and do useful work. This was an innovation, and in spite of all gloomy forebodings the system worked and proved successful. Turner was indeed a pioneer, and thousands of patients all over the country have benefited from his progressive and humanitarian outlook. "Licence" soon spread to other institutions; visitors from overseas flocked to Colchester, and the Royal Eastern Counties Institution was acknowledged to be in the lead in this field of treatment of the subnormal.

An able and energetic administrator, Turner was a convincing and persuasive speaker and an active member of many medical committees. He was always well informed, patient, and courteous, and he spoke with authority. He took a leading part in the proceedings of the Royal Medico-Psychological Association for many years and was elected president in 1933. Appointed C.B.E. in 1942, he retired in 1945 owing to ill-health, at the age of 74. His wife predeceased him, and he is survived by his brother, Major A. Turner. Frank Douglas Turner's kindness endeared him to his patients and colleagues, and he will be remembered for his charming personality, humane disposition, wise counsel, and his selfless devotion to the mentally weak. He gave of his best at all times.

F. R. CAWTHORN, O.B.E., M.B., B.S.

Dr. F. R. Cawthorn died at Mooropna, Victoria, Australia, on May 31 at the age of 48.

Frank Raymond Cawthorn was born at Melbourne on July 7, 1908, and graduated M.B., B.S., from Melbourne University in 1931. He served for one year as resident medical officer at the Royal Melbourne Hospital, and then proceeded to England, where he joined the Indian Medical Service. During preliminary training at the R.A.M.C. College at Millbank he won the prize in hygiene. He served in various military hospitals at Quetta and other places in India, and later was transferred to the civil branch of the Service and was civil surgeon and medical officer of health, Zhob, and agency surgeon and medical officer of health, Kurram Valley. He was trained as a specialist in radiology and had the distinction of being one of the few medical officers who attended the staff college at Quetta. On the outbreak of war in 1939 he was recalled to military service, and commanded the 52nd Combined Indian General Hospital of 1,000 beds in Burma and later became assistant director medical services of a division. His highly competent administration and cheerfulness, energy, and devotion to duty during a prolonged period of intense strain resulted in him being twice mentioned in dispatches, and he was appointed O.B.E. in 1945. Compulsorily retired from the I.M.S. on the partition of India, he returned to Australia and at first took up duty as a medical officer in the

Commonwealth Health Department. He then went into private practice at Singapore, but again returned to Australia, and went into private practice with a medical group at Ferntree Gully, Victoria. The strain of long-continued service in tropical regions left a debt against his health, which later failed. An attack of coronary occlusion forced him to abandon the rigors of private practice in a mountain area, and he was appointed medical superintendent of the Mooropna Base Hospital, where his energy, skilful administration, and cheerfulness as usual won him many friends. His sudden collapse and death during a hospital meeting terminated a versatile and colourful career. In former years he had been a prominent all-round athlete and had represented his university with success as a boxer. The deepest sympathy of all his former colleagues and friends is extended to his widow and two sons.—F. S.

RACHEL E. PORTER, M.B., B.Ch.

Dr. Rachel Porter, who practised in Gillingham, Kent, died on August 30 at the age of 58.

Rachel Elizabeth Porter was born at Castlederg, County Tyrone, on July 19, 1899. She was educated at Coleraine High School and obtained a scholarship to Trinity College, Dublin, which she entered in 1919. After graduating M.B., B.Ch. in 1926, she held an assistantship in South Wales, and in 1930 joined her friend and fellow-student, Dr. Agnes L. Kelly, in partnership at Gillingham, where she continued in practice until her death. Rachel Porter was a general practitioner in the best tradition. Skilful and competent, she was a friend to her patients. A striking trait of her character was compassion. She could be outspoken, but she never hurt. Gifted with a keen sense of humour, she loved telling stories against herself. She never spared herself, and, in spite of illness, died in harness. Her patients, friends, and colleagues will miss her.—I. W.

R. A. STRUTHERS, M.D., M.R.C.O.G.

Dr. R. A. Struthers, senior registrar in obstetrics and gynaecology under the Oxford Regional Hospital Board, died in a car accident on October 13. He was 37 years of age.

Ronald Anderson Struthers was born on July 6, 1920, the son of Dr. John A. Struthers, of Liverpool. During the second world war he served as a fighter pilot in the R.A.F. and then went up to Emmanuel College, Cambridge, to study medicine. He received his clinical training at St. Bartholomew's Hospital and graduated M.B., B.Chir. in 1949. He took the M.R.C.O.G. in 1953 and proceeded to the M.D. two years later. After graduation he held the appointments of house-surgeon, gynaecological house-surgeon, and registrar to the obstetrics and gynaecology department at St. Bartholomew's Hospital. Later he was appointed registrar in obstetrics and gynaecology under the Oxford Regional Hospital Board, working first at Oxford and then at Northampton. More recently he had been senior registrar at Oxford. His wife, formerly Miss Jean Brewer, died in 1954.

J. S. writes: The death of Ron Struthers in a motor accident on October 13 came as a tragic reminder to his many friends of the uncertainty of life. The first time I met Ron was when he successfully appeared before an appointment committee when applying from his teaching hospital, St. Bartholomew's, for a registrar post in the Oxford region. His modesty over his war record of combatant duties as a pilot in the R.A.F. was quickly appreciated by all members of the committee, and it was not surprising that with a good professional record and the unreserved support of his London teachers and chiefs he was appointed against strong opposition. At first Ron found it a little difficult to acclimatize himself to the demands of his new work at Oxford and later at Northampton. Anxieties over the illness of his wife, who died while he was at Northampton,

made things more difficult, but with characteristic courage he settled into his new work, and with the passing months became progressively happier. When he returned to Oxford after two years at Northampton to take the position of senior registrar his many fine qualities were immediately apparent. He was always in control of the situation, and his calmness and kindness were infectious. Patients loved him, and his medical colleagues and the nursing staff found him a most delightful member of the team. His integrity was above reproach, and there was no place for the second best in anything he did. Those of us who knew him well miss him greatly, and will long remember with affection and appreciation a fine gentleman and a doctor who was naturally endowed to render great service in the specialty he had chosen.

M. A. MILNE, M.B., Ch.B.

Dr. Mearns A. Milne, who was in practice for forty years at Montrose, Angus, died at Milltimber, Aberdeenshire, on October 23. He was 74 years of age.

Mearns Alexander Milne was born on December 12, 1882, and attended Aberdeen University, where he graduated M.B., Ch.B. in 1906. He went to Montrose in 1907 and, apart from three years' service in the first world war, was continuously in practice there until he retired in 1946. As a captain in the R.A.M.C. he served in France and also in the hospital ship in the Mediterranean area, taking part in the Dardanelles campaign. After the war, having succeeded Dr. Robert Soutar, he was appointed an honorary physician to the Montrose Royal Infirmary, and other appointments which he held included those of police surgeon, parish medical officer, medical officer to the old isolation hospital and to Lossie reform school. He was for many years keenly interested in the St. John Ambulance Association. An all-round sportsman, in his younger days he excelled at cricket and in later years played bowls and golf, being a past captain of the Montrose Royal Albert golf club. He also enjoyed fishing and shooting.

H. W. B. writes: To me, as his successor in practice, Mearns Milne acted as teacher and adviser during my introduction. I found him most helpful and kind and very generous. He had a keen sense of humour—the pawky humour of these parts. He was highly respected by his patients and in particular will be remembered by the fisher people of the village of Ferryden, where he was "club" doctor. Devoted to all aspects of his work, I found him most interested in the older people, to whom he gave great comfort and understanding. He was a keen musician and an excellent story-teller, his reminiscences of practice in years past being most entertaining. Our sympathy goes out to his widow, three daughters, and one son, the latter being a consultant chest surgeon in Bristol.

EDMOND GRASSET, M.D.

Professor Edmond Grasset, professor of bacteriology and preventive medicine in the University of Geneva and director of its Institute of Hygiene and Bacteriology, died in Geneva on October 30. He was 62 years of age.

Edmond-Louis Grasset was born in Geneva on September 29, 1895, and received his medical education at Geneva University, graduating M.D. in 1921. From 1922 to 1927 he was a research fellow at the Pasteur Institute, Paris, and was then appointed organizer and head of the serum department of the South African Institute for Medical Research, Johannesburg. His services there were recognized by the award of the honorary degree of D.Sc. by the university. He was a member of the International Committee of the Red Cross and acted as its delegate in South Africa during the second world war. He returned to Geneva in 1946 to take up the posts which he held at the time of his death. Grasset was a member of the World Health Organization's

Expert Committee on Biological Standardization, latterly serving as its chairman. He presided over the fourth international congress on poliomyelitis, which took place in Geneva last July. His many contributions to scientific literature consisted principally of papers on microbiology and serology.

J. C. GLEN, L.R.C.P.&S.Ed.

Dr. J. C. Glen, who was in practice at Gosport, Hampshire, for many years, died at Lee-on-Solent on October 26.

John Craven Glen was born on December 18, 1873, and studied medicine at Glasgow, taking the Scottish triple qualification in 1895. He then worked for a number of years at South Bank, Middlesbrough, but ill-health led him to take a practice at Bournemouth until the first world war. After serving as a captain in the R.A.M.C. he settled at Gosport, retiring in 1935. He was a lifelong member of the St. John Ambulance Brigade and the British Red Cross Society, and was one of the founders of the Gosport War Memorial Hospital.—J. E.

Sir ARTHUR DE SILVA, K.C.M.G., C.B.E. F.R.C.S.

The obituary of Sir Arthur de Silva was printed in the *Journal* of October 5 (p. 830).

Lieutenant-Colonel ERNEST SOYSA writes from Colombo: Ceylonese excel in the medical and legal professions. It was perhaps well for Ceylon that Arthur Marcellus de Silva missed by four marks the Government University Scholarship in 1898. Had that scholarship led him to Oxford or Cambridge he might have become, in accordance with prevailing custom, a judge or civil servant, but Ceylon would not have had the brilliant surgeon who was turned out in London. He was the first Ceylonese to become a Fellow of the Royal College of Surgeons of England, being admitted to the Fellowship at his first attempt and at the age of 25. A keen student of the science of medicine, he became a masterly practitioner in the art of surgery. His abiding interest in medicine stemmed from an initial experience as assistant to a general practitioner in the West End of London and later as junior physician at the General Hospital, Colombo.

A well-travelled man, he garnered a rich harvest of knowledge from the surgical clinics of Europe and America. His ability as an oto-rhino-laryngologist was recognized by foreign colleagues of world renown. His services were sought by patients from Africa to Australia, and Ceylonese who journeyed to foreign clinics for expert advice were asked why they had come so far when they had in their own country a specialist of the eminence of A. M. de Silva. He fashioned his operative technique to be in tune with the anaesthetic in surgery. Minimal incisions, bleeding, and handling of tissues, neatness, rapidity, and dexterity characterized his work. He rarely spoke in the theatre, and what little he said was never a rebuke or reprimand. His placidity and good temper never deserted him even when faced with aggravating provocation. Never did he expose a patient to danger for the sake of adding to his dramatic surgical triumphs, but he did not shrink from taking legitimate risks to safeguard life.

A. M. de Silva might have made a significant contribution to surgical literature from his experience of half a century, but modesty discouraged him from writing of his own opinions or work. His contribution to the alleviation of suffering among the poor and needy was his life's work, a contribution made, not only through his own labours in the General Hospital of Colombo, but also by training his pupils in the way he had trained himself. He had by wise counsel and practical guidance imparted his knowledge and technique so admirably to his pupils that Ceylonese to-day are

in the forefront of the surgical world. His prowess transcended the confines of diagnostic brilliance, operative skill, and tutorial ability. It was distinguished by quiet confidence and breadth of vision. Scrupulous care for the lesser details ensured that the greater aggregates would be safe in his hands. His students learned from him not only surgery but also human kindness. As an examiner he was reputed to be strict, but he preferred to assess a candidate's knowledge rather than probe the depths of his ignorance. He has passed on full of years and dignity, having mellowed the traditions of national service with his example of appropriateness in all things. Great men do not know they are great. Such a man was Sir Arthur Marcellus de Silva, surgeon, humanitarian, and gentleman.

J. S. MAXWELL, M.B., F.R.C.S.Ed.

The obituary of Mr. J. S. Maxwell was printed in the *Journal* of October 19 (p. 946).

N.G.C.H. writes: Anyone who knew John Maxwell must have read of his death with the feeling that humanity had suddenly become the poorer. Personal loss of this sort, particularly the loss of a man young in years and spirit, makes objective judgment difficult, but here, surely, was a life exceptionally endowed and modestly lived.

I do not think enough general recognition has been given to the contribution which Maxwell made to raising the standard of surgical care in India during the war, particularly in the building up, in 128 I.B.G.H. in Secunderabad, of a service covering 1,000 orthopaedic beds that was of the standard of a teaching hospital at home. At any time this would have been something of a feat: in the face of shortages of equipment in an India still clinging to the niceties of a peacetime medical administration, it was little short of miraculous. Certainly he was fortunate in his commanding officer, and in the consultant surgeons to India Command and to Southern Army; but the creation of a centre adequate for the needs of the worst of the Burma wounded was largely his doing, and few others could have achieved it.

In his work he showed a combination of attitudes that one would like to think were peculiarly Scottish. Supremely competent, supremely self-effacing in his contacts with his patients, he would yet show neither tolerance nor regard for anything or anybody that stood in the way of their treatment. There can have been few more enlivening spectacles in wartime India than his preparing to deal with any administrative bumbledom, particularly that entrenched obstructionism of the higher ranks that is the despair of lesser folk. If his antagonists then found him scornful, or even arrogant, it was the arrogance of one who knows, humbly, that he is speaking for the traditions of his profession and for the interests of the sick.

There are two qualities, says Eric Linklater, that are becoming in a man—a fine scorn in youth, and a deep humility in age. John Maxwell had both these throughout his professional life, and it was they, tempered by his sense of fun, that illumined his work and his personality, and made him so inspiring a teacher and so generous a colleague. It is the greater pity, when he had so much to offer by example to the young surgeon, that his opportunities were so limited and his time so short.

J. P. HUBAN, C.S.I., O.B.E., M.B., B.Ch.

The obituary of Major-General J. P. Huban was printed in the *Journal* of October 5 (p. 830).

Major-General S. L. BHATIA, I.M.S. (retired), writes from Bangalore, India: I was grieved to hear of the sad demise of my friend Major-General J. P. Huban. I knew him well. During the course of service in the I.M.S. I succeeded him twice, once as additional deputy director-general in New Delhi in 1941, and subsequently as surgeon-general with the Government of Madras in 1947. He was a man of great

integrity of character, an able officer, and always most friendly and courteous towards his colleagues. I had the highest respect and regard for him. All those who knew him will always cherish his memory with great affection.

G. H. COLT, M.B., F.R.C.S.

The obituary of Mr. G. H. Colt was printed in the *Journal* of November 9 (p. 1118).

F.C. writes: I should like to add a personal note of George Herbert Colt to your obituary, as I had known him for fifty years or more. He had an original and fertile brain and was frequently introducing work-saving methods and appliances both in his professional work and in his many hobbies. After holding a house-surgeonship at St. Bartholomew's Hospital he became a junior anaesthetist to the hospital, a specialty in which he excelled, owing, no doubt, to his mechanical ability apart from his wide knowledge of medicine and surgery, and many, including myself, are grateful for the practical help he gave us. From anaesthesia, like a few others lost to this specialty, he passed to surgery, and was appointed lecturer in clinical surgery to Aberdeen University. Some twenty-five years later he returned to London and practised at Harley Street, when I renewed his acquaintance. Colt was a good mechanic and always acquired a workroom near at hand; even while in Harley Street he rented a room in the city which he converted into a workroom and went there as opportunity offered. This workroom was destroyed by enemy action during the second world war; but, not to be frustrated, he acquired a workroom at Gerrards Cross, at Hampstead, and later at Chilworth, Surrey, his places of residence.

Colt had a lovable and sympathetic nature and was always doing kindnesses, usually without any monetary reward. He never considered his own health, which was not too good, for he had often been seriously ill, having contracted double pneumonia in 1918 during the influenza epidemic, and some three or four years ago he again contracted pneumonia while suffering from diabetes. He appeared to ignore the diabetes, apart from the daily insulin injections. The death of his second wife, formerly a Miss Constance White, saddened his life, and I think, contributed to his own death a few months later, for anyone who had known this talented and beautiful character would fully appreciate his grief. Colt lived a very active life and would have been a bad invalid, as he could not tolerate inactivity. To die in his shoes, as he often expressed it, would have been his wish. On the day before his death he went to London as usual. I saw Colt on the Sunday before his death, when he walked up some four or five hundred feet to St. Martha's Church on the South Downs near Newlands Corner to attend morning service and to visit his wife's grave. He was buried there some ten days later.

J. B. DUNLOP, O.B.E., M.B., B.Chir.

The obituary of Dr. J. B. Dunlop was printed in the *Journal* of November 9 (p. 1120).

R. L. L. writes: Dr. J. B. Dunlop was one of the two most erudite medical men I have had the fortune to know. He was a classical scholar of his college, and to the end of his days maintained a keen interest in classical scholarship. It was not at all unusual for him to refer a patient to one's out-patient session with a letter written wholly or in part in either Latin or Greek, and to the horror of new house-physicians he often asked for ward admission of some child suffering from "eclampsia." But the new house-physician soon learned to admire the wide knowledge and up-to-date learning in medicine of Dr. Dunlop. I remember vividly a telephone message from him at 8 o'clock one morning a few years ago asking for information about phosphatase at a time when phosphatase was known only to a very few as an active enzyme. Our deepest sympathy goes to his sister, his devoted companion and housekeeper for so many years.

Medico-Legal

EDINBURGH WOMEN'S HOSPITALS

The Secretary of State for Scotland should not permit the South-eastern Regional Hospital Board to appoint a male consulting physician to the Bruntsfield and Elsie Inglis Hospitals, Edinburgh, unless a suitably qualified woman practitioner is not available to fill the post. Lord Walker expressed this judgment in the Scottish Court of Session on November 15.

More than half a century ago the Bruntsfield and Elsie Inglis Hospitals in Edinburgh were established with money raised by women to provide hospital facilities for women desiring the services of women consultants. These hospitals were vested in the Secretary of State under the National Health Service Act, and in July, 1956, the medical committee of the board of management of the Edinburgh Southern Hospitals Group recommended that the medical consultant appointment which was about to become vacant, should continue to be filled by a woman consultant. It also recommended that the appointment at the Deaconess and Longmore Hospitals, hitherto filled by a man, should be an open appointment.

In November, however, the South-Eastern Regional Hospital Board decided to combine the appointment at both pairs of hospitals and to advertise it as open to men and women. In face of representations by the board of management of the Southern Hospitals Group the regional board stuck to its decision, whereupon the board of management appealed to the Secretary of State for Scotland.

Intense feeling had been aroused by the regional board's decision. The appeal was supported by numerous organizations and by a petition signed by 28,000 people. It was pointed out, among other things, that if a man was appointed to fill the combined vacancy any woman desirous of attention from women doctors only would be deprived of the services of a woman consultant physician, since there was no other available in the region. The Minister decided not to interfere, and this exhausted the steps available under the Act to those who, like the Southern Hospitals Board of Management, were convinced that the regional board's decision was wrong and contrary to both lay and medical opinion in the region. Meanwhile Dr. Margaret Martin, in January, 1957, had retired from the position of senior consultant physician to the Bruntsfield and Elsie Inglis Hospitals.

In June ten Edinburgh women brought an action against the regional board and the Minister and sought an interim interdict, which was agreed to, restraining the board from filling the appointment for four months, and the action was heard before Lord Walker in the Court of Session.

The pursuers claimed that, as a matter of law, the board must so far as practicable secure that the staff of the two hospitals consists entirely of qualified medical women, that it was practicable for the existing vacancy to be filled by a woman, and that the Secretary of State was not entitled to allow the regional board to appoint a man. The case for the board was that the Minister delegated to it the task of administering the services in its area to the best of its ability; that its duty was to appoint to the vacancy the person they considered most suitable; and that its discretion in this was not open to challenge in the courts. A similar stand was taken by the Solicitor-General, who appeared for the Secretary of State. The Solicitor-General emphasized that the Secretary of State and the regional board had not decided that women were to be excluded. If a woman was the most suitable candidate she would get the appointment.

In his judgment Lord Walker said the substantial dispute was whether or not Section 6 (4) of the National Health Ser-

vice (Scotland) Act, 1947, imposed an enforceable legal duty on the Secretary of State. This section laid down that the Secretary of State "shall so far as practicable secure that the objects for which any such property was used immediately before the appointed day are not prejudiced by the exercise of the power hereby conferred." The regional board and the Secretary of State contended that "practicable" meant being consistent with the due performance of his general duties under the Act. Lord Walker thought that their approach involved the fallacy of overemphasizing the remoter context and ignoring the immediate context. It was not legitimate to put some strained meaning on the word which would withdraw the subject from judicial cognizance.

The women who brought the case desired an opportunity of proving that there was an adequate supply of qualified women to fill the vacant post, and that if the post were advertised as open to women only it would be practicable for a suitable appointment to be made. He considered that it would not be possible for the court, without usurping the function of the statutory bodies concerned, to entertain the question of whether there was such a supply of qualified women for the post. He therefore refused proof of this.

It had been pleaded that the Secretary of State was unnecessarily involved in the action because the performance of his duty was primarily the concern of the regional hospital board, with which he would not interfere, but Lord Walker held that the Minister was a necessary party to the action. He therefore made an order that it was the duty of the Secretary of State to secure that a male practitioner was not appointed to the post until after it had been advertised as being open to women practitioners only and it had appeared that no woman suitable for the appointment had applied. In the meantime he prohibited the board from appointing a male consultant to the hospitals.

CRIMINAL APPEAL TO HOUSE OF LORDS

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Under Section 1 (6) of the Criminal Appeal Act, 1907, by which the Court of Criminal Appeal was constituted, if in any case the Director of Public Prosecutions or the prosecutor or defendant obtains the certificate of the Attorney-General that a decision of the Court of Criminal Appeal involves a point of law of exceptional public importance, and that it is desirable in the public interest that a further appeal should be brought, he may appeal to the House of Lords. This provision thus includes an exception to the general principle in criminal cases that the prosecution cannot appeal against an acquittal. It is an odd provision in view of the fact that it is quite likely that leading counsel for the prosecution before the Court of Criminal Appeal in a case involving questions of law of exceptional public importance will be the Attorney-General himself.

The position is well illustrated by what has happened in the case of *Regina v. Head*.¹ Mr. Head, a Workington bus driver, was convicted at Carlisle Assizes on May 25, 1957, of "having carnal knowledge" of a mental defective contrary to s. 56 (1) (a) of the Mental Deficiency Act, 1913, and sentenced to four months' imprisonment. Mr. Head appealed to the Court of Criminal Appeal, and his case was that the woman with whom he had had intercourse had been detained as a defective under an invalid order. The Secretary of State, in committing her to an institution as a moral defective, had acted on two medical certificates, neither of which contained any evidence on which it could be said that she was mentally defective, strongly vicious, or had criminal propensities.

At the hearing both the Attorney-General, who appeared for the Crown, and counsel for the Minister of Health and the Board of Control conceded that the order committing the woman as a moral defective was a nullity which would have been so declared if challenged by *habeas corpus* or *certiorari*. They argued, however, that it was not incumbent on the

² *Scotsman*, October 30, 1957.

³ *Ibid.*, November 16, 1957.

¹ *The Times*, October 22, 1957.

² *Daily Mail*, November 12, 1957.

prosecution to prove more in order to make out an offence against the section than that the woman had been detained in or was on licence from one of the institutions specified in the Act. There was then a presumption that she was a mental defective which was rebuttable. The Attorney-General said that he was not so much concerned to uphold the conviction as to establish that it was not necessary for the prosecution to prove in the first instance that the woman concerned was mentally defective.

The Lord Chief Justice announced that the court, consisting of himself, Mr. Justice Donovan, and Mr. Justice Havers, were clearly of opinion that the conviction must be quashed, but that as the case was important they would take time to deliver a considered judgment in writing. This has not yet been delivered, and it has been announced² that the Attorney-General had granted a certificate under s. 1 (6) of the 1907 Act to the Director of Public Prosecutions so that it is now open to the Crown to appeal to the House of Lords. Appeals by defendants to the House are rare—by the Crown rarer still.

Meanwhile Mr. Head is on bail.

NUISANCE FROM HOSPITAL CHIMNEY

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

The Public Health Act of 1936 defines certain statutory nuisances, among them the emission of large quantities of black smoke. It also provides machinery by which, if the smoke comes from buildings other than private dwellings, proceedings can be taken before the local magistrates for an order compelling the owner to abate the nuisance. Such proceedings are cheap and simple compared to common-law proceedings in the High Court to achieve the same end. Section 106 of the Act, however, provides that, where a smoke nuisance is caused on "premises occupied for the public service of the Crown," the local authority is to report the circumstances to the appropriate Minister, who, if satisfied that such nuisance exists, is to cause steps to be taken to abate it. The machinery by way of complaint to the magistrates asking for an abatement order is thus excluded.

Proceedings were brought by the town clerk of Nottingham under the Public Health Act against the Nottingham Area No. 1 Hospital Management Committee, complaining that a serious nuisance existed by reason of a chimney at the General Hospital, Nottingham, which had been emitting black smoke for seven years. The magistrates found the complaint proved, and that the cause of the nuisance was failure to install suitable plant and sufficient plant, and failure to keep the steam load within the rated capacity of the boiler.

The hospital management committee appealed against the magistrates' decision by case stated to the Divisional Court of the Queen's Bench Division. Their ground was that the hospital premises were "occupied for the public service of the Crown" within s. 106 of the Public Health Act, 1936, and that therefore, although the committee would have been liable if sued in a common-law action for nuisance in the High Court, the magistrates had no jurisdiction to entertain the complaint.

In his judgment¹ the Lord Chief Justice said that the hospital management committee were the occupiers of the premises, and occupied them for the purpose of carrying on duties which were imposed by statute on the Minister. It was proper to say that the provision of hospitals under the National Health Service Act, 1946, was for the public service of the Crown, and so the effect of s. 106 of the Public Health Act, 1936, was that the simple and speedy procedure which could be taken against private persons, and could for example have been taken against the hospital had it remained a voluntary hospital, was excluded. Counsel for the management committee had told the court during the hearing that the nuisance had been cured and that the work had cost over £80,000 at a time when the committee could not spend more than £10,000 without the Minister's consent. A third boiler

¹ *The Times*, October 17, 1957.

was still needed, and could not be delivered till early the following year. This was not the only case, and it had wide implications. The Lord Chief Justice hoped this did not mean that all the hospitals taken over by the Minister were belching out black smoke, which would be inconsistent with the duties laid down under the National Health Service Act.

Medical Notes in Parliament

Doctors' Pay Prospects

Mr. H. HYND (Accrington, Lab.) asked the Minister of Health on November 12 whether the doctors' claims for higher remuneration would be vetoed under the Government's wage-freeze policy. Mr. D. WALKER-SMITH said the remuneration of doctors in the National Health Service would be considered in the light of all the circumstances prevailing at the time when the report of the Royal Commission was received.

Drugs for Private Patients

Sir WAVELL WAKEFIELD (St. Marylebone, Con.) asked the Minister of Health on November 18, in view of the fact that people were told they could benefit in whole or in part from participation in the Health Service, when he was proposing to allow people who employed doctors privately to have their drugs on the same basis as those who employed doctors within the Health Service. Mr. WALKER-SMITH said that this proposal, which would involve legislation, raised difficulties, notably that it would increase the cost of the drug bill. Its implications were being explored with the British Medical Association, but he could not hold out hope of embarking at the present time on a course which must lead to increased expenditure.

Unprofessional Conduct

Mr. V. COLLINS (Shoreditch and Finsbury, Lab.) asked the Minister if, in cases where doctors in the Health Service had been severely censured and fined, he would refer the cases to the General Medical Council so that it could consider whether the doctors had been guilty of infamous conduct in any professional sense. Mr. WALKER-SMITH replied that it was already the practice to send to the General Medical Council particulars of all cases which, it seemed, might come within its purview. Mr. COLLINS asked if that meant that when a doctor had been heavily censured his name would automatically be submitted to the G.M.C. Mr. WALKER-SMITH referred him to Rule 12 of the Medical Disciplinary Committee Procedure Rules, which would show the procedure for referring such matters to the Council.

Sewage Outfall Infection

Dr. REGINALD BENNETT (Gosport and Fareham, Con.) asked the Minister what advice his department gave to the Gosport Borough Council about the safety, or otherwise, of bathing close to sewer outfalls; and why his department recommended the removal of notices stating that such bathing might be dangerous. Mr. WALKER-SMITH told him that it was for the medical officer of health to advise his authority on such matters. The question of removing the notices was entirely one for the local authority in the light of such advice. Dr. BENNETT asked him to advise authorities not to be too sanguine about the hitherto undiscovered connexion between bathing in dirty water and poliomyelitis. Mr. WALKER-SMITH said there was no definite evidence of transmission from this source. He added in answer to Mrs. H. SLATER (Stoke-on-Trent, North, Lab.) that it was a question of what safeguards were sensible and practical. Investigations were going on, but they did not show any significant risk attaching to sea-bathing. It was obviously wise to avoid bathing near sewer outfalls.

Doctors' Pay—Further Prospects

Mr. A. BLENKINSOP (Newcastle upon Tyne, East, Lab.) asked the Prime Minister on November 19 whether he had directed the attention of the Royal Commission on Doctors' and Dentists' Remuneration to the Government's statement that increases of remuneration should be related to increases in productivity. Mr. MACMILLAN said no, the terms of reference were as he had announced them. He had no doubt that the Royal Commission had regard to the general movements of affairs, like any other people. Mr. H. GAITSKELL (Leeds, South, Lab.) asked whether the Government was liable to impose a veto on any recommendation for changes in salary scales among doctors and dentists. Mr. MACMILLAN said no, only the Right Hon. Gentleman would make so foolish a supposition. Mr. GAITSKELL replied that the Prime Minister was as usual rude and arrogant. Neither his answer nor his manner disposed of the issue here. Mr. MACMILLAN repeated the terms of reference, and added: "It would be foolish not to recognize the fact that the Royal Commission, I have no doubt, like any other body of men, are cognizant of the general economic conditions of the country."

Effects of Corporal Punishment

Mr. SOMERVILLE HASTINGS (Barking, Lab.) on November 14 asked the Secretary of State for the Colonies whether, in view of the known danger of even light corporal punishment to those suffering from enlargement of the spleen, he would make compulsory in malarious districts medical examination of all prisoners or detainees before the administration of corporal punishment. Mr. J. PROFUMO, the Under Secretary, said that so far as prisoners or detainees were concerned none might receive corporal punishment for offences against discipline in any territory, whether malarious or otherwise, unless a medical examination had been made and the prisoner or detainee pronounced fit to receive this kind of punishment. If Mr. Hastings had any particular case in mind he would gladly make inquiries.

Migrant Doctors and Dentists.—The President of the Board of Trade is arranging for doctors and dentists to be recorded separately from next January in the statistics of those entering and leaving the United Kingdom by sea.

Shortage of Radiographers.—At December 31, 1956, there was an estimated deficiency of 523 whole-time radiographers in England and Wales—i.e., 14.8% of establishment. The corresponding figure at June 30, 1957, was 563—i.e., 15.7% of establishment. The actual number employed fell by only three during this period. Comparable figures for 1955 are not available.

Registration of Opticians.—Legislation for the registration of opticians will be introduced as soon as Parliamentary time permits.

Universities and Colleges

UNIVERSITY OF OXFORD

Dr. P. J. R. Phizackerley has been elected to a Weir Junior Research Fellowship in Biochemistry at University College. In Congregation on October 17 the degree of B.M. was conferred on A. J. MacI. Smith.

The Horatio Symonds Studentship in Surgery held by Michael Peter Wright, B.M. (Magdalen College), has been extended for a second year from July 1, 1957.

A second Goodger Scholarship has been awarded by the Board of the Faculty of Medicine to Gillian Barbara Fowler (St. Anne's College).

Thomas Pomfret Kilner, D.M., F.R.C.S., Nuffield Professor of Plastic Surgery in the University from 1944-57, has been elected to an Emeritus Fellowship of St. John's College.

UNIVERSITY OF LONDON

The following candidates at the London School of Hygiene and Tropical Medicine have been approved at the examination indicated:

ACADEMIC POSTGRADUATE DIPLOMA IN PUBLIC HEALTH.—F. L. da Costa, M. M. Hasan, N. V. Karve, W. S. Kulesza, J. E. B. McPhail, M. A. Malik, P. Sribodhi, Ah Yen Wong Shiu Leung.

The following candidates have been approved at the examinations indicated:

ACADEMIC POSTGRADUATE DIPLOMA IN CLINICAL PATHOLOGY.—Dulcie Aldis, M. E. Babiker, Monica B. Bishop, P. D. Byers, J. S. Cornes, K. G. Gadd, D. J. Hansman, C. Isaacson, A. S. Khan, P. R. L.-C. Lam-Po-Tang, D. C. Malik, D. P. Manandhar, A. D. Moore, V. Rajapillai, H. Rifkin, S. J. Rifkin, C. P. Schwinn, D. A. Sugerman.

EXTERNAL DIPLOMA IN CLINICAL PATHOLOGY.—B. Boczarow, F. M. Chaudhary, C. O. Le C. Hughes, K. P. Khan.

On September 27 the degree of M.D. was awarded by the Senate to: E. H. Cooper, G. E. Flatman, R. A. Parker, A. B. Tompkins.

The degree of Ph.D. in the Faculty of Medicine was awarded to N. C. Hughes Jones, B.M., B.Ch., on September 27.

UNIVERSITY OF BIRMINGHAM

The following have been promoted to senior lectureships from October 1, 1957: Dr. Kathleen Hall (Histology, in the Department of Physiology); Dr. J. Hardwicke (Experimental Pathology); Dr. R. Lannigan (Pathology); and Dr. P. B. Bradley (Electrophysiology, in the Department of Experimental Psychiatry).

The title of University Research Fellow has been given to the following during the tenure of their present awards or appointments in the University: *Department of Medicine*: Dr. J. Butler (Senior Registrar); Dr. P. S. Brown (working in the Department of Clinical Endocrinology); Dr. T. J. Reeves (Associate Professor of Medicine in the University of Alabama). *Department of Social Medicine*, Dr. E. G. Knox (Medical Research Council Research Fellow).

The following appointments are announced: *Lecturer in Medicine*, Dr. P. C. Harris; *Lecturer in Physiology*, Dr. K. Brown-Grant; *Lecturer in Medical Biochemistry and Pharmacology*, Dr. B. Shaw (formerly Research Fellow); *Temporary Lecturer in Physiology*, Dr. J. D. Cumming; *Research Fellow in Social Medicine*, Dr. I. M. Leck; *Research Fellow in Paediatrics and Child Health*, Dr. A. Nestadt.

Dr. R. G. Brown (Lecturer in Social Medicine) and Dr. Mary M. Weeks (Research Fellow in Paediatrics and Child Health) have resigned their appointments.

UNIVERSITY OF LEEDS

The following candidates have been approved at the examinations indicated:

M.D.—Doreen Moorhouse.
M.B., Ch.B.—K. A. I. Cassimally, S. E. Cornford, B. W. Fowles, D. H. Fox, Beryl Head, Cita V. Kershaw, Ann V. Kirkbride, C. W. Landon, M. McGregor, M. G. Mayne, Elaine Merrington, M. D. Morris, S. A. Rance, P. J. Robinson, D. C. Robson, H. D. Rogers, C. Skipper, A. W. Thorpe, M. P. Wales, I. H. White.
D.P.M.—M. W. Atkinson.
D.P.H.—Kathleen Haigh.

UNIVERSITY OF SHEFFIELD

Dr. C. N. Eccles has been appointed full-time Demonstrator in Anatomy.

Dr. C. J. Edmonds has been appointed to the Boots Research Fellowship for work in the Department of Pharmacology and Therapeutics.

Dr. F. R. Johnson has resigned his appointment as Lecturer in Anatomy.

Vital Statistics

Influenza

The following table shows the age distribution of deaths from influenza in the 160 great towns of England and Wales.

Week Ending	0-	1-	15-	25-	45-	65+
Sept. 14 ..	1	9	3	4	14	16
" 21 ..	2	18	8	17	39	37
" 28 ..	3	25	22	47	102	83
Oct. 5 ..	2	36	28	57	159	160
" 12 ..	4	36	32	58	213	248
" 19 ..	5	22	22	54	189	308
" 26 ..	4	11	17	32	114	218
Nov. 2 ..	4	7	5	19	68	160
" 9 ..	2	0	1	6	48	92
Total: Deaths ..	27	164	138	294	946	1,322
% ..	1	6	5	10	33	46

The numbers of deaths from influenza and pneumonia have continued to fall throughout the country. In the week

ending November 9, deaths from influenza reported from the great towns were as follows, with the figures for the previous week in parentheses: England and Wales 149 (263), Scotland 13 (20), Northern Ireland 5 (8), and Eire 10 (17).

latter figure compares with about 157,000 in the corresponding week last year.

The accompanying graph shows numbers of deaths in the 160 great towns in England and Wales from early September to the latest date for which figures are available.

The maps below show the numbers of deaths from influenza plus pneumonia as a percentage of the total deaths. These are deaths reported from the great towns for the latest two weeks for which figures are available.

Week Ending November 9

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 444, whooping-cough 431, diphtheria 4, measles 1,676, acute pneumonia 742, acute poliomyelitis 61, dysentery 216, paratyphoid fever 5, typhoid fever 8.

Deaths from influenza plus pneumonia as percentage of deaths from all causes in week ending November 2.

Infectious Diseases

A small increase in the incidence of most infectious diseases was reported in England and Wales during the week ending November 2. The rises in the number of notifications included 322 for measles, from 1,414 to 1,736, 85 for dysentery, from 197 to 282, 66 for food-poisoning, from 108 to 174, 52 for whooping-cough, from 349 to 401, and 45 for scarlet fever, from 399 to 444; the only fall of any size was 454 for acute pneumonia, from 1,897 to 1,443.

The largest increases in the incidence of measles were 64 in Kent, from 68 to 132 (Sittingbourne and Milton U.D. 58), 59 in Glamorganshire, from 118 to 177 (Port Talbot M.B. 115), and 40 in Cheshire, from 25 to 65 (Nantwich U.D. 45). Only small fluctuations were recorded in the local trends of scarlet fever and whooping-cough. 5 cases of diphtheria were notified, being 2 more than in the preceding week; 2 of these cases were notified in Staffordshire, Tipton M.B. A fall in the number of notifications of acute pneumonia occurred throughout the country; the chief exceptions were rises of 39 in Surrey, from 67 to 106 (Epsom and Ewell M.B. 25), and 39 in Bedfordshire, from 17 to 56 (Luton M.B. 43). Other areas with a large number of notifications of acute pneumonia were 42 in Gloucestershire, Bristol C.B., 31 in Staffordshire, Stoke on Trent C.B., 26 in London, Woolwich, and 25 in Monmouthshire, Abercarn U.D.

The notifications of acute poliomyelitis numbered 60, being 3 fewer for paralytic and 3 fewer for non-paralytic cases than in the preceding week. The largest returns were Yorkshire West Riding 5 (Doncaster C.B. 2) and Norfolk 4.

The largest centres of dysentery were Yorkshire West Riding 83 (Leeds C.B. 30, Bradford C.B. 19, Huddersfield C.B. 13), Lancashire 53 (Liverpool C.B. 24, Huyton with Roby U.D. 11), London 32, and Leicestershire 18 (Leicester C.B. 18).

The largest rise in the number of notifications of food poisoning was 44 in Cheshire, from 4 to 48, due to an outbreak of 46 cases in Hazel Grove and Bramhall U.D.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during

Deaths from influenza plus pneumonia as percentage of deaths from all causes in week ending November 9.

the years 1948-56 are shown thus - - - -, the figures for 1957 thus ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending November 2 (No. 44) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included). London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenzal pneumonia.

§ Includes puerperal pyrexia.

Medical News

Poliomyelitis Vaccination.—In a circular to local authorities, dated November 19, the Ministry of Health gives details of the following extensions to the Government's poliomyelitis vaccination programme: (1) the offer of vaccination before next summer to all children under the age of 15 and to expectant mothers; (2) when increased supplies become available as a result of the import of Salk vaccine, the offer of vaccination to general practitioners, local authority ambulance men, and the families (i.e., households) of both these groups, and also to the families of the specially exposed hospital staff who are already being protected. Pregnant women should be vaccinated as early in pregnancy as possible, as the severity of poliomyelitis is enhanced in pregnancy. If the parents of children eligible for vaccination, or pregnant women, decline to have Salk vaccine, they are to be given opportunity later to be vaccinated with British vaccine. The first distribution of Salk vaccine, after its testing in Britain, is expected to be made towards the end of next month or early in January. By the end of this year, or soon after, states the Ministry, enough vaccine will have been distributed to local health authorities for the vaccination of all children born between 1947 and 1954 inclusive and in 1955 or 1956 whose names were registered when the offer was first made to these groups. The offer of vaccination to further children born in these years is to remain open. Authorities are now also asked to make "a continuing offer of vaccination" to children born in 1943-6 inclusive, to children born in 1957 who have reached the age of 6 months, and to expectant mothers. A letter about these arrangements has also been sent to executive councils.

College of General Practitioners.—The College's annual dinner was held on November 15 in the Hall of the Society of Apothecaries, with Dr. IAN GRANT in the chair. In welcoming the guests by categories rather than by names, Dr. GLYN HUGHES said that their young College was growing fast and had had friendship and a helping hand from many. After identifying most of the professional institutions in this country, Dr. Hughes said there were two names he must mention : one was that of Dr. G. E. Godber, of the Ministry of Health, and the other Professor Robert Platt, president of the Royal College of Physicians. In response, Professor PLATT said that medicine in hospital and medicine in general practice had now diverged. "You," he said, "are developing your own techniques, which are independent of what we do in hospitals. We are no longer properly preparing students for general practice, any more than we are preparing them for any other branch." One of the subjects which should be treated separately was general practice. Who should teach ? There had, Professor Platt said, to grow up a standard of general practice and an *élite* of general practice. The College of General Practitioners was the most important factor in all this. It was a mistake to make the National Health Service the scapegoat of all that went wrong to-day. Also in reply, Dr. GODBER sang the praises of the College, observing that the general practitioner was the only person who could act as a referee for the patient. The general practitioner had a part to play in research and in the study of the natural history of disease. In reply, the president of the College, Dr. IAN GRANT, said that they had as yet no test to distinguish them as members of the College. Their desire was that general practice should be rehabilitated in this country, and the foundation of the College was an act of faith in this respect. They had made much greater progress than had been hoped for, and in time they expected to have premises near the Royal College of Surgeons in Lincoln's Inn Fields. The last speaker was Dr. JOHN HUNT, whom Dr. Grant had described as "the irreplaceable secretary."

Anglo-French Exchange Bursaries.—Applications are now invited for next year's bursaries for young British doctors

under the exchange scheme arranged by the French Embassy in London between the Institut National d'Hygiène, Paris, and the Ciba Foundation, London. The value of the French grants is 60,000 francs a month (tax free). The grants will be awarded for periods of two to four months to medical men who wish to obtain clinical experience or carry out research in France. Preference will normally be given to candidates who hold teaching posts or are in positions where they can pass on the experience they have acquired. Application forms may be obtained from the director of the Ciba Foundation, 41, Portland Place, London, W.1. The closing date for applications is February 2, 1958.

Royal College of Physicians of Edinburgh.—At a quarterly meeting of College on November 5 the following were elected fellows :

J. A. Hislop, W. Goldie, R. F. Thomas, Rabindra Nath Chaudhuri, H. E. Taylor, R. J. Twort, J. W. Ferguson, J. L. Markson, H. V. L. Finlay, T. McLaren Galloway, A. R. Currie, C. Harris, J. B. Lowe, J. F. Galpine, F. L. Ritchie, I. C. Gilliland, P. W. Hannay, J. W. Farquhar, N. R. Grist, A. S. Douglas, M. F. Oliver, J. D. Robertson, M. A. Khan, D. G. C. Whyte, J. H. Bowie, A. G. Macgregor, E. B. French, J. A. Strong, G. J. Summers, J. M. Johnston, F. J. Wright, G. L. Montgomery, A. Kennedy, J. H. F. Brotherston, K. Cowan, J. Marshall, J. A. W. McCluskie, E. G. Oastler, and I. Gordon.

The following were elected members :

Sir Samuel Manuwa, J. H. Hutchison, L. G. Topham, R. G. Paley, R. G. MacFarlane, N. Kumar Sen, E. B. Naug, S. P. D. Gupta, D. N. Gupta, G. C. Anbu-Nathan, A. D. Macdonald, H. A. K. Rowland, D. N. Bose, J. F. Boyd, W. D. Elliott, R. H. Scott, J. N. Singh, H. A. Aponso, L. K. Manning, Ratanisr, Mehta, M. M. Khin, I. G. Johnston, C. G. B. Downie, A. de S. Lawrence, G. Howitt, M. S. E. Ibrahim, I. Reef, J. D. Frankish, B. J. Lemass, S. Gupta, S. M. Haque, T. H. Beare, P. J. Lipsitz, N. G. Sanerkin, H. Boon Wong, E. A. Cameron, W. J. H. Leckie, E. M. Ashenhurst, M. Traub, R. E. Cronje, J. P. Eckert, M. R. P. Hall, M. J. A. McDonald, D. H. Garrett, E. L. Fischer, G. L. Money, G. K. Warrior, J. Ferguson, S. K. Gupta, J. G. Sloman, R. W. B. Penman, V. Marks, and A. E. Hugh.

Buckston Browne Prize Essay.—The council of the Harveian Society of London announces as the subject for next year's essay "The Clinical Significance of Tiredness." The prize, which consists of a medal and £100, is open to "any member of the medical profession registered in the British Isles or Dominions" under the age of 45. Essays must be submitted by October 31, 1958. Further information may be obtained from the Society's hon. secretaries, 11, Chandos Street, London, W.1.

Cambridge University.—The Vice-Chancellor, Lord ADRIAN, O.M., has announced acceptance of a grant from the Ford Foundation of \$54,600 in aid of developments in psychopathology; and also (subject to certain life interests) a bequest of about half his estate from the late Lieutenant-Colonel W. L. Harnett, formerly a surgeon in the Indian Medical Service. After his retirement from the I.M.S., Colonel Harnett was for many years medical secretary of the clinical cancer research committee of the British Empire Cancer Campaign. His bequest is "for increasing medical knowledge and aiding every form of medical research."

Doctor Added to A.E.A. Health Committee.—The Prime Minister has appointed Professor B. W. WINDEYER, director of the radiotherapy departments at the Middlesex Hospital and Mount Vernon Hospital, to the committee he set up after the Windscale accident to review the Atomic Energy Authority's health and safety arrangements (*Journal*, November 16, p. 1171). Sir ALEXANDER FLECK, F.R.S., the committee's chairman, is stated to have suggested the addition of a medical man to this committee.

Russian Visitors.—Three Russian experts arrived in Britain this week to study our radiological departments. They come from the Giprozdrav Institute, Moscow—the State Institute

Nov. 23, 1957

for the planning of public health establishments. The visitors are Mme. M. P. PEREPELITSINA, director of the Institute; Mr. S. G. KONEVSKIY, an architect; and Mme. Z. F. LAPATNIKOVA, a radiologist. The British Council has arranged for them to visit radiology departments in London, Cambridge, Manchester, and Scotland. Their visit ends on December 3.

Commonwealth Fund, New York.—During the year ended June 30, 1957, the Commonwealth Fund disbursed grants totalling \$3.8 million, of which 90% went towards studies in medical education, medical research, community health projects, and medical fellowships. The great majority of the funds went to universities and workers in the United States, but the medical faculties at McGill University and the University of British Columbia both received grants (\$12,285 and \$9,500, respectively) to assist them in analysing their medical curricula. Travelling fellowships to the United States were awarded to Mr. J. STEVENS, orthopaedic registrar at the Western Infirmary, Glasgow, and to Dr. J. C. LANE, director of aviation medicine in the Australian Department of Civil Aviation. The Fund's offices are at Harkness House, 1, East Seventy-fifth Street, New York, and there are British, Australian, and New Zealand committees of award or nomination.

Drummond Fellowship.—The Trustees will consider in March applications for a Drummond senior fellowship for research in nutrition. The value of the fellowship will be £1,100 per annum, to which may be added a grant for expenses of research not exceeding £50 per annum; in addition up to 10% of the stipend may be paid towards superannuation. The fellowship will normally be tenable for two years. Full particulars can be obtained from the hon. secretary, Drummond Trust, University College London, Gower Street, London, W.C.1, with whom application forms must be lodged not later than January 31, 1958.

Christmas Seals.—N.A.P.T., the British Diabetic Association, and the National Spastics Society have prepared Christmas seals this year. The National Association for the Prevention of Tuberculosis offers seals in sheets of 100 different designs, price 4s. per 100. These are obtainable from Tavistock House North, London, W.C.1. The British Diabetic Association has Christmas seals in sheets of 48 penny seals (12 different designs). These are obtainable from 152, Harley Street, London, W.1. The National Spastics Society offers booklets of 120 seals in 12 designs, price 1d. a seal, obtainable from 28, Fitzroy Square, London, W.1.

Royal Society of Edinburgh.—Professor J. N. DAVIDSON, Gardiner professor of physiological chemistry at Glasgow, and Professor D. WHITTERIDGE, F.R.S., professor of physiology at Edinburgh, were among the six vice-presidents elected at the annual meeting of the Royal Society of Edinburgh last month.

Royal Faculty, Glasgow.—At the annual meeting of the Royal Faculty of Physicians and Surgeons of Glasgow on November 4 the president (Professor STANLEY ALSTEAD), visitor (Mr. ARTHUR JACOBS), hon. treasurer (Dr. J. A. W. McCLUSKIE), and hon. librarian (Dr. A. L. GOODALL) were re-elected. Dr. GAVIN B. SHAW was elected hon. secretary in place of Dr. A. H. IMRIE.

Hon. F.R.C.S. for Sir Simon Marks.—The council of the Royal College of Surgeons, at its meeting on November 14, elected Sir SIMON MARKS an honorary fellow of the College. Sir Simon Marks recently made it possible by his generosity for the College to resume its building programme (see *Journal*, November 9, p. 1126).

M.R.C.P.I.—The following were admitted members of the Royal College of Physicians of Ireland on November 1: M. W. Browne, M. W. P. Cerney, P. J. Meehan, and I. C. Roddie.

Birmingham University.—Dr. A. P. D. THOMSON, senior lecturer in anatomy, has been appointed to the newly established office of senior tutor and assistant dean of the medical faculty.

Professor C. F. W. Illingworth, Regius professor of surgery at Glasgow, will visit Brisbane next September as Edwin Tooth guest professor of surgery. He will be abroad for about two months.

COMING EVENTS

"How to Pass Examinations."—The B.M.A. Metropolitan Counties Branch invites senior medical students to a Brains Trust on "How to Pass Examinations" on November 28 at B.M.A. House at 5 p.m. (tea 4 p.m.). The meeting is also open to medical practitioners. The question master will be Mr. A. LAWRENCE ABEL, and his panel will consist of Mr. DONALD FRASER (obstetrics and gynaecology), Dr. J. B. HARMAN (medicine), Dr. LANGTON HEWER (anaesthesia), and Mr. C. E. SHATTOCK (surgery).

Cardiac Problems for General Physicians.—Symposium arranged by the National Association for the Prevention of Tuberculosis. December 6, 3.30–6.30 p.m., at B.M.A. House. Admission by ticket (price 10s.) from N.A.P.T., Tavistock House North, Tavistock Square, London, W.C.1.

"School Health and Health Education."—Seminar for medical officers of health, February 25-28, 1958, at the Ivanhoe Hotel, London, W.C.1. Details from Central Council for Health Education, Tavistock House North, Tavistock Square, London, W.C.1.

University College, London.—Reunion for former undergraduates and postgraduates who entered the College during 1934–8, February 28, 1958. Details from the assistant secretary. University College, Gower Street, London, W.C.1.

Transatlantic Discussion at R.S.M.—The Section of Surgery of the R.S.M. is staging a Transatlantic television discussion on December 4 at 8 p.m. The subject is "Advances in the Chemotherapy of Cancer." The American panel, which comprises Dr. L. M. TOCANTINS (moderator), Dr. J. BURCHENAL, Dr. R. P. CUSTER, Dr. S. FARBER, Dr. E. FRET, and Dr. H. SKIPPER, will be sitting in Philadelphia.

NEW ISSUES

SPECIALIST JOURNALS AND ABSTRACTS

All the journals listed below are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Preventive and Social Medicine.—Issued quarterly (£3 annually). The new issue (Vol. 11, No. 3) includes: BLOOD GROUPS AND SUSCEPTIBILITY TO DISEASE. J. A. Fraser Roberts. THE NATURE OF THE DETERMINANTS OF RHESUS ISOIMMUNIZATION. George Knox and William Walker.

Knox and William Walker.
 SOME ASPECTS OF GROWTH WITH NORMS FROM BIRTH TO 18 YEARS. W. H. Hammond.
 AN EXAMINATION OF THE ASSOCIATION BETWEEN HOUSING CONDITIONS AND PULMONARY TUBERCULOSIS IN GLASGOW. J. S. McMillan.
 OBSERVATIONS OF ROUTINE MEDICAL EXAMINATIONS OF UNIVERSITY ENTRANTS IN NORTHERN IRELAND. W. Johnston, E. A. Cheesman, and J. D. Merrett.
 A NOTE ON THE ASSOCIATION BETWEEN SMOKING AND DISEASE IN MEN IN THE SEVENTH DECADE. R. G. Browne, Thomas McKeown, and A. G. W. Whitfield.

British Journal of Ophthalmology.—Issued monthly (£6 annually). The new issue (Vol. 41, No. 11) includes:

THE EYE IN SYMBOLS OF	GENERAL OCULAR	VASCULAR DYNAMICS.	DISEASE: HYPERTENSION AND ARTERIO- SCLEROSIS. Robert Leishman.	Stewart Duke-Elder and David M. Maurice.
--------------------------	-------------------	-----------------------	---	--

Ophthalmic Literature.—Two new issues (Vol. 10, No. 5, and Vol. 11, No. 1) are now available. They contain a comprehensive selection of abstracts of the literature on ophthalmology and related subjects. Six issues and a volume index each year: annual subscription £4 4s. (or in combination with *British Journal of Ophthalmology*, £9).

Abstracts of World Medicine.—Issued in the first week of each month, this journal contains abstracts of important papers selected from the current medical literature of the world. Annual subscription £4 4s.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, November 25

GUY'S HOSPITAL.—At Physiology Theatre, 4.45 p.m., Endocrine Demonstration: Thyrotoxicosis and Progressive Exophthalmos. Guest speaker, Dr. I. C. Gilliland.
INSTITUTE OF NEUROLOGY.—5.30 p.m., Professor F. Brücke (Vienna): E.E.G. Patterns in the Rabbit's Hippocampus as a Test for Drugs Acting on the Central Nervous System.
● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—3 p.m., Mr. J. A. Stallworthy: Surgical Accidents in Obstetrics and Gynaecology.
MANCHESTER MEDICAL SOCIETY: (1) SECTION OF ODONTOLOGY.—At Lecture Room, Dental Hospital 4.30 for 5 p.m., Mr. S. S. Rose: Physiology of Xerostomia. (2) SECTION OF GENERAL PRACTICE.—At Large Anatomy Theatre, Manchester University, 8.30 for 9 p.m., Professor Fraser Brockington: A Doctor Looks at the Far East.
SOCIETY OF APOTHECARIES OF LONDON.—5 p.m., Professor G. M. Wilson: Clinical Research Aspects of Isotopes. 6.15 p.m., Dr. J. F. Loutit: Radiation Hazards.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, 5 p.m., public lecture by Dr. H. Harris: Human Biochemical Genetics.

Tuesday, November 26

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, W.C., 5.30 p.m., Dr. G. Gordon: Central Sensory Representation.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. D. I. Williams: Use of Vitamins in Dermatology.
MANCHESTER REGIONAL DERMATOLOGICAL ASSOCIATION.—At Clinical Sciences Building, York Place, 8.30 p.m., in conjunction with North-west England Faculty of College of General Practitioners. Lecture for general practitioners. Brains Trust, Chairman, Dr. P. B. Mumford.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Dr. Arthur Willcox: Polyarteritis Nodosa.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Artis and Gale Lecture by Mr. H. R. S. Harley: Development of the Sinus Venous Type of Atrial Septal Defect.
ROYAL STATISTICAL SOCIETY: MEDICAL SECTION.—At Keene Lecture Theatre, 2nd Floor, Westminster Medical School, S.W., 5.30 p.m., Dr. C. H. Wood and Dr. A. S. Fairbairn: Observer Variability in the Use of Respiratory Questionnaires.
ST. MARY'S HOSPITAL MEDICAL SCHOOL (WRIGHT-FLEMING INSTITUTE THEATRE).—5 p.m., Dr. K. V. Bailey: Assessment of an Obstetric Situation.
SOCIETY OF APOTHECARIES OF LONDON.—5 p.m., Dr. Hannah Steinberg, Ph.D.: Pharmacological Aspects of "Tranquillizers." 6.15 p.m., Dr. M. Shepherd: Use and Abuse of "Tranquillizers."
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. N. G. Hulbert: Neurological demonstration.

Wednesday, November 27

BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—8 p.m., Dr. P. M. Jeavons and Dr. P. B. Bradley, Ph.D.: Scope and Limitations of Electroencephalography.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. A. Tickner: Fats and the Skin.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. N. Pattinson: Some Congenital Abnormalities of the Pulmonary Arteries.
● INSTITUTE OF NEUROLOGY.—5.30 p.m., Dr. D. J. Williams: The Epilepsies.
● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—4 p.m., Mr. H. R. MacLennan: Elderly Primigravida and Her Treatment.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. J. G. Sandrey: Epididymitis.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. W. T. Cooke: Disorders of Fat Metabolism.
ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Weild Lecture by Mr. D. M. Wallace: Bladder Tumours—A Challenge to the Medical Profession.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. Stephen Hall: Impact of Tuberculosis in the Household (illustrated).
SOCIETY OF APOTHECARIES OF LONDON.—5 p.m., Dr. C. F. Hawkins: Ulcerative Colitis—The Medical Aspect. 6.15 p.m., Mr. B. N. Brooke: Ulcerative Colitis—The Surgical Aspect.

Thursday, November 28

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, W.C., 5.30 p.m., Dr. H. J. Taylor: Physiological Problems Associated with Diving and Underwater Swimming.
● DONCASTER MEDICAL SOCIETY.—At Earl of Doncaster Arms Hotel, 7.30 p.m., "Ladies Night" Dinner and Ball.
HONEYMAN GILLESPIE LECTURES.—At University New Buildings, Teviot Place, Edinburgh, 5 p.m., Dr. J. B. Stanton: Recent Approaches to Disorders of Speech and Language.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. C. D. Calnan: Epidermal Sensitization.
LIVERPOOL MEDICAL INSTITUTION.—8 p.m., joint meeting with Liverpool Psychiatric Club, Dr. S. Barton Hall and Dr. Hugh Jarvie: Psychological Symptoms of Organic Significance.
LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Royal Free Hospital School of Medicine, 8.30 p.m., social evening. Light-hearted "Any Questions?"
LONDON COUNTY MEDICAL SOCIETY.—At County Hall, 5.30 p.m., Professor M. L. Rosenheim: Modern Management of Hypertension.
LONDON UNIVERSITY.—At St. Mary's Hospital Medical School (Wright-Fleming Institute Lecture Theatre), 5 p.m., Professor G. Mayer (Bordeaux University): Physiological Factors in Implantation of the Egg.
NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, 8.30 p.m., Mr. J. C. Scott: Report on Four Months in Canada.
RESEARCH DEFENCE SOCIETY.—At Physiology Lecture Theatre, University College, W.C., 5.30 p.m., 26th Stephen Paget Memorial Lecture by the Rt. Hon. Lord Cohen of Birkenhead: Some Reflections on Animal Experiments.
ROYAL EYE HOSPITAL.—(1) 5.15 p.m., Dr. T. H. Whittington: The Reduced Eye. (2) At Courage Laboratory, 8 p.m., lecture and lantern slide demonstration by Mr. C. R. McCash: Plastic Surgery in the Region of the Eyes.

SOCIETY FOR ANALYTICAL CHEMISTRY: WESTERN SECTION.—At Cathedral Hotel, Salisbury, 7.45 p.m. joint meeting with Mid-Southern Counties Section of Royal Institute of Chemistry. Dr. I. MacIntyre: Current Practice in Chemical Pathology.
SOCIETY OF APOTHECARIES OF LONDON.—5 p.m., Professor E. Boyland, D.Sc., Ph.D.: Recent Work in Malignant Disease—Aetiology. 6.15 p.m., Dr. J. A. Stock, Ph.D., A.R.I.C.: Recent Work in Malignant Disease—Chemotherapy Aspect.
WEST OF ENGLAND CHILD HEALTH GROUP.—At Department of Child Health Lecture Theatre, Bristol Royal Hospital for Sick Children, 8.30 p.m., Miss C. N. Grose, S.R.N., S.C.M.: Breast-feeding.

Friday, November 29

BRITISH TUBERCULOSIS ASSOCIATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., joint meeting with Society of Medical Officers of Health. Dr. H. D. Chalke: Role of the Medical Officer of Health in Tuberculosis Control; Dr. K. Neville Irvine: Value of B.C.G. Vaccination in Children; Dr. C. M. Smith: Present Position of Milk Control; Dr. F. C. S. Bradbury: Problem of the Chronic Patient as Regards Control and Rehabilitation.
● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. I. Muende: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. Smart: clinical demonstration.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., clinical discussion for general practitioners. Mr. J. C. Hogg: Indications for the Removal of Tonsils and Adenoids.
MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—At 11, Chandos Street, W. 7.30 p.m., Mr. A. J. King: Syphilis of Bone.
PLYMOUTH MEDICAL SOCIETY.—At Greenbank Road Hospital, 8.30 p.m., clinical evening. (Cases from 8 p.m.)
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Mr. J. S. Hilary Wade: Injury to the Recurrent Laryngeal Nerve at Thyroidectomy.
ROYAL MEDICAL SOCIETY, EDINBURGH.—8 p.m., dissertation by Mr. David Lees.

Saturday, November 30

ROYAL SOCIETY.—2.30 p.m., Anniversary Meeting.

Sunday, December 1

COLLEGE OF GENERAL PRACTITIONERS: MIDLAND FACULTY.—At Powick Hospital, 10.30 a.m. to 12.30 p.m., symposium by Dr. C. A. H. Watts, Dr. A. M. Spencer, and Dr. R. A. Sandison: Scope of Psychiatry in General Practice.
MANCHESTER UNIVERSITY: FACULTY OF MEDICINE.—At Theatre 1, Clinical Sciences Building, York Place, 11 a.m., in conjunction with North-west England Faculty of College of General Practitioners. Lecture-demonstration for general practitioners. Dr. R. W. Fairbrother: Antibiotics.
UNIVERSITY COLLEGE HOSPITAL.—10.15 a.m., lecture-demonstration for general practitioners by Dr. R. F. Tredgold: clinical demonstration in Psychiatric Medicine in General Practice.

APPOINTMENTS

MANCHESTER REGIONAL HOSPITAL BOARD.—A. Ansell, M.D., D.M.R.D., Maximum Part-time Consultant Radiologist, Crumpsall, Booth Hall, and Monsall Hospitals; D. Donnellan, M.D., M.R.C.P., Whole-time Consultant Geriatrician to the Salford Group of Hospitals; L. L. White, M.D., D.C.H., Whole-time Consultant Pathologist to Booth Hall and Monsall Hospitals; D. L. Boardman, M.B., Ch.B., D.Path., Whole-time Consultant Pathologist to the Oldham and District Hospital Centre; Susanne Shafar, M.B., Ch.B., D.P.M., Whole-time Assistant Psychiatrist (S.H.M.O.), North Manchester Hospital Centre; Carolyn C. Rigby, M.B., Ch.B., D.Path., Whole-time Assistant Pathologist (S.H.M.O.), Hope Hospital, Salford; N. Berlyne, M.B., Ch.B., D.P.M., Whole-time Assistant Psychiatrist (S.H.M.O.), Stockport and Buxton Hospitals; J. Hewet, M.B., Ch.B., F.R.C.S., Consultant General Surgeon, Stockport and Buxton Group of Hospitals; J. W. Boland, M.B., Ch.B., F.R.C.S.Ed., F.F.R., D.M.R.T., Consultant Radiotherapist to Christie Hospital and Holt Radium Institute, Manchester.

SMITH, IRVINE B., M.B., B.Chir., F.R.C.S., Part-time Consultant Surgeon to the Burton-on-Trent Group of Hospitals.
SOUTH-EAST METROPOLITAN REGIONAL HOSPITAL BOARD.—J. S. S. Fairley, M.D., Senior Administrative Medical Officer; J. R. Lauder, M.R.C.S., L.R.C.P., Deputy Senior Medical Officer; and W. B. D. Miller, M.B., D.Phil., Med., Consultant in Physical Medicine, Isle of Thanet Group of Hospitals.

BIRTHS, MARRIAGES, AND DEATHS

DEATHS

Blackstock.—On October 25, 1957, at The Elms, Eskbank, Midlothian, Robert Patrick Hall Blackstock, L.R.C.P.&S.Ed., L.R.F.P.S.
Carter.—On October 22, 1957, at St George's Hospital, London, S.W., Charles Noel Carter, M.B., B.Ch., of 29, Chester Row, London, S.W. Cousins.—On October 31, 1957, at his home, 176, Chorlton Road, Brook's Bar, Manchester, William John Cousins, M.B., B.Ch.
Edwards.—On October 25, 1957, at 11, Dower House Crescent, Southborough, Kent, Lancelot Charles John Edwards, M.R.C.S., L.R.C.P.
George.—On October 24, 1957, William George, M.C., T.D., M.B., Ch.B., J.P., of Strawberry Bank, Lancaster.
Glen.—On October 26, 1957, at Lee-on-Solent, Hants, John Craven Glen, L.R.C.P.&S.Ed., L.R.F.P.S.
Grogono.—On October 26, 1957, Jonathan Grogono, M.R.C.S., L.R.C.P., of Southwold, Suffolk, late of Leighton Buzzard, Beds, aged 76.
Morris.—On October 21, 1957, Ethel Remfrey Morris, M.B., B.S.
O'Loughlin.—On October 18, 1957, at Oldchurch Hospital, Romford, Essex, William Smith O'Loughlin, M.D., M.R.C.O.G.
Paton.—On October 22, 1957, Ronald Stewart Paton, M.B., Ch.B., of Atholl Place, Perth.
Pyle.—On October 27, 1957, at Fearn, Ross-shire, John Pyle, M.C., M.B., Ch.B.
Struthers.—On October 24, 1957, at his home, Summerhill House, Bristol, George Struthers, M.B., Ch.B., aged 53.
Taylor.—On October 18, 1957, at Forest View, Rodborough Common, near Stroud, Glos, James Ewen Taylor, M.B., Ch.B., late of Villa Rosa, Carnoustie, Forfarshire, aged 78.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Genetic Hazard of Chest Radiography

Q.—(1) Does radiography of the chest (miniature or full-size) involve any genetic or other hazard to the person x-rayed? If so, how frequently is it justifiable to radiograph the chests of (a) those such as teachers, nursery staff, and others in close contact with children, and (b) those whose work especially exposes them to risk of tuberculous infection such as nurses and laboratory workers? With regard to the latter, is there an age at which their radiological surveillance becomes less imperative? (2) Do mass radiography surveys on the scale, for instance, of those now proceeding in Scotland carry any genetic or other risk?

A.—(1) There is no evidence that radiography of the chest, miniature or full-size, involves any genetic or other hazard to the person x-rayed. The rigorous standards of the Medical Research Council's report¹ permit 250 miniature or 1,000 large x-ray films to be taken during any one individual's lifetime, using present techniques.

People in contact with children should be x-rayed annually, irrespective of their age. People whose work exposes them to the risk of tuberculous infection should have a six-monthly radiograph up to the age of 30, and an annual radiograph after that age.

(2) Mass radiography surveys carry no genetic or other risk.

Primary Lung Cancer in Domestic Pets

Q.—Some writers have expressed the opinion that there is a relationship between bronchial carcinoma and atmospheric pollution. If this is so, one would expect to find an increasing incidence of lung cancer in dogs, cats, and other pets kept in large towns. What evidence is there on this?

A.—Lung tumours are not common in animals,¹ and, at any rate in London, there is no suggestion of an increasing incidence of such tumours in dogs and cats. For example, of 464 neoplasms of cats examined at the Royal Veterinary College since 1940, only three were considered to be primary lung carcinomas; in a corresponding series of 2,361 tumours from dogs, not more than six were primary lung tumours.² It is interesting that ten Thijs and Ressang³ have recently reported what appears to be a statistically significant increase of lung cancer in dogs in Utrecht, but even there the numbers seen were small: only 22 cases of lung cancer in dogs were diagnosed there since 1924, 16 being seen in the last four years. Continued observation is clearly needed.

However, such studies on dogs and cats do not necessarily have any bearing on the aetiology of lung cancer in man. It does not follow that increasing atmospheric pollution must lead to an increase in lung cancer in domestic pets, as is suggested in the question: for example, these animals might not live long enough to develop lung cancer even if they did inhale an effective amount of carcinogenic material, or their bronchial epithelium might be less susceptible. There is also the possibility that aerial contamination might in fact be responsible for cancer in dogs and cats at some site other than the lung. There is no definite proof of this, but there are some suggestive observations. In the London tumour surveys mentioned above² there was a high incidence of squamous-cell carcinoma of

the tonsil of the dog and of similar carcinomas of the upper alimentary tract of the cat (tongue, gum, tonsil, and oesophagus particularly). There is some indication that cancer of the tonsil is much commoner in dogs living in London than elsewhere, and it may be that when a dog breathes through its mouth it brings a carcinogenic agent in the air into contact with a susceptible epithelial tissue (bilateral cancer of the tonsil being occasionally seen). Similarly, the cat, in cleaning its coat and swallowing fur, may take a carcinogenic agent into its mouth and oesophagus. It is not yet known whether cancer of the upper alimentary tract is commoner in London cats than in their country cousins, but a study of the furs of town and country cats for the presence of possible carcinogenic agents might show that they reflect their degree of aerial contamination by such agents.

The implication of this question is an important one, and a watch is being kept for primary lung cancer in domestic pets.

Repeated Piperazine for Threadworms

Q.—Is there any risk in giving repeated courses of piperazine citrate? A child aged 2 becomes readily reinfected with threadworms, and suffers from perianal irritation and disturbed nights. Piperazine brings rapid relief. In spite of treating the whole household, relapse occurs.

A.—Although toxic reactions following the use of repeated courses of piperazine have not yet been reported it would be premature to state that there is no risk of them occurring. The relapses reported in the case described emphasize that treatment of threadworm infections with piperazine alone may be ineffective; hygienic precautions should therefore always be combined with drug treatment.

The average length of life of female threadworms is four weeks; and, if reinfection can be prevented, all the worms will die and the patient be cured in about this time even without drug treatment. Reinfection is usually caused by patients scratching the perianal area where the eggs have been laid and thus transmitting the eggs to the mouth on the fingers, particularly under the nails. Keeping the fingernails short and clean, and scrubbing the hands after each visit to the lavatory and before each meal, will of themselves bring about a cure in the majority of cases and should certainly be recommended for the situation under consideration.

Dust, particularly that from bedclothes, often becomes contaminated with threadworm eggs. The bed-linen should therefore be changed at the commencement of treatment, and thereafter contamination can be kept to a minimum by wearing closely fitting underpants at night and by bathing each morning so as to wash away the eggs which may have been laid on the perianal skin during the night.

Psychiatric Grounds for Sterilization

Q.—We have recently been given valuable information in your *Journal* on the subject of the psychiatric grounds for termination of pregnancy.¹ I should be grateful for information about the psychiatric grounds for sterilization.

A.—This answer deals only with sterilization of the female.

A Departmental Committee on Sterilization (the Brock Report, 1934) advocated legislation to allow voluntary sterilization of a mentally defective person or one who has had mental disorder or one believed likely to transmit mental defect or disorder; but such changes have not been effected in the law, which is that sterilization on psychiatric grounds is lawful only if done in good faith to prevent a woman becoming a physical or mental wreck. Such psychiatric grounds

are similar to those for therapeutic abortion,³ though even more limited; a breakdown related to a pregnancy does not always preclude a later normal pregnancy. The medical defence societies would probably not cover a doctor unless he were acting with due care and within the law, and it is prudent, therefore, in any borderline case to consult one's defence society before advising operation.

The difficulty is that there is little definite knowledge of the long-term effects, good and bad, of sterilization. The chances of a *volte-face* later on, in spite of present clamant demands to be sterilized, are very great. Such patients are best referred to an experienced psychiatrist, as there must always be a genuine therapeutic purpose amounting to a "just cause," and with the criteria as yet so inadequately defined the decision is not an easy one. Moreover, most patients will respond to modern psychiatric methods of treatment, and operation is thereby unnecessary.

The consent of the husband should be obtained, as, if his wife is sterilized without it, he might petition successfully for divorce on the grounds of cruelty.

Prognosis of Treated Myxoedema

Q.—What is the prognosis in myxoedema controlled by thyroid medication? Should such patients be accepted as "good lives" for the purposes of life insurance?

A.—The prognosis in treated myxoedema is excellent, and such patients, because of their regular medical supervision, should be regarded as particularly first-class lives for life insurance. Obviously this statement applies only to patients who regularly attend their doctor and dutifully take their daily thyroid. If there is a risk of thyroid being forgotten (for instance, with an elderly or absent-minded patient), then a young relation should be made responsible for its proper administration or else there is a risk of relapse and the patient is not a "good life."

Coronary Thrombosis Despite Anticoagulant Prophylaxis

Q.—A patient of mine has suffered second and third attacks of coronary thrombosis while on prophylactic phenindione therapy. Despite a constant dosage the prothrombin activity in this case proves remarkably variable. Is it worth continuing the anticoagulant therapy?

A.—It is difficult to say whether phenindione therapy should be continued after this patient's third attack of coronary thrombosis, because no information is given about his cardiac function. Also, the questioner does not state whether anticoagulant therapy was easy to control before the second or third attacks of coronary thrombosis. If, for example, control was perfectly adequate after the first and second attacks, but has become variable only after the third, it is possible that the patient has some congestion of the liver which is making control of anticoagulant therapy extremely difficult. It is probably correct to say that, if a patient has cardiac failure of a degree sufficient to impair hepatic function which cannot be controlled by ordinary measures, then anticoagulant therapy on an out-patient basis should be stopped.

Such evidence as is available at the moment suggests that the mortality and complication rates in cases of myocardial infarction may be reduced by anticoagulant drugs, probably by their action in minimizing thrombo-embolic complications and perhaps also in limiting spread of clot in the thrombosed coronary vessel. As in this case, anticoagulants do not seem to prevent myocardial infarction. Therefore, if cardiac function remains satisfactory, it may be worth continuing anticoagulant therapy even after three attacks of infarction.

Disposal of Surplus Carbohydrate

Q.—By what routes and in what forms does the body dispose of carbohydrate ingested in excess of metabolic requirements, other than by deposition as fat or glycogen? If an abnormally large quantity is ingested, may it result in the alimentary enzymes being unable to catabolize it and partially digested carbohydrate being excreted in the faeces? I ask this because I have several times encountered patients who admit to consuming up to 30 spoonfuls of sugar daily in their tea, as a mere preliminary to the otherwise gross indulgence of a sweet tooth; and I have observed the association of such habits with boils, pruritus ani et vulvae, and thrush.

A.—The digestive enzymes are able to cope with considerable quantities of carbohydrate. Amounts taken in excess of metabolic requirements are normally stored as glycogen or fat, unless taken in such excess as to cause vomiting or diarrhoea. There is, of course, an association between boils and pruritus on the one hand and diabetes mellitus on the other, and this association probably depends on the high tissue sugar levels found in diabetes. It is doubtful, however, whether in healthy subjects excess dietary carbohydrate would raise the blood sugar above normal.

Tears at Periods

Q.—What is the explanation of the regular occurrence of a copious flow of tears at the time of menstruation? Could this be related to "menstrual migraine" in some way, or is a psychological or allergic aetiology more probable?

A.—The most likely explanation is that these symptoms are part of a premenstrual tension syndrome. The premenstrual tension syndrome was dealt with in detail by two papers¹ and a leading article² in this *Journal* a few years ago.

Asthmatic attacks, migraine, rhinorrhoea, and emotional upsets are only a few of the symptoms, both somatic and emotional, which may occur. As was pointed out in the leading article, the time of onset of these symptoms is usually but not always immediately premenstrual, but their recurrence is characteristically cyclical. The aetiology of the syndrome is still not completely understood, but the evidence suggests that it is largely due to a hormonal imbalance—an abnormally high oestrogen/progesterone ratio.

 Dan Mason Research Fellow, West London Hospital Medical School

W. S. C. COPEMAN, O.B.E., M.D. F.R.C.P.
 Physician-in-Charge, Rheumatism Department

It has been shown in controlled trials by the joint committee of the Medical Research Council and Nuffield Foundation (1954, 1955) and by the Empire Rheumatism Council (1955, 1957) that the average case of rheumatoid arthritis fares as well with aspirin as with cortisone. However, there are certain cases which remain active in spite of treatment with rest in hospital and salicylates or gold, and some of these we have treated with corticosteroids, a number of them continuously for six years. In the early days we gave oral cortisone for preference, but owing to the shortage of supplies we sometimes used corticotropin (A.C.T.H.) as an alternative. When reporting to the Medical Research Council three years ago we found that we had then treated 50 cases with cortisone, and in only two had we been able to stop the drug on account of a remission; whereas of 42 who had received corticotropin we had been able to withdraw the drug in 12.

Treatment with cortisone, its newer analogues prednisone and prednisolone, or corticotropin is not infrequently associated with serious side-effects. The suggestion, therefore, that clinical remission occurred in more cases treated with corticotropin than with cortisone indicated that further observations might give valuable information, though the disadvantages of daily injection had to be accepted.

Since the original report of Hench, Kendall, Slocumb, and Polley (1949) on the clinical effects of cortisone and corticotropin, efforts have been made to discover methods of measuring adrenocortical activity. In 1950 Porter and Silber reported studies on urinary steroids, whilst in 1955 Appleby, Gibson, Norymberski, and Stubbs published a method of estimating total 17-hydroxycorticosteroids (17-(OH)CS) in urine which could be carried out as a routine laboratory procedure. Since this method is a measure of glucocorticoid metabolism it

gives a quantitative indication of the total adrenal stimulation produced by corticotropin.

Selection of Patients.—This method has been applied, in conjunction with clinical observation, to severe active cases of rheumatoid arthritis which have failed to respond to classical methods of treatment. At the beginning of treatment the majority of these patients could no longer work or were compelled by their illness to take so much time off that they were anxious about the future. The women were unable to do their normal housework. Patients with tuberculosis, diabetes, psychoneurotic tendencies, or a history of peptic ulcer or severe dyspepsia were excluded.

We are reporting on 49 patients studied during the last two and a half years while on a long-term regime of self-administered corticotropin. In all these cases, which have been observed for at least six months, regular clinical and biochemical observations have been made.

Method of Study

By collaborating in a number of multi-centre controlled trials we have gained experience in the clinical assessment of rheumatoid arthritis. It has become clear that many of the tests generally used are too subjective and that the more complicated ones are not suitable when patients are studied at frequent intervals for months or years. For this study we have chosen two clinical measurements which can be done rapidly and which our experience has shown to be the most satisfactory of a large number tried.

Tenderness of selected joints to firm pressure is assessed in three grades: 1 point if the patients admit tenderness; 2 points if they wince; and 3 points when they refuse to allow the test to be repeated. The total points are divided by the number of joints tested to give an average "score" for tenderness.

Strength of grip is measured with an ordinary sphygmomanometer. The rubber blood-pressure cuff is rolled and inserted in a cloth bag measuring 6 by 3 in.

5056

(15 by 7.5 cm.): this bag measures 2 in. (5 cm.) in diameter when inflated to a pressure of 30 mm. Hg (Fig. 1). The patient squeezes the bag as hard as possible, and the average of three readings is recorded for each hand.

FIG. 1.—Grip test.

The erythrocyte sedimentation rate is estimated by the Westergren method at monthly intervals.

Urinary Steroids.—Estimation of the urinary excretion of total 17-(OH)CS by Norymberski's method are done weekly throughout treatment and more often during the initial stages.

The collection of urine specimens by out-patients originally presented a problem. It was found impracticable for patients to bring a whole 24-hour specimen to the hospital each week. Therefore while in hospital for the start of treatment they are taught in the biochemical laboratory to measure a 24-hour specimen. When they leave hospital they are lent a litre-measuring cylinder and a number of 1-oz. (31-ml.) containers with wooden cases which can be posted. As nearly all these patients are now working they collect their specimens at the week-end, using small plastic bottles for urine collection when they go out during the day. An aliquot of the well-mixed specimen with a note of the 24-hour volume is sent by post to the laboratory each week. The accuracy of the 24-hour urine collection is checked by creatinine determinations.

Patients are admitted to hospital and treated only with rest in bed and adequate salicylates for at least a week. During this time daily urinary steroid estimations are carried out. If there is no improvement with rest, corticotropin is then started with the object of suppressing symptoms of active disease, abolishing tenderness, and substantially increasing the grip. In our experience this has always been accompanied by a rise in corticosteroid excretion.

Once symptoms are relieved and the initial adrenal stimulation is produced, we maintain a dose which will continue to suppress symptoms, whether this raises the corticosteroid excretion or not.

The average stay in hospital has been four weeks, and during that time the patients are taught to inject themselves daily with corticotropin by the subcutaneous route just as diabetics give themselves insulin. In this

series it is estimated that 26,000 injections have now been self-administered without mishap.

After leaving hospital these patients attend as out-patients about once a month for clinical assessment and send a specimen of urine each week for steroid estimation to the laboratory.

Controls.—For controls, patients with rheumatoid arthritis on salicylates or gold were used. Fig. 2 shows that full salicylate dosage produces no increase in corti-

FIG. 2.—Daily 17-(OH)CS estimations during control period on salicylates.

FIG. 3.—A six-months study with 17-(OH)CS estimations during gold therapy.

corticosteroid excretion, which, though varying from day to day, falls well within the normal range. Fig. 3 shows a study of a patient who received weekly gold injections for six months; again there is no evidence of adrenal stimulation.

Observations.—Of the 49 patients on whom we have carried out regular corticosteroid estimations during treatment six have gone into remission, 35 are still having corticotropin therapy, one has died, and seven have stopped treatment, six because of side-effects and one because of the development of apparent resistance to corticotropin.

As already stated, we have adjusted the dosage of corticotropin to the clinical course of the disease whilst recording the corticosteroid excretion as an indication of resultant adrenal activity. In this respect our study differs from that of West (1957), who aimed to produce continuous adrenal stimulation with a daily 17-(OH)CS excretion of between 20 and 35 mg. and then studied the effect of this on the course of the disease.

Clinical and Biochemical Responses

Initial Response

Corticosteroid estimations were carried out from the start of treatment in 41 cases. In all these there has been a rise in 17-(OH)CS excretion concomitant with clinical suppression of the disease, as indicated by a significant diminution of joint tenderness, increase in the strength of the grip, and a fall in the sedimentation rate. The level, however, to which the corticosteroid excretion has been raised has varied a good deal, but it does not appear that a high level is necessary to achieve a clinical response. West (1957) states that elevation of 17-(OH)CS excretion by 50 to 100% above the pre-treatment level results in complete or partial suppression of symptoms and signs of disease activity. We have reviewed our observations in the light of this statement and agree with it, although in a few patients elevation of 17-(OH)CS excretion of this order has been accompanied by only slight but measurable clinical improvement. We have only once observed a favourable clinical response without a rise of 17-(OH)CS excretion at least 50% above the pre-treatment level: this was a patient whose excretion of 17-(OH)CS before treatment was unusually high (18 mg./24 hours) and who showed a good clinical response to corticotropin when it rose to 21 mg./24 hours.

Long-term Treatment

Most patients appear to need continuous but usually only slight adrenal stimulation (as evidenced by a raised 17-(OH)CS excretion) to maintain clinical suppression. On a constant dose of the same batch of corticotropin there is a general tendency for 17-(OH)CS excretion to fall off after a few weeks, and this is associated, as a rule, with clinical relapse. This apparent acquired resistance to corticotropin is a relative one; an increase in dose, sometimes by as little as 5 units, or a change of batch, results in a further rise of corticosteroid excretion and resumption of clinical improvement. Since we have been using biochemical control we have only once seen almost complete resistance to corticotropin. This was in a patient who, after responding satisfactorily for seven months, relapsed severely in the face of intense emotional stress and failed to show any significant clinical or biochemical response to several potent preparations of corticotropin in doses up to 30 units every six hours.

Less frequently than the development of partial resistance to a given batch of corticotropin, we have observed an apparent increased sensitivity, with a rising 17-(OH)CS excretion, although the dose remains constant. The significance of this pattern of adrenal response is yet to be elucidated.

These variations in adrenal response to corticotropin during long-term treatment (Fig. 4), and the variation in strength between batches, discussed below, mean that fairly frequent adjustments of dosage may be necessary to maintain clinical suppression without causing excessive adrenal stimulation. It is possible to achieve this, and even after several months' treatment we have found that the pattern of clinical and biochemical response remains the same. We also agree with West (1957) that the clinical suppression of disease activity associated with a given level of corticosteroid

FIG. 4.—Correlation between 17-(OH)CS output and clinical response.

excretion does not diminish during long-term treatment. This is in contrast to our experience with cortisone, where not infrequently clinical suppression diminishes although side-effects persist.

Variation in Strength of Batches of Corticotropin

The variation in strength between different batches of the same preparation of corticotropin is a practical difficulty in long-term treatment. We suspected this variation early in our work with corticotropin, but were unable to confirm it until biochemical control became available.

Fig. 5 shows the type of variation which can occur. This woman had been having corticotropin for four years without biochemical observations but with satisfactory suppression of symptoms until she changed to batch N.34110. There was immediate and severe relapse. The steroid excretion at that time indicated little adrenal stimulation. On another batch (P.80001), in the same dosage, immediate suppression of symptoms occurred with marked adrenal stimulation. It also brought side-effects, mooning and acne, but even in

FIG. 5.—Variation between different batches.

half the dosage it produced three times the steroid excretion of the previous batch. This is not an isolated example of batch variation. We have found that 17-(OH)CS excretion in patients shows general agreement on the relative potency of individual batches. In the case of some of the earlier "highly purified" preparations this variation was due to rapid deterioration during storage, which has now been overcome. It should also be appreciated that the "official" method of assay (ascorbic acid depletion in rats) has wide limits of error, and the permissible limits of accuracy of labelled strength are 50 to 200%; but it is probable that variations of the order of 80-125% are detectable when using corticotropin clinically, especially when the aim is to produce only relatively slight adrenal stimulation.

Remission of Disease

Six of the 49 cases treated with corticotropin in the last two and a half years have gone into remission. The drug has been withdrawn and it has not proved necessary to recommence it.

We have come to recognize a clinical and biochemical pattern in those patients who go into remission (Fig. 6). In all cases there has been a good clinical response to adrenal

FIG. 6.—Clinical and biochemical pattern when the disease goes into remission.

stimulation with a fall of the sedimentation rate to the normal range. Continued adrenal stimulation has been necessary for variable periods to maintain clinical suppression; eventually, however, the expected fall in 17-(OH)CS excretion after a period on a constant dose of one batch has not been accompanied by clinical relapse, and we have been able to withdraw corticotropin gradually.

Withdrawal Effects

One of the main problems encountered in the treatment of rheumatoid arthritis and other diseases with cortisone and the newer oral steroids is the danger of distressing general symptoms which accompany the relapse of the arthritis when the drug is withdrawn. These symptoms, which are due to involution of the adrenal cortex, include profound fatigue, asthenia, hypotension, dizziness, and muscular weakness, possibly with fever. During the course of this study, in testing the strength of a variety of batches and preparation of corticotropin, we have often changed patients abruptly from a strong batch giving adrenal stimulation (17-(OH)CS > 30 mg./24 hours) to a weak batch giving no apparent adrenal stimulation (17-(OH)CS < 10 mg./24 hours), but although we have seen severe relapse of the arthritis on these occasions there have seldom been any general symp-

toms. Neither have we seen general symptoms when the corticotropin has been withdrawn during a remission, though this has always been done slowly.

We can only speculate on the reasons why withdrawal of corticotropin should be so much easier than that of cortisone. At first sight it would appear that the tendency to suppress endogenous hormone production would be common to both forms of therapy. There is, however, one factor which may be significant in this respect: even with the long-acting corticotropin preparations the effect of an injection lasts only about 12 hours, so that with daily injections adrenal stimulation, and therefore presumably suppression of endogenous corticotropin production, is intermittent.

Pregnancy

We have been able to study one patient who had corticotropin throughout her pregnancy. This is worth recording, as in a search of the literature we have been unable to find a similar report.

Mrs. B. aged 39, who had had two previous normal pregnancies, the last eight years earlier, was injecting herself with corticotropin with adequate suppression of arthritic symptoms and was leading a normal life. In April, 1956, she became pregnant, and it was noted that there was marked adrenal stimulation with a daily excretion of 65 mg. of 17-(OH)CS. We attempted to withdraw corticotropin in June because of a tendency to hypertension, but a severe clinical relapse occurred with a drop in steroid excretion, and the drug had to be restarted. However, during the last four months of pregnancy satisfactory clinical suppression was achieved with a dose of only 5 units per diem as compared with the 15 units she had required before pregnancy. A normal premature female child was delivered by caesarean section at about eight and a half months. Following the birth there was a rapid relapse of the arthritis which made necessary a rise in the corticotropin dosage. Some four weeks after delivery a marked increase in adrenal stimulation occurred, culminating in a steroid excretion of 116.7 mg. per diem, which then fell slowly to the previous level on the same dose (Fig. 7).

FIG. 7.—17-(OH)CS output followed throughout pregnancy.

The diminished requirement of corticotropin during the later months of pregnancy fits in with the recognized tendency to clinical remission of arthritis during this time, and with the evidence of increased adrenal activity described by Bayliss (1955). The severe relapse when corticotropin was stopped during the fifth month, however, shows that the natural increase in adrenal activity was not of itself sufficient to produce suppression of the disease. We have no explanation to offer for the sharp rise in 17-(OH)CS excretion in the post-natal period.

Side-effects

All but three of these 49 cases showed side-effects, if only of slight degree, at some time during treatment. The incidence of these is shown in the accompanying Table. In

Incidence of Side-effects			
	Women (33)	Men (16)	Total (49)
Hypertension (diastolic pressure 100 mm. Hg or above)	9	5	14
Weight increase (7 lb. (3.2 kg.) or more above normal weight)	11	5	16
Oedema	11	4	15
Moon-face	25	7	32
Chemosis	9	3	12
Pigmentation	9	6	15
Androgenic effects (acne, hirsuties, menstrual disturbance)	21	4	25
Glycosuria	4	1	5
Osteoporosis	1	1	2
Dyspepsia, peptic ulcer, haematemesis	2	2	4
Mental disturbance	2	2	4

the majority of cases these side-effects have not been severe and have not influenced treatment. We have, however, had one death from haematemesis ascribable to corticotropin—discussed below—and have stopped treatment because of side-effects in six cases. The predominant features which made this necessary were: osteoporosis with pathological fracture in one case, androgenic effects in two cases, chemosis in one case, fluid retention in one case, and mental disturbance in one case.

We have observed certain trends in the incidence of side-effects at different levels of adrenal stimulation; these are discussed below.

Hypertension.—All patients have shown some rise of blood pressure when the 17-(OH)CS excretion has risen significantly above the normal range. When the excretion has been between 25 and 35 mg./24 hours about 15% of patients have shown a rise of the diastolic pressure to 100 mm. Hg, and when the excretion has exceeded 40 mg./24 hours the proportion has risen to about 45%. As a rule these rises in blood pressure are transient and closely parallel the rises in corticosteroid excretion. We have not seen chronic hypertension arise in this way, but in a few cases, when a high corticosteroid output has been maintained for two to three weeks, the hypertension has persisted after a reduction in dose of corticotropin has brought the 17-(OH)CS down to a lower level, and the blood pressure has then fallen only gradually over a period of weeks or months.

Glycosuria.—As with the blood-pressure responses, some patients have shown transient glycosuria when corticosteroid excretion has been high. One patient developed a true "steroid diabetes": this was a man who showed evidence of marked adrenal stimulation when he was given what proved to be a very powerful batch of corticotropin. Despite rapid reduction of the dose, his 17-(OH)CS excretion rose from 40 to 105 mg./24 hours over a period of five weeks. It then fell to about 80 mg., but after a further three weeks he developed glycosuria, with polyuria and thirst, and a glucose-tolerance test showed a diabetic type of curve; corticotropin was withdrawn, and with the fall in 17-(OH)CS excretion glucose tolerance gradually reverted to normal, although there was a significant time-lag. Characteristically, at no time was ketonuria detected.

Fluid Retention and Weight Increase.—All patients have put on some weight while having corticotropin, but many of them were underweight when treatment was started, and we have taken an increase of 7 lb. (3.2 kg.) or more above their normal weight as being excessive. Improvement of appetite almost always follows effective corticotropin administration, and many patients have to be warned to watch their weight. The majority are able to maintain a normal weight without any drastic dietary restriction, but in about 20% strict measures are necessary. On the whole it is this group which shows a tendency to fluid retention.

these side-effects appear to be due to individual susceptibility rather than adrenal over-stimulation, and almost without exception are apparent as soon as the daily 17-(OH)CS excretion rises above 15 mg. (the upper range of normal values). In these cases where fluid retention is easily produced we have found acetazolamide useful in permitting corticotropin therapy to be continued.

Moon-face and Chemosis.—Mooning of the face is a feature so common with all forms of corticosteroid therapy that it can hardly be called a side-effect. It is quite independent of fluid retention. With similar levels of adrenal stimulation it appears to occur much more readily in women than in men, and is often detectable when 17-(OH)CS excretion rises only just above the upper limit of normal. In five patients in this group we have observed conjunctival congestion and oedema in association with severe mooning. We have not seen this feature with other forms of corticosteroid therapy even when mooning has been very marked. This chemosis has developed in all five cases when 17-(OH)CS excretion has been raised above 45 mg./24 hours, but has tended to persist for some weeks after the excretion has fallen to 20 mg. or even lower.

Androgenic Effects.—We have found that evidence of androgenic overactivity is very common in women receiving corticotropin. Of the 33 women in this series, 21 showed some side-effects of this kind, although in the majority they were not severe. Acne was the commonest manifestation, especially in younger women, but hirsuties was not uncommon and menstrual disturbances occurred quite often; out of 21 women who gave a history of more or less regular menstruation, 13 experienced some definite irregularity whilst on treatment. In premenopausal women these androgenic effects often occurred when the 17-(OH)CS excretion was raised only slightly above the normal range—that is, to 15-25 mg./24 hours—and there appeared to be individual susceptibility. As a rule androgenic effects were not apparent until the patient had received an effective dose of corticotropin for at least three weeks. In two women it proved to be impossible to produce suppression of the disease without causing severe acne, and corticotropin had to be abandoned on this account. In one of these, 17-ketosteroid as well as 17-(OH)CS estimations were performed, and it was found that corticotropin was causing an almost equal excretion of each. In men and post-menopausal women acne and hirsuties (and loss of scalp hair in women) have been much less common and have been seen only when the 17-(OH)CS excretion has been at least moderately high, usually above 35 mg./24 hours.

Pigmentation.—This is presumed to be due to impurity of the corticotropin preparations, and one would therefore not expect any close relationship between its occurrence and 17-(OH)CS excretion. It might be anticipated that difference in melanophore-stimulating activity could be detected between different batches of corticotropin, but we have not observed this. As with the androgenic side-effects, there appears to be considerable variation in individual susceptibility, and usually pigmentation is not noticeable until adrenal stimulation has been maintained for two to three weeks.

Dyspepsia, Peptic Ulcer, and Haematemesis.—We have been impressed by the absence of dyspepsia when using corticotropin rather than oral steroid therapy. A few patients who had complained of dyspepsia of flatulent type before starting treatment had some persistence when on corticotropin, especially if they became rather "over-stimulated" and felt "blown-out." In two cases, however, symptoms of this type cleared up after starting corticotropin. We are thus generally in agreement with West (1957), who states that none of his 66 long-term patients having corticotropin had any dyspepsia. One of our patients had very mild dyspepsia for a short time and subsequently perforation of a duodenal ulcer. As mentioned above, one patient died after severe haematemesis. He was the patient who developed "steroid" diabetes after prolonged adrenal over-

stimulation, and this aspect of the case has been discussed. Withdrawal of corticotropin to control the diabetes resulted in severe relapse of his arthritis, so it was restarted in small dosage. Although he then proved to be very sensitive, as shown by a rapidly rising 17-(OH)CS excretion, the glycosuria did not recur. Three weeks later he had severe and persistent haematemesis. As the bleeding did not cease, surgical treatment was undertaken, but at operation no ulcer or bleeding-point could be found. A partial gastrectomy was performed, but haemorrhage continued post-operatively and he died. At necropsy no definite bleeding-site could be identified, but the whole upper intestine appeared to be thinned and oozing blood diffusely.

Conclusion.—There seem to be certain broad patterns in the occurrence of side-effects. Some, such as fluid retention and androgenic effects, depend largely on individual susceptibility and often occur with only slight adrenal stimulation. Others, such as hypertension and glycosuria, occur only with higher levels of 17-(OH)CS excretion and are usually transient, but if overstimulation is not soon checked there may be a considerable time lag between the subsequent fall of 17-(OH)CS and reversal of these side-effects. Androgenic effects are common in women of menstrual age and occur with much lower levels of adrenal stimulation than in men or older women; these side-effects and also pigmentation are not apparent for two to three weeks after the rise in 17-(OH)CS excretion, but persist for several weeks after the level has fallen to normal.

Summary

Since the anti-inflammatory effects of cortisone and corticotropin in rheumatoid arthritis were first reported the main work in both the clinical and the biochemical fields has been on oral steroids.

Our interest in corticotropin was originally stimulated by the finding that, after using it for three years as an alternative to cortisone, six times as many patients had gone into remission. This observation has not been confirmed in the subsequent series reported here.

However, we have learnt that treatment of severe rheumatoid arthritis with self-injected corticotropin (A.C.T.H.) over long periods is a practical procedure, and when used with biochemical estimations has certain advantages over oral cortisone and its newer analogues. These advantages are: (1) The level of adrenal stimulation produced by corticotropin can be estimated by measurement of the total urinary excretion of 17-hydroxycorticosteroids (17-(OH)CS). This can be done for out-patients by the method described. (2) When corticosteroid excretion is seen to fall the dose of corticotropin can be raised before severe clinical relapse occurs. (3) When the corticosteroid excretion is seen to rise it is possible to reduce the dose of corticotropin before excessive adrenal stimulation occurs.

We have studied 41 patients with the help of biochemical estimations from the beginning of treatment. In every case suppression of activity with a fall in sedimentation rate followed the administration of corticotropin in a dose which proved sufficient to raise the urinary excretion of 17-(OH)CS by a significant amount. In 23 cases the excretion was doubled, and in 17 it was increased by more than 50%. We have not seen a single case where clinical suppression of the disease was not accompanied by a significant increase in corticosteroid excretion.

After the initial response, dosage has had to be adapted to the fluctuation of the disease activity, or the development of an altered sensitivity to the hormone. We have observed that it has not been necessary to maintain a high level of adrenal stimulation in order to

obtain continued clinical improvement; and that adequate clinical and biochemical response can be maintained for years with only minor adjustments of steroid dosage. The occurrence of remission is recognized if at any time during a period of satisfactory clinical response a fall in the patient's 17-(OH)CS excretion is noted, without any concurrent relapse of the disease. One of the difficulties in the use of corticotropin is the variation in the strength of batches. This is a matter which is being explored continuously by the manufacturers, and a constant standard will undoubtedly be achieved in time.

We have observed that the more severe side-effects such as hypertension and glycosuria occur only when a high level of hydroxycorticosteroid excretion has existed for some weeks and that they are reversible. Androgenic side-effects, particularly acne, occur commonly in women before the menopause with only slight adrenal stimulation. We are impressed with the absence of dyspepsia in our patients. Only one developed peptic ulceration, whereas in 83 consecutive cases treated with oral steroids during the last five years 13 have developed gastric or duodenal ulceration. If corticotropin is withdrawn, relapse of the arthritis will follow, but this is not accompanied by the distressing general symptoms which attend the withdrawal of cortisone and other oral steroids.

We consider that biochemical control during long-term treatment of severe cases of rheumatoid arthritis with corticotropin results in a more accurate and less dangerous dosage regime than was formerly practicable. If a simple method were devised for testing the urinary corticosteroid excretion within a fairly wide range it would bring this additional method of control into the realm of routine clinical medicine.

A method of controlling dosage is described and discussed with reference to long-term treatment with biochemical estimations. It seems that the use of steroid therapy in a severe case of rheumatoid arthritis will probably not alter the basic course of the disease; the satisfactory suppression of the inflammatory element will, however, enable the patient to regain independence and live a normal life.

We would like to thank Professor F. G. Young, F.R.S., and Dr. P. M. F. Bishop for their advice and help. The corticotropin used for this study was partly provided by the Ministry of Health, and supplies were also given to us by the following firms: Crookes Laboratories Ltd. and Organon Laboratories Ltd., of England; Armour Laboratories and Wilson Laboratories, of the United States; and Nyegaard and Co. A/S, of Norway.

The five-hundred-thousandth microscope to be made by the firm of Ernest Leitz was presented last month to Dr. Paul A. Weiss, head of the department of developmental biology at the Rockefeller Institute, New York. In 1907 the firm gave Robert Koch their 100,000th microscope; the 150,000th went to Paul Ehrlich in 1912; the 200,000th to Martin Heidenhain, histologist, in 1921; the 300,000th to Ludwig Aschoff in 1930; and the 400,000th to Gerhard Domagk in 1949.

TWO YEARS' EXPERIENCE OF PREDNISONE IN RHEUMATOID ARTHRITIS*

BY

GEORGE R. FEARNLEY, M.D., M.R.C.P.

GEOFFREY V. BALMFORTH, M.B., B.S.

AND

ROY BLATCHLEY, M.B., B.S.

From the Rheumatism Clinic, Gloucestershire Royal Hospital

Early in 1955 Bunim and his colleagues reported on the use of two analogues of cortisone, prednisone ("metacortandracin") and prednisolone ("metacortandralone"), in the treatment of rheumatoid arthritis. These two steroids differ from cortisone and hydrocortisone respectively in possessing a double bond between carbon atoms 1 and 2 of the A ring of the molecule. This small structural change is responsible for two notable differences between parent and offspring; the latter are weight for weight three to four times as potent as cortisone, and they do not cause sodium retention in therapeutic dosage. There is little to choose in action between prednisone and prednisolone; in general their effects are the same as those of cortisone, except that they have gained in some quarters a particular reputation for promoting dyspepsia, peptic ulceration, and haemorrhage.

In 1955 both steroids became available for hospital use and later were released for prescription on form E.C.10. The situation has thus arisen that two powerful drugs, about which comparatively little has been published in this country, are widely available. In this instance a volume of advertising has eclipsed the literature, and both steroids can be obtained not only as such but in compound form, either with an antacid or in small amount in combination with aspirin. Satisfactory proof is lacking that the first confers safety or that the second is efficacious. We here record our experience with one of these steroids, prednisone, over a two-year period. It must be emphasized that what follows is a retrospective analysis of the practice of a rheumatism clinic, and not a report of an organized clinical trial designed in advance and statistically controlled.

The Patients

From June 15, 1955, to June 15, 1957, in a new rheumatism clinic, a total of 167 patients with rheumatoid arthritis were seen. Many of these patients in the past had received gold, phenylbutazone, cortisone, and corticotrophin; most had received simple analgesics of aspirin type; none to our knowledge had been given either prednisone or prednisolone. The practice of the clinic was to assess each patient when seen, or after any necessary investigations, in regard to activity, extent and severity, and interference with function. Patient with mild arthritis and little limitation of function are advised about rest and exercise, the value of aspirin, and simple self-administered physiotherapy. They are referred back to the care of their own doctors, but usually asked to attend the clinic for review at six-monthly or yearly intervals. Patients with moderately severe disease attend the clinic regularly and are given interrupted courses

*Based on the opening paper in a symposium on steroid therapy in rheumatic diseases at the meeting of the Section of Physical Medicine at the Annual Meeting of the British Medical Association, Newcastle upon Tyne, 1957.

of physiotherapy, splintage, local hydrocortisone where applicable, and simple orthopaedic appliances when indicated. Severe cases fall into the following categories: (1) those with severe acute arthritis, often of recent onset; whenever possible such patients are admitted for in-patient treatment; (2) patients who have recently become bed-fast or chair-fast; again some but not all of these require admission; and (3) patients whose capacity for work is becoming impaired. Obviously these groups are not distinct; there is much overlap. Nearly all patients in groups 2 and 3 have had a prolonged trial of aspirin type of analgesic in adequate dosage, and many have had a variety of other drugs as well. The patients in these two groups present a therapeutic challenge, and neither they nor very often their doctors are always comforted by an assurance that they will do as well on aspirin as anything else. Our policy with regard to groups 2 and 3 has been to treat each patient according to his or her merits, but to restrict drug therapy whenever possible to the aspirin group for a period of time at least. Latterly we find that, with increasing experience of prednisone, we tend to use it rather earlier than we did initially and that the criteria for its administration have become less stringent.

Drugs Used

Table I shows the drugs used in the treatment of 167 patients with rheumatoid arthritis, together with the transfers from one drug to another. It has been possible to maintain the majority (105) on aspirin. The 15 patients started

TABLE I.—Drugs Used in 167 Cases of Rheumatoid Arthritis

Drugs Used	Initially	Finally
Aspirin	129	105
Phenylbutazone	15	15
Cortisone	8	0
Prednisone	15	47

Transfers		
Aspirin	to prednisone	16

"	" phenylbutazone	9
Phenylbutazone	" aspirin	1
"	" prednisone	8
Cortisone	" aspirin	1
"	" prednisone	8

on phenylbutazone are not identical with the 15 patients having phenylbutazone at the final assessment because of transfers between groups. Cortisone was used initially in only eight patients, and only one patient was transferred from aspirin to cortisone, and later back to aspirin. The reason for this is that quite early in the two-year period the results obtained with prednisone appeared better than those obtained with cortisone, and we have for some time stopped using the latter. Fifteen patients were started on prednisone when first seen, but by June, 1957, the number receiving this steroid had risen to 47, the increase being accounted for by transfers from the other groups. It will be noted that all eight patients started on cortisone were eventually changed to prednisone.

In addition to the 47 patients who had been started on prednisone by June, 1957, there were two who moved to another neighbourhood, and, being unavailable for assessment, are not included. In three patients of the prednisone group the drug was discontinued; in two, a man and woman, because of spontaneous remission at six and eight months after prednisone was started, and in one, a woman, because of severe hypertension at five and a half months. The arthritis of this patient has also gone into remission, but the hypertension persists and has recently been complicated by subarachnoid haemorrhage. Unfortunately this patient is one of the few who did not have a blood-pressure reading taken at the start of steroid therapy, the hypertension being discovered two months later. The remaining patients, 44 in number, are still receiving prednisone. The Chart overleaf shows the age and duration of disease of the prednisone-treated patients; the greater number are in the older age groups.

The initial dose of prednisone was 5 mg. eight-hourly, and in only one patient has the dose been increased to 20 mg. daily. In eight patients the dose was reduced to 2.5 mg. eight-hourly, but the remainder have not tolerated reduction and are maintained on the 5-mg. dose. Recently we started

Age of patients on prednisone and duration of their rheumatoid arthritis.

to use an initial dose of 2.5 mg. eight-hourly, but this does not apply to the patients in this series. Patients on steroid therapy were for the most part seen monthly at the clinic. Lately those well under control and devoid of complications were seen at intervals of two months. At each attendance inquiry was made about dyspepsia in particular, and a routine blood pressure, urine, and weight check carried out. We have not found it necessary to determine serum electrolytes. A barium-meal examination was done in any patient who developed anything more than mild transient dyspepsia.

Complications

Table II shows the complications encountered in relation to duration of prednisone therapy. Dyspepsia was fairly common, in line with the experience of others, occurring in

TABLE II.—Complications During Prednisone Treatment of 47 Patients

Months of Therapy:	0-		6-		12-		18-24		Totals
	F	M	F	M	F	M	F	M

Other							1		1

11 patients. In four patients the dyspepsia was mild and transient; in five it was persistent, requiring an antacid for its control, but the barium-meal examination has so far been negative. These patients are being closely observed, but all of them appear to be free of epigastric pain provided that a dose of antacid is taken with each dose of prednisone. They regard this as a minor price for the improvement in their arthritis, but we are unable to feel complacent, since we do not believe that control of symptoms in this way necessarily confers safety. For this reason we reject the use of tablets containing prednisone together with an antacid, certainly when used routinely from the outset, since nobody has proved that epigastric pain after taking prednisone is not a pointer to the risk of perforation or haemorrhage, and to mask such a pointer seems indefensible. But we also prefer to give a separate antacid to patients who have developed

epigastric pain on prednisone, since this serves to remind doctor and patient that all is not as well as it should be. Two patients have developed peptic ulcers. In one, whose barium-meal examination showed an active duodenal ulcer, prednisone was gradually withdrawn, with resulting relapse of the arthritis. The other patient whose barium meal showed a prepyloric ulcer is being maintained on prednisone and an ulcer regime in response to her entreaties. A recent barium-meal examination no longer showed an ulcer crater.

Although dyspepsia was the commonest complication, its incidence in these patients (23%) was less than that in the 24 patients given phenylbutazone, of whom 11 developed dyspepsia, an incidence of 46%.

Of the remaining complications, obesity has not been a problem; it was pronounced in four patients and is now controlled by diet in three of them. A few patients developed mooning of the facies, and two had a mild acneiform eruption. The blood pressure was raised in two patients. In one, mentioned previously, it cannot be definitely ascribed to steroid therapy; in the second, a middle-aged woman, the blood pressure rose from 140/80 to 190/100 since she had prednisone, but this is not considered sufficient to withdraw the drug.

Diabetes occurred in one case, an account of which is given below. Another patient, a middle-aged woman, already a diabetic, requires increased insulin while on prednisone. One patient, a woman with a past history of "nervous breakdown," in spite of great improvement of her arthritis became agitated and depressed and the drug has recently been withdrawn. Another patient, a woman, developed a syndrome of agitation, tiredness, and generalized weakness, all of which have subsided on continued prednisone.

Results

In a busy rheumatism clinic it is not always possible to make as many observations as are desirable. For this reason some of the currently used criteria—for example hand grip, joint tenderness, range of joint movement, and E.S.R. were not used routinely. When first seen each patient with rheumatoid arthritis was fully examined, and their joint status assessed in regard to the joints involved, also their range of movement and function. The patients' functional status was recorded in the conventional five grades, as follows. Grade 1, confined to bed; grade 2, bed or chair existence with limited mobility indoors; grade 3, able to get about but capable of only limited housework—unfit for employment; grade 4, capable of light work; grade 5, fully active. Particular note was taken of the patients' background and responsibilities and their capacity to fulfil the latter. At the time of analysis, therefore, it was possible to contrast the patients' status and function in relation to their responsibilities and social activities to that which obtained when they were first seen. From the patients' point of view we believe that successful treatment means, firstly, diminution of discomfort, and, secondly, which in part is consequent upon the first, the capacity for work and the capacity for enjoyment. "I can now look after my garden, which I could not do before" may be to the patient a therapeutic triumph.

Table III shows the functional status of 47 patients treated with prednisone when first seen and at the time of final assessment. It can be seen that there has been a shift to

the right, there being finally no patients in grade 1, eight patients in grade 5, as opposed to 1 initially, an increase of the number in grade 4, and a decrease of the number in grade 3. Table IV shows the change in functional status related to the duration of therapy. Only one patient, a

woman, deteriorated in functional status; 16 of 30 women and 9 of 17 men improved; in the remainder functional status was unchanged.

(one of these was the patient whose functional status had dropped two points; the functional status of the other had remained unchanged). Two patients reported no improvement, six reported only moderate improvement, 37 reported marked improvement. In all, 43 patients believed themselves to have improved since treatment with prednisone. This is greater than the "inevitable 60%" expected to improve whatever the therapy.

Although others have found it necessary to increase the dosage after a period to combat return of symptoms (Black *et al.*, 1955), so far we have not had occasion to do so. We do not subscribe to the popular practice of starting with a large dose and tapering down to a smaller maintenance dose, because some of the dramatic initial improvement may be lost as the dose is reduced in the presence of massive depression of the patients' own adrenals. It seems more logical to begin with a small dose and increase it if necessary.

The following case histories illustrate two very different problems in which prednisone has been helpful.

Case A.—A man of 35 had rheumatoid arthritis of six months' duration involving the whole of the right hand and wrist. No other joints were involved, but in the presence of a useless left arm and hand resulting from Erb's palsy he was quite unable to work as a clerk. Large doses of aspirin, wax baths, and a night splint were first tried without effect. He was then given phenylbutazone without improvement. After two weeks on prednisone, 5 mg. thrice daily, his right hand was virtually normal and he returned to work.

Case B.—A retired Army officer aged 64, when first seen in October, 1955, could barely get about the house with the aid of crutches. He was in constant pain or discomfort and his morale was very low. Although the rheumatoid arthritis was generalized, with characteristic deformities of the upper limbs, his greatest sources of pain and disability were his knee-joints, both of which were in flexion deformity with about 50% limitation of movement. Passive movement revealed the coarse creaking one associates with gross cartilage destruction. He was admitted and

advised to have an arthrodesis on one knee, but this he steadfastly refused in the hope that "some new treatment might come along." For a time, and rather unexpectedly, both knees improved on hydrocortisone injections every fortnight, and he was able to get about painlessly on his crutches. Gradually, however, the injections became less effective and at the end of a year he experienced relief for only two or three days after the injection. A past history of peptic ulcer and severe haematemesis had hitherto forbidden systemic steroid therapy. However, after a "hydrocortisone holiday" of nine months he reverted to his previous state, brightened by two to three days' relief every fortnight. After full discussion with him of the risks involved, he was admitted to hospital in October, 1956, for prednisone therapy. In spite of fears to the contrary, he had had no ulcer symptoms up to the time of writing, was free from pain, got about the village in which he lived, and daily went for a walk of about a mile on his crutches. After being on prednisone for two months he developed diabetes, which required insulin for its control.

To begin with, both in-patients and out-patients with severe disease were given an initial trial of aspirin, whatever their previous treatment. As our experience with prednisone has increased, however, we have tended to use it earlier, often without an initial trial of aspirin in patients who have had adequate aspirin dosage without relief for some time before attending hospital. This applies especially to young women with heavy family responsibilities, and men and women who have recently had to stop work or are on the point of being unable to continue. The demand of these patients for something to be done can be urgent, and, when it is, a detached and philosophical attitude to their disease would be inhumane. Fortunately such patients are a minority: in this series they represent most of the 15 who were started on prednisone when first seen.

Of the 167 patients with rheumatoid arthritis, 15 (about 10%) were deemed to require prednisone initially; but at the end of two years 47 (about 30%) were receiving the drug. This may seem a large percentage, but it must be remembered that most patients are referred to hospital because their disease is severe. The figure should not be taken as applicable to the rheumatoid population as a whole.

Discussion

The enthusiasm for cortisone in the treatment of rheumatoid arthritis which swept America some years ago was fortunately modified in this country by the cold scrutiny of the M.R.C. and E.R.C. cortisone-aspirin trials. It is no criticism of the conclusions of these trials, however, to suggest that, valuable though they were in putting cortisone in a proper perspective, they did not, nor did they attempt to, solve the therapeutic problem of the individual patient. It would be unrealistic to question the validity of the general experience of particular patients who have done badly on aspirin and well on cortisone, who have relapsed when the latter has been reduced or withdrawn and remitted when the drug has been reintroduced. For a time, at any rate, some patients have done well on cortisone, and whether their rheumatoid status turns out to be no better after, say, five years on cortisone than after five years on aspirin is not the only consideration. For this reason we believe that rheumatologists, with a few exceptions, have continued to use cortisone if only as a last resource. The practice of physicians throughout the country is, however, unknown, with the notable exception of Copeman *et al.* (1952, 1954), whose searching reports have been invaluable. Certainly, when the question of steroid therapy comes up at panel discussions, there is an atmosphere of disagreement and uncertainty. It must be admitted, however, that many, though not all, patients who improve on cortisone do not maintain their response; that it is a drug of great hazard is indisputable.

Because cortisone had been welcomed with hope and rejected with disappointment, the advent of prednisone and prednisolone evoked limited enthusiasm. Nabarro *et al.* (1955) feared that their absence of sodium-retaining effect might be a disadvantage in that one of the safeguards against increasing dosage to a really dangerous level would be removed.

After the two-year analysis reported here had been completed the first report of the Joint Committee of the Medical Research Council and the Nuffield Foundation was published (1957). In this carefully controlled trial prednisone comes out rather better than cortisone. In America, Black *et al.* (1955) conclude: "Prednisone has been found to be an effective antirheumatic agent in patients with rheumatoid arthritis whose response to other steroids was unsatisfactory. Its antirheumatic potency still appears to be three to four times that of cortisone or hydrocortisone. The return of rheumatic symptoms after 4 to 20 weeks of maintenance therapy may be controlled by a slight increase in the dosage."

The patients' assessment of their own improvement is often viewed with some scepticism, and the well-recognized response of many patients to a placebo justifies this. At the same time, in the everyday practice of medicine subjective improvement is only too often the sole criterion of successful therapy. The history of the treatment of rheumatoid arthritis is so beset with extravagant claims for dubious remedies that a healthy scepticism is desirable; but, like the tendency it counteracts, it too can be overdone. The conventional grades of functional status do not tell the whole story. We have been especially impressed by the fact that the improvement of some of our patients consists not so much in doing more than they did previously as in doing what they have always had to do more quickly, more comfortably, and more expeditiously. There is unfortunately no easy test for this kind of improvement. Without labouring the point, we believe that a report of subjective improvement supplemented by confirmatory answers to experienced questioning is of value.

Three fundamental questions, we believe, must be applied to any new drug used in rheumatoid arthritis: (1) Does it produce substantial relief in a high proportion of patients? (2) Is such relief maintained, and if so for how long? (3) Does the benefit obtained outweigh the risks and complications? From our experience with prednisone the answer to the first question is yes. In regard to the second, we believe that relief has been satisfactorily maintained in most patients so far, but it must be admitted that this belief depends in part on what our patients tell us, which may be subject to many fallacies. The answer to the third question at present is yes; further experience, however, could well cause revision of this opinion. If it be accepted that the newer steroids will help most patients for a time at least, the physician's problem is to know which patients it is justifiable to subject to the hyperadrenal state, however mild, with the risk of the attendant complications. We believe it justified in the cases of the wage-earner on the point of incapacity, the housewife unable to look after a young family, and the patient who is deteriorating rapidly despite all other measures. Whether steroids should be given to patients with milder disease or less arduous commitments cannot be decided until a great deal more experience throughout the world has been gained, and in fact may not need to be decided if research should produce a better and safer remedy.

Summary

The practice of a rheumatism clinic, relating to the treatment of 167 patients with rheumatoid arthritis seen over a two-year period, is reviewed.

Prednisone in a dosage of 15 mg. daily was given to 15 of these patients when first seen; by the end of two years 47 patients were receiving the drug, the increase being accounted for by the failure of other drugs.

The commonest complication of prednisone therapy has been dyspepsia, which occurred in 11 patients, two of whom developed peptic ulcers.

Improvement of functional status occurred in about 50% of patients given prednisone; subjective improvement was reported by 90%.

The value of, and indications for, prednisone in rheumatoid arthritis are discussed.

SEA-SNAKE BITE

A SURVEY OF FISHING VILLAGES IN NORTH-WEST MALAYA

BY

H. A. REID, M.B., M.R.C.P.Ed., D.T.M.&H.
Specialist Physician

AND

K. J. LIM, M.B., M.R.C.P.Ed.
Formerly Medical Registrar
General Hospital, Penang, Malaya

In their vast habitat round the shores of the Indian and western Pacific Oceans sea-snakes abound. As they are all venomous and many are highly poisonous, it is fortunate they are not aggressive. Fishermen handle them daily, but there are few records of their being bitten. However, Smith (1926) maintained that casualties were not infrequent, the paucity of reports being due to the incidents occurring in remote localities. Responsible medical authorities rarely observe such cases.

As part of research on sea-snakes, their bites, and poisoning (Reid, 1956) we planned a survey of fishing villages in north-west Malaya to try to find out the incidence of bites, how victims were bitten, and their fate, together with any information of relevance of interest.

Area Surveyed

Fig. 1 indicates the recorded world habitat of sea-snakes (excepting one species, *Pelamis platurus* (Linn.), which extends to western America and eastern Africa). Inset is Malaya. In Fig. 2 the 17 villages visited are shown. They constitute most of the fishing communities of Penang Island and the adjoining 80 miles of coastline of the States of Kedah and Perlis. It was impracticable to include three small villages and the city of George Town, as fishing folk there are too scattered.

TABLE I.—Numbers of Sea-snake Bites per Village with Approximate Populations

Name of Village	Approximate Population	No. of Visits	No. of Sea-snake Bites			
			Fatal	Severe	Trivial	Total
1. Telok Bahang	2,000	3	2	—	—	2
2. Tanjong Bungah	2,500	2	2	4	4	10
3. Tanjong Tokong	5,000	2	2	1	2	5
4. Batu Maung	600	4	—	1	3	4
5. Damar Laut	1,100	2	—	2	—	2
6. Telok Kumbar	3,200	10	4	6	9	19
7. Gertak Sanggul	700	2	—	2	2	4
8. Pulau Betong	500	2	—	—	2	2
9. Jalan Bahru	800	3	—	—	2	2
10. Sungei Pinang	1,700	4	3	4	7	14
11. Panteh Acheh	800	2	—	7	2	9
12. Kuala Mudah	3,000	2	2	3	2	7
13. Tanjong Dawai	1,700	11	5	4	4	20

	40,100	53	41	48	55	144

FIG. 1.—Recorded world habitat of sea-snakes (dotted area), with inset of Malaya.

No reliable population statistics exist for these villages. Approximate figures in Table I were obtained by the Health Department, Federation of Malaya, and include all ages, sexes, and races. Populations per village vary from 500 to 7,300, the average being about 2,500. In many of the larger villages a minority are fishing folk. Malays and Chinese are roughly equal in total numbers, although individual villages varied.

Methods

We visited the villages with a member of the Health Department known to the fishermen concerned. A bag containing a variety of species of dead sea-snakes and coastal water-snakes was opened in the appropriate coffee-shop where fishermen congregate in leisure hours. The snakes always attracted a large audience, with whom we talked. If possible, we saw Chinese separately from

Malays, as this established better confidence. The trend of questions was purposely from generalities on sea-snakes to particulars of actual bites. A form on general information was personally completed in the coffee shop, or shortly afterwards if we thought its production would lessen co-operation. The reverse side was used for details of individual bites, these being obtained from victims or close witnesses in fatal cases. The survey was started in February, 1955, and during the ensuing 14 months 53 visits were made to 17 villages. The number per village varied from 1 to 10 according to accessibility and the response.

In the tables expressing our results, cases are divided into fatal, severe, and trivial. They are judged as severe if unequivocal

paresis was described and/or at least two days' work was lost owing to the bite. These criteria are not altogether satisfactory, because several victims stayed off work for two or more days, although they did not appear to have severe poisoning as judged by the symptoms related. Also, a few victims returned to work within 48 hours, but their cases might be judged severe—for example, having "bulbar" symptoms and trismus—rather than trivial, although they had no paresis. However, the classification has the merits of simplicity and clarity. The majority of trivial cases had no symptoms of poisoning.

Answers to all the questions were not always available, particularly in fatal cases where the witnesses did not know all the facts and in the less recent incidents where the victim had forgotten some of the details. Consequently several tables do not comprise the total 144 cases. All 144 were in our opinion unequivocal instances of sea-snake bite (see under "Symptoms").

Results

A total of 144 sea-snake bites was disclosed, the number per village being listed in Table I. Two victims were bitten twice, one three times, and another on four occasions. The response was remarkably uniform. The villagers talked freely about sea-snakes, and for the most part were remarkably well informed. But immediately the topic of bites was approached the attitude changed and all knowledge of victims in that district would be denied. Eventually, cases in a neighbouring village would be admitted. Later, Chinese would recall Malay victims in their own village (if we were talking with Chinese, and vice versa), then instances amongst their own race, and finally themselves. This great reluctance to talk about bites is mainly due to superstitions. It is the chief reason for failure to realize the frequency of bites among fishing folk. Also, victims may forget having been bitten, especially if trivial or no symptoms of poisoning ensued, which seems to be a common experience. This is borne out by Table II, in which more cases are conceded each year, reaching a maximum in 1955. Moreover, there is a disproportionate increase of cases with trivial or no symptoms of poisoning in recent years. It is unlikely that the sea-snakes have altered their toxicity or habits in the space of twenty-odd years. Reluctance to talk is more likely

TABLE II.—Years in Which Sea-snake Bites Occurred. There is a Steady Increase in Recent Years, Particularly of Trivial Cases

Year	Sea-snake Bites			
	Fatal	Severe	Trivial	Total
1945 or before	16	14	12	42
1946-50	10	15	6	31

to affect recent rather than remote cases. We therefore conclude that a significant number of victims forget the incident.

A third factor reducing the reliability of our figures in estimating the incidence is the number of people with whom we talked in each village. It was impracticable to talk with more than about a dozen villagers at each visit. Many victims may have existed in a village, unknown to the people whom we interviewed. To counteract this we visited the headman of each community on our first visit. On leaving we asked the headman and any other people with whom we had talked to spread the news around the village that we were interested in sea-snakes and their bites for research pur-

FIG. 3.—Collection of sea- and water-snakes in a fishing village coffee-shop always attracted an audience and stimulated discussions. The sea-snake being held up is an *Enhydryna schistosa*.

poses and that we would like to talk personally to as many victims as possible. We repeatedly reassured them that this was our sole purpose, that we did not intend to take blood from any victims or suggest their admission to hospital (we discovered that these were common fears even though they had been bitten years previously). On subsequent visits we followed up as many cases and as much partial information as possible. In the smaller villages we think we saw a representative number of the inhabitants, but in the few larger ones it is probable a significant number of victims who would have been willing to admit their bites were not seen.

Sex, Age, and Race.—In Table III details of sex, age, and race are given. As would be expected, about 90% are males. The age incidence also is merely a reflection of the

TABLE III.—Distribution of Sea-snake Bites According to Sex, Age, and Race

Other	2	2	1	5

groups at risk. The racial incidence and mortality are approximately equal for Malays and Chinese with the exception of the relatively large number of Malay children bitten compared with Chinese. Of 14 victims aged 14 years or less, 12 were Malays (including all seven fatal cases). The difference is probably due to Malay children wading and playing in river-mouths, a habit less favoured by Chinese.

Circumstances of the Bite.—Details of the activity leading to the bite, and location of the victim at the time, are recorded elsewhere (Reid, 1956, Table I). Handling nets accounted for nearly half the bites, the sea-snakes escaping their scrutiny. Further particulars about the nets and fishing methods are mentioned below under "General Aspects." One-third were bitten washing in a river-mouth or wading, usually to or from their boat. They probably trod on the snake—a matter of bad luck considering how often fishing folk have to pursue such activities. River-mouths, particularly those with fishing villages, are favourite haunts of sea-snakes. Five victims were bitten while swimming in a river-mouth. We were careful to explain this as meaning "feet off the river-bed." One victim felt the snake coiling round his forearm and biting his hand. Trivial poisoning followed. Two severe bites were in the thigh and forearm respectively, one swimmer was fatally bitten in the hand, and in another fatality the site of the bite was not known. Presumably these five were unlucky enough to hit an on-coming snake.

Of 52 incidents out at sea, only 10 were fatal, whereas 22 of the 50 bitten near the shore or in a river died. However, we make no conclusions from these figures regarding the respective danger of these locations. There was no evidence that the season or weather influenced the frequency or mortality of bites. One-third were bitten at night, but only 10 were engaged in activities such as sorting fish or nets, where lack of light might be a contributory factor to the bite. Twelve victims were bitten whilst engaged in similar activities during daylight. One victim aged 16 had established a reputation for playing with sea-snakes. He was fatally bitten picking up a *Hydrophis* 30 cm. long.

Identification of the Sea-snake.—On asking victims or witnesses (of fatal cases) to identify the snake from the collection presented at the survey visit, many were unable to do so. Table IV lists 65 incidents in which the species was

TABLE IV.—Offending Sea-snake Species Identified by Victims or Witnesses (in Fatal Cases) from Collection Presented at Survey. Species Frequency and Mortality Correspond Well with Experimental Findings

Sea-snake Species	Sea-snake Bites			
	Fatal	Severe	Trivial	Total
<i>Enhydryna schistosa</i> (Daudin)	7	11	6	24
<i>Hydrophis cyanocinctus</i> (Daudin)	4	1	5	10
" <i>spiralis</i> (Shaw)	2	3	3	8
" <i>klossi</i> (Boulenger)	1	5	10	16
<i>Kerilia jerdoni</i> (Gray)	—	—	2	2
<i>Lapemis hardwickii</i> (Gray)	1	1	—	2
<i>Microcephalophis gracilis</i> (Shaw)	1	1	1	3
	16	22	27	65

identified. The findings should be regarded with due reserve, but it is interesting to note the remarkably close correspondence between the frequency of alleged offending species and its occurrence in the area as judged by 600 specimens recently collected (Reid, 1956). Even more arresting is the accuracy with which the fatalities correspond to experimental findings. Thus *Enhydryna schistosa* and *Hydrophis cyanocinctus* have a relatively high mortality compared with *Hydrophis klossi*. Experimentally the venom yield of *H. klossi* is so small that it is unlikely to kill adult men. In two instances an *E. schistosa* was described as clinging like a limpet, having to be pulled off. One victim died, but the other recovered after severe poisoning.

Bite Marks.—Among 69 victims, search found no marks in three instances (one fatal, one severe, one trivial), and in one severe case only a "graze" was seen. One puncture mark was noted in four cases, two marks in 33 cases, three in 8 cases, four in 7 cases, and multiple marks in 13 cases. There was no correlation between the number of marks seen or the distance between them and the degree of poisoning. All bites were painless after the initial prick, and no swelling, prolonged oozing, or local reaction was observed. On

22 occasions teeth or fangs were extracted by a hair or needle from the site of the bite. In four instances only one fang was withdrawn, in eleven instances two fangs were withdrawn, in three instances three teeth, in one instance four, and in three cases it was claimed that 12, 18, and 23 teeth were withdrawn. Attempts were unsuccessful in nine instances. Fishermen regard this manoeuvre as diagnostic and therapeutic, but there was no correlation between the number extracted and the fate of the victim or the species of the alleged offending sea-snake.

Site of the Bite.—Table V lists the site of the bite in 112 cases. As is usual in snake bite, two-thirds were bitten in the lower limb because one way or another the victim treads on the snake. Acton and Knowles (1914) maintained that

TABLE V.—Site of Sea-snake Bite. The Low Mortality in Bites on Fingers or Toes is Noteworthy

Site of Bite	Sea-snake Bites			
	Fatal	Severe	Trivial	Total
Finger	—	6	12	18
Hand	5	1	7	13
Forearm	1	1	—	2
Arm	—	1	1	2
Toe	—	10	3	14
Foot	1	10	14	25
Leg	10	9	4	23
Thigh	5	4	2	11
	27	42	43	112

bites of elapid and hydrophine snakes, by reason of their short, fixed fangs, were usually ineffective unless a good grip was obtained, such as on a finger or toe. The findings in the survey point to the opposite conclusion. Thus, of 32 victims bitten on a finger or toe, only one died, whilst of 80 bitten on the hand, foot, or more proximally, 26 died.

Latent Period and Death Time.—The latent period between the bite and the onset of symptoms varied from five minutes to eight hours. The duration of this period and of the death time (time from the bite to death) is sometimes regarded as being proportional to the dose of venom injected. The higher the dose the shorter these periods become (intravenous injection, which would greatly shorten the latent period, probably never occurs in sea-snake bite, as the fangs are too short). However, our findings do not support this alleged dose/latent period/death time relationship. Although the average latent period in 13 fatal cases was 1.4 hours compared with 1.8 hours in 28 severe cases, the variation in both categories was up to eight hours. No correlation was found between the latent period and death time in 11 fatal cases, as follows:

Latent Period	Death Time	Latent Period	Death Time
1 hour ..	6, 36, 42 hours	3 hours ..	25 hours
1 1/2 hours ..	4, 4, 21 "	4 " ..	21 "
2 hours ..	24, 25 "	8 " ..	20 "

Similarly, no correlation was found between the latent period and the recovery time in either severe or trivial cases. One victim had no symptoms until eight hours after the bite, yet died 12 hours after they started. The duration of the latent period is therefore not reliable in prognosis.

Symptoms

Table VI gives the approximate percentage of symptoms occurring in 125 cases. The clinical paradox of trismus and flaccid limb weakness is an outstanding feature of sea-snake poisoning, and the characteristic triad in severe or fatal cases is trismus, flaccid body paresis, and "haemoglobinuria." Among fatalities the proportion with red or black urine was only 35%, but many died without urine being passed or its colour noted. One-quarter of the severe cases also had red or black urine. For some time this appeared to be another paradox, because, experimentally, sea-snake venoms are only feebly haemolytic. Theoretically, haemoglobinuria should indicate an enormous dose of venom, inevitably fatal. However, recent clinical research

TABLE VI.—Percentage Incidence of Symptoms in 125 Cases. Of the 55 Trivial Cases 32 Had No Symptoms of Poisoning At All

Symptom	Percentage with Symptom

has shown this pigment to be myoglobin, not haemoglobin, thus resolving a number of enigmas. At the time of the survey we did not realize the significance of another clinical observation—namely, the severe muscle pains and tenderness which our hospital patients have suffered. This important symptom does not therefore feature on the list.

From the survey four features would appear to have had prognostic significance—increased sweating, difficulty in swallowing, ptosis, and breathing change. Coupled with breathing changes are, of course, other signs of respiratory insufficiency such as cyanosis and convulsions. These are terminal. Increased sweating may also occur in respiratory failure, but the symptom as referred to here is an early one. It may be noted before any paresis is evident.

Among 44 severe cases, 24 victims returned to work within a week, 12 within one to two weeks, and 8 within one to three months. If paresis was mild, complete recovery occurred within a few days, but if it was moderate or severe it usually took several weeks. There may be total paralysis as related dramatically by one fisherman who six hours after the bite was unable to speak, swallow, or move at all (including his eyelids). He was presumed dead and had the unpleasant experience of hearing his coffin being brought into the room and his funeral discussed. However, someone felt his pulse, so he escaped being buried alive. Full recovery took three months.

Of the 55 bites classified as trivial, only 23 produced symptoms of poisoning, the commonest being a feeling of general coldness. Thirty-two, or almost one-quarter of the total, had no symptoms of poisoning at all. These were unequivocal sea-snake bites. In each instance either the sea-snake was seen or the bite took place out at sea, where water-snakes do not occur, and the characteristic dot-like marks were painless after the initial prick.

Treatment

About half the victims had a tourniquet applied, but many ligatures were of unsuitable material or were applied too close to the bite for them to be effective in delaying absorption. In the absence of effective antivenene, immediate amputation is the only first-aid measure likely to help the patient (Reid, 1956). In the survey, however, nobody knew of any victim trying it. Amputation is only practicable in finger or toe bites. Table V shows that if it had been universally practised 31 victims would needlessly have lost a finger or toe and one victim's life might have been saved. Fishermen were unanimous in saying they would rather risk death than lose a finger or toe. It is doubtful if propaganda would persuade them otherwise even if pursued with missionary zeal. Only seven had excised the site of the bite

(one fatal, from the arm; two severe, from the foot; four trivial, one from a toe and three from a finger). Judging from the victims' descriptions and the six scars seen, it is unlikely that the excisions were sufficiently radical to affect the issue. There were no instances of incision and suction being attempted.

Thereafter the procedure followed depended on the victim's race. If Chinese, herbal brandy made from a variety of herbs in rice wine was almost invariably taken. It was also customary to avoid smoking, talking, and eating for 24 hours after the bite (a rational prophylactic procedure considering the possibility of "bulbar palsy," inhalation of vomit, etc.). Malays, on the other hand, would usually consult a *bomor* (medicine-man), who relied mainly on incantations. Malays and Chinese usually disparaged the other's methods and alleged a resulting high mortality, but the survey figures did not support either advocate. Only 18 of the total 144 sought orthodox medical help in hospital or dispensary. Despite this small proportion, many said they would come to hospital if they knew a "special injection" were available for sea-snake bite. This opinion is supported by the fact that, although a specific antivenene is not yet available, the numbers of sea-snake victims admitted to hospitals in north-west Malaya steadily increase each year.

General Aspects and Folklore

Except in one village, fishermen said they encountered sea-snakes every time they fished. They were more numerous in January-March, specially during or after stormy weather. No general change in the frequency or habits of sea-snakes was known to have occurred during the villagers' lifetime. The number of snakes varied according to the method of fishing, from nil up to a total of 100 or more each day. The first action on hauling in the catch is to spot sea-snakes, pick them up quickly by the tail, and throw them overboard. This responsibility usually rests on one member of the crew, who becomes adept. Malays often used a stick rather than fingers for lifting the snakes. The sea-snakes are never killed. Line fishing is not common in the area surveyed, but an average of 20 sea-snakes per 300-hook line was quoted by two fishermen using this method in shallow water. Usually they cut off the line concerned, but one victim was bitten trying to disengage a sea-snake and thereby save the hook. He had trivial symptoms following the bite, but thereafter conformed to custom, cutting the lines with sea-snakes.

As would be expected, sea-snakes were very rare in entangling structures (gill nets). They were not numerous in engulfing structures (drive-in nets), and some entrapping structures (palisade traps, lift nets, falling nets). But a gape net known by the Chinese as *ch't cheh* invariably caught 10-20 sea-snakes each lift. A conical net with the mouth held open by two poles stuck into the sea-bed and the tail raised by floats is used in shallow water and lifted two or more times daily according to the tide. However, although this net invariably traps large numbers of sea-snakes, only 4 of the 50 victims bitten whilst handling nets were using this method. The other net in which sea-snakes are numerous is a small drag seine called a *kesa* by the Chinese. It also is used in shallow water, being dragged along by two or three fishermen who are in the sea. Twenty-seven of the 50 were bitten handling a *kesa*, 16 (6 fatal, 5 serious, 5 trivial) being in the sea at the time and 11 (7 serious, 4 trivial) in the boat pulling in or sorting the net.

All species of sea-snake presented at the survey visit were recognized at one or more villages. Much the commonest was *E. schistosa*, and thereafter in descending frequency, *Hydrophis spiralis*, *H. cyanocinctus*, *Lapemis hardwickii*, *H. klossi*, and *Kerilia jerdoni*. In contrast, *Hydrophis melanotosoma* Günther, *Microcephalophis gracilis*, and *Praescuata viperina* (Schmidt) were rarely recognized. The harmless non-fanged water-snake *Acrochordus granulatus* (Schneider) was universally mistaken for a sea-snake and regarded as highly poisonous. As it is often caught with sea-snakes and has tapering bars, slightly flattened tail, and

narrow ventral scales the mistake is understandable. Generally speaking, *E. schistosa* was considered the most dangerous. All fishermen agreed that sea-snakes never attacked human beings spontaneously. The only exception was one man who claimed to have been chased by an *E. schistosa* whilst in a fish-trap. But others present laughingly disbelieved him. Several fishermen recounted sea-snakes swimming between their vest and body: all would be well so long as they kept still. As one fisherman put it, if sea-snakes were aggressive there would be no more fishing.

According to Herre (1942) sea-snakes are inclined to be aggressive during the breeding season, but this was not confirmed by the fishermen. However, they appeared to know little or nothing about the breeding habits, season, etc., of sea-snakes. It was agreed that sea-snake bite was commoner in some river-mouths. Lowered salinity, making the snakes more aggressive, and available food increasing their frequency, were two reasons put forward, but the majority admitted ignorance of the cause. Several species were known to swim up river, particularly *E. schistosa*, and one fisherman thought the latter accounted for the frequency of river-mouth bites. In captivity it is certainly the most aggressive species of those mentioned above (Reid, 1956).

In contrast to *A. granulatus*, water-snakes such as *Cerberus rhynchops* (Schneider) were distinguished by all as harmless. Everyone knew their round tapering tails, and many mentioned the differences in the shape of the head and the belly—the broad scales being quite different from those of sea-snakes. These water-snakes were common in river-mouths and shores. Children played with them in every village, many being adept at catching them. People were bitten quite often. The majority admitted they could not distinguish such bite marks from those of a sea-snake (our cases of bites with no symptoms of poisoning were not due to water-snakes for the reasons already given). Two fishermen said the water-snake marks were semicircular and more teeth were left in. One of us has been frequently bitten by specimens of *C. rhynchops* in captivity, and teeth have been left in on almost every occasion. It is a back-fanged snake which presumably ejects venom only on swallowing.

All fishermen were well acquainted with the commoner symptoms of sea-snake poisoning. It was recognized that many victims developed few or none of these symptoms, but this was invariably regarded as being due to the treatment received (a comforting outlook often shared by the medical profession in relation to snake bite). Deaths were attributed to disregard of advice or delay in receiving treatment. Land-snake bites were much less common in these villages. Offered the alternative of a cobra or a sea-snake bite, preference for the former was unanimous. Similarly, they laughed when asked whether they would rather be stung by catfish, sting-ray, or jellyfish in preference to a sea-snake bite. Anybody who has had the extremely painful and unpleasant experience of these fish stings will realize the significance of this laughter. Fear of sea-snakes was admitted by all—"more than anything else," as one fisherman put it. Another philosophically likened them to war—both the inevitable lot of mankind. Night-time, and the consequent difficulty in seeing the snakes, was particularly feared (although analysis of the survey figures did not suggest this is an important factor in sea-snake bite). These fears are prevalent despite the vaunted confidence in their respective treatments. There is no doubt that if these fishing folk knew a specific antivenene were available much of their fear would be abolished.

Superstitions and Myths

The reluctance to admit to specific instances of bites is in great contrast to the freedom with which they discuss general aspects of sea-snakes. One reason for this reluctance is suspicion. Deaths due to sea-snake bite are often notified as "fever," etc., in order to avoid necropsy or delay in burial (Reid, 1956): many suspected we intended to make trouble on this account. But the most important factor was superstition. Most Malays admitted frankly to these super-

stitions, whereas many Chinese scoffed at them. However, we received the impression that the Chinese were in reality just as deeply under their influence as the Malays. Four common superstitions are: (1) Talk about sea-snake bites offends the sea-snakes and may change their timidity to aggression. (2) If a victim talks about his bite he will be bitten again. (3) If a pregnant woman hears of a sea-snake bite the victim will die. (4) If faecal droppings of a house lizard fall on a victim he will die.

The first three discourage the victim from broadcasting his misfortune, whilst the fourth superstition precludes his being treated in his home. In practice, the victim tells his best friend to fetch the *bomor* (medicine-man). If all goes well, no one else in the village is informed of the incident. But, as one *bomor* rather cynically admitted to us, if the victim is not satisfied and sends his friend for a second *bomor*, the first one spreads the news so that a pregnant woman will hear of it. The discredit of the inevitable death will then fall on the second *bomor*.

Other common beliefs include: (5) The presence of a *bomor* in a village attracts sea-snakes and causes more bites. (6) If fresh lime is taken shortly after a bite the symptoms will recur and probably be fatal. (7) Drinking blood of a sea-snake or eating its tail gives protection against poisoning. A few Chinese fishermen admitted doing this, and others sometimes ate them for general medicinal effect. None ate sea-snakes as ordinary food, although one Chinese said his father had been fond of them. Malays believed eating sea-snakes would cause shedding of their own skin. (8) Both Chinese and Malays had heard of the *ular belerang*, a sea-snake so poisonous that, if it bites the rudder, all in the boat will die. A few claimed to have seen this snake, always far out in deep water of more than 20 fathoms. They described it as about 30 cm. long, 2 cm. thick, usually a striking yellow colour with a longitudinal black stripe (a *belerang* is Malay for sulphur). The descriptions suggest a young *P. platurus*. Experimentally its venom is as toxic as that of *E. schistosa*, perhaps more so.

(9) Originally, sea-snakes were harmless and pythons were the most poisonous snakes in the world. The pythons used to live in a certain well where they feasted on the fish. One day, in the absence of the pythons, a fisherman caught all the fish and took them away. A crow watching from a near-by tree broke the news to the returning pythons, pointing out the footprints of the marauder. The poisonous pythons were so incensed that they bit one of the footprints and the fisherman promptly died. At his funeral feast the villagers ate the fish he had caught. The crow then jeered at the hungry pythons: though their poison was so potent it could kill a man by biting his footprint, it was not powerful enough to recover the fish. Mortified with shame at this revelation, the pythons swam far out to sea and vomited their venom near the shore and thus became non-poisonous. The *ular belerang* inhabiting the deeper seas swallowed most of the pythons' venom, while coastal sea-snakes (the majority) acquired the rest. This is why the *ular belerang* is now the most poisonous snake in the world.

Discussion

A survey such as this can only indicate trends. We would emphasize that the results by themselves can form no basis for generalizations. The individual figures expressed in the various tables must all be regarded with due reserve.

We obtained records of 102 sea-snake bites occurring in the 10-year post-war period. Because of the reluctance of the fishermen to disclose bites, the number forgotten, and the relatively small proportion interviewed in the larger villages, we consider this is a gross underestimate of the true incidence in the area surveyed. Of these 102 bites, 40 occurred in 1955. In this year also, 30 victims were admitted to hospital from Kuala Perlis village, representing 1% of the population at risk (in 1956 admissions rose to 51). Our

1955 survey total for this village was only six, of whom five were admitted to hospital. Thus we have survey or hospital records totalling 65 sea-snake bites in north-west Malayan fishing villages during 1955. Kuala Perlis and roughly half the villages surveyed are situated at a river-mouth, and in them the number of bites was consistently higher than in the other villages. Several river-mouth villages recounted many more bites than in Kuala Perlis. We consider a yearly incidence of $\frac{1}{4}$ -1% of the population at risk in river-mouth villages and $\frac{1}{4}$ - $\frac{1}{2}$ % in the rest would be a conservative estimate. If this is correct, there is a total of at least 150 victims of sea-snake bite each year in the villages surveyed. These contain about one-tenth of the Malayan fishing population.

On the east coast of Malaya the incidence may well be similar, as during 1955-6 30 victims (with 4 deaths) of sea-snake bite were admitted to Kota Bharu Hospital from scattered fishing communities of about 10,000 population (Dr. Thelma M. Ward, personal communication). It is known that some victims do not come to hospital or dispensary. If we assume this rough approximation to be reasonable, is it representative of the general incidence amongst the Asian fishing community? The two species *E. schistosa* and *H. cyanocinctus* abound virtually throughout the area shown in Fig. 1. Presumably they may bite fishing folk there as often as those in the north-west Malaya. On the other hand, different fishing methods may greatly decrease the risks. Also, regional changes in habits, toxicity, etc., of the sea-snakes may occur. On the 1951 Galathea Expedition, H. Volsoe (personal communication) noted that specimens taken in the Malacca Straits were far more aggressive than those captured off the Indian coast.

As already recorded (Reid, 1956), the mortality in the survey is not regarded as representative of sea-snake bite in general. In our opinion the true figure lies between 25% and 3%, being nearer 3%. If the potential danger of *E. schistosa* to man as judged by venom yield and toxicity is about the same as that of the Indian cobra and the Australian tiger-snake the mortality of sea-snake bite is low. Fairley (1929) quoted the mortality of tiger-snake casualties as 40%. The relatively low mortality from sea-snake bite may be due to most victims being bitten by species much less toxic than *E. schistosa*. One of us believes it is unusual for poisonous snakes to inject much venom when, as in human subjects, the bite is defensive (Reid, 1956). However, it must be admitted that mortality rates, indeed all statistics in snake bite, are highly suspect. Apart from the mortality—which is negligible compared with such "killers" as tuberculosis—fear of sea-snakes is an important feature in the lives of Asian fishermen. We consider that on this account alone it is well worth while undertaking research to improve the treatment of sea-snake bite and poisoning. Unlike land-snakes, an abundant source of sea-snakes is constantly available, and adequate venom could be obtained if a sea-snake station were to be set up as proposed recently (Reid, 1956). The basic toxicology of sea-snake poisoning could then be elucidated and rational treatment, including an effective polyspecific antivenene, should ensue. We are confident such measures would be welcomed by the fishing folk and would greatly increase their security and happiness.

Summary

A survey of fishing villages in north-west Malaya indicates a high incidence of sea-snake bites. It is estimated that a total of 150 victims are bitten each year in the villages surveyed. The latter contain about one-tenth of the fishing population of Malaya, itself a minute area amongst the world habitat of sea-snakes.

Relevant findings from the 144 sea-snake bites recounted in the survey are presented. Some of the more pertinent or interesting items of general knowledge, folklore, and superstitions amongst the fishermen are described.

The mortality of sea-snake bite appears to be low, but fear of them is universal and a potent source of worry. Effective treatment, including a polyspecific antivenene, would be a great boon to Asian fishing folk.

We wish to thank the State Surgeon, Kedah and Perlis, the Chief Medical Officer, Penang and Province Wellesley, the Director of Fisheries, Federation of Malaya, and many members of their departments for helpful co-operation in the survey; and Mr. C. J. Sundram for the maps.

PROPHYLACTIC USE OF OXYTETRACYCLINE FOR EXACERBATIONS OF CHRONIC BRONCHITIS

BY

AND

A. A. C. DUTTON, B.M., B.Ch.

From the Departments of Medicine and Bacteriology,
Postgraduate Medical School of London

Investigations both here (Elmes *et al.*, 1953) and elsewhere (Mulder *et al.*, 1952; Stuart-Harris *et al.*, 1952; May, 1953) have shown that exacerbations of chronic bronchitis are usually associated with proliferation in the sputum of one or more of a few species of bacteria which have become recognized as pathogens. Of these, *Haemophilus influenzae* is the organism most often found. *Streptococcus pneumoniae* is the next most frequent, while beta-haemolytic streptococci, *Staphylococcus pyogenes*, and *Klebsiella friedländeri* are occasionally found. Exacerbations are usually sequels of upper or lower respiratory infections by a virus or follow exposure to cold or to smoky fog. Subsequent bacterial invasion is thought to prolong exacerbations, to increase their severity, and to play an important part in causing permanent damage to the lungs (Reid, 1954).

Since wide-spectrum antibacterial drugs are effective against these organisms they should be able, given early enough, to prevent bacterial multiplication and its consequences. There is evidence (McVay and Sprunt, 1953; Helm *et al.*, 1956; May and Oswald, 1956; Edwards *et al.*, 1957) that the tetracycline group of drugs given continuously over long periods may control persistent bronchial infection and reduce the frequency and severity of acute exacerbations. These drugs are, however, too expensive for continuous use among the vast numbers of patients with chronic bronchitis in this country, most of whom have only one or occasionally two exacerbations each winter, between which they are able to continue at work. The trial described in this paper was to determine whether a short course of oxytetracycline given at the first sign of the onset of an exacerbation could reduce its duration, and thus provide an economic method of reducing loss of working time.

Clinical Method

The criteria for selection of patients for the trial were that they should be under the age of 65, be in regular employment, have had a productive winter cough for not less than three years, during which time they had had at least two illnesses with purulent sputum, causing loss of time from work. The patients had no other disabling disease. Twenty-one of them were attending a bronchitis clinic; other cases were referred by local general practitioners at our request. Of 125 cases so referred, 67 were selected (16 failed to attend and 42 were unsuitable in one way or another). Eighty-eight patients were therefore admitted to the trial at various times between November, 1954, and November, 1955. Special clinics were held on Saturday mornings to reduce loss of time from work. Each patient was seen at approximately monthly intervals in the winter and at two- to three-monthly intervals in the summer.

It was decided to make the trial a "double blind," by allocating oxytetracycline tablets to some patients and indistinguishable dummy tablets (containing lactose) to the others, neither doctors nor patients knowing which was which. This was achieved by allocating oxytetracycline and control tablets in equal proportions to the serial numbers 1 to 99, using Fisher and Yates's (1948) table of random numbers. The patients were each given a serial number in the order in which they entered the trial and were prescribed tablets of the same number. The key list of numbers was held by the hospital's chief pharmacist, who dispensed 28 oxytetracycline or control tablets according to the serial number of each patient. Table I shows the distribution of

TABLE I.—Comparison between the Oxytetracycline and Control Groups before the Trial

	Oxytetracycline	Control
Males	37	37
Females	5	9
Mean age and range	54.6 (31-65)	53.5 (28-65)
Mean dyspnoea grade and range*	2.289 (1-4)	2.283 (1-4)
Time lost in days during 18 months before trial	76.6 (0-560)	71.24 (0-547)

* Grades ranging from 1 (normal) to 5 (breathless on least movement) (Fletcher, 1952). The figure used was the grade of dyspnoea noted by the patient when he was feeling well.

patients in the oxytetracycline and control groups according to age, sex, degree of respiratory disability, and amount of time lost from work during the 18 months preceding their admission to the trial. The two groups were similar except for a small preponderance of females in the control group.

On their first attendance a full clinical history was taken from the patients and the results of examination of their cardiovascular and respiratory systems were recorded. They were then given the following instructions:

"If you have a head cold, increased difficulty in breathing, increased cough and phlegm, or any other chest symptoms which you think may indicate the beginning of a chest illness, take one tablet after breakfast, dinner, tea, and supper—that is, four tablets in the day. Continue with the tablets for at least five days at first. If you are then quite well again, stop the tablets. If not, continue taking four daily until they are finished. If you develop looseness of the bowels or diarrhoea while you are taking the tablets take three tablespoonfuls of the medicine† daily. If diarrhoea continues stop the tablets. If, in spite of taking the tablets, your chest gets worse, consult your doctor. Please put a specimen of your phlegm into one of the containers: (a) before you start taking the tablets, (b) when you have been taking the tablets for five days, (c) five days after you stop the tablets. The specimens should be brought to the bacteriology department of the hospital on the same day either by yourself or a friend. Please report to the clinic as soon as you are well again."

On subsequent visits to the clinic details of the onset, symptoms, and duration of any chest illnesses were recorded, further supplies of tablets were given, and further clinical examinations were performed if necessary. Many patients

†Chalk and opium mixture (N.F.).

were given additional routine treatment and advice. The majority received antispasmodic drugs, usually ephedrine or choline theophyllinate by mouth, with or without a hand inhaler, using either 1% isoprenaline or the combined spray of adrenaline and atropine (N.F.). On a few occasions patients who continued to produce purulent sputum after a week's course of "tablets" were given a course of an antibacterial drug (usually tetracycline) to which the bacteria in their sputum were sensitive.

Bacteriological Method

The sputa were examined in most cases within six hours of expectoration. Gram-stained films were made from the purulent part of the sputum. The whole specimen (or 5 ml. when the total volume was greater than this) was then homogenized with an equal volume of saline and some glass beads for 10 minutes on a mechanical shaker. (This method was checked against multiple sampling of unhomogenized sputum by Dr. Mary Ralston and found to be efficient.) Cultures were made on whole heated blood-agar plates containing 0.2 unit of penicillin per ml. of agar, which is selective for *H. influenzae*, and on blood-agar plates having a central ditch filled with agar containing an initial concentration of 25 µg. of oxytetracycline per ml. The plates were incubated at 37° C. for 18-24 hours. The sensitivity of the organisms to tetracycline was related to the Oxford staphylococcus.

Clinical Results

During the period of observation the 88 patients had a total of 146 exacerbations. Table II gives the distribution of these exacerbations between those who took oxytetra-

TABLE II.—Number of Exacerbations and Number for which Tablets were Taken in Oxytetracycline and Control Groups

	Oxytetracycline	Control
No. of patients	42	46

cycline and control tablets for at least five days and those who took tablets for shorter periods or not at all. The patients did not always take the tablets at the onset of each exacerbation. Sometimes the initial symptoms were unusual, exacerbation. Sometimes the tablets, some first went to see their general practitioner, who gave them some other treatment, and some had no confidence in the tablets. Side-effects were not important in deterring patients from taking tablets. Twenty-two had mild diarrhoea or loose stools; these being easily controlled by chalk and opium mixture; four of these cases were receiving control tablets. One case receiving oxytetracycline had severe diarrhoea, which prolonged his illness. Mild and brief anal pruritus was experienced by six patients taking oxytetracycline.

Comparison	P	Comparison	P
(a) v. (c) unlogged	0.2-0.1	(a) v. (e)	0.01-0.001
(a) v. (c) logged	0.3-0.2	(b) v. (f)	<0.001
(b) v. (d) unlogged	0.1	(c) v. (e)	0.2-0.1
(b) v. (d) logged	0.1-0.05	(d) v. (f)	0.02-0.01

The severity of the exacerbations was assessed by the number of days off work and by the number of days during which the patient had respiratory symptoms, especially cough and sputum, of greater severity than usual. The severity of the exacerbations for which oxytetracycline, control, or no tablets were taken is shown in Table III. The patients who took oxytetracycline tablets were on the average ill for two-thirds as long as those who took control tablets and had half the number of days off work. However, individual exacerbations varied considerably in length, so that this difference may have occurred by chance. As is seen from the histogram, there are outlying cases in the control group

A comparison between the numbers of exacerbations grouped according to the length of time off in days.

which have an undue influence on the mean. The chief difference between the groups is the higher proportion of exacerbations with no loss of time from work in the group given oxytetracycline. The effect of the outlying cases can be partially eliminated by using a logarithmic time scale, but this makes no material difference to the statistical results. None of the differences between control and treated groups are significant at a level of 1 in 20.

As the general practitioners were free to give any treatment they thought fit to those whose illnesses were not responding to our tablets, they might have shortened the illnesses with antibacterial drugs; in fact, we ourselves sometimes gave tetracycline to such patients. Some supplementary treatment was given for 4 out of the 57 exacerbations treated with oxytetracycline and to 9 out of 56 receiving control tablets. One would expect patients on control tablets to require supplementary treatment more frequently, but this difference is not significant ($P=0.2$ to 0.1 on χ^2 test). When the exacerbations for which supplementary treatment was given are omitted there is still no significant difference between the length of the exacerbations in the oxytetracycline and control groups ($P=0.2$ to 0.1).

We were surprised to find that exacerbations treated by either kind of tablet were shorter than those for which no tablets were taken (Table III). The exacerbations for which oxytetracycline was taken were significantly shorter and also caused less time off work than those which were untreated. Exacerbations treated with control tablets were of intermediate duration, and the difference between them and the untreated was also significant on the basis of days off work.

We thought that a possible explanation might be that the untreated exacerbations had a more serious pathogenesis, with an onset unassociated with obvious respiratory symptoms, so that the patients did not take the tablets promptly. The untreated exacerbations were therefore divided into those for which no tablets were taken because the onset was unusual (14) and those with a typical onset but for which tablets were not taken for some irrelevant reason such as their being mislaid or the patient being away from home at the time (19). The mean duration of illness in these two groups did not differ significantly, being respectively 33.7 and 29.35 days ill and 21 and 17 days off work. The type of onset did not therefore explain the difference in length of treated and untreated illnesses.

We sought evidence that the mere fact of attending the clinic and being given tablets and other treatment had affected our patients' loss of time from work.

We compared the loss of time from work during the winter of 1953-4 with the loss during the winter of 1955-6 in the group of patients who were under continuous observation and treatment during the second winter. This group is relatively small (40 patients), because only those making regular claims for sick benefit were included, and some of our patients were self-employed or received full pay for short periods of absence from work. Comparison between the sickness absences during 1953-4 which the patient reported when first interviewed, and the absences recorded in our notes during observation and treatment in 1955-6 (Table IV) shows that although there are the same number of illnesses in each winter the illnesses are half as long. This is a statistically significant difference which might have been attributed to treatment.

Because of the possibility that the patients had exaggerated their past sickness absences we obtained figures for sickness absence for which these patients had received benefit from the Ministry of Pensions and National Insurance. These figures differ from ours in two respects (Table IV).

TABLE IV.—Comparison Between Time Lost from Work in the Winter Before the Trial with that Lost During the Second Winter of the Trial by Patients Making Regular Claims for Sickness Benefit

		Sept., 1953, to April, 1954	Sept., 1955, to April, 1956
Our figures	No. of illnesses	41	41
	Total days off	1,786	807
	Mean length of illness (days)	43.56	19.8*
M. of P. and N.I. figures	No. of illnesses	48	44
	Total days off	1,580	1,125
	Mean length of illness (days)	32.92	25.56†

* P = 0.05 to 0.02 (t test). † P = 0.5 to 0.4.

Firstly, the patients slightly overestimated their past loss of time from work, but attributed it to fewer illnesses. Secondly, during the period of observation they admitted to less absence from work than they claimed from the Ministry. These differences are statistically significant and not entirely accounted for by the inclusion in the Ministry's figures of respiratory illnesses which we had not considered

TABLE V.—Bacteriological Findings Before, During, and After Exacerbations

Specimen	Total No. of Specimens	No. of Specimens Producing Moderate or Heavy Growth of:				No Pathogen (Not Even "Scanty" Growth)
		<i>H. influenzae</i>	<i>Str. pneumoniae</i>	Other* Pathogens	Coliform Species	
Initial sputum:						
Control	33	19 (58%)	5 (15%)	0	0	12
Oxytetracycline	27	19 (70%)	3 (11%)	0	0	4
Before treatment:						
Control	38	28 (74%)	12 (32%)	1	0	5
Oxytetracycline	31	23 (74%)	15 (48%)	1	0	2
During treatment:						
Control	35	18 (51%)	5 (14%)	1	0	10
Oxytetracycline	27	7 (26%)	0	0	4	11
5th day after treatment:						
Control	27	17 (63%)	6 (22%)	2	1	6
Oxytetracycline	27	6 (22%)	3 (11%)	0	3	6

* *Staph. pyogenes*, 3; *Klebsiella friedländeri*, 1; beta-haemolytic streptococci, 1.

due to exacerbations of bronchitis. The Ministry's figures show a shortening of the illnesses during the winter of observation by 22%, which is not statistically significant.

We cannot use the Ministry's figures for a comparison between treated and control groups because it happens that the control patients for whom figures were available had a much higher past sickness rate.

Bacteriological Results

Most of the sputa produced by patients on entering the trial were mucoid in appearance, but nevertheless a high proportion yielded *H. influenzae* (63%) (Table V). May (1954) found that 13% of mucoid and 80% of purulent sputa yielded *H. influenzae* in bronchitis. In addition 13% of the initial sputa in our series yielded *Str. pneumoniae*. No other pathogens were found.

Although a slightly higher proportion of the initial specimens from the patients who were to receive oxytetracycline yielded *H. influenzae*, the proportion in specimens obtained at the onset of the exacerbations ("pre-treatment specimens") is identical in the two groups (74%). Treatment with oxytetracycline reduced by two-thirds the proportion of specimens yielding *H. influenzae*, and this effect was still apparent five days after the treatment ended. This change is statistically significant, whereas the less marked changes in the specimens from the control group are not.

The expected increase in *Str. pneumoniae* with exacerbations was found. The figures for the control group are compatible with the way in which this organism tends to disappear spontaneously from the sputum. More specimens from the oxytetracycline group yielded *Str. pneumoniae* at the onset of exacerbations (48%)—nevertheless this organism was not isolated from any specimen during treatment and was infrequently isolated five days after treatment.

No tetracycline-resistant strains of *H. influenzae* or *Str. pneumoniae* emerged; coliform type bacilli were isolated from a few specimens but had no clinical effect. No coagulase-positive staphylococci resistant to oxytetracycline were isolated from any specimen even after several courses of this drug. It made no difference to the length or frequency

TABLE VI.—Length of Exacerbations (in Days Ill) Related to the Bacteria Grown from the "Initial" and "Pre-treatment" Sputa

Specimen	Organism	Treatment	No. of Patients	No. of Exacerbations	Mean Length	Variance
Initial	<i>H. influenzae</i> present	Oxytetracycline	23	40	12.34	3.18
	<i>H. influenzae</i> present	Control	21	31	14.26	6.09
	<i>H. influenzae</i> absent	Oxytetracycline	4	9	10.55	8.89
	<i>H. influenzae</i> absent	Control	12	29	14.69	6.61
Pre-treatment	<i>H. influenzae</i> present	Oxytetracycline	—	26	11.42	2.66
	<i>H. influenzae</i> present	Control	—	32	20.26	26.5
	<i>Str. pneumoniae</i> present	Oxytetracycline	—	18	11.67	1.82
	<i>Str. pneumoniae</i> present	Control	—	13	30.0*	137.4

* Including one exacerbation lasting 163 days.

of the exacerbations whether *H. influenzae* was or was not present in the initial specimen of sputum (Table VI), and in either case oxytetracycline was no more effective than dummy tablets. Moreover, it was immaterial to the length of the illness whether the predominating pathogen at the onset was *H. influenzae* or *Str. pneumoniae*. Although oxytetracycline-treated exacerbations were shorter, whichever the pathogen, the differences were not significant.

Discussion and Conclusions

The results of our trial were unexpected and illustrate the difficulties of this sort of investigation. Not only are exacerbations of chronic bronchitis ill-defined entities of variable aetiology, but they are also variable in severity, duration, and incidence. There is no precise method of estimating their length and severity symptomatically, and the criterion of loss of time from work is manifestly dependent on many factors, such as the weather and the nature of the work, in addition to the severity of symptoms. Even our patients' account of their loss of time from work while under observation was unreliable.

Had we chosen as a basis for comparison either the length of time lost in exacerbations treated with oxytetracycline against those for which no tablets were taken, or treated exacerbations during the period of observation compared with the patients' own accounts of a previous winter's experience, our results would have been different. On this basis our figures would have appeared to show a definite benefit from taking oxytetracycline tablets. But when comparison is made with the effect of dummy tablets, the placebo effect of these reduces the significance of our results below the conventional probability limit of 1 in 20. A preliminary analysis after the first six months of the trial revealed a mean reduction in days lost from work of 2.8 days per exacerbation, but because of the variance this could have occurred by chance once in three times. After 18 months the probability of the observed difference occurring by chance had fallen to between 1 in 10 and 1 in 20. It is likely that had we been able to continue the trial for another winter we might have obtained figures with a chance probability of less than 1 in 20.

Although our figures do not show a "significant difference" by conventional statistical standards, there are other reasons for believing that the difference between the treated and control groups was due to the oxytetracycline. There is a strong clinical impression that this drug is effective in many exacerbations of bronchitis, and it caused a significant fall in the number of both *H. influenzae* and *Str. pneumoniae*—organisms which have been shown to be important pathogens in bronchitis—in the sputum of our cases. It is probable that many exacerbations in both groups may have been simple coryzas with little bacterial invasion of the bronchial tree: these would be unaffected by oxytetracycline, and they may have masked a real benefit from treatment of the remainder.

The treated group lost on the average 5.2 fewer days from work per exacerbation compared with the control group and 18.5 fewer days compared with the group receiving no tablets. Each course of treatment cost 42s., which works out at 8s. per working day saved, compared with the cost of no tablets, and 2s. 4d. per day saved, compared with no tablets. If this saving was due to oxytetracycline then this compares favourably with the figures of 29s. per day achieved by May and Oswald (1956), using continuous treatment throughout the winter. Furthermore, none of our patients developed tetracycline-resistant staphylococci in the sputum as the result of the treatment.

Between June, 1953, and June, 1954, male insured workers in Great Britain lost nearly 15 million days' work owing to sickness diagnosed as "bronchitis" (Ministry of Pensions and National Insurance, 1953-4). The average weekly wage that year was £10, so that with sickness benefit the cost to the community may be estimated at about £30 million. The

simple measures which we adopted might greatly reduce this figure. We would only advocate our procedure of giving a supply of the drug to take without consultation for those patients who are intelligent enough to understand the instructions.

Summary

* Eighty-eight patients with established chronic bronchitis, in regular employment, were observed during two winters. Half were given oxytetracycline, 1 g. daily, to take for a week at the onset of exacerbations of their bronchitis, the rest were given indistinguishable control tablets to take in the same way. The oxytetracycline-treated group lost half as much time from work with each exacerbation as the control group, but, since this difference could have occurred by chance once in ten times, it cannot be regarded as certainly due to the oxytetracycline.

The exacerbations for which any treatment (oxytetracycline or control tablets) was taken were significantly shorter than untreated exacerbations. According to the patients' own reports they lost significantly less time from work during the winter they were observed than during a previous winter, but examination of sickness benefit records showed this to have been largely due to misreporting.

Only two pathogenic organisms were isolated from the sputum either at the beginning of the trial or at the onset of the exacerbations—*Str. pneumoniae* and *H. influenzae*—and their presence or absence did not affect the length of the exacerbations. Oxytetracycline banished *Str. pneumoniae* from the sputum in every case and *H. influenzae* in two-thirds of the cases. No resistant strain of either pathogen emerged, nor did any resistant *Staph. pyogenes* appear even after several courses of oxytetracycline.

It is suggested that regular medical supervision of cases of chronic bronchitis, perhaps including prompt treatment of exacerbations with antibacterial drugs, might lessen the present enormous economic loss and human suffering caused by chronic bronchitis in Great Britain.

We thank the general practitioners of this area and the consulting staff of the hospital for referring cases, Messrs. Pfizer Ltd. for supplying the oxytetracycline and dummy tablets, and the staff of the Ministry of Pensions and National Insurance for giving us details of our patients' sickness benefit records. We are indebted to Dr. P. Armitage, of the Statistical Research Unit of the London School of Hygiene and Tropical Medicine, for assistance with the design of the trial and the analysis of the results. We acknowledge the willing co-operation of the staff of the various departments of the hospital which enabled us to investigate and follow up the patients during and after the usual clinic hours, and in particular of the pharmacists who issued the tablets according to the master list.

ABNORMALITY OF PHOSPHOLIPIDS IN RED CELLS OF PATIENTS WITH PAROXYSMAL NOCTURNAL HAEMOGLOBINURIA

BY

I. M. HARRIS, B.A.

T. A. J. PRANKERD, M.D., M.R.C.P.

AND

M. P. WESTERMAN,* M.D.

Medical Unit, University College Hospital Medical School, London

Crosby (1953) concludes a detailed review of paroxysmal nocturnal haemoglobinuria (P.N.H.) by saying that it is an acquired disease in which abnormal red cells, white cells, and platelets are produced; that the lesion of the cells probably involves the stromal proteins so that they become susceptible to the proteolytic effect of a system of normal plasma enzymes; and that the severity of the disease depends upon the degree of susceptibility of the cells to the plasma system.

Whilst there have been a number of investigations into the plasma haemolytic factors in this disease, little attention has been paid to the red cell. Conflicting evidence of the electron microscopic abnormalities of the cells have been reported (Matthes *et al.*, 1951; Douglas and Eaton, 1955; Braunsteiner *et al.*, 1956), but otherwise there are few published data about abnormalities in these cells other than their well-known susceptibility to haemolysis at acid pH. The following investigation was designed to study the state of phospholipids in P.N.H. cells, since it is known that some of these are in a dynamic state (Altman, 1953; Prankerd, 1957) whilst the protein component of the cell is static (Muir *et al.*, 1952).

Methods

The basic method used in this work has been that described by Dawson (1954) in his analysis of phospholipid in liver cells. Cells were separated from whole blood by centrifuging and washed once with 0.9% saline. The cells were packed by centrifuging at 3,000 g. for 10 minutes and then haemolysed with an equal volume of distilled water. The haemolysate was extracted with boiling ethanol-ether (2:1) for 5-10 minutes and the mixture allowed to stand at room temperature for 15 minutes. The subsequent steps in the purification and alkaline hydrolysis of the extracted lipids were carried out as described by Dawson, and the final aqueous solution of phosphate esters was dried on Whatman No. 1 paper and chromatographed two-dimensionally in saturated phenol-water for eight hours and in trichloroacetic acid-*tert*-butanol for six hours. The individual spots were developed by spraying with ninhydrin and then later with a molybdate spray (Hanes and Isherwood, 1949). Each spot was finally cut out and the phosphorus in it estimated (Prankerd and Altman, 1954). Analyses for total lipid, by drying to constant weight; cholesterol, by method of Bloor (1916); lipid nitrogen, by method of Koch and McMeakin (1924); and phospholipid, by method of Youngburg and Youngburg (1930), were also made, after extraction by refluxing for two hours with the same solvent.

Results

Table I gives the results of analyses of total lipid and some of its fractions in 10 instances of six cases of P.N.H. and 24 control subjects. The significant differences would

*Trainee of the National Institute of Arthritis and Metabolic Diseases, U.S.A.

appear to be the higher values for lipid nitrogen and cholesterol found in the P.N.H. cells with normal total lipids and lipid phosphorus. In three cases of P.N.H. the serum cholesterol was also estimated and found to be below the normal range.

Table II summarizes the amounts of phosphate ester derivatives separated chromatographically from the phospholipids in normal and P.N.H. subjects. The methods used in separation and hydrolysis of the phospholipids cannot be expected to give quantitatively comparable yields on each occasion, but since the same method is employed in each case it may be assumed that any loss is randomly distributed amongst the individual lipids, and the two ratios of different types of phospholipid to each other at the bottom of Table II would therefore be comparable.

The statistical differences between the normal and P.N.H. groups can be seen to lie in the highly significant (at 1% level) differences in the ratios of choline phosphate to serine phosphate found on the chromatograms. The individual

" " " C/S .. $t=4.85$, $P<0.001$.

amounts of these esters suggest that the difference is due both to a deficiency in choline phosphate and to an increase in serine phosphate.

Discussion

At present we can only conclude that there is a fundamental difference between the phospholipids of the P.N.H. cell and the normal, such that there appears to be less phosphatidyl choline and more phosphatidyl serine per unit of packed cell, and that these cells contain greater amounts of lipid nitrogen and cholesterol than normal. It also appears that the serum cholesterol in P.N.H. is reduced; but similar reductions have been reported in other anaemias (Muller, 1930), so that this finding may not be specific. Several of the patients were studied at various periods after transfusion, but none had been transfused within two months of examination, and it is likely that the presence of normal cells in the analysed sample would weight the results towards normal, so that, taking this into consideration, the differences become even more significant.

A number of other types of anaemia have been investigated in this way and changes such as these have not been found, nor has the presence of reticulocytes been shown to

affect the results. The results reported by no means cover all the lipids or even phospholipids in the red cell, and it may well be that other constituents are involved also. This, and the relationships these abnormalities have to the mechanism of the disease, form a problem under further investigation.

We thank Professor J. V. Dacie for kindly providing many of the samples of P.N.H. blood for this study.

RED-CELL SURVIVAL IN PAROXYSMAL NOCTURNAL HAEMOGLOBINURIA

EFFECT OF PHENINDIONE AND CORTISONE

BY

F. P. MULDOWNY, M.B., M.R.C.P.Ed.

M. M. BLUHM, Ph.D., B.Sc., D.I.C., A.Inst.P.

AND

E. J. WAYNE, M.D., Ph.D., F.R.C.P., F.R.F.P.S.

From the University Department of Medicine, Gardiner Institute, Western Infirmary, Glasgow, and the Regional Physics Department, Glasgow

Paroxysmal nocturnal haemoglobinuria (P.N.H.) is a rare form of haemolytic anaemia in which the essential abnormality lies in the cells rather than in the plasma (Dacie and Firth, 1943; Dacie and Mollison, 1949; Crosby, 1953; Dacie, 1954). The only treatment of proved value in the condition is repeated blood transfusion, but it has been claimed that anticoagulant therapy may be beneficial. The basis for this form of treatment is the observation by Crosby and Dameshek (1950) that haemolysis is produced by a factor normally present in plasma which is activated by thrombin. A patient with P.N.H. was given dicoumarol and the degree of haemolysis diminished. Haemolytic crises, however, still occurred, and the authors conclude merely that "dicoumarol offers an intriguing possibility for treatment." They mention its additional value as a protection against the spontaneous thromboses to which these patients are so liable. In a later paper Crosby (1953) refers to three cases treated by dicoumarol, with apparent success in two.

Other cases subjected to anticoagulant therapy have been recorded. Kalant and Cyr (1952) noted that treatment with dicoumarol "coincided with a remission lasting five weeks." Perkins *et al.* (1955) report four cases, in two of which they thought the evidence was in favour of a diminished degree of haemolysis when the patient was receiving dicoumarol. Wang *et al.* (1956) describe a case in which both phenindione ("dindevan") and biscoumacetate ("tromexan") were thought to have extended the interval between transfusions given at a fixed haemoglobin level.

Both corticotrophin and cortisone have been used clinically in the treatment of P.N.H. Crosby (1953) states categorically that these substances are of no benefit. Fudenberg *et al.* (1954), however, describe a case in which the patient showed symptomatic improvement during six months of corticotrophin treatment. There was no evidence of intravascular thromboses over this period. Feichtmeir *et al.* (1955) discovered a patient suffering from P.N.H. who had present in his serum a haemolysin active against normal red cells and in whom cortisone produced a remission. Dicoumarol treatment had failed.

From the evidence in favour of these two forms of treatment it is clear that the chief difficulty in assessing their value lies in the tendency for spontaneous fluctuation in severity to occur in this disease. When conventional haematological criteria are used studies must necessarily be continued over weeks or months. A more precise index of improvement is the mean lifetime of red cells, and this can be measured by the use of red cells labelled with radioactive chromium (^{51}Cr). This method has the important advantage of providing a quick assessment of results. Accordingly, the effect of phenindione and of cortisone on the survival of ^{51}Cr -labelled cells was studied in a case of P.N.H. The survival time of the patient's cells transfused into a normal recipient and that of normal donor cells transfused into the patient were investigated at the same time.

Case Report

The patient, a 37-year-old man, was first seen by us in February, 1956. His presenting complaint was of dyspnoea on exertion. He had had no illness until March, 1951, when he had been investigated elsewhere for the same symptoms. He was then considered to be suffering from an iron-deficiency anaemia of undetermined aetiology, and thereafter received sporadic doses of oral iron, and two courses of intravenous iron therapy. He continued to feel moderately lethargic and short of breath, and these symptoms became worse after a bout of "influenza" in December, 1954. He then first noticed that his urine was at times dark in colour. He was admitted to the urological department, where routine urine tests, cystoscopy, and excretion pyelography revealed no abnormality. The haemoglobin was 9.5 g. per 100 ml. and the M.C.H.C. 29%. Occult blood was absent from the faeces, and barium meal and follow-through yielded negative results. Sternal marrow smears showed normoblastic hyperplasia. Free acid was present in the gastric juice. Nothing further was added on this occasion to the previous diagnosis of iron-deficiency anaemia of undetermined aetiology. The patient was discharged on oral iron therapy, and continued to feel unwell in a greater or less degree until his admission to the medical unit. His complaint was of breathlessness on exertion, tiredness, and weakness.

On examination there was obvious pallor of skin and conjunctivae. No enlargement of liver, spleen, or lymph nodes was noted. The results of laboratory investigations were: Hb. 5.9 g. per 100 ml.; P.C.V., 20.5%; M.C.H.C., 28.9%; W.B.C., 4,000 per c.mm.; reticulocytes, 8%; platelets, 80,000 per c.mm. No significant abnormality was detected in a stained film of peripheral blood. Occult blood was not present in the faeces. The urine contained urobilin, and tests for haemoglobin were strongly positive despite the absence of red cells on microscopical examination. The serum bilirubin was 0.6 mg. per 100 ml., and 24-hour faecal urobilinogen (mean of four-day period) was 280 mg. The Wassermann and Donath-Landsteiner reactions were negative. The direct Coombs test was negative on two occasions. Ham's acidified serum test (Ham, 1939) and Crosby's acid-serum-thrombin test (Crosby, 1950) were positive on each of three occasions. Spectroscopic examination of the

patient's serum revealed the typical absorption bands of oxyhaemoglobin and methaemoglobin. Methaemalbuminaemia was not detected.

Methods

25 ml. of the patient's blood was added to a sterile rubber-capped bottle which contained 30 μ C. of ^{51}Cr in the form of sodium chromate, and to which 5 ml. of acid-citrate-dextrose solution had been added immediately beforehand. The bottle was incubated for 45 minutes at room temperature, and the cells were washed three times with sterile isotonic saline. Then 20 ml. of this saline-cell suspension was administered to the patient by intravenous injection from a calibrated syringe, and two 1-ml. samples were taken from the remainder and diluted each to 50 ml. with distilled water. The packed cell volume of the injection suspension was determined, and the activity of the supernatant saline was measured by diluting 1 ml. to 50 ml. with distilled water and counting a 10-ml. aliquot. Blood samples were taken from a different vein 15 and 30 minutes after injection. Determinations of the packed cell volume were carried out on these samples, and the remainder was lysed with saponin and 10-ml. aliquots were taken for counting. The total red-cell mass was then determined from the following equation:

$$\text{Red-cell mass} = \frac{\text{Counts/min. injected} - \text{Counts/min. in supernatant}}{\text{Counts in blood/min./ml.} \times \frac{100}{\text{P.C.V.}}}$$

The packed cell volumes of the 15- and 30-minute samples were corrected for trapped plasma according to the figures of Chaplin and Mollison (1952). The number of counts injected was calculated from the count rates of the standard dilutions as follows:

$$\text{Counts/min. injected} = \text{Counts/min./ml.} \times \text{Dilution} \times \text{Volume injected}$$

The counts in the supernatant saline were determined in the following equation:

$$\text{Counts/min. in supernatant} = \frac{\text{Counts/min./ml.} \times \text{Dilution} \times \text{Volume injected} \times (100 - \text{P.C.V.})}{100}$$

The red-cell survival curve was plotted on semi-logarithmic paper by expressing the count rate of the subsequent daily blood samples as a percentage of the count rate 24 hours after administration of the dose. Each daily count rate was corrected for changes in packed cell volume where this value differed from that of the 24-hour sample. No correction was made for elution of ^{51}Cr from the red cells, the results being expressed simply in terms of the time required for one-half of the ^{51}Cr activity to disappear from the circulation (Donohue *et al.*, 1955).

Total red-cell mass estimations were derived from measurements of plasma volume by means of the Evans

blue (cellulose extraction) method (Bedwell *et al.*, 1955). Haematocrit values were obtained with Wintrobe tubes spun at 3,000 r.p.m. for 55 minutes. Correction for trapped plasma was made according to the figures of Chaplin and Mollison (1952), and the true venous haematocrit was then corrected by the factor 0.91 to calculate total body haematocrit (Chaplin *et al.*, 1953). The red-cell mass was calculated as follows:

$$\text{Red-cell mass} = \frac{\text{Plasma volume} \times \text{Total body haematocrit}}{(100 - \text{Total body haematocrit})}$$

A preliminary study of the mean survival time of the cells was carried out before treatment with phenindione and cortisone. Dosage of the former was then adjusted so as to maintain the one-stage prothrombin activity between 15 and 20% in accordance with the recommendations of Crosby (1953). This regime was maintained for seven weeks, and during the period the effect of cortisone (200 mg. daily for 12 days) was studied. At the end of this time the administration of both phenindione and cortisone was continued and the patient was given the packed washed red cells of 4 pints (2.3 litres) of group A blood as recommended by Mollison (1951). There was no evidence of any reaction, and the haemoglobin rose from 7.0 to 10.1 g. per 100 ml. Five months later his haemoglobin had fallen to 7.4 g. per 100 ml. and he was given a further transfusion of six pints (3.4 litres) of washed red cells without a reaction. He returned to work, and 10 weeks later was still engaged as a welder. His haemoglobin was then 9.9 g. per 100 ml.

Results

The results of the cell-survival studies are shown graphically in Figs. 1-3. Each point represents one measurement, the limits of error being the standard deviations calculated from the count rates obtained. The statistical error in counting was by far the most important source of error, and the limits are chosen so that there is a 70% probability of the correct result lying within them. Each sample was counted in an Ekco scintillation counter type N.550 for long enough to give at least 1,000 counts (net) except for the last eight readings in Fig. 1(b) when 500 counts (net) were obtained.

Fig. 1(a) shows the red-cell-survival curve obtained in a normal subject, and gives a value of 25 days for the half-life survival time. This is in good agreement with other published estimates (Read *et al.*, 1954).

Fig. 1(b) shows the red-cell-survival curve in the patient, phenindione being given at the point indicated. Inspection of the curve suggests that the change in half-life, if any, is too small to be detected. To confirm this, the best straight line (based on the square of the difference between the observations and the straight line being a minimum) was fitted to the observations from the 1st to the 26th day, and

FIG. 1.—Comparison of survival of red cells in a normal subject (a) and in the case of P.N.H. before and during the administration of phenindione (b).

FIG. 2.—Survival of red cells in the case of P.N.H. during the continued administration of phenindione and later of cortisone.

FIG. 3.—(a) Survival of normal red cells transfused into the case of P.N.H. (b) Survival of red cells from the case of P.N.H. transfused into a normal subject.

again for the observations from the 27th to the 53rd day. The half-lives calculated from these straight lines did not differ significantly (see Table).

On the 35th day it became necessary to give a further dose of labelled cells, and Fig. 2 shows the resulting survival curve and the effect on it of the administration of cortisone. Phenindione therapy was continued during this phase. Again no change was detected. A straight line was fitted to the observations during cortisone therapy from the 54th to the 66th day. Again the half-life did not differ significantly from the previous value (see Table).

Effect of Drugs on Survival Time of Red Cells

Day	Experiment	^{51}Cr Survival Time (Days) and Standard Errors
1-26	P.N.H.: patient: no therapy	15.5 $\pm$ 0.5
27-53	" " during phenindione	14.4 $\pm$ 0.4
54-66	P.N.H. patient: during phenindione and cortisone	17.5 $\pm$ 2.3
68-88	Transfused normal cells in P.N.H. patient	24 days
68-76	Transfused P.N.H. cells in normal subject	15 "

The survival times of transfused washed normal red cells in the patient and of the patient's washed red cells in a normal subject were also measured. The resulting curves are plotted in Fig. 3, and the half-life values are given in the Table. It is seen that haemolysis of the patient's cells continued at the same rate in the normal subject, and the normal cells survived normally in the patient.

The total red-cell mass before treatment, determined by the ^{51}Cr method, was 921 ml. compared with the estimate of 905 ml. derived from an Evans blue (cellulose extraction) determination. The theoretically normal red-cell mass, based on total body weight, was 1,870 $\pm$ 275 ml. (Huff and Feller, 1956). After treatment the red-cell mass determined by the Evans blue technique was 990 ml.

Discussion

Previous observers have suggested that phenindione, corticotrophin, or cortisone may reduce the degree of haemolysis in P.N.H. In these experiments the measure of the lysis in P.N.H. has usually been indirect and has not rate of haemolysis has usually been indirect and has not been related to the total red-cell mass. Moreover, observations have taken place over periods of time so long that spontaneous fluctuations in the rate of haemolysis may have occurred. The observations which we present here were designed so as to avoid these defects. The mean survival time of red cells has been found to be unchanged; the total red-cell mass altered by only 85 ml. from the beginning to the end of the studies; the reticulocyte count remained at the same level during administration of the drugs. It seems clear that in our case the administration of phenindione for 26 days and of phenindione and cortisone for 12 days had no demonstrable effect on the rate of haemolysis.

We should like to stress that whenever the survival of red cells is being studied estimates of the red-cell mass at the beginning and end of the set of observations should be made. This is discussed by Strumia *et al.* (1955). In our case this was done, and no correction for this effect was necessary, since there was no significant change in the red-cell mass during the course of the study. It is also necessary to re-determine the 24-hour excretion of urobilinogen in the faeces to late the total red-cell mass, since this can be used as a quantitative measure of haemolysis only when viewed against the background of total circulating haemoglobin (Miller *et al.*, 1942). Our case provides an illustration of the importance of this qualification. The mean 24-hour faecal urobilinogen during a four-day period was 280 mg. This value is at the upper limit of the normal range of 40-280 mg. quoted by Whitby and Britton (1953). When, however, it is expressed as a function of total circulating haemoglobin the resulting figure for the haemolytic index is 106, compared with the normal range of 11-21.

The results of observations on the cross-transfusions between the patient and a normal donor show that the abnormality lies in the cells rather than in the plasma. This agrees with the results of Dacie and Mollison (1949), who used the differential agglutination technique. The survival curve obtained over a period of 26 days before the use of drugs in our patient (Fig. 1) shows no evidence of flattening. This is in contrast to the case studied by Dacie and Mollison in which some of the cells were remarkably resistant. Hinz *et al.* (1956) studied three cases, using ^{51}Cr techniques, and in two found evidence of a mixed population of cells, some of which disappeared at a rapid rate and others at a rate approaching the normal. They suggest that the clinical severity of the disease is related to the proportion of cells with an extremely short life. They found that the haematological finding which correlated best with the mean half-life of the red cells was the reticulocyte count. On this view our case would not be regarded as severe, and it may be significant that Crosby (1953) thinks that the less severe cases are less likely to respond to anticoagulant therapy.

Our results show that at least in one case of P.N.H. neither phenindione nor cortisone had any effect on the mean survival of the patient's red cells. The previously recorded evidence of positive results is not convincing when one takes into account the notorious variability in the course of the condition. We present these observations because the disease is rare and so far as we are aware no similar studies have been reported. We should like to point out the desirability of investigating the effects of anticoagulants on further and more severe cases of P.N.H., using the ^{51}Cr technique. The administration of anticoagulants should be considered in all cases, since 50% of deaths have been attributed to thrombotic incidents (Crosby, 1953). We can confirm the value of transfusion with washed normal erythrocytes.

Summary

The results of studies of the blood volume and of the mean survival time of red cells with ^{51}Cr -labelled cells in a case of paroxysmal nocturnal haemoglobinuria are presented.

Phenindione and cortisone produced no effect on the rate of haemolysis, on the total red-cell mass, or on the reticulocytosis. Transfusion with washed normal red cells preceded a long remission. The merits of the labelled-red-cell technique in the study of the treatment of haemolytic states are pointed out.

We are grateful to Professor G. M. Wilson and Dr. G. A. Tudhope, of the Department of Pharmacology and Therapeutics, University of Sheffield, for helpful advice.

NATURE OF OEDEMA IN PARALYSED
LIMBS OF HEMIPLEGIC PATIENTS

BY

A. N. EXTON-SMITH, M.D., M.R.C.P.
Physician, Whittington Hospital, London

AND

D. J. CROCKETT, M.B., F.R.C.S.
Institute of Clinical Research, Middlesex Hospital

The formation of oedema in the paralysed limbs of hemiplegic patients has been a well-recognized phenomenon for over half a century. Hare (1898) and Allen (1899) each described a case of "unusual oedema" in hemiplegia. In 1936 Luhan reviewed the literature and stated that 28 cases had been recorded; in addition he described in detail seven further cases. Although the mechanism of this type of oedema has not been clearly defined, it has usually been attributed to a disturbance of the blood vascular system in the affected limbs. Weiss and Ellis (1931) believe that the oedema results from an increase in capillary pressure which is in turn due to diminution in arteriolar tone in the paralysed limbs, while Bucy (1949) states that there is an increase in capillary permeability. We now produce new evidence that, in the upper limb at least, a major part in the formation of hemiplegic oedema is played by an impairment of lymphatic function. This evidence is based on a critical examination of the protein content of oedema fluids.

Clinical Features

Oedema in the paralysed limbs, occurring at some time during the clinical course, was noted in 21 patients in a series of 130 cases of hemiplegia. Thirteen of the oedematous patients had hemiplegia alone with no other important clinical condition, and in these cases it was noteworthy that the oedema was either confined to the arm or was more pronounced there than in the leg. In the remaining eight patients, who had other pathological processes besides hemiplegia contributing to oedema formation, the swelling was often more marked in the paralysed leg than in the arm. These clinical features are summarized in Table I.

TABLE I

Group	Clinical Condition	No. of Cases	Oedematous Limb		
			Arm Only	Leg Only	Arm and Leg
1	Hemiplegia alone	13	11	0	2
2	Hemiplegia with:				
	(a) Cardiac failure	4	0	2	2
	(b) Venous thrombosis of leg	4	0	2	2

In the 13 patients with hemiplegia alone the oedema was confined to the paralysed side; and in all but two of these only the upper limb was swollen. Where hemiplegia was associated with cardiac failure there was oedema of both legs, but it was more marked and more persistent on the paralysed side. The four patients in group 2b (see Table I) had a complete flaccid hemiplegia, and the phlebothrombosis developed while they were bedridden; two had oedema of the hand before the occurrence of venous thrombosis in the leg. In the absence of complicating factors oedema has been most easily detected on the dorsum of the hand; and volume measurements of the hands, using a water-displacement method (Eccles, 1956), have shown an increase of from 8 to 30% in cases tested. An 8% increase corresponded to the least detectable degree of pitting oedema.

The time of appearance of oedema after the onset of hemiplegia varied from 2 days to 10 weeks, but the most usual time was about two weeks after the paralysis. The duration of oedema was always more than two months (excluding patients who died in less than this period), and was sometimes as long as six months.

Although generally only patients with the most severe degree of paralysis developed oedema there were notable exceptions. In three patients oedema in the upper limbs appeared, and increased in amount at a time when the patients were making rapid recovery from hemiplegia with almost complete return of motor power. The duration of the oedema in these exceptional cases also appeared to be as long in the other patients, and in two female patients it persisted long after they had been discharged home able to perform their household tasks.

Results of Protein Estimations

Samples of oedema fluid were collected by miniature Southey-type needles inserted subcutaneously, and their protein content was estimated by an ultra-micro-Kjeldahl method (Crockett, 1956). In cases of uncomplicated hemiplegia the concentration of protein in fluids removed from oedematous hands varied from 1.2 to 4 g./100 ml., and the mean value for 13 patients was 2.8 g./100 ml. There was found to be a rough correlation between the protein content and the interval between the onset of hemiplegia and the occurrence of oedema. This is shown in the chart.

Relationship between protein content of oedema fluid removed from the hand and duration of paralysis in patients with uncomplicated hemiplegia.

Patients of group 2 had specimens taken from the paralysed oedematous leg and at the same time from the hand when it was oedematous. The results of these protein estimations are shown in Table II. In all cases the oedema

TABLE II.—Protein Content of Oedema Fluids Removed From Hand or Foot in Hemiplegic Patients with Either Congestive Cardiac Failure or Femoral Venous Thrombosis

Group	Clinical Condition	Case No.	Protein Content (g./100 ml.)	
			Hand	Foot
2a	Hemiplegia with congestive cardiac failure	4	2.2	1.3
		8	—	0.7
		9	—	1.3
		17	2.1	0.6
2b	Hemiplegia with femoral venous thrombosis	1	—	0.8
		13	1.8	1.4
		14	1.2	0.7
		20	—	1.7

fluid from the leg contained a lower concentration of protein than that from the arm. This may be attributed to the fact that oedema of the leg was in part due either to congestive cardiac failure or to femoral venous thrombosis, and these conditions produce an oedema fluid of low protein content.

Interpretation of Results

Normal capillary walls allow the escape of only a small amount of protein from the blood stream. Landis (1934)

calculated that normal capillary filtrate has a protein content of about 5% of the plasma protein level. It is probable that the protein of tissue fluid re-enters the blood vascular system only via the lymphatics (Drinker and Yoffey, 1941; Taylor *et al.*, 1957).

In a previous report (Crockett, 1956) it has been shown that an estimation of the protein content of oedema fluid is often of value in determining the cause of oedema. As the result of the investigation of fluids in a variety of clinical states it was found possible to distinguish three classes of oedema: the mechanical filtration oedemas with a low protein level (0.1 to 0.9 g./100 ml.) occurring in cardiac failure, hypoproteinaemia, and venous obstruction; and those in which high protein levels are found attributable either to a failure of drainage of tissue-fluid protein—namely, lymphatic failure of drainage of tissue-fluid protein—or to oedema and paralytic oedema (1 to 4 g./100 ml.)—or to an increase in the permeability of capillary walls as in burns and allergy (4 to 6 g./100 ml.).

In every patient with oedema due to hemiplegia alone without any other major pathological process, the oedema fluid has been found to contain a high concentration of protein. Similar high protein fluids have also been found in cases of post-traumatic stiffness and in patients with paralysis due to lower motor neurone lesions.

Impairment of Lymphatic Function

It has been suggested that oedema in hemiplegia is due to an increase in the permeability of the capillaries in the paralysed limbs (Bucy, 1949); our evidence does not support this view. We believe that the most important factor responsible for the development of oedema (with its high protein content) in "uncomplicated" hemiplegia is a relative lymphatic insufficiency. Some of the observations supporting this belief are:

1. The oedemas of hemiplegia and of lymphatic obstruction resemble each other in that they show a similar relationship between protein concentration and time. The increase in protein content with duration contrasts with the high protein content which is found immediately after the onset of such conditions as angioneurotic oedema and burns. In these conditions the oedema is due to increase in capillary permeability. (In fluid from one case of angioneurotic oedema the protein level was 4.2 g./100 ml. and in a burn oedema the protein level was 4.7 g./100 ml. In each case the sample was collected within 24 hours of the onset of oedema.)

2. The electrophoretic pattern of the oedema fluid in hemiplegia resembles that found in the low-protein oedemas—for example, cardiac oedema. A characteristic feature of this pattern is absent or greatly reduced α_2 -globulin. We have found that all types of oedema (including lymphatic oedema) in which the capillary permeability is believed to be normal show this pattern. On the other hand, where the capillary permeability is increased, as in burns and allergic oedema, the electrophoretic pattern of the oedema fluid resembles that of serum and the α_2 -globulin is present in normal amounts.

3. In a number of cases of hemiplegic oedema we have determined the protein concentration of the capillary filtrate by an indirect method. The procedure was as follows:

The volume of the hand on the hemiplegic side was measured by means of a water-displacement tank (Eccles, 1956). A specimen of oedema fluid was taken for estimation of its protein content. A cuff was applied to the forearm and inflated to 40 mm. Hg. After four hours the cuff was removed and the hand volume and the oedema protein concentration were again estimated. The experiment was repeated on another two occasions, and further sets of protein and volume estimations were made. The capillary transudate protein concentration (p) is given by the formula

$$p(V_2 - V_1) = v(P_1 - P_2) + (P_2V_2 - P_1V_1)$$

When V_1 =initial volume of oedematous hand; V_2 =final volume of oedematous hand; v =hand volume less the volume of extracellular fluid in which the protein is dissolved; P_1 =initial oedema fluid protein; P_2 =final oedema fluid protein.

Example.—Values from three experiments in a patient with hemiplegic oedema of the hand.

A. $V_1=574$ ml. $V_2=684$ ml. $P_1=2.28$ g.-% $P_2=2.08$ g.-%	B. $V_1=574$ ml. $V_2=650$ ml. $P_1=4.88$ g.-% $P_2=3.33$ g.-%	C. $V_1=625$ ml. $V_2=676$ ml. $P_1=3.95$ g.-% $P_2=3.25$ g.-%
---	---	---

Solution for v as simultaneous equations:

A & B, $v=450$ ml. A & C, $v=434$ ml. B & C, $v=455$ ml.	Mean value for $v=445$ ml.
--	----------------------------

Solution for p assuming $v=445$ ml.

A, $p=0.70$ g.-% B, $p=0.69$ g.-% C, $p=0.77$ g.-%	Mean value for $p=0.72$ g./100 ml.
--	------------------------------------

Normal hand volume was 500 ml.

This value for the protein content of the capillary filtrate ($p=0.7\%$) accords closely with that obtained by Stead and Warren (1944), who measured the protein content of the oedema fluid obtained in normal subjects by compressing the forearm at 30 mm. Hg for 12 hours. Their results showed that at a venous pressure of 30 mm. Hg the protein content of the transudate for normal capillaries was within the range of 0.4 to 1.3 g./100 ml.; the average value was 0.8 g./100 ml. Comparison with our results indicates that the permeability of the capillaries is not increased in the limbs of hemiplegic patients.

Immediate Cause of Oedema

Thus it seems probable that the fluid which enters the tissue spaces has the composition of normal capillary filtrate and contains only a very small amount of protein. In the course of time, owing to defective removal of protein by the lymphatics, the concentration of protein in the tissue fluid rises. The high extravascular protein concentration reduces the effective colloid osmotic pressure of the plasma, which is one of the chief factors preventing the loss of fluid from the blood stream. Landis (1934) has shown that a fall in plasma colloid osmotic pressure has quantitatively the same effect in increasing the rate of capillary filtration as a rise in capillary pressure. In all but two of the uncomplicated hemiplegic cases in the present series, the hand oedema fluid had a protein concentration greater than 2 g./100 ml. Electrophoresis shows the fluid protein to be proportionately richer in albumin than plasma, and therefore osmotically more active. It is probable that a protein level in excess of 2 g./100 ml. is sufficient in itself to cause oedema. There are, however, in nearly all cases other factors which increase capillary filtration rate and promote oedema formation.

Ancillary Factors Contributing to Oedema Formation

1. *Arteriolar Dilatation.*—Weiss and Ellis (1931) found that the surface temperature over the paralysed side in cases of hemiplegic oedema was increased, especially in the arm. Moreover, the difference between the oxygen content of the blood in the brachial artery and cubital vein was diminished on the paralysed side compared with the normal. They conclude that there is a disturbance of cerebral vasomotor regulation which leads to diffuse arteriolar dilatation, increased blood flow and capillary pressure, and a greater capillary filtration rate on the paralysed side. In two of our patients whose oedema appeared early there was a clinically detectable increase in skin temperature in the paralysed arm, and it is likely that an increase in the rate of transudation of fluid from the capillaries has been the result of arteriolar dilatation in these cases. Many observers have drawn attention to the difference in temperature on the two sides of the body in hemiplegic patients. Bucy (1935) states that early in cases of hemiplegia the temperature of the skin is commonly higher on the affected side than on the other; whereas in chronic cases the hemiplegic side is cooler. However, the proportion of patients showing these vasomotor disturbances is unknown.

2. *Local Increase in Venous and Capillary Pressure Due to External Causes.*—(a) *Dependency of paralysed arm:* In two cases oedema appeared while the patient was sitting in a

chair, and the most likely explanation is that the paralysed arm had been allowed to hang in a dependent position. (b) *Lying on the paralysed side*: Hemiplegic patients who are kept in bed often lie on the paralysed side in order to give more freedom of movement to the normal arm. In several cases this was thought to be a factor in causing oedema. (c) *Effect of splinting*: In one case oedema in the paralysed arm directly followed the application of a light "polythene" splint which was used to correct flexion deformity of the fingers.

3. *Congestive Cardiac Failure*.—Several authors have noted that hemiplegic oedema is more common in those patients who have previously experienced episodes of congestive cardiac failure (Weiss and Ellis, 1931; Luhan, 1936; Bucy, 1949). In the present series two cardiac patients (well controlled by digitalis and mercurials) developed hemiplegia and became oedematous on the paralysed side. In two other hemiplegic patients oedema appeared only after the development of congestive cardiac failure. In each case the oedema was more marked in the paralysed leg. When the cardiac failure was treated oedema was more persistent on the paralysed side than on the other; moreover, the protein content of the oedema fluid gradually increased—for example, in one case from 0.7 to 2.0 g./100 ml. Thus the oedema which initially has a low protein content owing to the predominant effect of cardiac failure may become converted to a high-protein oedema; the improvement in cardiac efficiency and the use of mercurial diuretics lead to a removal of water and electrolytes from the tissues, but the protein remains owing to the relative lymphatic insufficiency on the paralysed side.

4. *Thrombophlebitis*.—Four of the hemiplegic patients developed venous thrombosis in the paralysed leg. In two cases the patients had oedema of the affected arm prior to the venous thrombosis; subsequently, the affected leg became very much more oedematous than the arm. The protein levels of the oedema fluids were 1.2 and 0.7 g./100 ml. for the upper and lower limbs respectively in one patient and 1.8 and 1.4 g./100 ml. in the other. In the other two patients no oedema was present until the occurrence of the venous thrombosis, after which the leg alone became oedematous (protein levels of 0.8 and 1.7 g./100 ml.). In the absence of cardiac failure oedema of the paralysed leg and not of the arm, in the hemiplegic patient who is nursed in bed, is rare. Any patient who has remained recumbent following the cerebrovascular accident and who subsequently develops oedema of the paralysed leg alone should be suspected of having phlebothrombosis, and treatment should be instituted accordingly.

Discussion

The removal of the tissue-fluid protein requires effective lymphatic function, which in turn depends very largely on the activity of skeletal muscle. Lymphatic flow also varies with the position of the limb (McMaster, 1937); elevation considerably increases flow, and dependency will stop the movement of lymph in the main lymphatic trunks. In most cases of hemiplegia lymphatic drainage is sufficient to prevent the accumulation of protein in the tissues, provided that the rate of transudation of fluid from the capillaries is not increased. All the ancillary factors which have been considered above lead to an increase in the rate of capillary transudation, and in such circumstances the accumulation of fluid and protein in the tissue spaces occurs. The greater the extent to which these factors are concerned in the causation of oedema the lower will be the protein content of the oedema fluid. This we find to be the case; patients with congestive cardiac failure and hemiplegia have a lower protein content of their oedema fluid than those with hemiplegia alone. On the other hand, when the ancillary factors are operative to a minimal degree oedema will be long in appearing, but its protein content will be high by the time enough fluid has accumulated to be detected clinically.

In all patients in our series the oedematous limbs showed a soft swelling which pitted readily on pressure. Moreover,

there was no alteration in skin colour. Gilbert and Garnier (1897), however, described a case of "tumescence" of the hand and "un aspect éléphantiasique" in the leg of a patient 20 years after she had sustained hemiplegia at the age of 31. The hand was violaceous red in colour and it resembled "la main succulente" of syringomyelia, although there was no muscle-wasting and the motor power in the arm was comparatively good. They concluded that this condition may appear in long-standing hemiplegia and that it is due to vasomotor disturbances.

Raymond and Courtellemont (1904) consider that "la main succulente" with its firm non-pitting swelling is rare in hemiplegia, but a condition of "white oedema" occurs very much more commonly. Their patient developed swelling of the hand one hour after the onset of hemiplegia. On account of this very early onset, the good general condition of the patient, and the return of almost full movement in the arm they attribute the formation of oedema to vasomotor disturbances.

Many authors have postulated the existence of vasomotor centres which are involved in the cerebral lesion in cases of hemiplegia with oedema, and in the descriptions of the post-mortem examinations of the recorded cases particular attention is paid to the situation of the pathological changes in the brain. Parhon and Goldstein (1899) concluded that the vasomotor centres are contained in the corpus striatum, especially the head of the caudate nucleus. Luhan (1936), however, states that thus far results of clinical studies which have been checked with post-mortem observations have not furnished any critical evidence for localizing a cerebral vasomotor centre. In our series necropsy was performed on seven of the eight patients who died. Although the cerebral lesions were usually extensive the situation of the pathological changes was not essentially different from that generally found in cases of hemiplegia without oedema.

Summary and Conclusions

Oedema in the paralysed limb is noted in about 16% of cases of hemiplegia. It is usually more marked in the upper limb than in the lower, and it may be confined to the hand.

The oedema fluid has a high protein content, and it is believed that the most important factor in its causation is impairment of drainage of protein from the tissues by the lymphatics consequent upon the loss of muscular activity. The retained protein reduces the "effective colloid osmotic pressure" of the plasma and leads to accumulation of fluid in the extravascular extracellular compartment. Removal of oedema from the paralysed limb is favoured by encouragement of lymphatic drainage.

Contributory factors responsible for the development of oedema in hemiplegia include increased venous pressure caused by lying on the affected arm, a dependent position of the paralysed arm when it is flaccid, splinting, venous thrombosis, and congestive cardiac failure. Arteriolar dilatation due to a disturbance of vasomotor regulation in the brain may also play a part.

In the cases investigated we have been unable to find evidence of any increased permeability of the capillaries to protein in the hemiplegic side.

Hemiplegic patients who are confined to bed, and who subsequently develop oedema in the paralysed leg and not of the arm, should be suspected of having thrombophlebitis in the leg.

One of us (D. J. C.) was in receipt of a grant from the research funds of the Middlesex Hospital for work carried out under the guidance of Mr. Rainsford Mowlem, to whom we owe our thanks. We also wish to acknowledge the help given by Dr. A. Abrams, Dr. E. Boesen, Dr. R. Martin, Dr. C. E. Salter, and Dr. D. Vardy, who collected many of the samples of oedema fluid.

TRICUSPID ATRESIA

BY

A. L. GWEE, L.M.S., M.R.C.P.

Among congenital heart diseases, tricuspid atresia is by comparison a rare complaint (White, 1951) and by itself is incompatible with life. Gibson and Clifton (1938) reported one case in a series of 105 congenital cardiac cases, Abbott (1936) had 16 out of 1,000 cases, and we had only one case out of 106 cases (Gwee, 1956, unpublished). However, compensatory mechanisms in the form of other coexisting congenital cardiac malformations sometimes enable a patient to live for many years. Taussig (1947) pointed out that the method of compensation may be either a communication of the two atrial chambers by an interatrial septal defect, the vestigial right ventricle receiving its blood supply through a ventricular septal defect, or persistent ductus arteriosus with interatrial defect and non-functioning right ventricle. White (1951) stated that tricuspid atresia is almost always attended by compensatory septal defects. Blackford and Hoppe (1931) regarded it as a functionally two-chambered heart.

Quite often the coexisting deformities produce no pathognomonic clinical signs, and in fact some cases may even be silent. Their presence is nevertheless suspected from the fact that the circulation must be able to complete its circuit to be compatible with life. The diagnosis is being made with increasing frequency in life, and in more and more cases knowledge of the coexisting defects is obtained pre-mortem by means of special investigations, of which angiocardiology and cardiac catheterization are probably the most informative.

Clinically, the patient is a cyanotic child with polycythaemia and gross clubbing of fingers and toes, and, cursorily inspected, may well pass for a case of Fallot's tetralogy (Alexander and White, 1947). A closer examination, however, may reveal in some cases a left ventricular apical impulse to suggest the true nature of the anomaly. Electrocardiography typically, though not necessarily, shows a left axis deviation and suggests left hypertrophy (Rihl, Terplan, and Weiss, 1929; Burchell, 1949). With the clinical appearance of Fallot's tetralogy, this finding is almost diagnostic of tricuspid atresia

(Astley, Oldham, and Parsons, 1953)—one of the few occasions when the electrocardiograph is of value in the elucidation of cardiac malformations. Radioscopy usually shows a large left ventricle, and the appearance may resemble that of truncus arteriosus, which, however, produced more cyanosis and is seldom seen beyond infancy. Also, the plateau-like appearance in truncus arteriosus is usually more marked, and the vascular pedicle remains the same size on rotation during radioscopy (Taussig, 1947). The diagnostic triad therefore consists of clubbing with cyanosis, left axis deviation in the electrocardiogram, and a characteristic appearance on radioscopy (Taussig, 1936). However, the shape may vary considerably (Astley *et al.*, 1953), and the pulmonary vascularization may be normal or markedly oligoemic. An exact diagnosis of all the coexisting anomalies may be impossible even after very exhaustive studies.

The salient differences of these cyanotic types of congenital heart disease are shown in the Table.

The life expectancy is usually short, although Abbott's (1936) series of 16 cases included a case of Hedinger's (1915) surviving up to 56 years. The review of Edwards and Burchell (1949) shows that the longevity of the patient depends to a large extent on the presence or absence of a transposition of great vessels. In their review, 45 cases were classified into four groups, thus: (1) No transposition of great vessels, (a) pulmonary

Signs and Symptoms

	Cyanosis	Clubbing	Polycythaemia	Stunting of Growth	E.C.G.	Pul. Vasc.	Death
Fallot's tetralogy	++	++	++	++	R.V.H.	Sparse	Often reach adult life
Eisenmenger's complex	Later	Later	++	May be little	R.V.H.	Normal	" "
Tricuspid atresia	++	++	++	++	L.V.H.	Sparse	Usually infancy and childhood
Truncus arteriosus	++++	++	++	++	L.V.H. or normal	"	" "

atresia, closed ventricular septum; (b) subpulmonary stenosis. (2) Transposition of great vessels, (a) pulmonary and subpulmonary stenosis; (b) no pulmonary or subpulmonary stenosis.

Of these, 28 cases belong to group 1b with subpulmonary stenosis and 4 to group 1a with pulmonary atresia. The life expectancy of groups 1a and 1b is stated to be quite short, the oldest being four years (Bellet and Stewart, 1933) and the causes of death being cardiac failure, bronchopneumonia, intracranial venous thrombosis, brain abscess, and bacterial endocarditis, in that order of frequency (Edwards and Burchell, 1949). The presence or absence of persistent ductus arteriosus and the adequacy of the pulmonary circulation do not seem to influence the length of survival.

Case Report

A male Chinese aged 20 was first seen on September 26, 1955, with a history that he had been breathless and blue as far back as he remembered, and that at about 5 years of age his fingers and toes began to get bulbous at the tips. Three weeks before admission he was short of breath and febrile. His legs and body became swollen.

On examination he was very cyanosed, with gross clubbing of fingers and toes. He was on the small side, height 4 ft. 8 in. (142 cm.), with no adult secondary sex

characteristics. His blood pressure was 134/102. The neck veins were engorged and pulsatile, the pulse was 90 a minute and regular. The apex beat was felt at the fifth left interspace, 3 in. (7.5 cm.) from the midline with a left ventricular impulse, and on auscultation both heart sounds were loud, with a rough systolic murmur, maximal at the left fourth interspace near the sternal margin. No thrill was palpable. The liver was enlarged two fingerbreadths below the costal margin and pulsatile.

Investigation showed polycythaemia of 7 millions with haemoglobin of 20.4 g. per 100 ml. E.C.G. showed left axis deviation. Screening and radiography confirmed the presence of a prominent left ventricle with poor pulmonary vascularization. A clinical diagnosis of tricuspid atresia was made, and angiocardiology subsequently showed direct passage of dye into the left auricle, causing it to opacify early. The aorta was in the normal position, but the pulmonary artery was not seen. The case was regarded as one of tricuspid atresia with interatrial septal defect and no transposition of great vessels.

He was digitalized and kept resting in bed, with improvement, but cardiac failure occurred again in January, 1956, and this time the course was progressively downhill until he died suddenly on April 12, 1956.

Post-mortem examination showed an enlarged heart, mainly left ventricle. The tricuspid valve was completely atretic, and its position was indicated by a dimple on the right

Necropsy specimen showing probe in interventricular septal defect and a small vestigial right ventricle to the left of it, indicated by arrow.

auricle. A large interatrial septal defect 1.5 cm. in diameter, representing the persistence of septum secundum, connected the two auricles. The right ventricle was only a small cavity, measuring 1 by 0.5 cm., opening into the left ventricle through a small interventricular septal defect about 1 cm. in diameter (see Fig.). A normal pulmonary artery with valvular stenosis (valve opening 0.5 cm. in diameter) arose from the vestigial right ventricle. Ductus arteriosus was completely obliterated. The lung showed congestive changes with an infarct in the right lower lobe. Evidence of subacute bacterial endocarditis was found on the pulmonary valve cusps, which were grossly deformed but three in number. All other organs were normal except for a large thymus, which could possibly account for the observed deformity of the dye column across the mediastinum during angiocardiology.

Summary

A case of tricuspid atresia with pulmonary stenosis and without transposition of great vessels, surviving to the age of 20, is reported.

The special investigations and the post-mortem findings are correlated.

We are grateful to Dr. T. Balasingham for his necropsy report.

COLD CONIZATION WITH SPENCER'S TRACHELOTOME FOR CERVICAL EROSION

A REVIEW OF 35 CASES

BY

R. G. EMERSON, M.B., B.A.O., D.Obst.R.C.O.G.
Major, R.A.M.C.; Late Gynaecological House-Surgeon,
Royal Salop Infirmary

Read (1955), referring to the problem of the unhealthy cervix, states: "It would appear obvious that in the case of all cervical lesions, before treatment is undertaken, the presence of malignant change must be excluded. Reliance on clinical appearance alone, except in minimal lesions, can be dangerous, and recent work has shown that even the clinically innocent-looking cervix can be the site of early malignant metaplasia."

Until the present day, cervical erosions have been treated in the out-patient departments of most centres in Great Britain by means of the electrocautery, while only in clinically suspicious cases have the patients been admitted to hospital for cervical biopsy as a prelude to cauterization. As a result cases are by no means unknown where an erosion has been cauterized on several occasions without healing taking place, followed by a belated biopsy examination showing the presence of a carcinoma of the cervix. Then, again, even in those cases which heal after cauterization it is certain that many instances of carcinoma-in-situ will be overlooked, with the result that invasive carcinoma may occur at a later date. It would therefore seem better that these patients should all have biopsies carried out as a preliminary to any form of treatment. More acceptable still would be a procedure, such as conization, where diagnosis and treatment are combined in one operation.

Historical

Conization of the cervix, as either a diagnostic or a curative measure, is not a new technique. As long ago as 1815 Lisfranc (1834), in the treatment of a case of suspected cervical carcinoma, is reported to have removed a wedge-shaped portion of the cervix which extended from the vaginal margin up as far as the internal os. Forty-five years later Hughier, of Paris, Marion Sims, and Thomas Emmett were all performing similar operations (Emmett, 1874). By 1916 Arnold Sturmdorf had devised an operation, the basis of which was conization followed by inversion of flaps of vaginal mucous membrane over the bare areas. In 1928 Mortimer Hyams introduced the electroconizer, the purpose of which was the removal of the endocervical mucosa. This instrument had an electrode only $\frac{1}{4}$ in. (3 mm.) wide, and was suitable for removing only a very limited portion of the cervix. The instrument was later improved upon by

Crossen (1935, 1949) in 1933, when he enlarged the head of the electrode to allow a much greater area of the cervix to be removed. As in the original Sturmdorf operation, flaps were used to cover over the bare areas.

Until this time the emphasis on conization had been mainly as a method of treatment, whereas with the introduction of the electroconizer it was recognized that affected tissue could be removed in a condition suitable for microscopic examination. Nevertheless, such specimens did suffer from the disadvantage of carbonizing the most important portion of tissue available to the pathologist and as a result did not gain much in popularity.

Biopsies continued to be made with punches, curettes, sharp spoons, and scalpels, usually at random, but sometimes guided by the application of Schiller's iodine. More complete specimens were again made possible when Ayre devised his angled circular biopsy knife, but, unfortunately, even with this it was not possible to include the whole of the endocervix in the specimen. Gusberg (1949), of New York, produced the endocervical coning biopsy curette, which is probably one of the first cold-conizing instruments. Although this could be used in the out-patient department of a hospital it suffered from similar disadvantages to Ayre's knife, and, in fact, Gusberg states that whenever necessary it should be supplemented by the use of a curettage and scalpel biopsy. About the same time increasing use was being made of the cold knife for conization in a further attempt to obtain better biopsy material. Harris and Peterson (1955) have reported on 367 patients on whom cold-knife conization was performed as a diagnostic procedure, and Scott and Reagan (1956), using an Ayre's knife for conization, emphasize how superior the method is when compared with other previous methods.

Spencer's trachelotome.

During 1955-6 two new instruments designed specifically for the purpose of cervical conization were reported on in the literature. The first was the trachelotome designed by Dr. Frank Spencer (1955), of Honolulu, and the second the conizing and biopsy knife of Professor J. Ullery (1956), of Ohio. The former was invented for the purpose of "obtaining an adequate biopsy in cases where suspicious or positive smears have been reported and no visible lesion is present," whereas the latter "evolved from the difficulties of present-day methods of obtaining biopsy specimens from the uterine cervix and of curing certain lesions."

It seemed to me that Spencer's trachelotome might be a useful instrument for the treatment of cervical erosions, while yet fulfilling the needs of adequate biopsy material, and it is with this in view that the following series of cases have been examined.

Technique

Under general anaesthesia the patient is placed in the lithotomy position on the operating table, and after routine toilet and towelling dilatation of the cervix and curettage of the uterus are performed in all cases. It was found that a dilatation up to a No. 12 Fenton dilator was adequate in most instances, but in the case of the more extensive lesions dilatation had to be carried out up to a No. 14 dilator. A vulsellum forceps is then applied to each side of the cervix at the positions of 3 o'clock and 9 o'clock, just beyond the limits of the erosion. They are used to steady the cervix and apply counter-pressure. The head of the trachelotome is then introduced into the cervical canal up

to the level of the internal os and with short cutting movements in a clockwise direction the whole of the cervix is circumscribed. Where the erosion is large or the lips of the cervix are patulous it may be necessary to pivot the handle to varying degrees upon the head in order to include the whole of the affected area.

The instrument is then withdrawn and the specimen which has been collected in the head is later removed and sent for pathological examination along with any curettings obtained from the uterus. In order to control the bleeding from the cervix the cervical canal is then tightly packed with a rolled No. 4 absorbable gelatin sponge ("sterispon") and on removal of the vulsellum forceps the vagina is tightly packed with a long 3-in. (7.5-cm.) wide sterile gauze pack. The following day the vaginal pack is removed and the patient is allowed to become ambulatory. For 14 days after the operation a pessary containing penicillin, sulphanilamide, and sulphathiazole ("tampovagan P.S.S.") is inserted high into the vagina at night. Most patients are discharged home on the fourth or fifth post-operative day.

Difficulties of Operation

The operation itself is a simple one, but certain difficulties may be encountered. Occasionally with a large erosion, or in the presence of ectropion, it may be difficult to apply the vulsellum forceps to a portion of the cervix outside the diseased area. Spencer, in his original article, recommended that these should be applied at the position of 12 o'clock and 6 o'clock, but I maintain that if applied as described above one gets a better view of the area of operation and also a much more secure grip on the cervix. With the larger erosion care has also to be taken to include the squamo-columnar junction in the biopsy material, otherwise the erosion will not be completely removed, nor will a most important part of the cervix be available for pathological examination.

Irregular cutting movements with the blade may result in small tags of tissue being left around the external os, and these should be trimmed with a scalpel.

If conization has been over-enthusiastic too much cervical tissue may be removed, with the result that one has a large external os and cervical canal and thin anterior and posterior cervical lips.

Finally, bleeding may be heavy during the operation, but in only one case was it necessary to control it by means of electrocoagulation. In all other cases tightly packing the cervical canal with gelatin sponge and then packing the vagina with 3-in. (7.5-cm.) sterile gauze was sufficient. The latter served the dual function of maintaining the cervical pack in position and of acting as a haemostatic agent in its own right.

Results of Treatment

In all, 35 cases were treated by this method, and of these patients 57% were aged 35 or more (see Table). Results were assessed both from the physical cure of the erosion and from the effect of the treatment on symptoms.

Effect of Treatment on Physical Condition of the Erosion.—In 83% of cases the erosion was found to be completely cured four to six weeks after operation, while in the remaining 17% further treatment, usually with the electrocautery, was required before cure was complete. In the latter group of cases light cauterization, on one occasion, or on two occasions at the most, was all that was needed to produce a healthy cervix. Of the cases which required further treatment, 50% were classified originally as large erosions, 33% as moderate, and 17% as small. Where symptoms had existed for up to two years 87% of cases were cured in the first instance; from two to five years the cure rate was 75%, and over five years 75%. In patients under 40 years of age 82% of erosions were cured, while in those over 40 83% were cured.

Effect of Treatment on Symptoms.—With regard to the effect of the operation on symptoms, 80% of all cases were

considered to be cured, while in the remaining 20% there was improvement only. As would be expected, where there was an associated disease it was found that the rate of cure of symptoms fell to 76%, in contrast to 83% cure where there was no such associated condition. It was also found that the longer the symptoms had been present the less chance there was of complete cure. Up to two years the rate was 87%, between two and five years 75%, and more than five years 63%. In those patients who were less than 40 94% became symptom-free, compared with 67% in the group over 40.

Complications

As previously mentioned, bleeding at operation may be a troublesome complication, and it was found that the larger the erosion the greater this was likely to be. Where the erosion was classified as large 40% bled heavily; where it was of moderate size 26%, and when small only 18%. The period during the menstrual cycle at which the operation was performed did not appear to influence the amount of blood loss. On occasion bleeding was also found to occur several days after the operation. In two cases this was thought to be severe enough to warrant readmission to hospital and repacking of the vagina, while in a further three cases bleeding was brisk but was controlled with sedation and bed rest.

Sepsis was under consideration as a possible complication, but in actual fact was not encountered during the series. Its absence is probably due to the routine use of topical penicillin and sulphonamides for the two weeks following operation.

Most patients complained of some abdominal discomfort for a day or two after the operation, but in no case was this severe. In one instance there was temporary retention of urine which was thought to be due to an unduly tightly packed vagina. This was relieved once the pack had been removed.

As a later-occurring complication stenosis of the cervical canal was found in one case only. This was treated by gentle and repeated dilatations of the cervix in the out-

patient department. In one other case it was thought that too much cervical tissue had been removed, and the result was a large cervical canal with thin anterior and posterior lips. Whether this will later give rise to further trouble, should she become pregnant, remains to be seen.

Comment

The results of treatment by the above method would seem to compare favourably with those obtained when the electrocautery is used. The most important advantage of this technique over all others already mentioned is the fact that an excellent biopsy specimen is obtained for pathological examination. How important this can be is underlined by the fact that, in the small series treated, one case of carcinoma-in-situ was in fact diagnosed that would probably have been overlooked if some other method had been employed.

The disadvantages of the method are the need for admission to hospital and the greater incidence of bleeding, both at operation and later, when compared with other methods. The latter complication could, however, probably be overcome if, as Ullery recommends, conizations were followed by light cauterization in all cases. This was not done in this series, as it was thought that it might be more apt to produce stenosis of the cervix later.

What the effects of cold conization of the cervix on future pregnancies are likely to be can only at the moment be a matter of conjecture. It does not seem reasonable to suppose that these will differ greatly from the effects of conization with an electrode as reported on favourably by Champion and Thompson (1951).

Summary

A series of 35 cases of cervical erosion treated by means of cold conization with Spencer's trachelotome is described.

It is suggested that this is a superior method of treatment in that it provides an excellent specimen of tissue from all the possible sites of origin of carcinoma of the cervix.

I wish to thank Mr. Vivian Barnett and Mr. H. G. Wolskel, consultant gynaecologists to the Royal Salop Infirmary, for their advice and encouragement and for the provision of suitable cases. Thanks are also due to Dr. G. H. Grant and Dr. M. Symons, consultant pathologists, for their examinations of the specimens, and to Mr. Ross for his photograph of the trachelotome.

Speaking at a meeting of the court of Leeds University on November 20, Sir CHARLES MORRIS, the vice-chancellor, discussed the student entry. The size of the medical school had remained unchanged, he said, because of deliberate policy by the university, in common with that of other universities; and the signs were that this policy would continue for the coming years. There were, as was well known, plenty of candidates for admission to the medical faculty, "though not perhaps plenty of as high quality as could be desired"; but no steps had been taken in recent years to increase the number of places available for them. It was accepted that in the light of national requirements there had been, and was now, no shortage of doctors, the vice-chancellor added. In so far as the university as a whole was concerned, it could be said with confidence that the quality of those admitted was fully maintaining itself, and that in some departments, mainly technological, it had improved greatly since the war and was still improving.

Medical Memorandum

Spurious Labour in Pseudocyesis

The occurrence of a spurious form of labour at "term" in pseudocyesis is well recognized but rarely witnessed. The following case was seen for the first time as an emergency presenting in labour, and illustrates some features of this peculiar condition.

CASE REPORT

A nulliparous married woman aged 28 attended hospital as an emergency case on December 11, 1954, stating that she was expecting a baby and had had labour pains for the past hour. They were now strong and occurred every three minutes. The membranes had not ruptured and she had not seen a show. She had not booked anywhere. There was no history of previous pregnancies. The last menstrual period had begun early in March, 1954; previously her periods had been regular 5/28 and normal. The only relevant past history was of an abdominal operation at the age of 4, about which she could provide no details. She said she had been well throughout her pregnancy.

At first glance she passed for a pregnant woman, and while she was being prepared for examination efforts were made to find her a maternity bed. On examination she was extremely obese. Her temperature, pulse, and respirations were normal, and there was no anaemia; heart and lungs were normal; B.P. 140/85. The breasts were very obese and pendulous; no colostrum could be expressed and the areolae were not pigmented. The abdomen was as large and protuberant as a full-term pregnancy and extremely obese; there were three separate lower abdominal scars and inconstant suprapubic tenderness. Palpation was rendered difficult by the gross obesity of the abdominal wall, and no foetal parts could be identified; the fundus uteri was not defined and no foetal heart sounds were heard.

Vaginal examination revealed a normal vulva and vagina; the cervix was firm, closed, and nulliparous and the uterus non-pregnant, retroverted, and so far as could be ascertained abnormality in the urine. A straight radiograph of the abdomen showed no foetal parts and was normal. Throughout the examination the patient had bizarre intermittent pains, quite unlike those of normal labour. She found it difficult to describe the character or site of the pains, but they appeared to be located deep in the pelvis rather than in the abdomen. The pains were alarmingly sudden in onset and were associated with considerable grimacing, a pretence at crying, and marked movement of the feet. Lasting only a few seconds, they would disappear with equal suddenness.

The patient was told that it was extremely doubtful whether she was actually in labour. She paid no attention to this remark and her pains continued unabated. She was asked why she thought she was pregnant and replied disdainfully that of course she was, as she had had no periods for nine months, during which time her abdomen and breasts had become progressively larger. In reply to a direct question she said she had felt foetal movements for the past two months. At first she was unable to explain why she had not attended an antenatal clinic or made arrangements for her confinement. Subsequently she said she had attended an antenatal clinic in Ireland a month previously and had been told there that she was pregnant. Further questioning about this showed the story to be a complete fabrication, and she begged not to be reminded about it. It proved impossible to reconcile her history of only one abdominal operation with the presence of three separate scars. Progressively stronger expressions of doubt about her supposed pregnancy failed to impress her. It was only when she had been told quite firmly that she was not even pregnant, let alone in labour, that her pains ceased. Her only emotional reaction was the uttering of some tearful sobs. The abdomen remained as large as ever.

She then admitted that she had been married for two years and desperately wanted a baby, but had failed to con-

ceive. She welcomed the suggestion that she might be helped by attending the fertility clinic, and promised to attend the following week. Saying that she now felt well enough to go home, she got up and walked out of the hospital. She failed to attend the clinic.

COMMENT

Bivin and Klinger (1937) collected the details of 444 cases of pseudocyesis and found that the condition lasted nine months in 42% of 331 cases in which the duration was recorded. Labour pains occurred in 138 cases in which the pseudocyesis had lasted nine months or more. Spurious labour was often experienced by nulliparae, both married and unmarried. Of the seven cases of pseudocyesis which occurred in the Boston Lying-In Hospital from 1927 to 1940 (Rutherford, 1941), one patient experienced labour pains at term. She had a very obese abdomen, and labour ceased when she was told she was not pregnant; she did not revisit the clinic. Fried *et al.* (1951), describing their personal series of 27 cases, state that foetal heart sounds were reported as having been heard in two patients in labour in the maternity ward. Labour had occurred at the "expected date" and ceased abruptly when the patients were told they were not pregnant. Of the four cases reported by Ingerslev (1951), one was admitted in spurious labour.

The simulation of pregnancy and labour may be sufficiently realistic to deceive the patient's friends and relations, and, on not a few occasions, the unsuspecting accoucheur. Rhythmic pains in no respect different from those of normal labour, "broken waters," and the occurrence of a show have all at times been reported, and foetal heart sounds have been heard or rather imagined. One case reported by Bivin and Klinger (1937) narrowly avoided caesarean section, and in another labour lasted over a fortnight.

The bizarre nature of the pains in the above case immediately aroused suspicion, and it was interesting to note that foetal movements had been felt only for the past two months. Fried *et al.* (1951) state that foetal movements frequently differed from those of normal pregnancy in time of appearance, vigour, and location. Rutherford (1941) draws attention to the absence of pouting of the umbilicus in pseudocyesis. The condition occurs in both parous and nulliparous women over a wide age range, but the majority of the patients of Fried *et al.* (1951) were in their middle twenties. Of their 27 patients 26 were childless and spoke of their strong desire for a child; 24 gave histories of infertility extending from 2 to 17 years. O'Neill's (1955) case gave a seven-year history of infertility. On the other hand, three of Ingerslev's four patients had previously had children.

Psychic factors undoubtedly play an important part in the aetiology of pseudocyesis. An intense longing for pregnancy and a great fear of pregnancy, particularly in the unmarried, are particularly potent causes. There may be an associated personality defect, as instanced by the above patient's invention of a story of a visit to a clinic in Ireland a month previously. It was noteworthy that she could not name a single town in Ireland. The action of psychic factors on the anterior pituitary, possibly through the medium on the hypothalamus, may account for the hormonal changes which may occur in this condition (Fried *et al.*, 1951).

Several theories have been advanced to account for the abdominal enlargement in pseudocyesis, but in many cases it is simply due to gross adiposity. Treatment may be rendered difficult by the patient's absolute refusal to accept the diagnosis, particularly if she has previously been informed that she is pregnant. Psychotherapy may be necessary; or even endocrine therapy.

Reviews

BRITISH SURGERY

Textbook of British Surgery. Edited by Sir Henry Souttar, C.B.E., D.M., F.R.C.S., and J. C. Goligher, Ch.M., F.R.C.S. Volume 2: The Central Nervous System—the Eye—Ear, Nose and Throat—Mouth, Salivary Glands, and Jaws—Neck—The Breast—The Oesophagus—The Heart and Lungs. (Pp. 694+viii; illustrated. £5 5s.) London: William Heinemann Medical Books Ltd. 1957.

In their preface to the *Textbook of British Surgery* the general editors, Sir Henry Souttar and Professor J. C. Goligher, write: "The advances of surgery in the past twenty years have been so great that no one individual can master all the fields which they have opened. On the other hand it is important that candidates for the higher examinations should be familiar with the whole subject, for only thus will they be able to select for their future career the branch for which they are best adapted." This is of course profoundly true, although familiarity with the whole subject might be regarded as an axiom of proper surgical education rather than a means of selecting a future specialty. There can be no doubt, however, that the day of the truly general surgeon is rapidly passing, and in consequence it becomes increasingly important that in a book which ranges over the whole subject the coverage in each branch should be most carefully scrutinized. It must be sufficiently informative and detailed to meet the intelligent interest of those working in other branches, and yet not overloaded with specialist knowledge; in particular it must cater for the needs of those entering for the higher examinations, never overlooking the fact that for the most part the examiners for these distinctions are themselves general surgeons with perhaps a special interest.

The second of the four volumes of this work has now been issued, and we believe that it answers these requirements most admirably. It includes such important sections as those on the central nervous system; heart and lungs; oesophagus; eye; ear, nose, and throat; breast; mouth; and neck, all written by acknowledged experts. From the viewpoint of the general surgeon it is to be noted that too much preliminary knowledge and information is not assumed, as it is in many special books written to-day, yet, on the other hand, the text is not cluttered with elementary details. In other words, a creditable *via media* has been followed, as would be expected from the known versatility of the senior editor. The illustrations—there are some 350 in this volume—are excellently chosen and reproduced; in particular the line drawings representing individuals suffering from various cardiac lesions deserve attention as a succinct method of visualizing a case. The general production of the book too is of a high standard. On the whole the text is well written, although in a few places the composition could be improved, and there are very few printer's errors: Figs. 266 and 267 are printed sideways for no obvious reason; caption numbers in Fig. 268 are wrong; "patient" for "patent" appears on page 520. We noted two unusual spellings which, as they are repeated, must be deliberate: thus "scella tursica" in place of "tursica," and "membraneous," which the *O.E.D.* allows as a possible variant of the common "membranous." "Tetralogy" also is retained despite Ffrangcon Roberts's criticism that the "correct expression is 'Fallot's tetrad.'" But these are carping criticisms of an outstanding publication, deserving of the highest praise, which will be of great value to surgical examination candidates and to surgeons in general.

NORMAN C. LAKE.

EPIDEMIOLOGY FOR THE CLINICIAN

Uses of Epidemiology. By J. N. Morris, M.A., F.R.C.P., D.P.H. (Pp. 135+viii; illustrated. 17s. 6d.) Edinburgh and London: E. and S. Livingstone Ltd. 1957.

If, as the author states, epidemiology is the Cinderella of medical sciences, this book shows how wrong is that

opinion, for this is a vivid, exciting book. It may sound dull to be told that it explains how epidemiology can be used along with clinical and laboratory methods to increase our knowledge of disease; how it reveals the incidence of a disease in a community and tries to disentangle the various "causes"; how it may help to establish the full picture of a clinical syndrome, pick out odd geographical variations of disease incidence, or calculate the chances of any one person in any given circumstances suffering from any particular disease. But it is not. The author shows how epidemiology is concerned with life and death, discusses whether how we live affects how we die; it may try to find "what precedes the bronchitis, emphysema and cor pulmonale seen in hospital," or it may be concerned with the effects of married women going out to work, the mass use of antibiotics, the building of new power stations, or the eleven-plus examination. The effects of smoking on lung cancer and the relation between atheroma and ischaemic heart disease are problems which demand the epidemiological approach.

The book shows how these epidemiological methods can be applied to widely differing problems. It is written for the clinician rather than the epidemiologist, and its purpose is to stress the relationship between epidemiological and clinical medicine. There are many figures and tables and even a few graphs, but this need not deter the least statistically minded reader: the author's style makes everything clear. The book can be read in a few hours and can be recommended as light medical reading for jaded clinicians, whether in hospital or general practice. The more intelligent of them, along with their public-health colleagues, will read it more than once; they will acquire thereby a new and fresh outlook on their clinical problems.

A. B. CHRISTIE.

BLOOD TRANSFUSION

A Guide to Blood Transfusion. By R. J. Walsh and H. K. Ward. (Pp. 164; illustrated. £A.1.) Sydney: Australian Red Cross Society (N.S.W. Division) Blood Transfusion Service. 1957.

This short book will surely prove extremely useful. It covers quite a wide field and deals with the blood donor, the preparation of blood products and their uses, transfusion apparatus and the technique of transfusion, blood-grouping and compatibility tests, the complications of transfusion, and the use of transfusion in treating haemolytic disease of the newborn; and it includes some advice on the setting up of a transfusion service in a hospital—and all this within a compass which can easily be spanned in an evening's reading.

As in many first editions of textbooks, some things have been included which seem a little out of place. For example, there are tables giving the amount of blood which may be removed from donors according to their sex, weight, and haemoglobin value. Surely it is a little fanciful to suggest that if a woman has a haemoglobin concentration of 11.7 g. per 100 ml. and weighs 6 stones (38.1 kg.), she can safely give 200 ml. (but not 250 ml.). There is certainly no harm in reminding everyone that very small people contain less blood than large ones, but since most transfusion services take a fixed amount (about 420 ml.), provided the donor's haemoglobin value is above a certain agreed level, the most practicable way of protecting the small donor is to set a lower limit of size (weight). Though very few matters of importance in transfusion have been omitted, it would have been well to mention, in discussing the complications of transfusion, that the duration of the infusion has a considerable influence on the incidence of thrombophlebitis.

Perhaps the part of the book which is most controversial is that dealing with cross-matching. Here there is a tendency to overpraise simple tests, and the Coombs test receives rather rough handling: it is described, for example, as "tedious but accurate if controls are included." By contrast, the use of 10% polyvinylpyrrolidone as a suspending medium, which the authors favour, is described as "simple, rapid, and

accurate" and "the method of choice for general use." Since this test has not been very widely used, so that experience of it is limited, and since it is most doubtful whether it is really as sensitive as the indirect Coombs test, one would not like to see it adopted as the standard procedure.

The book contains much sensible advice and can be recommended as a highly lucid, brief, and useful account of transfusion as it is at present practised.

P. L. MOLLISON.

HUMAN PLEASURE AND BEHAVIOUR

Problems of Human Pleasure and Behaviour. By Michael Balint, M.D., Ph.D., M.Sc., L.R.C.P., L.R.C.S. (Pp. 300. 25s.) London: Hogarth Press and Institute of Psycho-Analysis. 1957.

The papers reprinted in this book were originally read or written over a period of 33 years (1923-56). They are arranged under three general headings. Part I, "The Individual and the Community," contains seven essays ranging from "The Adolescent's Fight against Masturbation" to "Notes on the Dissolution of Object-representation in Modern Art." Part II, "Clinical Problems," includes papers on reality testing, fetishism, and parapsychology, as well as "The Doctor, His Patient and the Illness." In Part III, "Men and Their Ideas," there are essays on Pavlov, the Marquis de Sade, as well as appreciations of the eminent psychoanalysts Ferenczi and R  heim. Of necessity such a wide variety of topics is not of equal interest or worth. Some of the papers are frankly antiquated, and where case records are given they are tantalizingly incomplete, especially when in one instance the author studied the patient for "more than a thousand sessions." Nor does nosology in terms of "Meynert's amentia" and "anxiety psychosis" recommend itself psychiatrically. But the book will be of historical value to those who wish to study the shift of psycho-analytic interests in the period covered.

RICHARD A. HUNTER.

WITH THE PARTISANS IN YUGOSLAVIA

Guerilla Surgeon. By Lindsay Rogers, M.B.E., F.R.C.S. (Pp. 254. 18s.) London: Collins. 1957.

Inspired by his memories of Johnston Abraham's *My Balkan Log*, the author volunteered for service with the partisans in Yugoslavia. He had already served in the victorious North African campaign. After a short course of special training, which included lessons in the art of escaping given by Jasper Maskelyne, he joined the partisans at Vis and went on to Dalmatia, Croatia, and then Bosnia. He sought adventure and found it, with a few extras. Conditions were terrible, with starvation diet, poor equipment, and enemies who gave little quarter. Rape, rapine, and murder were common occurrences. Hospitals, when found by the enemy, were burnt and the staff often killed. On one occasion a notice was picked up saying that Lindsay Rogers should be taken alive, "if possible." At a later date Rogers went on to Slovenia, where equipment was better but hospitals still had to be hidden in the remotest recesses of the forest. So well were they camouflaged that on one occasion the enemy camped within 200 yards for three weeks without discovering the hospital.

Rogers did excellent surgery under poor conditions and richly merited the honours he gained. He met Tito and attended the official liberation parliament. He writes with an easy style, possesses a sense of humour, and evinces poetic feeling. The base camp in Italy was the scene of bickerings, and he writes that he was glad when "the day came when we returned to the war to get some peace." Among the partisans a love affair meant a death sentence. Goyko loved Ian and was executed. Rogers comments: "The gentians will be bluer there, and the crocus more golden and the nightingale's song will be sweeter near where

Goyko lies." On one occasion he felt home-sick for New Zealand and thought of "the long road from Tapanui where the river slides over the silver stones and the gold of youth was sought and never found." Some of us would like to write like that.

ZACHARY COPE.

SCHOOLS OF PSYCHO-ANALYTIC THOUGHT

Schools of Psychoanalytic Thought. By Ruth L. Munroe. (Pp. 670+xvi. 42s.) London: Hutchinson Medical Publications. 1957.

When one encounters a wordy and voluminous work ostensibly dedicated to the description and evaluation of schools of "psycho-analytic thought" but including amongst these schools the systems of Jung, Adler, Horney, Sullivan, Rank, Rado, and others, who in most material respects abjured, disclaimed, rejected, or modified beyond recognition the Freudian system, one may justifiably wonder why the author was at such protracted pains to write it. And it would appear that Dr. Munroe, who is Clinical Professor of Psychology at the City College of New York and who engages largely in diagnostic testing, feels not only that she is thereby particularly well equipped to assess the relative merits of these various schools, but that with the help of a few concepts of her own she can unify the warring factions. These concepts she interpolates freely at the end of each chapter. Like most eclectics, her selections tend to flatten out the outstanding features of each system; and when to this is added the fact that her own ideas tend to confuse rather than to illuminate an already confused subject it is not surprising that her book is as heavy to read as it is to hold. Its main merit is that when any given issue is hard for her to assess Dr. Munroe suggests that further study or research is desirable—along her own lines, of course. Nevertheless her work will no doubt be extremely popular amongst eclectics, who may, however, regret that the author did not boil it down to two compact handbooks—one on Dr. Munroe's own theories of mind, and the other on the differences existing between various "schools" of clinical psychology.

EDWARD GLOVER.

FLUORIDATION IN THE U.S.A.

The Fight for Fluoridation. By Donald R. McNeil. (Pp. 241. +x. 30s.) New York and London: Oxford University Press. 1957.

The early chapters of this book are about the way in which mottled enamel and stained teeth gradually came to be associated, in America, with an absence of caries and the presence of fluorides in the water supplies. The later parts are about the attempts to apply this knowledge to improving the teeth of people in the community at large. The text bristles with the names and doings of prominent men. As represented by the author these are a little undignified at times and remind one of the intrigues and activities of the Homeric gods and heroes. Nevertheless the book appears to be factually correct and well documented. It can be recommended with confidence to anyone who would care to read a journalistic account of the matter, and particularly of the way this kind of discovery is exploited in the United States. We take our causes less seriously as a rule in this country, although we have had our troubles too over such things as Home Rule and brown bread. The author does not pretend to be impartial, and some of the chapter headings, such as "The Shoe Leather Surveys," "Wisconsin Takes Over," "Closing Ranks," "The Battle of Stevens Point," and "Seattle—a Major Test," give one an inkling of the way the book is written. Those who want an objective scientific account of an interesting biochemical discovery will not get much satisfaction from the book, and those who are at all allergic to journalistic medical science might be better to avoid it.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 30 1957

SHERRINGTON CENTENARY

The centenary of the birth of a great man of science is an occasion for commemoration so that all can share in the praise of famous men. Charles Scott Sherrington was born a hundred years ago. When he reached the age of 90 on November 27 ten years ago this *Journal* published some articles on his life and work in a *Festschrift* number which, with the memoirs published in the year of his death five years ago, will give his biographer the nucleus of the life which one day, it is hoped, will be written. Neurophysiology has never failed to attract men of exceptional mental endowment, and Sherrington occupies a very special place among them. Perhaps this is so because of three distinct accomplishments with which he was endowed. He possessed an outstanding character—unassuming, warm-hearted, and generous. He was a man of wide culture: nurtured in the cradle of the humanities, he retained throughout his life his love of classics, of art, of archaeology, of history, and of literature most of all. His excursions into poetry—recently appraised by Wilder Penfield¹—are eloquent marks of his sensitive perception and thought. And then there was Sherrington the disciplined scientist in the most strict sense of the word. His extended but articulated series of physiological researches, his school of admiring disciples, his classic monograph, the *Integrative Action of the Nervous System*, may be looked upon both as the cause and as the evidence of his brilliance. Sherrington was a reflective thinker, and as he grew older his writings and ideas became more those of a philosopher than a physiologist, culminating in his stimulating monograph, *Man on his Nature*. It has been pointed out elsewhere² that Sherrington enjoyed various other advantages besides those of character, culture, and scientific brilliance. He was gifted with quite an exceptional memory. As a technician he was uncannily dexterous. He was by nature a tireless worker, for he was endowed with robust health. He was blessed with that intangible gift of being lucky—fortunate in his education, his choice of career, his academic appointments, and in his contemporary setting, he came to neurophysiology at a most opportune time, “finding it something of a terra

¹ Penfield, W., *Brain*, 1957, 80, 402.² *Nobel Prize Winners*, edited by L. J. Ludovici, 1957, London.

incognita and leaving it a well-charted though complex macrocosm.”

Sherrington's career was in many ways remarkable. Even as a Cambridge undergraduate he interested himself in physiology and undertook one or two problems of research at the instigation of his chiefs and senior colleagues, Michael Foster, J. N. Langley, and W. H. Gaskell. While still a student he visited Strasbourg in order to see something at first hand of the work of Goltz. Soon after qualification he made it his business to revisit Europe, and to work—even if for short periods—in the laboratories and classrooms of Virchow, du Bois Reymond, Helmholtz, Waldeyer, Zunz, Cajal, Pflüger, and Koch. His first duties as a young doctor lay in the domain of applied bacteriology, for he journeyed to Spain, and later still to Italy, to assist in the control of cholera epidemics. This experience in the field gave him the opportunity of making important contributions to our knowledge of morbid anatomy of this disease. In 1891 Sherrington succeeded Sir Victor Horsley as professor-superintendent of the Brown Institution in the Wandsworth Road, London, a post which he held for four years. He then proceeded, at the age of 38 years, to the chair of physiology at the University of Liverpool, where his sustained productivity flourished and bore fruit in abundance. It was not long before he became recognized as the outstanding authority upon the functions of the nervous system, working in a complementary and contemporaneous fashion with Pavlov, that other brilliant and original “philosopher of the nervous system.” In 1904—that is, nine years after his appointment to Liverpool—he was invited to deliver the Silliman lectures at the University of Yale. These were not actually published, as the *Integrative Action of the Nervous System*, until 1906, which then rapidly achieved the well-deserved status of a scientific classic, comparable with the works of Harvey, Willis, and Claude Bernard. Sherrington was invited to occupy the chair of physiology at Oxford in 1913—an appointment for which he had applied without success some eighteen years previously. Though the laboratory facilities were scarcely comparable with those at Liverpool, the shortcomings were offset by the academic climate at Oxford, disturbed only too soon by the outbreak of the first world war. Sherrington retained his chair until 1935, when he retired at the age of 78, loaded with honours and held in affectionate esteem. But his life's work was not yet over. His remarkable Gifford lectures appeared in 1941, and his Philip Maurice Deneke lecture entitled “Goethe on Nature and on Science” in 1942. Four years later he published his important historical work which he entitled *The Endeavour of Jean Fernel*.

HORMONE THERAPY OF RHEUMATOID ARTHRITIS

It is eight years since P. S. Hench and his colleagues¹ described the dramatic short improvement that can be obtained in patients with rheumatoid arthritis during the administration of cortisone or corticotropin (A.C.T.H.), but there is still doubt about the value of such hormonal therapy given over a long period. Carefully controlled trials conducted by the Empire Rheumatism Council² and by the Joint Committee of the Medical Research Council and Nuffield Foundation³ have shown that over the course of years aspirin gives the same results as cortisone in the treatment of patients with rheumatoid arthritis. During the early months of cortisone administration a sense of well-being is induced, and there is some increase in haemoglobin and some improvement in the sedimentation rate, but in later years this advantage is lost and serious complications become more common. Many physicians find the results of these trials difficult to accept because they remember so clearly their own patients in whom a change from aspirin to cortisone produced immediate and striking improvement, whereas a change from cortisone to aspirin is often accompanied by temporary deterioration. There are two causes of this apparent discrepancy. First, the different time of onset of side effects. With aspirin toxic effects such as dyspepsia, tinnitus, and deafness appear immediately and are closely related to the daily dosage. But there is little tendency for these side effects to increase with duration of therapy, so that the maximum tolerated daily dosage can be continued for many years. It is quite different with cortisone: the undesirable side effects develop slowly and are related to the duration of therapy; indeed, some complications such as osteoporosis with multiple fractures may only become clinically apparent after 4–5 years of treatment. The maximum tolerated dosage depends on the duration of treatment. High doses of several hundred milligrams daily can be tolerated for a few days, but when treatment is continued over months or years the tolerated dose quickly falls. Treatment with cortisone has often been started at a dose of 100 mg. per day or more, and this, though

E

often immediately effective, is usually well above the tolerated maximum dosage over a long period. Indeed C. H. Slocumb, H. F. Polley, and L. E. Ward,⁴ of the Mayo Clinic, state that the maximum tolerated daily dose of cortisone for long-term therapy of rheumatoid arthritis is 20–30 mg. for post-menopausal women and 37.5–50 mg. for men, the dose for younger women being intermediate. There is, however, no evidence that cortisone is effective in controlling severe rheumatoid disease when given in such low dosage.

In addition to the well-known complications of cortisone treatment Slocumb and his colleagues recognize a syndrome of chronic hypercortisonism characterized by swings of mood, aching in the muscles and joints, and excessive fatigue. These symptoms may easily be attributed to increasing activity of rheumatoid arthritis and thus lead to an increase in dose when in fact the dose is already too high. Then there is the problem of stopping treatment. Cortisone inhibits the adrenal cortex, and prolonged administration in high dosage produces an unresponsive and atrophic adrenal cortex which may take several months to regain normality. As a result of ceasing cortisone the patient suffers from a very unpleasant and even hazardous period of hypocortisonism. This is often accompanied by an exacerbation of rheumatoid arthritis, and occasionally evidence of vascular and visceral lesions of the type seen in systemic lupus erythematosus or periarteritis nodosa appear for the first time during this period.

The more potent delta-1 analogues of cortisone and hydrocortisone now known as prednisone and prednisolone cause less sodium retention than the original corticosteroids and can therefore be given in effectively higher dosage. In 1955 J. C. Bunim⁵ and his colleagues showed that patients with severe rheumatoid arthritis who had ceased to respond to cortisone improved when given prednisone. Similar improvement was observed during the early months of a controlled trial in Britain, but by the end of the first year the average daily dose of prednisone for patients in this trial had been reduced from 20 mg. to 14 mg., with loss of much of the improvement which was observed immediately after change-over from cortisone to prednisone.⁶ Bunim and his colleagues, who have the longest experience, having treated 39 patients with severe rheumatoid arthritis for over two years with prednisone, reported at the Ninth International Congress on Rheumatic Diseases held in Toronto in June that there had been 6 deaths among the 39 patients and an alarming incidence of gastro-intestinal bleeding, psychoses, and pathological fractures. They therefore concluded that a daily dosage of over 15 mg. of prednisone could not safely be maintained in patients with rheumatoid arthritis. Slocumb and his

colleagues, however, place the upper limit for prolonged therapy at 5 mg. daily for post-menopausal women and 9 mg. for men. Elsewhere in this issue Drs. G. R. Fearnley, G. V. Balmforth, and R. Blatchley (p. 1263) report encouraging results from prednisone therapy in 47 out of 167 patients with rheumatoid arthritis, but only 7 of these patients had had prednisone for over 18 months, and the average dose of 15 mg. daily appears to be at the upper limit of safety. These encouraging early results must therefore be accepted with caution.

Certain limited conclusions seem warranted at this stage. In the management of rheumatoid arthritis prednisone and prednisolone appear to be superior to cortisone or hydrocortisone for oral administration. Once steroid therapy has been continued for more than a few months it is difficult to stop it, although the benefits are likely to decrease and the complications to increase with each year of treatment. From this it follows that the best indication for steroid therapy is a short expectation of life. If the patient is only likely to live a few years and has severe disease the dangers and complications of treatment with steroids in high dosage can be accepted and the short-term benefits enjoyed. But only a very small number of patients with rheumatoid arthritis fall into this category. When the patient has a good expectation of life and substantial remission of activity in rheumatoid disease is still a possibility, it is probably unwise to embark on prolonged steroid therapy, since in most patients satisfactory results can be obtained by conservative treatment with rest, splintage, and carefully graduated exercise, as described by J. J. R. Duthie and his colleagues.⁷ Unfortunately facilities for this are at present available only to a small number of patients with rheumatoid arthritis.

Although the results of long-continued steroid therapy in rheumatoid arthritis are generally unsatisfactory, the results of prolonged adrenocortical stimulation with corticotropin appear to be more promising, especially since it is now possible to assess the degree of adrenocortical stimulation by estimation of urinary 17-hydroxycorticosteroids.⁸ In the opening pages of this issue Dr. Oswald Savage and his colleagues at the West London Hospital report a most careful study of 49 patients with rheumatoid arthritis treated by adrenal stimulation. The dose of corticotropin was adjusted on the basis of clinical response, but the degree of adrenal stimulation was assessed by frequent, often weekly, estimation of urinary 17-hydroxycorticosteroids. H. F. West⁹ has recently reported a similar study of 42 patients with severe rheumatoid arthritis in whom the dose of corticotropin was adjusted to maintain the urinary 17-hydroxy-

corticosteroids at between 20–35 mg., which is roughly double the normal output. In both these series a satisfactory number of remissions occurred—6 out of 49 and 5 out of 42. Furthermore, a satisfactory suppression of the symptoms and signs of the arthritis was achieved in many patients with a degree of adrenocortical stimulation which did not cause serious side effects. There was little evidence of the decreasing efficacy and increasing toxic effects so characteristic of prolonged steroid therapy; and interruption or cessation of adrenal stimulation did not seem to be followed by the prolonged and distressing symptoms of hypocortisism which so often accompany the withdrawal of steroid therapy. West particularly stresses the lack of progression in radiological changes in the joints and the frequent healing of erosions. There are, however, serious practical difficulties with this form of treatment. Response to corticotropin varies greatly in different patients, and there are also wide variations in potency between preparations of this hormone and even between different batches of the same preparation. Repeated estimations of 17-hydroxycorticosteroids are therefore essential for the proper control of dosage, but even with careful supervision alarming signs of overdosage may develop in a few days after a change of batch number. Acquired resistance to corticotropin developed in a high proportion of West's patients: because of this, treatment had to be abandoned in 20 out of 66 patients, and it had also to be given up in an additional 16 because of dangerous complications such as hypertension, oedema, psychosis, and heart failure. There were also some alarming allergic reactions to corticotropin. This form of treatment is therefore not yet suitable for general use. There is an urgent need for preparations of corticotropin which are purer and of less uncertain potency, so that controlled clinical trials of prolonged adrenal stimulation in rheumatoid arthritis can be undertaken.

CATCHING COLD

Epidemiological observations in the field have confirmed the common view that one may catch a cold from another sufferer, probably by direct contact, the frequency and intimacy of contact being important factors.^{1–3} Such "wild" colds are more infectious than the "pedigree" colds maintained by serial transmission at the Salisbury research unit,⁴ where it was found that the virus lost infectivity after drying.⁵ Age is important, and it is clear that children are more susceptible to infection than adults and are more often responsible for introducing infection into the home.^{1, 5, 6} Apart altogether from greater contact with

children, women are more susceptible to both natural and experimental infection.^{5, 7–9} Some people regularly catch more than their quota of about two colds per season, and some are more susceptible to repeated experimental infections.^{5, 6, 10} Post-infective immunity to both natural and experimental infections is regrettably transient at best.^{2, 6, 8, 11} Despite the well-known seasonal prevalence and the observed coincidence of outbreaks with low temperature and humidity,⁸ experimental chilling has not been found to induce colds or reduce resistance to small doses of virus.⁹

A recent report by H. F. Dowling and colleagues from Chicago¹² describes the results of intranasal inoculations of over 1,000 young adults with bacteria-free filtrates of secretions from patients with common colds. These filtrates, innocuous to eggs, mice, and tissue cultures, were diluted in buffered haemoglobin solution; this bland diluent alone was used for control inoculations. After inoculation, volunteers spent from two to four hours in a controlled environment, either comfortable or at one of two levels of chilling. The subjects were then dismissed, reporting back on the second, third, fourth, and sixth days thereafter for examination by clinicians who did not know which experimental groups their subjects were in. Significantly more colds were induced in persons with a history of allergy (45% as compared with 31% in those with no allergic history). Neither smoking nor the presence of tonsils and adenoids had a detectable influence on susceptibility. Among the women, 13 chilled and infected in the middle third of the menstrual cycle, 10 developed colds—that is, 77%. This figure was significantly more than the 28 and 30% developing colds after similar treatment in the first or last third of the cycle. Except for the women in the ovulatory phase, chilling alone had little effect. Of 97 women infected in mid-cycle but not chilled, only 37% developed colds. An analogy is drawn with the observations of L. Weinstein and colleagues¹³ on 50 females affected by poliomyelitis; in 78% the onset of menstruation fell within the 10-day interval from 5 days before to 4 days after the onset of illness. Recalculation of these data on the basis of a 12-day

incubation period showed that 78% of the infections were initiated between the fourth day before and the fifth day after ovulation, the same period of greatest susceptibility to experimental colds. Lack of correlation between the appearance of the nasal mucosa at the time of challenge and the subsequent development of colds did not suggest that the enhanced susceptibility was attributable to vascular engorgement induced by oestrogens, and Dowling and his colleagues suggest the possibility of other mechanisms such as oestrogenic effects on general metabolism.

The finding that previous tonsillectomy did not influence susceptibility to experimental infection is in line with the observations of natural infections by other workers.^{14, 15} Tonsillectomy may appear to benefit an individual simply because after the operation he is older than before, and for this reason alone liable to catch fewer colds. That tobacco smoking neither predisposes to natural infection nor exerts any protective effect has also been observed by C. Buck.¹⁶ Although everyday experience apparently supports the firmly held popular conviction that chilling can bring on a cold, subjective assessment of this may be swayed by heightened awareness of cold during the chilly prodromal stages of the disease. It has been a common experience in several wars that soldiers could endure remarkable conditions of wet and cold without catching colds. The transience of solid post-infective immunity, together with the surprisingly high resistance of most people to coryzal infection,² adds importance to research into factors responsible for altered susceptibility to this miserable affliction.

DANGERS OF NITROUS OXIDE

In the welter of new discoveries at the spearhead of anaesthetics the common everyday things tend to be overlooked. It is therefore both refreshing and stimulating to find that the widespread practice of administering nitrous oxide for the extraction of teeth has come under critical review. Stimulated by personal interest and observation, J. G. Bourne¹ circulated a random sample of 386 dentists with a questionnaire whose main point was: "Have you ever known a patient who did not immediately regain consciousness after gas but remained unconscious or stuporous for half an hour or more?" As a result of the answers obtained, he estimated that at least 15,000 cases of this sort have been seen in the life and experience of practising dentists, and that such cases occur in dental practice in Great Britain at the rate of 500 a year. He then studied the arterial blood pressure of 15 subjects during nitrous oxide anaesthesia in the commonly used upright position. In one case a sharp fall of blood pressure occurred, to which Bourne gives the name "fainting." He comes to the conclusion that the cause of delayed recovery of consciousness after

nitrous oxide is anoxia of the brain, and that the danger of anoxia is considerably increased if the patient has a fall of blood pressure at the same time. Anoxia and "fainting" are two factors of a vicious circle, the one giving rise to the other.

This is not the first time that the dangers of cerebral anoxia in connexion with nitrous oxide have been pointed out. C. B. Courville² as long ago as 1939 wrote a book entitled *The Untoward Effects of Nitrous Oxide Anesthesia* in which he pointed out these dangers. He had gathered data at necropsies on patients who had died after nitrous oxide anaesthesia at times varying from hours to weeks. The use of nitrous oxide has persisted for the simple reason that there is no inhalation anaesthetic with similar effects. The speed of recovery, with, in the vast majority of patients, no after-effects, the speed of induction, and the absence of any danger of explosion form a combination not yet equalled. However, the recently described alternative of pre-set mixtures of cyclopropane and oxygen,³ with either helium or nitrogen⁴ as a quenching gas, may well be an immediate answer. The intense search initiated by the Medical Research Council for a potent non-inflammable anaesthetic agent may also soon provide another, if halothane⁵ is not already one answer. But nitrous oxide is certain to continue in use for some time, and at least two precautions, emphasized by Bourne, have to be taken with it. Firstly, the oxygen content must be high enough to avoid any possibility of anoxia, even when given in the vertical position of the dental chair. Recently A. Tom⁶ re-emphasized, what has been known by a generation of dental anaesthetists, that nitrous oxide with oxygen in a concentration of about 20% usually produces adequate analgesia for dental extraction in a relaxed pink patient in a high proportion of cases. Secondly, when possible the patient should be horizontal rather than vertical. This is a matter on which dental opinion will no doubt be divided, but in the light of Bourne's evidence dental surgeons should reappraise the need for the chair as distinct from the couch.

While in no way denying the need for these safety measures, no one could condemn nitrous oxide out of hand without bearing in mind the background of safety of this useful anaesthetic. F. F. Cartwright⁷ points out that, on a basis of Bourne's figures (14 deaths in two and a half years), the mortality due to nitrous oxide would be about 1 in 226,000. In two London teaching hospitals over a period of 32 years 1 death had occurred in an estimated total of 400,000 administrations. In addition to the safeguards already mentioned, an additional one is adequate training and skill on the part of the administrator. No amount of oxygen in the mixture can prevent anoxia due to respiratory obstruction, nor can the horizontal posture prevent asphyxia due to the inhalation of blood. When nitrous oxide is compared with more

potent anaesthetics like cyclopropane and halothane, it may be noted that with these vapours dangerously high concentrations may be inhaled, and the patient brought near to death without a warning sign as noticeable as cyanosis—a sign which probably accounts more than anything else for the safety of nitrous oxide.

KLINEFELTER'S SYNDROME

In 1942 H. F. Klinefelter, E. C. Reifenstein, and F. Albright¹ described a "syndrome characterized by gynaecomastia, aspermatogenesis without a-Leydigism, and increased excretion of follicle-stimulating hormone." They reported on the findings in testicular biopsies from these patients—sclerosis and hyalinization of the seminiferous tubules, associated in some cases with apparent hyperplasia of the Leydig cells—and suggested that Sertoli cells might be the source of a testicular hormone ("X-hormone") other than testosterone, the absence of which allowed over-secretion of pituitary gonadotrophin. Later, C. G. Heller and W. O. Nelson² showed that gynaecomastia was an inconstant part of the picture, being absent in the more eunuchoidal subjects. Further reports of cases have appeared in the literature from time to time, and in 1953 de la Balze *et al.*³ demonstrated histological abnormalities of the Leydig cells. But during all this time the condition was generally looked upon as something of a rarity, if not a curiosity, known to endocrinologists and to those interested in male infertility but scarcely to the majority of doctors.

A dramatic change in the situation has come about in the past year or so since it has been shown that some of these patients have female sex-chromatin patterns,⁴⁻¹² a finding confirmed by further reports coming from all over the world. There is not much doubt that these individuals are examples of sex reversal carried to a stage which had not hitherto been considered possible in man, since it affected not only the general bodily appearance (the "phenotype") but also the gonads. Furthermore, since in some cases spermatogenesis has been

demonstrated in some of the testicular tubules,^{13 14} it follows that the process of sex reversal has involved even the germ cells. This is therefore a far more fundamental degree of sex reversal than is seen, for example, in gonadal dysgenesis (such as "Turner's syndrome") or in male pseudohermaphrodites of female phenotype (to which the unfortunate term "testicular feminization" has been applied).

Nelson¹⁵ has drawn attention to the different testicular histology seen in chromatin-positive and in chromatin-negative cases of Klinefelter's syndrome. In the former, which he calls "true Klinefelter's syndrome," the majority of tubules are completely hyalinized and very small, indicative of the early onset of the sclerotic process—that is, prior to the time at which normal pubertal enlargement occurs. Variable numbers of tubules show little or no hyalinization and then usually contain Sertoli cells only. In the chromatin-negative cases, which he calls "false Klinefelter's syndrome," the tubules may be completely sclerosed but are larger and more uniformly spaced. Aggregation of Leydig cells is unusual in the "false" type, and they do not show the morphological abnormalities seen in the "true" type. Nelson suggests that a more reasonable nomenclature would be to abandon the term Klinefelter's syndrome altogether and to call the chromatin-positive types "female pseudohermaphrodites with gonadal dysgenesis" and the chromatin-negative types "early testicular atrophy due to tubular fibrosis."

The findings of B. Lennox and his colleagues¹⁶ in Glasgow should counteract any tendency there may be to regard this disorder as excessively rare, for they discovered 27 cases among patients attending a male sub-fertility clinic, and of these 10 were chromatin-positive. In this series Klinefelter's syndrome accounted for nearly a third of all cases of high-grade subfertility, with a sperm count of less than 1 million per ml., about two-fifths being genetic females. Of all the men attending this clinic with sperm counts of less than 40 millions per ml., 1 in 30 was a genetic female. The authors know of 19 cases of chromatin-positive Klinefelter's syndrome in Glasgow alone and suggest the incidence of the condition may be similar to that of haemophilia. Genetic studies by this group¹⁷ show that both varieties of the syndrome are similar hereditary diseases, the mechanism being that of a sex-controlled dominant: in chromatin-positive cases it is transmitted by the fathers and in chromatin-negative cases by the mothers. Psychiatric studies by R. G. Pasqualini and his colleagues¹⁸ have shown that many of these patients have a low intelligence quotient, averaging only 82 as compared with 101 in a series of other hypogonadal patients.

In the chromatin-positive cases the genetic factor presumably affects the cortico-medullary balance of the gonad at the indifferent stage.¹⁹ In a genetic female the cortical tissue should prove dominant, leading to the development of ovaries and the suppression of the medullary part (the reverse happens in genetic males). But in this disorder cortical dominance fails to appear and instead the medulla develops into a testis. The

foetal hormones produced by this structure determine the development of male external genitalia.

OFF DUTY

What do doctors do in their spare time—if any? A few clues were provided by an exhibition of doctors' hobbies presented last week by Benger Laboratories Limited at the Royal Society of Health. The impression it gave was of a great diversity of outside interest among the profession, though there was some variation in the quality of the exhibits, owing no doubt to the sponsors' reluctance to turn anything down. Over 350 doctors sent in entries, and there were over 420 separate items on display.

The predictable hobbies were well represented: a cruiser made of matchsticks, a model English village with figures that creaked into motion when a winch was turned, model trains, aircraft, and motor-cars, fretwork, embroidery (some astonishingly elaborate), and ceramics. Hours and hours of devoted patience appeared, in some cases, to have produced painstaking, detailed, and useless masterpieces, mute evidence of immense ingenuity. But there were plenty of surprises: several compositions for voice and piano ("Plaint of a Mermaid," "Alone Dear I'm Waiting"); a Newtonian astronomical telescope; two home-made decoy ducks; a pouring device for your cereal or detergent packet ("Controlled Pouring, Easy Pouring, Cannot splay into eyes and food, little spilt when knocked over—Do Not Touch"); and an item which must have gladdened the sponsors' hearts, a "Benger Housewife Scrapbook." One exhibitor had submitted a voluminous documentary and photographic history of the construction of his garage, another some samples of his expertise at darning socks. Some had sent in published books and articles; others, a little optimistically, unpublished books and articles.

The first prize in the exhibition went deservedly to Dr. M. E. Gordon for a pair of violins, copies of Stradivarius fiddles in Swiss pine and Italian maple, coloured and varnished with materials that reproduced those used by Stradivarius in 1721. These instruments set a standard of artistry and craftsmanship—not to mention display—which few exhibitors could hope to rival. Another strikingly beautiful exhibit, in a quite different class, was Dr. Grenville Tait's collection of eighteenth-century scarf pins. Philatelists, photographers, and painters were present in large numbers. Many photographs were of a high standard, though rather surprisingly not many of the paintings. Here in the visual arts section were opportunities for the archly diffident humour that sometimes besets the hobby-horseman. Some titles will illustrate: "Shall we venture?" "Thereby hangs a tail," "What big teeth, Granny dear!" Unfortunately, it was impossible to provide facilities to show films made by doctors, which might have been interesting. Nor was it possible to make room for the prize herd of Friesian cattle which one doctor, it was said, wished to display.

BY

If, as Huxham had believed, it were due to the acid in the apples, why were not the inhabitants of Worcester, Gloucester, and Hereford subject to it? The evidence of a physician of Worcester, Dr. Wall, was obtained on this point. Wall, of Worcester, was one of those erudite men who are always giving advice on many diverse subjects. Collectors of porcelain regard those pieces designed and decorated by him as prizes well worth the hunt. He was one of the founders of the Worcester Royal Infirmary. The evidence of such a man was incontrovertible; he wrote: "The counties of Hereford, Gloucester and Worcester are not subject to the colic . . . or any other endemic illness unless it be the rheumatism. . . . There is no lead, which can give occasion to the colic, used in any part of the *apparatus* for grinding or pressing the apples, or fermenting the liquor," but he had heard of a farmer "who wanting casks, filled a large leaden cystem with new cyder." All who drank of it were affected as the lead workers usually were, and eleven were admitted to the infirmary at one time.

The experience of Dr. Wall is contrasted with that at the Devon and Exeter Infirmary, where in less than five years 285 cases were admitted and 209 cured.

Dr. Andrew, of Exeter, is quoted as stating that, where the disease was obstinate, they endeavoured to get their patients to the hospital at Bath, "the Bath water, tho' not a specific, being esteemed by us as the most effectual remedy, both internally and externally used." Of 80 patients admitted to Bath hospital, 40 were said to have been cured and 36 greatly relieved. No doubt the sulphur in the spa water aided greatly in the elimination of the lead. It is salutary to think of the transfer of patients to so great a distance under voluntary arrangements so many years before the inception of the Welfare State.

Baker was not content with deductions from this evidence alone. He was able to show how the cider-presses in Devon, made of moorland granite, were held together by iron staples, into the holes of which was poured molten lead. The uneven cracks between the stones were treated in the same way. To complete the chain of evidence, it was necessary to prove that the cider itself contained lead, and he procured from a farm at Alphington in October, 1776, a supply of fresh cider which he submitted to a Dr. Saunders, "an ingenious gentleman, who teaches chemistry," for help in its analysis. As a control, cider from Hereford was used. Evidence of lead was obtained in five experiments in the cider from Alphington but not in that from Hereford. As might be expected, Baker's work aroused a great deal of opposition in the county, and efforts were made to disprove it: prominent among these was the druggist Cockworthy, the founder of the Plymouth pottery.

Baker's classic was the first successful systematic inquiry into the cause and prevention of an epidemic disease.

The Age of Cholera

Like plague, cholera invaded Europe from the East, and this kingdom had ample warning of its approach. In 1830 it broke out in Russia, and the Government sent out two medical observers to watch its progress and report on the best methods of treatment. In 1831 was established a Board of Health, whose chief members were the leading Fellows of the Royal College of Physicians. The board got rapidly to work and Orders in Council soon appeared, together with "certain rules and regulations proposed by the board."

How did the local authorities respond to these orders? Thomas Shapter describes the uncertain, fluctuating state of feeling in Exeter, but shows that within four days of the receipt of the Order in Council a public meeting was held and a local board of health constituted, consisting of the mayor and magistrates, the Lord Bishop and one other member of the Chapter, six medical gentlemen, and the three medical officers of the poor. There seems to have been a subtle difference between the medical gentlemen and the medical officers, which is worth noting as an indication of the relative status of the various sections of the profession.

At subsequent meetings, arrangements were made for the notification by "all medical practitioners, and all other persons within the city" to members of the board. One thousand pounds was voted for "the covering in and making such drains as may be absolutely necessary for the protection of the health of the inhabitants as also for procuring water and for cleansing the streets." A handbill was circulated in which the need for cleanliness—public and personal—was stressed. It was accompanied by first-aid instructions for cholera. These included the application of local warmth by hot blankets, repeated friction, bags of hot salt or bran, the exhibition of stimulants such as hot brandy and water, sal volatile in hot water, essential oils such as peppermint, cloves, and cajeput, and, in very severe cases where medical aid was unobtainable, 20–40 drops of laudanum. At the instance of the bishop, an address from the clergy was widely circulated which concluded with these comforting words: "We pray God to prepare you for any

trials or afflictions which he may be pleased to bring upon you: and to make this and every other visitation of his conducive to your happiness and salvation."

Exeter at that time was a city of 28,242 inhabitants, for the most part crowded within the walls. The streets were narrow and, except for the main thoroughfares, paved with rounded pebbles with a central gutter which was the only channel by which sewage and waste water was removed; and water was so scarce that it was seldom sufficient to wash it away. The main supply was from numerous wells, an ancient conduit, a few pumps, and the waterworks. These last had been improved, but were still quite insufficient for the needs of the people, and much of the water was obtained by dipping in the river in just the same way as is still the custom in the East. The water thus obtained was carried in buckets for use near the river and by small watercarts for those living further away. Night soil and sewage were collected by contractors, who were paid £63 per annum for the privilege, with the result that only when there was sufficient collected in one place did the contractors consider it worth their while to remove it. These were the conditions that the board of health set itself to correct. The whole city was surveyed. Orders to landlords instructing them to remove nuisances were issued by the mayor on threat of prosecution. Extra scavengers were employed, carts and horses purchased. To encourage cleanliness amongst the poor, special water tickets were distributed by the doctors, clergy, and others.

In preparation for the outbreak, the medical gentlemen took an active part in the organization of the medical arrangements. At general meetings of the profession they recommended that the town be divided into four districts with a medical officer in charge of each, and that in each section a station house be established, under the direction of a responsible person, from which blankets, warm-air baths, and other such appliances could be distributed, and where the following medicines could be held for the use of the medical attendants: opium, calomel, aether, ammonia, oils of peppermint and cinnamon, soda, mustard, turpentine, spirits of wine, and any other drugs which might be required—and brandy. Eight extra apothecaries were engaged by the corporation. The work of the profession was very heavy during the outbreak, and we learn that several of them broke down under the strain. When the epidemic was at its height a rota system was arranged, whereby two medical men did night duty at the Guildhall; for them the board of health engaged two carriages and employed a man to attend upon them and to make coffee. Nurses were also engaged, and these "very necessary persons" were paid at a rate of 2s. 6d. per day.

When the disease struck it rapidly increased, and after a fortnight over 100 cases had occurred, and of these 33 were fatal. Altogether, during the three months that it lasted there were 1,135 cases and 345 deaths.

Shapter gives a summary of treatment, from which we gather that nothing specific was considered effective. But Exeter had learnt its lesson; the water supply and sewage system were so improved that when in 1849 cholera again struck, although there were 2,366 deaths in the county, Exeter had only one or two cases.

Cholera came in epidemic waves, lasted a short time, and disappeared again; typhoid was nearly always present. In the case of typhoid William Budd was the man, North Tawton the place. While Budd was working in North Tawton in 1839 an epidemic of typhoid occurred, and he was quick to realize his opportunity. He says, "Having been born and brought up in the village, I was personally acquainted with every inhabitant of it; and being as a medical practitioner in almost exclusive possession of the field, nearly everyone who fell ill, not only in the village itself, but over a large area around it, came immediately under my care."

At that time it was held that typhoid, cholera, and many other infectious diseases were propagated through an atmospheric miasma. From his personal observations and from

careful inquiry, Budd knew that fever had not been present in the village for at least 15 years—"There was nothing," he said, "to separate from the open air the offensive matters which collect around human habitations. Each cottage, or group of three or four cottages, had its common privy, to which simple excavation in the ground served as a cesspool." Also, nearly every farm labourer kept his pig to "furnish manure for the little plot of potatoes which fed man and pig alike. Thus, often, hard by the cottage door there was not only an open privy, but a dungheap also." Thus the atmospheric conditions considered necessary for the propagation of fever were present, and always had been. "Meanwhile privies, pigstyes and dungheaps continued, year after year, to exhale ill odours, without any specific effect on the public health."

In July the first case occurred; by November there had been more than 80 cases. It was by watching the spread of the disease within the families and neighbouring villages that Budd was able to demonstrate its contagious nature. When the disease was at its height three people left the village after they had been infected, and communicated it to others in their new neighbourhoods. Two were sawyers who had hired themselves out to a timber merchant in North Tawton for a few weeks, and had lodged in a court with a common privy. Both, when they sickened, returned to their homes in Morchard. One, a married man, died after passing the disease to his two children; his widow escaped. The other, a single man, infected a friend who visited him, and gave the disease to his brother and two of his children. The third person to leave North Tawton was a widow who went to visit her brother at Chaffcombe about seven miles away and started a series of cases: her sister-in-law, her brother, several farm labourers and apprentices, and other servants were affected. A servant-girl, in order to lessen the burden of sick nursing, went to her home in Loosebeare about four miles away and there started a small epidemic in the village. Budd points out that "while at Loosebeare a large proportion of the inhabitants were lying prostrate with fever, in not one of the 20 or 30 exactly similar places was there a single case." From Chaffcombe, again, one of the boys went home to his mother's cottage, half-way between Bow and North Tawton, and caused the illness of his mother and the death of his sister, and from there a further series of cases resulted.

Step by step Budd showed how the disease had been passed from one person to another. Soon after, he moved to Bristol, where he became an honorary and consulting physician to the Bristol Royal Infirmary. Whenever opportunity occurred, he collected further cases to illustrate his hypothesis. These he published in 1873 in a book, *Typhoid Fever: its nature, mode of spreading and prevention*.

Conclusion

What are the lessons to be learnt from these disjointed jottings? First, I would say, that history shows us that epidemic disease is always threatening, and when one appears to have been conquered or has spent its force others take its place, sometimes appearing insidiously, so that at first we hardly realize the changing pattern of disease in our midst—sometimes, with catastrophic force, breaking into our daily lives, as Asiatic cholera did in 1832 and influenza did in 1918. Even to-day we find fresh diseases coming amongst us unexpectedly. The polio epidemics which we have experienced since the war are an example. Epidemics of Bornholm disease which have caused considerable trouble in various parts of the country during the past year are another. What, I wonder, will our future historians say about the epidemics of this age?

When it comes to the study of epidemiology, those situated in country districts, serving isolated communities, are in a far better position to help in unravelling the spread of disease. With an active chain of public health laboratories at the disposal of the country doctor, he can now make very real contributions to the advancement of medical science.

CHILDREN'S VISION AND TELEVISION

BY

A. H. GRIFFITH, M.B., B.S., D.P.H.
Senior Medical Officer, City of Cardiff

General Effects of Television on Child Development

The possible adverse or beneficial effects of television viewing on the physical, social, and mental development of children rarely form the subject of articles or discussions in medical journals, and only a few surveys have been carried out in order to determine these effects. This is surprising, as there are television sets in half the homes of the country, and during the last 10 years television viewing has developed from a curious pastime of a few Londoners into a regular nightly drawn-out vigil practised by a large mass of the population.

The existence of television in a home must necessarily affect the pattern of life of that family, probably only to a negligible degree but possibly to a considerable extent. It has been stated that the less-educated members of the community, those who have nothing in particular to do, and those in the lower socio-economic group take to television more readily and change their habits more radically than other sections of the community do.

The acquisition of a television set may accentuate the financial difficulties of some families, thereby adversely affecting the quality of meals and the standards of comfort provided; and outside the home it may restrict social, recreational, and other mentally or physically beneficial activities. On the other hand, the lure of the screen may induce parents to remain at home rather than visit public houses, clubs, etc., and encourage children to stay in instead of going to cinemas or wandering aimlessly in the streets. Does this mean that television encourages a more compact family life, or does it encourage each member to stare mutely at the screen instead of contributing to the intimate family chatter? Where members of the family have no hobbies, do not read, and have no interesting conversation to offer, it relieves the boredom of home life.

A survey carried out in Coventry revealed that one-fifth of the teenage children questioned admitted that television interfered appreciably with their homework. The programmes may stimulate thought, improve appreciation of the arts, extend knowledge of literature, and produce better understanding of social problems, but they may also encourage a child to depend on ready-made entertainment, dampen initiative, discourage rational reasoning, and decrease his readiness to accept responsibilities. The youth club which the child may

otherwise be attending might have fostered his social and emotional development better than the television.

The effects of television on the emotional development of children have not been assessed generally. In Minneapolis it was found that the younger children enjoyed western and adventure programmes which were really beyond their mental capacity to understand properly, whereas the older children, who are more subject to corruption and delinquency, preferred plays and sports programmes. It may be that the emotionally balanced and stable children are not disturbed by television programmes, but the emotionally weak find that artificially produced stresses create added emotional strains with which they cannot cope.

Television may affect the physical development of children. Dr. J. L. Dunlop, Principal School Medical Officer for Hertfordshire, reported that children tended to stay up late to watch the television, that they looked permanently tired and drowsy, and that those with defective vision suffered from eye strain. On the other hand, Dr. J. A. Scott, Principal School Medical Officer of the London County Council, is less emphatic on this point and suggests that the amount of sleep children obtain has not changed, because if a parent allows a child to be late to bed for one reason, be it television or cinema, the same parent would probably permit late hours in the absence of these particular attractions. This is in agreement with the findings of a B.B.C. survey in 1952, which found that young children watched the television on average under nine hours weekly and the older children over 11 hours weekly. Muscle fatigue and postural deformities may result if children maintain bad postures for long periods.

Reasons for Cardiff Survey

The eye muscles undergo the greatest physical strain, for they are continuously endeavouring to adjust the optical system in order that a clear, easily interpreted image may be received on the retina. The visual object may be blurred, moving, flickering, or badly illuminated. This strain on the eye muscles may be even more marked if an uncorrected error of refraction exists in the eyes of the viewer. Eye strain, if and when it occurs, may impair the efficiency of children's eyes as an optical system. It was this possibility of impaired vision resulting from television viewing that led to a survey being carried out in Cardiff. It was considered that if television viewing as practised by schoolchildren to-day causes eyestrain sufficient to affect children's eyesight we would find a greater proportion of children wearing glasses among the frequent television viewers than among the non-viewers. In this survey all children who have a television set at home, be it recently acquired or not, are placed in the same group as frequent television viewers, while those without a set at home are the comparatively infrequent viewers.

Incidence of Television Sets in Cardiff Schoolchildren's Homes

The investigation was done by school nurses in Cardiff during the autumn term of 1956. A total of 19,280 Cardiff junior and secondary modern school children aged 7-14 years were asked whether or not they had television sets in their own homes and whether or not they wore glasses or had been advised by ophthalmologists or opticians to wear glasses. Of the children questioned, 64.9% claimed to have television in their own homes, the percentage being rather higher for the younger children than for the older ones (Table I). This probably indicates that younger parents are more likely than the older ones to invest in television.

TABLE I.—Prevalence of Television in Homes of Cardiff Children, Autumn, 1956

Age	No. of Children Questioned	Having Television in Own Homes	
		No.	%
7 years	3,061	2,035	66
8 "	3,557	2,327	65
9 "	3,814	2,595	68
10 "	2,957	1,972	67
11 "	1,604	1,003	63
12 "	1,430	880	62
13 "	1,444	858	59
14 "	1,413	847	60
Total	19,280	12,517	64.9

Nearly all the television sets had been acquired since August, 1952, when the Wenvoe transmitting station was opened and reception became possible in the Cardiff area. Two-thirds of the children living in council houses had television sets, so the prevalence of television is approximately the same in council estates as in other areas. As the average council house tenant earns about £10 10s. a week and pays £1 10s. rent, the question of whether the additional cost of 15s. a week over a period of two years for a television set constitutes a serious financial burden is one that cannot be answered readily in general terms.

The method adopted in this investigation of determining whether children's vision is being adversely affected by television viewing is open to criticism. For example, parents who have television sets may be more thrifty, more careful in the management of their affairs, and more ready to seek advice regarding their children's handicaps. It may be that television viewing may have made some parents realize that their children's vision was unsatisfactory, whereas otherwise the defect would have passed unnoticed. Lastly, it may have caused parents to seek ophthalmic advice, with the result that minimal optical defects have been treated by optical correction, whereas otherwise they would not have been detected. On the whole, therefore, we would expect a greater proportion of the television viewers than of the non-viewers to be wearing glasses.

Incidence of Spectacles Among Child Viewers and Non-viewers

The incidence of schoolchildren wearing glasses is slightly higher among those with television sets, but the difference is not statistically significant, and, in view of the previous remarks, is not more than would be expected. When, however, the percentages of children with glasses at various ages are examined we find that the incidence of glasses is a little lower in the viewers group under 10, but much higher after that age.

TABLE II.—Numbers and Percentages of Children Prescribed Glasses Among Those With and Those Without Television Sets at Home

Age	No. of Children Questioned	Prescribed Glasses	
		No.	%
<i>Those with Television</i>			
7 years ..	2,035	159	7.8
8 " ..	2,327	192	8.3
9 " ..	2,595	278	10.7
10 " ..	1,972	243	12.3
11 " ..	1,003	170	16.9
12 " ..	880	151	17.2
13 " ..	858	139	16.2
14 " ..	847	150	17.7
Total ..	12,517	1,482	11.8
<i>Those Without Television</i>			
7 years ..	1,026	80	7.8
8 " ..	1,230	109	8.9
9 " ..	1,219	141	11.6
10 " ..	985	109	11.1
11 " ..	601	86	14.3
12 " ..	550	73	13.3
13 " ..	586	91	15.5
14 " ..	566	83	14.7
Total ..	6,763	772	11.4

Of the 5,560 children aged 10 or over who have television 15.3% had been prescribed glasses, but of the 3,288 children of the same ages who did not have television sets only 13.4% have been prescribed glasses. The standard error of the difference between these two proportions is 0.76, which, when doubled, is still below the actual difference in proportions—namely, 1.9. The difference between the incidence of glasses in the two groups is therefore not likely to be due to chance, and is statistically significant. The difference between the incidence of children wearing glasses is even greater (17%—14%=3%) in children aged 11 and over; and this again is statistically significant, as the standard error of difference between the two proportions is 0.96.

The higher incidence of children prescribed glasses in the television-viewing group aged 11 and over is not therefore a matter of chance. It cannot be taken for granted that television viewing in itself is the main or even a contributory factor. As stated earlier, there are many factors that could possibly increase the incidence of glasses among child viewers, but the survey shows that the significant factor or factors affect only the children over the age of 10.

There are at least three possible reasons why a significant difference in the proportion of children prescribed glasses was found only in those over the age of 10. First, Cardiff schoolchildren have routine vision tests at the ages of 5, 10, and 14 years, so most of those aged 7-9 have not had a vision test during the last two years at least. Therefore if television viewing has impaired the vision of some of these children it will not show in the figures obtained in this survey, as many of them have watched the television only during the last two years and have had no vision tests during that time. The same applies to the 13-year-old children, for they too have had no routine vision tests for over two years, and this fact is presumably the reason why the difference between the two percentages is less for the 13-year-olds than for any other age group after 10.

The second reason is that children over the age of 10, having reached the secondary modern schools, are allowed to stay up longer in the evenings to watch television.

The third reason is that children up to the age of 8 can usually cope with eye-straining conditions without the optical efficiency of their eyes being impaired, but in children over that age eye strain may accelerate and exaggerate the normal tendency towards myopia. The axial length of the newborn eye is 16 mm., but that of a child of 7 is 24 mm. Therefore, as the axial length of the eye increases considerably during the first few years of life, the optical system tends to become myopic, but this is prevented by a gradual decrease in the convexity of the lens and changes in the refractive indices of the cortex and nucleus. In fact, during the first seven years of life there is a slight increase in hypermetropia among half to three-quarters of children, but between the ages of 8 and 13 there is a rapid decrease in hypermetropia or an increase in myopia. Accentuation of this process during the ages of 8 and 13 accounts for the increase in the number of children with vision defects normally discovered at these ages.

TABLE III.—Number of Cardiff Schoolchildren Found with Defective Vision at Routine School Medical Inspection in 1955

Age when Examined	No. Examined	New Cases Requiring Treatment for Defective Vision	
		No.	%
5-	4,342	99	2.3
10-	4,287	246	5.7
14+	2,158	185	8.6

Eye Strain

Eye strain caused by constant difficulties of accommodation can and often does artificially exaggerate this trend towards myopia in those aged 8-13 years. Eye strain is defined as symptoms experienced in the conscious striving of the visual apparatus to clarify vision by ineffectual adjust-

ments. It depends on the uses to which the eyes are put, the efficiency of the visual apparatus, and the capacity of the individual to withstand sustained effort. The causes are numerous, but, whereas the novice may experience eye strain, frequent use and training may enable him eventually to manage the same task with a certain degree of smoothness and ease. For instance, the quick reader does not have to use his eyes so exactly as the slow reader, who has to study each word.

The causes of eye strain are listed as:

1. Visual factors (mainly those which cause muscle fatigue). (a) Accommodation asthenopia. (b) Strain on neuromuscular control of ocular movements in order to maintain convergence.
2. Light: (a) Illumination: (i) inadequacy, (ii) glare. (b) Distribution: (i) too much in periphery of visual field, (ii) specular glare—reflected light near the object. (c) Contrast: great contrast in illumination between area viewed and neighbouring areas demands frequent rapid adaptation. (d) Type: flickering.
3. Nature of Object: (a) Minute details and the small visual angle they subtend. (b) Lack of contrast. (c) Lack of clear definition of object. (d) Contrast movement and fixation difficulties.
4. Ocular Factors: (a) Uncorrected ametropia. (b) Heterophoria. (c) Difficulties of accommodation. (d) Convergence difficulties.
5. Constitutional Factors: (a) Muscular fatigue of the eyes due to overwork, malnutrition, exhaustion, insufficient sleep. (b) Mental fatigue at the interpretation level, especially when interest and attention are called upon to interpret blurred and indistinct images.

When it is realized that all the above factors can produce eye strain and how many apply to the conditions under which television is watched, it is no wonder that television often causes eye strain. On the other hand, muscular adjustments occur which improve the ease with which the visual processes function and make it possible for the degree of eye strain experienced to diminish with practice, provided that the work demanded of the eyes is not beyond their capacities. Obviously an uncorrected myope will suffer from eye strain before a person with normal vision will under similar conditions. Repeated attempts at accommodation often end in ciliary muscle spasm which increases artificially the degree of myopia and accentuates any tendency towards myopia in those aged 8-13.

The symptoms of eye strain are well known. Ciliary muscle spasm, which is the result of muscle fatigue, produces periods of blurred vision. This is temporarily relieved by resting the eyes and by rubbing them. Children using grubby fingers often infect their eyes in this way, causing chronic blepharitis and conjunctivitis. Tired, uncomfortable, bleary, watery eyes and headaches are often the consequences of eye strain.

Discussion

This survey depends on indirect evidence in determining whether or not television viewing impairs children's eyesight. It assumes that those children who have television in their own homes, even if only recently acquired, have spent more time watching it than those who have no television. No special examinations were carried out for the assessment of visual defects among the children in the survey. All those who wore glasses or were known to have been prescribed glasses were counted in the defective-vision group. If any factor or factors other than television eye strain caused an increase in the incidence of glasses then the increase would apply to children of all age groups. The significant increase is, however, confined to children over the age of 10, and a simple explanation for this is that eye strain due to television viewing accentuates the normal tendency towards myopia in children aged 8-13 years. The effect of impairment of the eyesight of television viewers aged 8, 9, and 13 years is not shown in the figures obtained in this survey because children of these ages have not had vision tests during the last three years.

This survey does not prove that television viewing does affect children's vision, but the indirect evidence suggests this may be so. If we are to accept the findings at their

of sulphamerazine which I have used with such satisfactory results has placed my patients in any jeopardy whatever.—I am, etc.,

London, N.W.4.

R. W. COCKSHUT.

SIR,—I agree wholeheartedly with every word of Dr. E. C. Atkinson's letter (*Journal*, November 16, p. 1175), in which he condemned the use of sulphamerazine. It is appalling, despite the undue number of fatalities and near-fatalities which have occurred, that this preparation has not been taken off the market.

In 1951 a patient aged 6 in my own practice died of anuria after 48 hours' normal dosage of "cremomazine." I reported her death to the makers' local representative and have never considered using this drug since. Surely no more fatalities need occur before this preparation is boycotted by the whole profession.—I am, etc.,

Belfast.

S. E. BROWNE.

Clinical Applications of Triiodothyronine

SIR,—In their article (*Journal*, November 2, p. 1028) Drs. A. W. G. Goolden and C. D. Burrell describe, as the first example of a case of hypothyroidism, a patient displaying definite psychotic signs ranging from mania to a paranoid state. They regard the clinical applications of triiodothyronine as limited, though proved; for example, very suitable in the treatment of a patient who developed paranoia of hypothyroid origin. It is stated that borderline hypothyroidism and hypometabolism are probably identical, difficult to diagnose, and often overlooked. A doubtful diagnosis is best established by a test with triiodothyronine.

For over a year I studied selected cases of mainly melancholic state with signs of fatigue, irritability, emotional instability, depression, and retardation, and their response to triiodothyronine. The above-mentioned symptoms considered by an endocrinologist will lead to the diagnosis of hypothyroidism, a general physician will be inclined to name it hypometabolism, and a psychiatrist will hardly hesitate to diagnose it as melancholia. Many of these cases responded well to L-triiodothyronine, and I believe that this hormone might have an increased scope of clinical application in psychiatry.—I am, etc.,

Bodmin.

ERNEST E. FELDMESSER-REISS.

Aphthous Ulceration of the Mouth

SIR,—Your interesting leading article on aphthous ulceration of the mouth (*Journal*, November 9, p. 1099) stresses the uncertainty of its aetiology. May not biting the buccal mucosa (often unremembered as a trivial chewing accident or unadmitted as a neurotic artifact) be the precipitating cause?—I am, etc.,

Hove, 4.

W. V. CRUDEN.

SIR,—Among the various treatments for aphthous ulceration of the mouth described in your leading article (*Journal*, November 9, p. 1099) there was no mention of the simple application of tinct. benz. co. on a pledget of cotton-wool to each ulcer after meals. I have used this treatment, with relief of pain within 12 to 24 hours and prompt healing, in all the frequent cases one sees in general practice, over the last six years. I am indebted to the dental surgeon who prescribed it for me when, as a student, I had a particularly painful ulcer on the lower lip.—I am, etc.,

Chelmsford.

R. H. WOOD.

Tropical Pulmonary Eosinophilia

SIR,—In the letter on tropical pulmonary eosinophilia by Dr. T. J. Danaraj (*Journal*, July 20, p. 161) one reads the following, "... but in 10 patients with mild eosinophilia and pulmonary symptoms who were not cases of eosinophilic lung..." Now, Sir, I would like to know the criteria by which eosinophilic lung is diagnosed. To me the whole thing is in a nebulous state. I have been studying the subject for a number of years now. I think that there

can be cases of eosinophilic lung without eosinophilia, just as there are cases of aleukaemic leukaemia. Anyhow, one thing is certain. If these so-called eosinophilic lung cases are observed for a sufficient length of time, one finds that some of them may have at one time eosinophilia without symptoms for varying periods, and some may have symptoms but no eosinophilia at other times. Also there are cases with very great increase in the number of eosinophils without pulmonary symptoms but having symptoms in some other physiological system (any system may be affected), and there are also cases with marked eosinophilia but no symptoms at all. To me the most reasonable thing seems to be to group all the cases under one name till the aetiology is known. Perhaps the name "eosinophilic syndrome" is as good as any other.—I am, etc.,

Kottayam, India.

J. C. AMPURAN.

Salmonella Infection

SIR,—The interesting memorandum on salmonella infection by Drs. J. M. Talbot and J. A. Hunt (*Journal*, November 9, p. 1095) dealt with the European variants in the debilitated, and it might be useful to contrast the more invasive American type as it presents in a previously robust patient who is under treatment in this region.

A 65-year-old female spent last winter visiting in Canada and U.S.A., when she felt perfectly fit and well. Shortly after returning to Scotland, however, she began to suffer a lassitude, loss of appetite, and occasional mild shivering attacks. She also noticed that the left thigh, which had always been thicker than its neighbour, was sometimes tender when she sat on the edge of a hard seat. This rather vague state of ill-health continued for some months, and when her temperature did not settle after a transitory respiratory infection she was admitted to hospital. Examination at that time did not reveal any physical abnormalities of note. A swinging temperature persisted with evening peaks of about 100° F. (37.8° C.), but occasionally with a rigor it reached 103° F. (39.4° C.). B.S.R. 50 mm. in one hour (Wintrobe); Hb 78%; W.B.C. 8,200; polymorphs 75%; lymphocytes 18%; monocytes 3%; eosinophils 4%. All the original serological tests were negative with the exception of the non-specific salmonella titre, which was positive to 1:1,920, but she subsequently developed a titre of 1:240 against salmonella group CO. X-ray examination demonstrated no abnormality of her alimentary tract or gall-bladder and repeated examination of her stools showed no pathogens. Soon after this the pain on the back of her thigh returned, and, though the appearance now suggested a very deep abscess, there was no bony change on x-ray. The temperature settled after the evacuation of a large volume of foul-smelling pus from which *Salmonella cholerae suis* was obtained. Recovery is at present under way.

Infection due to the American variety of *cholerae suis* is not often found in Britain, and there is no doubt that this patient was infected prior to her return to this country. It is interesting to compare this case with the commoner European infection by *cholerae suis* var. *kunzendorf* described recently by Drs. Talbot and Hunt (Case 2) and by Dr. A. M. Laylee (*Journal*, June 1, p. 1284). With this patient the power of invasion of the organism was much the same though she was robust. The lack of leucocytosis in the presence of a large abscess and raised B.S.R. has sometimes been described and should have helped towards a diagnosis. Neither the source nor the primary infection can be discovered, though she did indulge frequently in a Continental-type sausage.

Perhaps the greatest lesson to learn from such a case is to be more aware of intercontinental spread of infection.—I am, etc.,

Inverness.

RAE LL. LYON.

Early Separation of Handicapped Children from Parents

SIR,—I should like to use your columns to express my concern about the frequency with which young children are removed from home for educational purposes. It is now apparently quite a common procedure for children of 5 years who are partially sighted to be placed in boarding-schools, and in the case of deaf children even younger. I consider

this to have serious ill effects on their emotional development and likely to add maladjustment to their physical handicap.

It is interesting to note that there are statutory powers for removing children who are blind, deaf, or educationally subnormal from perfectly satisfactory homes against their parents' wishes, but in the case of maladjusted children, whose difficulties are probably due to unfavourable attitudes or circumstances in the home, enforcement is much more difficult. As a general rule it is undesirable for a child to go to a boarding-school before the age of 7 or 8, and in the case of children with physical handicaps it is even more important that they should stay in their parents' care and that some other method should be used to overcome their physical handicaps.—I am, etc.,

J. VINCENZI.

White Colne, Essex.

Use and Abuse of Blood

SIR,—Dare I accuse Dr. C. B. V. Walker (*Journal*, November 2, p. 1046) of talking through his hat? He incriminates "trainees" as being, it would appear, a major cause of "wastage of blood because they tend to over-transfuse. Surely the 'trainee,' lacking the 'mature judgment' of his chief, is more liable to under-transfuse, simply for the reason which Dr. Walker mentions in his first paragraph. Having recently been a trainee myself, I would claim that it is very much more the exception than the rule for housemen to over-transfuse.

I could suggest that some of the worst abusers of blood are the consultants themselves. Those who demand routine cross-matching for such operations as cholecystectomy, thyroidectomy, radical mastectomy, and the like would do well to exercise their "mature judgment" pre- as well as post-operatively in deciding whether a patient is going to require blood. Then again there are those who give a couple of pints (1 litre) pre-operatively because the haemoglobin is a little lowish, rather than investigate the anaemia properly. Consultants who, rather than keep their anaemias in for a few extra days, give a transfusion and send them out early are offenders too. Which is the more expensive—3 pints (1.7 litres) of blood or an extra three days in hospital?

Finally, may I add that the modern bureaucratic outlook appears to be affecting Dr. Walker to the full, as he willingly adopts the practice, very much in vogue, of putting the blame on the junior. Does he also call the consultant the trainer?—I am, etc.,

Chesterfield.

R. M. BADDELEY.

Blood-sugar Estimation

SIR,—This year several methods have been recommended which, in a most useful and simple way, allow for a rapid blood-sugar estimation. However, these tests carry certain disadvantages. The method of Drs. Mary Davies, R. G. Paley, and their assistants (*Journal*, March 2, p. 501) depends on a special apparatus (Dr. R. A. Osborn, p. 502). With Dr. W. M. Lancaster's test (*Journal*, July 13, p. 83) hypoglycaemia cannot be detected. Kohn's "tes-tape" method surpasses the above-mentioned examinations in its simplicity; the readings, however, have to be made within 15 seconds in order to avoid fading of the colour. In addition, it would appear to be preferable to use serum instead of whole blood, which would entail a delay in time until the serum has separated.

Ten years ago, I described a caramelization test¹ which may be executed with glassware and chemicals of a G.P.'s small routine laboratory equipment. This test is based on Moore's reaction, according to which glucose and other hexoses are caramelized by heat in a strongly alkaline solution to a brownish yellow product, the intensity of colour varying with the concentration of glucose in a given liquid. The resulting shades of yellow permit a rough estimation of the glucose level, with an accuracy of about 50 mg.%. The colour remains unchanged for eight hours, thus facilitating the emergency treatment of a case of diabetic coma and the assessment of the response to insulin. The procedure of the

test takes only 10 minutes. It reveals with certainty both hypo- and hyperglycaemia. An additional advantage is that the same blood filtrate may be used for an even simpler blood urea estimation,² and diabetic coma may thus be differentiated from uraemia. The disadvantages of this caramelization test are that (1) at least 3 ml. of blood is needed, which means venous puncture; (2) that, for comparison, the same glucose determination has to be carried out with the blood of a healthy person.

Procedure: take 4–5 ml. of venous blood. Add the same amount of 20% of trichloroacetic acid and deproteinize by vigorous shaking and filtration. Boil 3–4 ml. of the filtrate with 1.5 ml. of 30% NaOH (KOH) for one minute (no pipettes are necessary, the accuracy of a good syringe is enough). Results: watery or almost colourless means hypoglycaemia (below 70 or 80 mg.%), light lemon yellow (80–150), yellow (150–250), deep yellow (250–350), yellow brownish means over 400 mg.%. Blood with fluoride gives the same results. In cases of undiagnosed coma it is recommended to take 6–8 ml. of blood. Add to 2 ml. of the above filtrate 3 to 4 drops of Ehrlich's urobilinogen reagent. A light green colour indicates a normal urea content (below 50 mg.%), a green colour means urea of 60–100 mg.%, and a more deep green colour a very high urea.³ It goes without saying that both the glucose and the urea test are intended as an emergency method for a rapid orientation only.—I am, etc.,

Haifa.

Treatment of Leg Ulcers

SIR,—I should like to confirm Mr. A. Dickson Wright's remarks on the treatment of leg ulcers (*Journal*, November 9, p. 1111). I can record a case similar to that quoted by him. A man, aged 70, presented himself with a leg ulcer of 20 years' duration. All treatment had failed and he had recently had a ligation operation and a skin graft without, however, so far as I could ascertain, the all-important pressure bandaging. This also having failed, he had been advised to have an amputation. Under routine treatment with pressure bandaging and a "sorbo" rubber pad on a zinc ointment dressing over the ulcer he healed completely though more slowly than the usual case. Mr. Dickson Wright's original teaching on the treatment of varicose veins and their complications has been carried out in our clinic here for just over 25 years now, with results similar to those he has so convincingly demonstrated on many occasions.

Perhaps I may be permitted to mention a few points which may be of interest to those interested in this subject. Because of the allergic reactions he mentions, we have substituted for the elastic adhesive type of bandage either "ichthopaste" or "dalzoband," especially No. 4 where dermatitis is present, finishing with a covering crêpe bandage tightly applied. On the ulcer we apply a zinc ointment dressing with a sorbo rubber pad suitably shaped and bevelled. If one gets irritation from the sorbo rubber, as occasionally happens, we substitute a pad built up of layers of lint or gauze, though this is not nearly as efficient. We do, of course, use other types of bandage in certain cases, including the elastic adhesive type, but the others may be said to be our routine treatment. However, whatever the type of bandage used, the principle remains the same—namely, continuous pressure with an elastic pad over the ulcer.

May I make a plea for the operation carried out in our clinic? The "top tie" is, of course, the essential ligation of the internal saphenous vein flush at the junction with the femoral vein and including, of course, the ligation of all branches entering the internal saphenous within the field of operation. We then carry out multiple ligation along the course of the vein, as indicated by experience and the individual case, paying particular attention to "perforators."

No sclerosant is used, and the object is to eliminate the vein from the groin to the ankle, leaving no stretches open. This is undoubtedly time-consuming, but I consider the results we obtain justify it. The patient is encouraged to get about immediately, and in the majority of cases is fit to resume work after a fortnight, frequently less. Finally, I would join Mr. Dickson Wright in stressing the importance of the bandaging being done by the surgeons working in the clinic (as we do) or by someone whose experience is sufficient for them to carry out the treatment efficiently.—I am, etc.,

Belfast.

J. J. MORIARTY.

SIR,—As one who has personal reasons for being grateful for Mr. A. Dickson Wright's treatment of this condition, may I be allowed to make a few observations from the "receiving end"?

Following a deep femoral thrombosis many years ago, I have had a tendency to varicose eczema and ulceration. I find that massaging with olive oil keeps the skin under the malleolus reasonably healthy; but, of course, the main preventive treatment is an elastic bandage from the toes to as near the knee as it will go. In this connexion I should like to stress the importance of the bandage being at least 3½ in. (7.6 cm.), preferably 4 in. (10.2 cm.), in width. With a narrower bandage it is almost impossible to cover the heel adequately without making additional and unnecessary turns round the foot, with the result that insufficient bandage remains to cover the leg. It is essential that the heel should be covered, otherwise the bandage rides up over the malleolus.

After years of experience I am still undecided about the merits of a one-way or two-way stretch bandage. The former, being made of lighter material, is certainly cooler to the skin and leaves more room in one's shoes, but it tends to cut into the skin and has to be reapplied more than once during the day, which is not always convenient.—I am, etc.,

"A MEDICAL PATIENT."

SIR,—How right Mr. A. Dickson Wright (*Journal*, November 9, p. 1111) is to stress the importance of personal dressing of leg ulcers. During the 13 years that I worked at the varicose clinic at the Royal Waterloo Hospital our results were—to put it mildly—pitiable. The chief reason for this, I am convinced, was that the clinic was so large that all the dressings had to be done by nurses who were continually being changed every few months. It was only when I started a varicose clinic in 1943 at the Battersea Central Mission, which has now become the London Varicose Clinic, where all the dressings are done by myself and Dr. Stanley Rivlin, that we have been able to get increasingly good results.

The standard treatment which I now follow is to dress the ulcer with tulle gras impregnated with "viacutan" emulsion and Canada balsam 7.5%, as supplied by Ward, Blenkinsop & Co. Ltd. Over this I apply an "ichthopaste" bandage, and over all a 4-in. (10 cm.) crêpe bandage from the toes to the knee with a good pad of cotton-wool over the site of the ulcer. With this treatment I have even been able to heal a trophic ulcer on the heel for which a man was advised to have amputation of the leg by two surgeons. Most simple ulcers will heal soundly in well under three months—in some cases in only a few weeks.—I am, etc.,

London, W.8.

R. SIMPSON HARVEY.

Homoeopathy

SIR,—Dr. T. D. Ross (*Journal*, November 9, p. 1112), in proposing co-operation between homoeo- and allopaths in the treatment of infectious diseases, remarks that the opportunity for treating numbers of diphtheria cases has now fortunately passed, and he adds, in brackets, the astounding commentary, "largely owing to active immunization along homoeopathic lines." Our immunization records for mid-Sussex show that 93% of children have been immunized and the great majority have also been Schick-tested,

positives (other than pseudo-positives) receiving reinforcing doses as required. As far as I am aware, there are no homoeopathic practitioners in our area, although doubtless there are many people who rely on the system to cure their ills. Our figures are based on regular returns from private practitioners throughout the area; the records of council-run immunization clinics for under- and over-fives; regular information from the registrar of births; and, lastly, from the County Council, about new arrivals into the area. Obviously, in this area at all events, homoeopathy can play but a minute part in protection against diphtheria. Having pointed this out, let me emphatically disclaim any criticism of homoeopathy as a system. I am not qualified to judge. I would, however, much appreciate the opportunity of examining their results. Surely a simple method would be to Schick-test a sample of their immunized children; the result would at least have a one-sided effect and might well lead to further co-operation. My own experience in this direction is limited to testing one child who had had the homoeopathy immunization course, and he was Schick-positive—a single observation devoid of any special significance.—I am, etc.,

Haywards Heath, Sussex.

H. L. DUKE.

Maternal Anaesthetic Deaths

SIR,—I should like to comment on one point in Dr. A. H. Morley's letter (*Journal*, November 9, p. 1115). He quotes that 42 of 49 obstetrical anaesthetic deaths occurred in hospital. From this he argues that a forceps delivery is safer for the mother in her own home. What seems of more importance to me is that 14% of these deaths were at home. I should like to see an analysis of the numbers of anaesthetics given at home and in hospital for forceps delivery before concluding that hospital is significantly more dangerous. Until then I should like to see any patient of mine delivered instrumentally in hospital unless quite impracticable.—I am, etc.,

Glasgow, E.2.

D. STIRLING EDDIE.

Definition of Stillbirth

SIR,—Recently our attention was drawn to the fact that the phrase "has not breathed or shown any other sign of life" in the above definition is capable of varying interpretations. We wrote to the Registrar-General for a ruling on the matter and obtained the following reply, which may be of interest to your readers:

"For purposes of registration of stillbirths, the Births and Deaths Registration Act, 1953 (Section 4), defines stillborn child as

a child which has issued forth from its mother after the twenty-eighth week of pregnancy and which did not at any time after being completely expelled from its mother breathe or show any other signs of life."

The Registrar-General has been advised that in applying this definition beating of the heart should be regarded as constituting a sign of life. The English statutory definition (there is a similar definition in Scotland, but stillbirths are not at present registered in Northern Ireland) is considered in its effect to be comparable with the definition recommended by the World Health Organization in 1950, which uses the phrase "any other evidence of life, such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles."—I am, etc.,

London, W.1.

AUDREY WOOD,
General Secretary,
Royal College of Midwives.

Discharge from Trains

SIR,—Although Mr. D. Walker-Smith stated in a Parliamentary reply (*Journal*, November 9, p. 1122) that there was no evidence of infection being attributable to effluent discharged from trains, it still seems to me to be a very unhygienic, uncivilized, and outmoded practice. I feel sure that a coach or caravan owner who permitted the discharge

of effluent on to the road would not escape unscathed. Why then should British Railways not be required to provide chemical closets?—I am, etc.,

Liverpool, 18.

MYER GOLDMAN.

Chlorpromazine Jaundice

SIR,—The article about chlorpromazine jaundice by Dr. G. S. Graham (*Journal*, November 9, p. 1080) prompts me to report the following case.

A woman aged 82 years, who was known to have a diaphragmatic hernia, became depressed, confused, and irritable, and because of this she was put on to chlorpromazine 25 mg. daily for 12½ weeks. At the end of this time she was very much improved and the chlorpromazine was discontinued. Nineteen days later she felt generally unwell and complained of upper abdominal discomfort, nausea, and vomiting. Fourteen days after the onset of these symptoms, and 33 days after discontinuing the chlorpromazine, she became clinically jaundiced and bile appeared in the urine. She was afebrile, and the liver edge was palpable and tender. The serum bilirubin, as one would expect, was above normal, but her haemoglobin, leucocytes, blood film, and serum proteins were normal. There was no history of contact with a case of infectious hepatitis, and indeed it is over two years since a case of infectious hepatitis was seen in this practice. Within 10 days the jaundice had disappeared and she was symptom-free.

This case appears to be of interest, first, because of the length of time that the patient was treated with the drug without jaundice developing, and, secondly, because of the period that elapsed between the termination of treatment and the actual development of jaundice.—I am, etc.,

Great Yarmouth.

G. HURST.

Press Publicity

SIR,—As P.R.O. of a nationally known pharmaceutical company, I strongly sympathize with Dr. Margaret Hadley Jackson's fulminations (*Journal*, November 9, p. 1115) against certain sections of the lay press. It may interest her and some of your readers to know that pharmaceutical houses producing major therapeutic substances are sometimes faced with similar situations. One way of forestalling difficulties is to provide the lay press with stories of medical interest, the text of each having been previously scrutinized by a doctor with adequate knowledge of the subject under discussion.

Dr. Jackson's specific complaint would be upheld by the overwhelming majority of journalists in this country. I cannot feel, however, that the rendering of a medical paper into a garbled and fictitious "interview" can be such a frequent occurrence as Dr. Jackson's letter appears to suggest. Dr. Jackson is perhaps unaware of the interest of the Press Council in pursuing breaches of journalistic ethics. In any case, I strongly doubt whether her plea for legal redress beyond the present provisions of the law could be of advantage to anybody in the long run. In practically every profession there are incensed, perhaps rightly incensed, individuals who call for restrictions on the freedom of the press.

Dr. J. H. Millen (p. 1117), writing on influenza publicity, takes a more constructive attitude in suggesting that the British Medical Association should seek means of preventing journalistic excesses. Again one hopes, however, that any step taken would be a positive one, and not restrictive. The medical profession is possibly inclined to overlook that it has not a monopoly interest in sickness and disease. These are social facts, and as such always potentially "news." While deploring the occasional (actionable) excesses which Dr. Jackson describes, I suggest that the right course would be for the B.M.A. to set up, in conjunction with leading members of the pharmaceutical industry and of the press, a working party to investigate and improve liaison with the press.

Recently in Vienna a symposium on this theme was organized by the Austrian Medical Association. In Austria, where the public taste for the "sensational" touch is, if anything, more avid than here, great improvements are being achieved by such efforts. In the U.S.A. the Macy Foundation has sponsored at least two highly successful con-

ferences on the theme of communications between the medical profession and the lay press. In Germany the professional medical organization is already giving serious attention to the problem. In all cases the approach is a positive one. It would be very regrettable if the medical profession in Britain showed a different attitude or no attitude at all. It is perhaps also worth reminding your readers that it has never been made easy for journalists to obtain medical information. They are a much-snubbed profession.

Finally, I would draw attention to an astute remark by Dr. John Earle in his letter on the use and abuse of blood (p. 1116). "Medical gossip [he writes] is always good value." Why not ensure, then, by intelligently organized means, that more medical "gossip" of the right kind gets into the lay press? This, I suggest, could be a major long-term aim of the medical profession's public relations.—I am, etc.,

London, S.W.1.

ALAN HUET OWEN.

Preparation of Skin for Electrocardiography

SIR,—I agree with Dr. James Maxwell (*Journal*, October 19, p. 942) that the jelly used in preparation of the skin for electrocardiography is messy and needs considerable time to cleanse the skin and the electrodes. The jelly usually contains some gritty substance which is injurious to the smoothness of the electrodes; besides, the jelly is costly. Thus these two disadvantages can be added to the two mentioned by Dr. Maxwell. In public institutions, where every farthing spent is counted, electrocardiograph jelly is considered a costly item (particularly in our country) and a cheaper substitute is welcomed. I have used gauze soaked in saline and put between the skin and electrode without minimizing the accuracy of the tracings. Lately, in the Municipal General Hospital, Bombay, we have used liquid soap for preparing the skin for electrocardiography, with good results. It does not affect the smoothness of the electrodes nor is it messy. It is a very cheap but equally good substitute for the jelly. It will be interesting to know the experience of other physicians in this matter.—I am, etc.,

Bombay.

D. D. VORA.

Salicylate Intoxication

SIR,—The paper on encephalopathy during salicylate treatment of acute rheumatism by Dr. Michael Honey (*Journal*, October 26, p. 979) prompts me to report the following case.

A young man of 20 was admitted to hospital on March 22, 1956, with acute rheumatism. The joints affected were thoracic lumbar spine, right knee, and small joints of right foot. There was fever (temperature 100° F.—37.8° C.), tachycardia (pulse 96 per min.), and a loud blowing pansystolic murmur at the mitral area; E.S.R. 95 mm. in one hour (Westergren); W.B.C. 12,480/c.mm. (polymorphs 85%, lymphocytes 12%, monocytes 3%). He was given calcium aspirin, 15 gr. (1 g.) 2-hourly omitted at night, the aim being to raise the serum salicylate to over 35 mg./100 ml., along the lines advocated by Coburn,¹ and the usual general measures were applied. There was a good response to salicylate at first, but the right knee relapsed and the shoulders felt stiff, so the aspirin was increased to 20 gr. (1.3 g.) 2-hourly on March 26. A course of penicillin was also given to combat any residual throat infection which might be playing a part in producing the relapse. Improvement occurred again, and the E.S.R. fell to 37 mm. on March 28. On this date a very faint blowing early diastolic murmur was heard along the left sternal edge. On March 29 the aspirin was given as "paynocil," 2 tablets (=20 gr. (1.3 g.) aspirin) 2-hourly. On April 3 tinnitus and hyperpnoea were present, but were not considered to require reduction in dosage. By April 5 the early diastolic murmur was obvious, the pulse collapsing, and arterial pulsation was present in the neck; E.S.R. 29 mm. in one hour.

On April 16 he vomited after his paynocil, and the drug was temporarily omitted next day. There was no increase in tinnitus or hyperpnoea, but he complained of "feeling funny"; E.S.R. 19 mm. in one hour. On April 18 and 19 he was incontinent of urine. He said he felt exhausted. On examination, he was rather slow to respond, but was fully orientated and co-operative. The cranial nerves were normal. There was a little wasting of his lower-limb muscles; muscular tone generally appeared normal power moderate, and all his tendon reflexes were exceedingl

brisk. There was marked and sustained bilateral ankle clonus but no patellar clonus. The abdominal reflexes were present, and the plantar responses were down-going. Co-ordination and sensation were unimpaired. There was no change in the C.V.S. The chest was clear and he was hyperpnoeic. The abdomen was normal, the throat dry but not inflamed, and there was no pyrexia. The serum salicylate level was 33.3 mg./100 ml. Paynolil dosage was cut to 1½ tablets (=15 gr. (1 g.) aspirin) 2-hourly, with some improvement; but next day there appeared to be definite slight increase of tone in both legs, right more than left, and the ankle clonus was definitely sustained on the right side only. Plantar responses were down-going; abdominal and cremasteric reflexes present; arm jerks less brisk than formerly. His back was still stiff and the erectors spinae tender over a wide area. X-rays of lumbar and lower dorsal spine were normal and there was no meningism. Serum salicylates were reported as 44 mg./100 ml. Salicylates were then stopped. Although there was no evidence of haemorrhage and a prothrombin time was not available, it was thought advisable to give vitamin K.

The cause of the apparent early paraplegia was obscure, and in view of the original and persisting lower back symptoms and signs he was transferred to a neurosurgical unit for further investigations, including lumbar puncture, which were all negative. Further medical investigations were: three blood cultures, negative; Hb, W.B.C., M.S.U., X-ray chest and thoracic spine all normal. Gradual improvement continued, and subsequently "disprin" (20 gr. (1.3 g.)) four times a day was reintroduced. E.S.R. on May 18 was 3 mm. in one hour. On May 22 he returned to the original hospital, looking well, and with no abnormal signs in the C.N.S. or locomotor system. The signs in the C.V.S. were unchanged, except that now there was also a rough rumbling diastolic murmur with presystolic accentuation in the mitral area. This murmur could not be heard ten days later, but a faint blowing early diastolic murmur persisted at the left sternal edge, and his pulse was collapsing. He was discharged on June 15, when examination of the C.N.S. revealed no abnormality.

While there is no proof that the neurological state described was due to salicylate intoxication, on the evidence presented (high dosage, high serum salicylate level, reversibility when salicylates withdrawn) this seems the likeliest cause. That idiosyncrasy to salicylates was not responsible is indicated by the tolerance of 80 gr. (5.3 g.) daily when the drug was subsequently reintroduced. At the time a differential diagnosis of disseminated sclerosis was considered, and indeed this cannot be ruled out, but there is less evidence in its favour. A recent inquiry into the patient's health revealed that he has had no further trouble.—I am, etc.,

Weeton, Lancs.

D. E. HYAMS.

Psychopaths

SIR,—Your correspondent Dr. G. C. F. Roe (*Journal*, November 9, p. 1112) has been misinformed concerning the findings of the Royal Commission. It was not recommended that all grades of amentia should be called psychopaths. It was suggested that idiots, imbeciles, and low-grade feeble-minded patients should be called "severely subnormal," and that patients now known as high-grade feeble-minded should in future be called psychopaths. He states further that the intellectual attainments of idiots and imbeciles are nil, but in fact they extend from 10% to 50% of the average figure of the population. In the case of high-grade aments the intellectual attainment, far from being extremely poor, is in fact only a little below the normal range. I am prepared, however, to concede that not all feeble-minded patients are psychopaths.—I am, etc.,

Driffield, E. Yorks.

J. NEWCOMBE.

Femoral Hernia

SIR,—I have used the suprapubic extraperitoneal approach for femoral hernia 81 times, and agree with Mr. Robin Burkitt (*Journal*, November 16, p. 1176) that it is an excellent approach for both uncomplicated and strangulated hernias. Recurrences are extremely rare, and it is unnecessary to do any sort of repair if the peritoneum is well removed. I have had three incisional hernias. These have all occurred in extremely debilitated and chesty patients

with strangulation, but the resulting bulge is almost uncontrollable by any form of apparatus and requires reoperation. This is a serious defect of the operation.

I doubt whether this operation can be attributed to Professor A. K. Henry. Many surgeons had described operations on femoral hernia by the abdominal route, but these were usually transperitoneal. The first description I can trace was by Lawson Tait in 1883.¹ Various surgeons have independently described the extraperitoneal route. The first description was by Sir Lenthal Cheate in 1920.² His paper was a model of brevity, consisting of 50 lines and about 460 words. He had used the method for various sorts of hernia, but only mentioned one case of femoral hernia. No follow-up was given. Savini³ described the operation in 1921 and stated that it was a modification of the operation of G. Ruggi described in 1893. La Roque⁴ wrote a paper in 1922 in which he described 12 cases with some follow-up, but he also opened the peritoneum. Henry's description⁵ appeared in 1936. He made a very large incision, which few surgeons nowadays would advocate. He described a repair but thought it might be superfluous. He described one case which was bilateral, but gave no follow-up. I therefore think that if we are to designate operations by eponyms the priority here must go to that great scholar and surgeon, Cheate. It would appear that Cheate's paper went unnoticed. No doubt Professor Henry's great reputation as a surgeon-anatomist led to people taking more notice of his paper when it appeared.—I am, etc.,

Hull.

The Misnamed Stethoscope

SIR,—Dr. R. P. W. Kup writes (*Journal*, November 16, p. 1178) expressing doubts about electrocardiogram as the word for the end product of electrocardiography, and asks someone to elucidate. As one of the older generation who, until the moment of entering Cambridge, was brought up entirely on Latin and Greek—a circumstance for which, after recovery from initial shocks, I remain devoutly thankful—I will try to do as he requests. Electrocardiogram for the finished product is quite correct, for the Greek word *gramma* (γράμμα) is concrete, meaning the thing written or inscribed, while *graphe* (γραφή) means writing in the abstract or the art of writing. Electrocardiograph for the machine producing electrocardiograms is rather less correct, but we must not be too pedantic, and, as it is already compounded of three Greek words, "electrocardiograph" as an abbreviation for "electrocardiographic machine" is not the worst we have and is unlikely to have caused the batting of any eyelids among those of our masters who arrange these things to their delight. To incorporate the Greek *graptee* (γραπτήρ), a writer, or *grapheus* (γραφεύς), an inscriber, would give an impossibly ugly result, and if we did do so someone would at once write and say that both words are masculine while a machine must be neuter. An electrograph is at least derivatively feminine, which entitles it to be uncertain and coy.

In the world of radiology we have suffered even more. I remember at a meeting a long time ago someone protested at the use of "radiograph" for the finished x-ray film. Someone reminded him that the more correct "radiogram" had already been appropriated for a machine for making noises. He had to sit down and we have suffered ever since. "Skiagram," the inscription of a shadow, is both apt and correct, but has never been popular, presumably owing to its ugliness.—I am, etc.,

Bedford.

H. B. PADWICK.

SIR,—Dr. R. P. W. Kup's question (*Journal*, November 16, p. 1178) betrays once again the sadly felt absence of a classical education which these days, apparently, only very few aspiring medical men go through. The "graph" of

course, is the machine because it does the writing (γράφω, I write), and the "gram" is what it writes (τὸ γράμμα, the letter).—I am, etc.,

Sheffield, 3.

H. GRUNDMANN.

Mongolism in a Twin

SIR,—Dr. J. V. Morris in his interesting article on mongolism in a twin (*Journal*, November 2, p. 1038) states that only 14 cases have been reported in the British literature since 1876, and he describes an additional case. He quotes Morris and MacGillivray¹ as saying that mongolism in one of twins is not so rare in British literature as had been suggested.

Dr. J. S. Happel, of Alresford, has kindly reminded me of twins born at home and transferred to the Royal Hampshire County Hospital, Winchester, on April 3, 1957. The second twin, a male, was clearly a mongol, markedly jaundiced, cyanosed, and breathless due to a pronounced heart defect, having bilateral cataracts, and weighing 3 lb. 15 oz. (1.8 kg.). He died surprisingly well, and at 5 months weighed 11 lb. 4 oz. (5.1 kg.), when he contracted an upper respiratory infection and died within a few days. The other twin was also a male and weighed 6 lb. 11 oz. (3 kg.) at birth. He is quite normal and now thriving and well. There were two placentas. The mother was aged 36, and was delivered of a normal child in 1954 and again in 1955. She had a miscarriage in 1956. No history of twinning in her own family or in her husband's family can be traced.

Drs. Nicholson and Keay² state that among dizygous pairs the great majority are discordant for mongolism, and they go on to report mongolism in both monozygous twins of opposite sex which they describe as unique in the literature.—I am, etc.,

Winchester.

Cyanosis in Infancy

SIR,—Besides the causes mentioned in your annotation (*Journal*, November 2, p. 1045), cyanosis in infancy may be due to methaemoglobinemia. This can be caused by the feeds made up with water containing nitrates,¹ but the greatest number of cases reported in this country were due to the absorption of aniline from an ink used to mark the babies' napkins.² All those affected recovered, but in an American outbreak³ 4 out of 17 died. The early recognition of cyanosis from this cause is therefore important, so that the source of the intoxication may be removed and treatment with ascorbic acid or methylene blue given if necessary.—I am, etc.,

Oxford.

Splenectomy in Felty's Syndrome

SIR,—Drs. J. N. Blau and A. Willcox's advocacy of splenectomy in Felty's syndrome (*Journal*, November 9, p. 1094) prompts me to record an additional case.

Early in 1952 I was consulted by Dr. Meerapfel, of Sutton, about a woman of 56 who had had rheumatoid arthritis for 24 years. For the last two years a series of ulcers in her throat had caused a severe dysphagia. These additional symptoms had led her doctor to examine her blood, which had on each occasion showed a striking neutropenia. Her spleen was considerably enlarged, and, at my suggestion, she was admitted to hospital for splenectomy. This was performed on February 13, 1952, and was followed by an immediate and dramatic rise in the polymorph count, as follows:

Feb. 11.	Total	W.B.C.	500	per	c.mm.	polymorphs	5%
Feb. 13.	"	(pre-op.)	750	"	"	"	5%
"	"	(post-op.)	4,600	"	"	"	77%
Feb. 14.	"	"	8,200	"	"	"	78%

After the operation the ulcers healed and did not recur. The rheumatoid arthritis was, of course, unaffected, but the advantage gained by splenectomy was, as your contributors say, impressive.—I am, etc.,

London, N.W.1.

Conglutination of External Os

SIR,—I have recently had a most interesting obstetric experience, the like of which I had never seen before.

A young primigravida went into labour one morning two weeks before her expected date. Her pains were very slight, causing her very little inconvenience; when I examined her in the evening, I obtained the impression that the os was two fingers dilated. The following morning, after a night of slight pains, I examined her again, but this time could not make out the degree of dilatation. I asked Dr. J. M. McBride to see her, and, after examining her, he decided that the examination should be repeated under an anaesthetic and in good light. A self-retaining speculum was introduced, and we were surprised to see that there was no os at all, but merely a pin-hole opening through which blood could be seen oozing. At this stage the thought of caesarean section loomed very large, but Dr. McBride proceeded to enlarge the small opening until the head could be seen with the membranes intact. The patient was then left to come out of the anaesthetic in the hope that the artificial os would dilate. Nine hours later she delivered herself spontaneously of a 7 lb. (3 kg.) infant with very little trouble. Unfortunately, the delivery of the placenta was followed by a brisk haemorrhage, necessitating transfusion, but everything went well, and mother and child were able to go home on the ninth day, none the worse for the experience. Pelvic examination six weeks after delivery revealed, to my surprise, a completely normal cervix, with no evidence of laceration, and a perfectly normal parous os.

Having never encountered this anomaly before, I reviewed the textbooks and literature, and from my survey I feel satisfied that my case was one of atresia of the cervix or conglutination of the external orifice. Most textbooks give a description of this condition, but no figures as to its relative frequency, although Chassar Moir¹ states that "it is not so uncommon as compared with atresia of the internal os." In spite of this, my review has revealed only one reference to conglutination of the external os. This was in a report by G. F. Melody² in a paper entitled "The Obstructed Uterine Cervix." The following paragraph is reproduced verbatim.

In this rather unusual obstetrical complication the presenting part is well engaged in the pelvis, the cervix thin and effaced, and tightly stretched over the presenting part, and the os fails to dilate beyond a pin-point opening, the margins of which are rigid and sharp. This condition is more common in primiparas than in multiparas, but has been known to recur in succeeding pregnancies. The stenotic external os usually very promptly opens in response to digital insinuation; rarely Dührssen's multiple incisions are required.

I should be most interested to hear of similar cases, and to find out if this condition is as uncommon as the paucity of references in the literature would make one believe. I am very grateful to Dr. McBride for his skilful handling of the situation, and to Sister Camilous, of the St. Francis Nursing Home, for her calm efficiency in the emergency which followed the delivery of the placenta.—I am, etc.,

Glasgow, S.4.

"Butcher's Thigh"

SIR,—As a result of a case of accidental stabbing of the thigh by a thin-bladed butcher's knife, which fortunately passed by the major vessels, our attention has been drawn to two similar accidents in young persons which were fatal before any surgical aid could be obtained. Questioning of the senior butchers in shops where these fatalities occurred, and in fact all the other butchers we have met in the last year, reveals a complete lack of knowledge of this injury and the first-aid measures which are necessary to prevent exsanguination. In fact a butchers' organization has been

approached with an offer of instruction on these first-aid measures and so far no interest has been aroused.

Over a period of years we have heard of colleagues dealing with such accidents, often without being able to save life, and it appears that, while the Registrar-General can give no figures for this particular injury, a considerable number of deaths must occur yearly throughout the country. I would be grateful if any of your readers who have operated upon this type of accident could give me details so that a better picture of the frequency of the injury can be built up. Any communication will be promptly acknowledged.—I am, etc.,

Royal Infirmary,
Dundee.

J. R. S. PATERSON.

British Epilepsy Association

SIR,—Every consultant from time to time sees patients privately from whom, for various reasons, he would rather not accept a fee. These include doctors and their families, personal friends, and many others. In these circumstances at least one London consultant transfers the fee to the British Epilepsy Association, a lay organization which, as many of your readers know, is devoted to the welfare of epileptics throughout the country. Being entirely without State grants it is sorely in need of friends, and we therefore through your columns seek to draw the attention of other consultants to this practical way of disposing of fees they would rather not accept.

The General Secretary, British Epilepsy Association, 27, Nassau Street, London, W.1, would be glad to supply information about their work to anyone interested.—We are, etc.,

CYNTHIA COLVILLE,
Chairman, Executive Committee.
DENIS HILL,
Chairman, Medical Committee,
British Epilepsy Association.

London, W.1.

POINTS FROM LETTERS

Advertising Literature

Dr. W. S. SYKES (Morley, Yorks) writes: I recently kept all the drug advertising literature for a period of three months, instead of resorting to the usual practice of putting it straight into the waste-paper basket. There were 255 items, with a total weight of 14 lb. 14 oz. (6.8 kg.). The cost of postage was £2 2s. 6d. This was before the recent rise in postage rates. . . . If businessmen were not so unbusinesslike one would think it was worth their while to find out what the recipients think of this flood of wasteful shiny, expensive literature. Much of it is stupid, some of it infantile. Even the better ones can be intensely irritating because of the unintelligent lack of thought in their compilation and their complete disregard for the convenience of the recipients.

Appendicectomy

Dr. H. E. NEWMAN (Bournemouth) writes: Having had the pleasure of Dr. Leon M. Shirlaw's acquaintance, and knowing the high standard of his qualifications, I regret that I must find fault with his complaint of the word "appendicectomy" (*Journal*, November 9, p. 1117). I agree that the strictly correct term should be appendicectomy, but presumably the "c" replaces the "x" for phonetic reasons only. "Ectomy" means cutting out, and to say that the "append" had been cut out would have no meaning, surely.

Psychopaths

Dr. J. B. GURNEY SMITH (Redhill, Surrey) writes: Apropos the letter by Dr. G. C. F. Roe on this subject (*Journal*, November 9, p. 1112), I feel there is a great need for terminology in mental illnesses to be simplified and standardized. . . . Just as nowadays no one would dream of using dementia praecox when schizophrenia is implied, so I feel that dementia *per se* could usefully be supplanted by the more colourful word psycholysis, which does convey the idea of a breakdown of mental processes in a way that the term dementia does not do.

Vive le Sport

Dr. J. L. BLONSTEIN (London, S.W.11) writes: May I reiterate the experience of Dr. H. H. Slack (*Journal*, November 9, p. 1117)? Last night Chelsea were playing the Soviet Army at Stamford Bridge (also televised). Result—completely empty waiting-room; two doctors reading evening paper. The "flu" epidemic miraculously mastered.

Obituary

HELEN BOYLE, M.D.

Dr. Helen Boyle died at her home at Pyecombe, Sussex, on November 20, aged 88. A former president of the Royal Medico-Psychological Association, she was honorary psychiatrist to the Lady Chichester Hospital, Hove.

Born in Dublin on November 19, 1869, and brought up on the rugged headland which forms the northern arm of Dublin Bay, Alice Helen Anne Boyle spent the first 13 years of her life against the warmth of an Irish background. In her early teens she lived on the Continent with her mother, brother, and sister, receiving part of her education in France and Germany.

Soon after the family's return to England she began her medical training at the London (Royal Free Hospital) School of Medicine for Women, taking the Scottish triple qualification in 1893. Owing to adverse family fortune she took the Brussels M.D. (with distinction) the following year, because "it was the cheapest available."

Financial independence being a pressing necessity, she started her medical career as an assistant medical officer at the L.C.C. mental hospital at Claybury, the late Sir Robert Armstrong-Jones being at that time the medical superintendent. He became and remained till his death in 1943 her firm friend and an admirer of her work. While at Claybury she collaborated in some of the late Sir Frederick Mott's early work in psychopathology, and she was also the first psychiatrist to identify, establish, and isolate bacillary dysentery as an infective condition among mental patients. Experience in her early appointments influenced the whole of Helen Boyle's life and medical work. In the East End of London (she worked for a time as medical superintendent of the Canning Town medical mission) she saw how many patients arrived at last at the mental hospital because there were no means of providing the needed rest and relief from an environment which had become intolerable.

In the last years of the nineteenth century, with Dr. Mabel Jones as partner, Dr. Boyle set up in general practice at Hove, in Sussex. They were the first women doctors in the district, and, though they met with much friendliness, there was at first some hostility from their colleagues. Owing to the prejudice against women doctors it was impossible for them to become members of the honorary staff of local hospitals, but, nothing daunted, Dr. Boyle started a dispensary for women and children in Brighton. A few beds were attached for the treatment of in-patients, and from this humble beginning the Lady Chichester Hospital for the treatment of early nervous disorders was started in 1900 on, in Dr. Boyle's own words, "£200 and faith." The hospital had its medical and surgical sides, but in 1912 these became a separate institution, the New Sussex Hospital for Women and Children, and the Lady Chichester Hospital remained as a special hospital for the treatment of functional nervous disorders in women and children. A men's department was added in 1931, when the hospital was affiliated with the Royal Sussex County Hospital, and Dr. Boyle became the first psychiatrist to the department for nervous disorders in that hospital. She was able to take part in the Jubilee celebrations of the Lady Chichester Hospital in 1955, when the spring meeting of the Royal Medico-Psychological Association took place at Hove in her honour.

During the first world war she went, in 1915, to Serbia, where she served with the late Sir James and Lady Berry. For this work she had conferred on her the Order of St. Sava. She was a founder member of the Medical Women's Federation. It was while she was president of the London Medical Women's Association that steps were taken which led, with the help of the late Dr. Jane Walker, to the founding of the Federation.

Dr. Boyle's reputation as a pioneer in the modern scientific treatment of functional nervous disorders was not confined to this country; her name is honoured both on the European continent and in America. In 1920 she went to North America, at the request of several societies in Canada and the United States, to speak about her work and to see the latest developments in psychological medicine in those countries. On her return she succeeded in obtaining the support of the late Sir Maurice Craig and with him founded the National Council for Mental Hygiene in 1923, she herself personally paying the office rent for the first three years. The purpose of the council was to improve the mental health of the community and to co-ordinate all societies, associations, and other bodies concerned with mental hygiene in this country. Linking the council with similar bodies in other countries was the International Committee for Mental Hygiene, subsequently the World Federation for Mental Health; in 1953 Dr. Boyle received an invitation to become a member of the Comité d'Honneur of this body from its annual meeting in Vienna. At the annual general meeting of the International Committee in 1937 the late Mr. Clifford Beers (the founder and secretary of the National Committee for Mental Hygiene in the United States, and the founder of the international movement) spoke in glowing terms of the inspiration that Dr. Boyle had been to him and of the debt the movement owed to her. When the Royal Commission on Lunacy and Mental Disorders sat, before the passing of the Mental Treatment Act of 1930, Dr. Boyle gave evidence before it, both in her personal capacity and as a representative of the Lady Chichester Hospital. She was a founder member and vice-president of the National Association for Mental Health, the successor of the National Council for Mental Hygiene.

Dr. Boyle was a member of the British Medical Association for 63 years, and she was three times vice-president of a section at Annual Meetings—of the Section of Neurology and Psychological Medicine in 1913 (Brighton); the Section of Neurology and Psychiatry in 1921 (Newcastle upon Tyne); and the Section of Mental Disorder at the Centenary Meeting in 1932. She was chairman of the Brighton Division of the Association in 1924-5, and a member of the B.M.A. committee on lunacy law and mental disorder in 1929-30; of the conference with representatives of the Royal Medico-Psychological Association on the organization of a mental health service in 1935-6; and of the committee on mental health in 1938-40. She was the first woman to be president of the Brighton and Sussex Medico-Chirurgical Society and the first woman to be elected a member of the honorary medical staff of the Royal Sussex County Hospital, of which she became honorary consultant for nervous disorders.

The first woman president of the Royal Medico-Psychological Association (for the year 1939-40), she was elected an honorary member of the association, which she joined in 1898, for her services to it and to psychiatry. She served on the Feversham Committee on the voluntary mental health services, 1936-9, and was a member of its working subcommittee, and, at the request of the late Archbishop Temple, was one of the original members of the Churches' Council for Healing and served on its working committee.

Her career was marked by pioneer work and by long public service in the care and treatment of mental and nervous diseases from the time when the medical and psychological treatment of functional nervous disorders was almost unknown. To-day the medical profession recognizes such treatment not only as a legitimate but as a vitally important part of medicine, and the great progress made in this direc-

tion in the past 50 years must be largely attributed to Helen Boyle's labours.—C. L. H.

Dr. DORIS ODLUM writes: The death of Dr. Helen Boyle has left a sad gap in the ranks of the pioneers of mental medicine. Only those who had the privilege of knowing her and of working with her intimately can fully appreciate her greatness.

She had outstanding qualities both of mind and character. Her heart was deeply compassionate, and it was for this reason that very early in her career she became interested in the almost unknown subject of mental illness and the treatment of sufferers from all kinds of nervous and mental disorder. Over fifty years ago she started the Lady Chichester Hospital at Hove for the early and preventive treatment of nervous and mental disorders. This was the first voluntary hospital of its kind in this country, and, so far as is ascertainable, in the world. For many years she trod the lonely path of the pioneer whose vision is ahead of the times, but the first world war proved that she was right. Such large numbers of soldiers broke down with various kinds of mental and emotional illness that the vital importance of the problem was forcibly brought home to the heads of the fighting Services, the politicians, and the community generally. She became an outstanding international figure in mental health, and had been intimately concerned with every activity in this field during the whole of this century. She practised as a psychiatrist in Brighton and Hove for nearly fifty years and had her own nursing-home.

Dr. Boyle had a strong religious faith and was a founder member of the Churches' Council of Healing. She never found any difficulty in reconciling psychiatry and religion and believed that man was essentially a spiritual being. Her private and personal life was as rich and varied as her public career. Her home was an open house for her many friends and relations, and it was a delight to visit her. Her Irish charm, wit, and gaiety enchanted all who had the privilege of her personal friendship. One of her most lovable characteristics was the interest she took in helping her younger women colleagues. I shall never forget all that I owe to her inspired teaching, her wise council, and the way in which she helped me to start my career in psychological medicine.

Of her it may well be said that her monument is not in brass or the ephemeral glory of public honours, but in the hearts and minds of the many thousands whom she has helped and encouraged. Her spirit and the great movement that she did so much to initiate and inspire will live.

Dr. L. A. PARRY writes: I have known the late Dr. Helen Boyle for over fifty years and can claim an intimate and very happy friendship with her during that period. For some years she had consulting-rooms at my house in the Drive at Hove. Others have written of her pioneer efforts in the treatment of early nervous disease. I also can, of first-hand knowledge, speak of the fine work she initiated and assisted in for so many years. During my days in practice I was a frequent visitor at the Lady Chichester Hospital, which she founded. She was admired and loved by patients and staff. Her life showed so plainly how selfless she was: she lived for others. But she also enjoyed to the full her own life. She was a regular attendant at medical meetings, and seldom missed any of the social functions arranged by the various societies to which she belonged. And how she enjoyed them. She threw herself wholeheartedly into all that went on. Her lavish hospitality was a great feature of her life. How many times I have attended her New Year parties, where she delighted to entertain so joyfully a crowded house of the friends and colleagues she loved, and who loved her. To the last she was full of activity. Quite recently I met her at a special function of the Brighton and Sussex Medico-Chirurgical Society given to celebrate its thousandth meeting. She had been its distinguished president, the first woman to hold that post. My mind was turned back many years to the controversy which raged when I proposed her as the first woman member of the

society. The great Brighton doctors (and there were many celebrated ones then, as now) would have none of it. I always have a feeling of satisfaction when I think that we young doctors (I was then in that category) carried the day. Well, she has passed on. All of us, colleagues, patients, and friends, pay loving and respectful tribute to a great lady, a great colleague, and a great friend.

W. HEDLEY SUMMERSKILL, M.B., B.S., D.O.

Dr. Hedley Summerskill, consultant ophthalmic surgeon to the Portsmouth Group of Hospitals, died at Portsmouth on November 13 after a long illness.

William Hedley Summerskill was born in 1898. His medical training at Guy's Hospital was interrupted by a period of service as a probationary sub-lieutenant in the first world war, during which he served mostly in destroyers in the North Sea. He returned to Guy's after the war, and qualified L.M.S.S.A. in 1920. He was in general practice in London until 1931, when he was able to turn to the study of his future specialty of ophthalmology. He was an undergraduate at Exeter College, Oxford, for a time, and held

an appointment at the Oxford Eye Hospital, gaining the Diploma in Ophthalmology of the university in 1933. He then returned to London, where he was appointed clinical assistant to the Royal Eye Hospital, and graduated M.B., B.S. from London University in 1935. He served in the Merchant Navy as principal medical officer in several troopships during the early part of the second world war, and was eventually invalided.

In 1943 Summerskill settled in practice at Portsmouth, and was appointed temporary ophthalmic surgeon to the Portsmouth and Southern Counties Eye and Ear Hospital. He also held appointments at the Queen Alexandra Ministry of Pensions Hospital and at St. Mary's Hospital, Portsmouth. For a time he was temporary ophthalmic surgeon to the Royal West Sussex Hospital, Chichester, and in 1946 he was appointed ophthalmic surgeon to the Portsmouth Eye and Ear Hospital. His numerous hospital appointments were consolidated in 1948 into that of ophthalmic surgeon to the Portsmouth Group of Hospitals.

N.C. writes: The last ten years of Dr. Hedley Summerskill's active practice were marked by a succession of important contributions to ophthalmology, including the introduction of a new surgical method for dacryocystorhinostomy, and a rehabilitation of the Mules's operation of scleral implant after visceration. These achievements were recognized by the award to him of a Nathaniel Bishop Harman Prize in 1948, and the Treacher Collins Prize in 1957, by his contribution to the *British Encyclopaedia of Medical Practice* in 1952, and by an invitation to lecture in the United States in 1956. He was president of the Southern Ophthalmological Society in 1955-6.

Summerskill was one of a medical family. Himself the son of a doctor, he had two sisters, one of whom is a doctor and one of whom married a doctor, and all three have children in medicine. As a medical student he boxed for Guy's, but his chief interests in later life were sailing (he was chairman of the Royal Albert Yacht Club in 1952 and 1953), and collecting old medical books. His period of general practice saw his sole incursion into politics, when he stood, unsuccessfully, as Liberal candidate for Balham and Tooting in 1929. Summerskill was a man of great charm, behind which lay a shrewd and sincere mind. He was an easy colleague, and was much beloved by the many

generations of patients who passed through his hands. His wise counsel will be sadly missed by all with whom he came in contact, and our deepest sympathy goes out to his widow and his son, Dr. W. H. J. Summerskill, and daughter.

H. H. A. EMERSON, C.B., D.S.O., M.B., B.Ch.

Major-General H. H. A. Emerson, formerly Director of Hygiene at the War Office, died on November 17. He was 76 years of age.

Henry Horace Andrews Emerson was born on September 14, 1881, and was educated at Rathmines School, Dublin, where he became captain of the school, and at Trinity College, Dublin, where he was captain of the university boat club. He gained the Dr. Henry Hutchinson Stewart Scholarship in anatomy and physiology, and went on to graduate M.B., B.Ch. in 1905. He then entered the R.A.M.C. During the first world war he served in France and Flanders and was awarded the D.S.O. in 1917 and the Croix de Guerre in 1918; he was three times mentioned in dispatches. With the rank of brevet lieutenant-colonel he went to India in 1928, and became deputy director of Hygiene and Pathology at Army Headquarters. Promoted lieutenant-colonel in 1929, he became colonel in 1934, and major-general in 1937. From 1935 to 1939 he was director of hygiene at the War Office, and from 1937 to 1939 Honorary Surgeon to the King. He retired from the Army early in 1939, the year in which he was appointed C.B., but was re-employed for a time during the second world war. He married Miss Lillie H. Godfrey, of Courtrai, Belgium, and had one son and one daughter. Mrs. Emerson died in 1952.

Sir GORDON GORDON-TAYLOR writes: The obituary notice of Major-General H. H. A. Emerson which appeared in *The Times* of November 20 brought back to my memory my own attachment as an operating surgeon to the casualty clearing station (No. 44) which he commanded during the period of the third battle of Ypres in the 1914-18 war. I doubt if there was a happier or more efficient C.C.S. on the whole of the British front: it was certainly the best C.C.S. that I worked in, and I well remember that after the Canadians took Paschendaele and I received orders to report to another C.C.S. for the first battle of Cambrai I expressed bitter regrets to Sir Anthony Bowlby on my transference from 44 C.C.S., its commanding officer, and the goodly company of surgeons who had been my colleagues in this "forward" unit in the salient dealing with abdominal and thoracic wounded and gunshot fractures of the femur. That surgical group included Major-General D. C. Monro, C.B., C.B.E.; the late I. I. M. Shaw, of Edinburgh; the late C. H. Fagge, of Guy's; the late Lionel Colledge; the late Adrian Stokes; the distinguished pathologist, Alan Curry, of Halifax, Nova Scotia; A. J. Blaxland, of Norwich; Gerald S. Hughes, of York; Percy Chissell, of Ceylon; and William Moodie, who has distinguished himself in mental medicine. These would all have subscribed to this tribute to Emerson's ability and to his unvarying courtesy towards the temporary R.A.M.C. officers who worked in his unit.

JOHN MCGARRITY, M.D., D.P.H.

Dr. John McGarrity, who was medical superintendent of Little Bromwich Hospital for Infectious Diseases, Birmingham, for nineteen years before retiring six years ago, died at his home in Edinburgh on November 12.

John McGarrity was born in the village of Leadhills in Lanarkshire, the son of the Rev. J. McGarrity. He was educated at George Watson's College and Edinburgh University, where he graduated M.B., Ch.B. in 1915. After holding the post of resident physician in Edinburgh Royal Infirmary he joined the R.A.M.C., and served in India and Egypt during the first world war. On demobilization he held further resident posts in the Sick Children's Hospital,

Chalmers Hospital, and the City Hospital for Infectious Diseases, Edinburgh, where he became senior assistant to the late C. B. Ker, whose teachings he frequently quoted. During this period he obtained the D.P.H. of the Scottish Conjoint Board in 1922, and proceeded to the M.D., for which he was highly commended, in 1924. In the latter year he was appointed medical superintendent of the City Isolation Hospital, Cardiff, and lecturer in infectious diseases in the University of Wales, which posts he resigned eight years later on his appointment in 1932 as medical superintendent to Little Bromwich Hospital for Infectious Diseases, Birmingham, and lecturer in infectious diseases in Birmingham University.

F. L. K. writes: On Dr. John McGarrity's appointment to Little Bromwich plans had been already prepared for further development of the hospital. While these were being carried out he pressed the need for cubicle accommodation, and spent much time in the planning of this, being particularly interested in the problems of preventing cross-infection. His efforts were successful, and three new blocks of 48 beds each were ready for occupation just before the second world war started. On the introduction of the National Health Service he was fully occupied with the problems of the change of administration and drove himself to obtain the best that was possible for the hospital of which he was justly proud from an administration which he deplored. His health broke down as a result, and, after a very serious recurrence of an illness he had had in 1939, he was forced to retire in 1951. A frequent attendee at the meetings of the fever group of the Society of Medical Officers of Health, he served on many and varied committees, and his advice was always carefully thought out and forthright, and as a result much respected. He disliked the limelight and would never, however much he was persuaded, accept office on any committee or in any society. His contributions to the medical literature were mainly concerned with the Schick and Dick tests and diphtheria immunization, being one of the earlier diagnostician and always stressed the value of good observation in diagnosis. He examined new methods of investigation very critically before accepting them. His many residents and students look back with gratitude to his teaching. He was a member of the Ministry of Health panel for the diagnosis of smallpox, a subject in which he was an expert.

Dr. McGarrity had a great personal charm and was always ready to help all members of his staff, who readily brought him their troubles. Consequently his retirement was keenly felt by all those who worked under him. To those who had the privilege of being welcomed in his home his passing will leave a deep sense of loss of a true and valued friend. To his widow and daughter we extend our sincere sympathy.

OTTO POPPER, M.B., F.R.C.S.Ed.

The obituary of Mr. Otto Popper was printed in the *Journal* of September 14 (p. 648).

L. F. writes: Otto Popper, who died in Johannesburg on August 14, was a man of enthusiasm and activity: among his various interests was his workshop, where he invented a number of otolaryngological instruments, some of them of great efficiency and still in use. A man of warm heart and friendly manners, he was generous and straightforward in speech and action, and made friends in many walks of life and in many parts of the world. His studies had been pursued in several parts of Europe and in the United States. He remembered most happily his association with Professor Heinrich Neumann, the Vienna laryngologist. His later studies resulted in the publication of a modification of Lempert's fenestration of the labyrinth. The lecture-demonstrations he gave in the Argentine, the United States, and Europe turned out very successful and brought him much satisfaction. He leaves a widow, three daughters, and a son, to whom is offered the sympathy of a wide circle of friends.

H. F. BRIGGS, M.B., F.R.C.S.Ed.

Surgeon Captain H. F. Briggs died at Kingswood, Surrey, on October 18 after a short illness. He was 72 years of age.

Hugh Francis Briggs was born on November 18, 1884, and was educated at Dollar Academy and at Edinburgh University, where he graduated M.B., Ch.B. in 1907. Two years after graduation he entered the Royal Navy, and served until 1946. Elected F.R.C.S.Ed. in 1923, he was promoted surgeon commander in 1921 and surgeon captain in 1934. On retiring from the Royal Navy he became a member of a pensions appeal tribunal and was made chairman. He resigned from the tribunal on account of ill-health at the beginning of this year. He leaves a widow.

Medico-Legal

DOCTORS IN SLANDER SUIT

Damages of £25 and costs were awarded in the High Court on November 20 in a slander action against Dr. Octavius Cyril Carter, of Hursley, Poole Road, Bournemouth. The action was brought by Dr. Sydney James Van Pelt, practising at 126, Harley Street, London, in respect of a remark imputing to him unethical professional conduct, made at a cocktail party at a house in East Overcliffe Road, Bournemouth, on a Saturday evening towards the end of 1954. It was said that Dr. Van Pelt was not asking for exemplary damages. Any sum he was awarded would be given to charity. He had brought the action to clear his name against what he believed to be a "smear campaign" against him.

The words complained of were, "Oh, I've no time for that chap. His ethics are under discussion at Headquarters and you will probably hear more about it in the near future," or words to that effect.

Dr. Van Pelt, who qualified in Melbourne in 1933, was said to be a medical practitioner specializing in hypnotherapy, and was described as "a pioneer in modern hypnotherapy." He had founded the British Society of Medical Hypnotists, and was the founder and editor of the *British Journal of Medical Hypnotism*. In 1952 he had been consulted by the Minister of Health, the Home Office, and the National Association of Mental Health concerning the passing of the Hypnotism Bill. He was also a member of the B.M.A.

Dr. Carter was said to be a medical practitioner of considerable standing, practising in Bournemouth. In 1954 he was a member of the Journal Committee, the Family Doctor Committee, and the Private Practice Committee of the B.M.A., and also a member of the executive committee for Hampshire under the National Health Scheme. He would, it was submitted, be in a position and likely to know what was going on at B.M.A. Headquarters, and it was pointed out that at the time in question three members of the Ethical Committee were also members of one or other of committees on which Dr. Carter sat.

Dr. Arthur Shepherd gave evidence of a conversation between himself, his wife, and Dr. Van Pelt at a cocktail party, the date of which he thought was early in 1954. He said: "The subject of psychiatry, probably, or hypnotherapy came up. Dr. Van Pelt's name was mentioned, possibly by me. I have a great admiration for Dr. Van Pelt. As far as I remember, the words used were something about Dr. Carter had not much time for him. There was some murmur of something about ethics, and I think as Dr. Carter left—he left abruptly at that time—there was some little talk about we might hear something further at a later date."

As he thought it might help in some trouble Dr. Van Pelt felt he might be in with the B.M.A., he had telephoned him about the conversation, and also written to him on November 21, 1954, without mentioning Dr. Carter's name. Following the receipt by Dr. Van Pelt in May, 1955, of notification from the Ethical Committee of a complaint against him

in respect of alleged infringement of the rule of anonymity in connexion with advertising, Dr. Shepherd had written to Dr. Van Pelt on July 2, 1955, naming Dr. Carter as having spoken the words complained of. Dr. Shepherd agreed that he had changed his mind about the place where the words were said after his wife had informed him that he was wrong and had refreshed his memory. He also agreed that on meeting Dr. Carter in a Bournemouth hospital corridor in 1956 Dr. Carter had denied uttering any words defamatory of Dr. Van Pelt, and that he (Dr. Shepherd) had expressed regret that an action had been brought. He was extremely annoyed at Dr. Van Pelt taking it to heart, because it was a confidential matter.

Mrs. Betty Shepherd, giving evidence of the conversation with her husband and Dr. Van Pelt, which she put on a Saturday evening late in 1954, said: "We were discussing psychiatry and hypnotism. I believe that I said, 'Oh, we know Dr. Van Pelt,' and Dr. Carter said very hastily, 'Oh! Don't talk to me about that chap.' The next sentence I didn't catch except for one word, 'ethics,' and he murmured something about that we might hear something."

Dr. Van Pelt said that after leaving the Services in 1946 he specialized in hypnotherapy. In 1949 there had been repeated refusals to accept advertisements for the *British Journal of Medical Hypnotism* in the *British Medical Journal*, although later they had been accepted. In 1952 he and other B.M.A. members had submitted to the B.M.A. a petition for the formation of a group to study medical hypnosis. Following Dr. Shepherd's telephone conversation and letter in November, 1954, Dr. Van Pelt said he had taken no action at the time because "I just thought it was some drunken fellow at a cocktail party." On receiving the later letter, following the Ethical Committee's notification of a complaint, he had informed his solicitors and instituted proceedings.

Dr. Carter denied saying the words complained of. He said he was not antagonistic towards hypnotherapy; he was interested in it and wanted to know more about it. He had gone to the cocktail party early and remained only half an hour because his wife had just recovered from an illness; he did not want her to remain in a smoky atmosphere and thought the strain might be too much for her. He said there were no more than ten to fourteen people there while he was present. (This was confirmed by the later witnesses.) He remained in the company of his wife, Mr. and Mrs. Robert Beechey-Newman (intimate friends whom he had gone especially to see, not having seen them for some time), Colonel and Mrs. Sandall, and Mrs. Sinclair. He did not speak to Dr. and Mrs. Shepherd, except perhaps to say, "Hello." At the time he did not even know of Dr. Van Pelt. He did not agree that Dr. Van Pelt's name would have been made known to him by reason of applications by Dr. Van Pelt's journal for the insertion of advertisements in the *British Medical Journal*, which would be considered by the Journal Committee, of which he was a member, and the submission of the petition to the Council, of which he was a member. The agendas of these bodies were, he said, extremely heavy, and he produced a specimen of each in illustration of this. He denied having discussed Dr. Van Pelt at any meeting of the B.M.A.'s Ethical Committee.

Mrs. Dorothy Beechey-Newman said she remembered the cocktail party in question. Dr. and Mrs. Carter had remained in her company the whole time they were present. She did not recall having seen Dr. or Mrs. Shepherd, and was certain there was no discussion about hypnotherapy.

Colonel Thomas Sandall said Dr. Carter remained in his company at the party the whole time the doctor was there, except when the colonel left to get a drink. He had heard no discussion of hypnotherapy or hypnotism and had not heard the name of Dr. Van Pelt until recently.

Mrs. Gladys Carter, the defendant's wife, said that she had been in the company of her husband and Mrs. Beechey-Newman during the whole of their stay at the party. She did not see Dr. or Mrs. Shepherd there, and had not spoken to Mrs. Shepherd until the first day of the trial hearing. She added that the occasion of the party was the first time

she had been out for a very long time because of illness, and her husband had not left her side, as he was afraid the party might be too much for her.

Judgment

Mr. Justice Ashworth, giving judgment, said it had been admitted that if the remarks in question were made they were defamatory of the plaintiff. There were therefore only two issues before him: First, were the words spoken as alleged? Secondly, if so, what were the damages?

The judge said that, faced with a conflict of evidence between witnesses, none of whom was saying what he or she did not believe to be true, he looked for collateral evidence that would tend to support one side or the other. He found such evidence in a letter of November 21, 1954, which Dr. Shepherd wrote to Dr. Van Pelt the day after the party or thereabouts, and telephoned him, either before it was written or immediately after, in the course of which, without naming Dr. Carter, he did give the substance of the conversation and remarks which were the subject of this action. Dr. Van Pelt said that the telephone conversation did not trouble him much. He thought it was the remark of a drunken doctor at a cocktail party and didn't take any notice of it. But in May, 1955, events began to move with the B.M.A. On July 2, 1955, Dr. Shepherd wrote a letter which included a paragraph recording, though at a wrong date, the substance of the conversation of which complaint was now made, and naming Dr. Carter.

The Judge said he had come to the conclusion, not without regret, because it involved disbelieving some witnesses who were undoubtedly trying to help the court, that he did accept the evidence of Dr. and Mrs. Shepherd, and in particular he accepted the evidence of Mrs. Shepherd. She made a very favourable impression and he was not prepared to disbelieve her.

He thought that most of Mrs. Beechey-Newman's and Colonel Sandall's evidence was probably right, but, being asked to recall the party nearly three years afterwards, they had forgotten that there came a time when Dr. Carter talked to Dr. and Mrs. Shepherd, and had convinced themselves that Dr. Carter was in their company throughout his visit. He gave Mrs. Carter equal credit for her honest desire to be truthful, but she was handicapped inevitably by illness, and was obviously mistaken in saying that the Shepherds were not there at all. Dr. Carter had a handicap in the shape of deafness. The judge thought he had forgotten that in the course of that evening he spoke to the Shepherds, who perhaps diverted his attention from the rest of his little group. He believed Mrs. Shepherd when she said that hypnotherapy and psychiatry—in which Dr. Carter, on his own evidence, was interested—came up as a topic of discussion, and that he was prepared to offer them a moment or two of his short time at the party. He found, therefore, that the words were said.

DANGERS OF ARTIFICIAL RESPIRATION

At a recent inquest Professor J. M. Webster drew attention to the possible dangers of artificial respiration. A man aged 83 was seen to be lying on a garden path and help was sent for. Two firemen arrived and one of them performed artificial respiration by Schafer's method for about three minutes while the other sent for medical aid, and then between them they changed to the Schafer-Holger-Nielsen method, continuing for some minutes until the doctor arrived and certified death. At the inquest held at Birmingham before Mr. G. Billington on October 18 Professor Webster, pathologist, said that the man died from acute pulmonary oedema due to impending left-sided cardiac failure. Death was accelerated by haemorrhage from multiple fractures of the ribs and sternum, with pulmonary perforation. He did not think all the injuries were due to the fall but were probably caused by the artificial respiration. He said there was a well-recognized medical danger in compression methods of artificial respiration, particularly in old people.

The jury returned a verdict of accidental death.

Medical Notes in Parliament

General Practice Vacancies

Dr. DONALD JOHNSON (Carlisle, Con.) asked the Minister of Health on November 22 whether he was aware that many applicants, particularly those of assistant status, were dissatisfied with the present methods of selection exercised by executive councils in the filling of general practice vacancies; and, in view of the fact that the number of applicants for such vacancies was considerably in excess of the available vacancies, if he would instruct executive councils to have scrupulous regard to procedures of selection, so that all applicants were satisfied that they had had a fair chance of selection. Mr. D. WALKER-SMITH stated that the selection of candidates for advertised vacancies was the responsibility of the Medical Practices Committee. The committee was constantly in touch with executive councils, who usually made the preliminary selection and who were well aware that their procedure must satisfy the committee. Any applicant for an advertised vacancy, whether assistant or principal, could appeal to him against the decision of the Medical Practices Committee. The appeals he received suggested that appellants were usually dissatisfied not with the procedure of selection but rather with the fact that they themselves were not chosen.

Dr. JOHNSON asked for details about the numbers of general practice vacancies filled by executive councils during 1955 and 1956. Mr. WALKER-SMITH gave him these figures for single-handed practices declared vacant by executive councils in England and Wales:

	1955	1956
No. of vacancies	114	114
No. filled by principals	34	26
No. filled by principals in same executive council area	21	15
No. filled by assistants in same executive council area	16	14

Tuberculosis in School Meals Service

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked the Minister of Education on November 21 what instructions he had given to local education authorities as to the examination for active pulmonary tuberculosis of those engaged in the preparation and serving of school meals. Mr. GEOFFREY LLOYD told him that Circular 248 dealt with this subject. Mr. HASTINGS drew attention to a case in Clitheroe, in which a domestic worker in the school meals service suffering from active tuberculosis had apparently caused this disease in 13 schoolchildren, and possibly in 30. He asked that special care should be taken to see that those engaged in the preparation of school meals were healthy people. Mr. LLOYD immediately agreed to examine the matter further, and said he would be grateful for details. He would look again at the circular, in the light of a report from the standing advisory committee on tuberculosis of the Central Health Services Council which had just been received. Dr. EDITH SUMMERSKILL (Warrington, Lab.) asked for an undertaking that, in view of the vulnerability of schoolchildren, those who were engaged in handling school meals would be examined. Mr. LLOYD said he would not like to do that without consultations, but he saw the importance of the suggestion and would examine it carefully.

Pilot Scheme for Forces Proposed

Mr. SOMERVILLE HASTINGS asked the Minister of Labour on November 20 whether he would introduce a pilot scheme by which all recruits for the Services who were willing were subjected to tuberculin tests, and negative reactors urged to accept B.C.G. vaccination before entering the Services. Mr. IAIN MACLEOD said, "No." Suitable facilities were already available to men in the armed Forces for tuberculin tests and B.C.G. vaccination. Mr. HASTINGS asked if it would be worth while to press strongly for a pilot scheme. Tuberculosis contracted in the Forces represented a heavy loss in both manpower and finance. Mr. MACLEOD thought

it would not be practicable to bring this in at an earlier stage than that of the medical boards, because they were brought together for a special purpose, and could not do the ordinary follow-up after 72 hours, and so on, that would be necessary.

Bill to Register Opticians

A Bill to provide for the registration of opticians and the enrolment of bodies corporate carrying on business as opticians, to regulate the practice of opticians and the conduct by such bodies corporate of their business as opticians, and for connected purposes, was presented by Mr. R. RUSSELL (Wembley, South, Con.) on November 20. It is a Private Member's Bill, and, as the third Bill for second reading on December 6, has a sporting chance of further progress.

Prepacked Medicines

In reply to Mr. ERIC JOHNSON (Manchester, Blackley, Con.), who suggested on November 21 that the Pharmacy Acts should be amended so that the attendance of a qualified pharmacist would not be necessary for the retail of a prepacked advertised patent medicine containing a trivial amount of a scheduled poison, the HOME SECRETARY said that it would not be practicable or desirable to depart from the established practice. By this practice exemptions from the law relating to the retail sale of poisons were confined to specified poisons contained in specified substances or preparations. Mr. JOHNSON accepted the need for caution, but thought that to require the presence of a qualified pharmacist for the sale of something like "veganin" was ultra-cautious. Mr. BUTLER preferred to rely on what might be done under the powers to make exceptions in the 1933 Pharmacy and Poisons Act, and the Third Schedule to the Poisons Rules.

Fluoridation of Water Supplies

Captain R. PILKINGTON (Poole, Con.) asked the Minister of Health on November 25 how far it was intended to extend the experiments of fluoride in drinking-water. Mr. WALKER-SMITH stated that no further demonstrations on the lines of those now proceeding were contemplated, but the Secretary of State for Scotland and he would in due course consider what arrangements were desirable for extending fluoridation to other areas where the water was deficient in fluoride.

Coastal Sewage

Dr. REGINALD BENNETT (Gosport and Fareham, Con.) asked the Minister what positive evidence he had that the live poliomyelitis virus discharged into the sewers from infected persons was incapable of spreading the disease among swimmers who bathed at an outlet of untreated sewage. Mr. WALKER-SMITH said he had none, but, while the possibility that sewage might play some part in the spread of poliomyelitis could not be ruled out, there was no evidence that the disease had been contracted from this source.

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked what official researches had been carried out to determine the treatment necessary to render sewage incapable of the conveyance of infectious diseases before discharge into the sea; and how long this treatment took. Mr. HENRY BROOKE, Minister of Housing and Local Government, told him that on the information at present available he did not think that the situation called for research on the lines suggested.

Fees for Death Certificates

Mr. DENIS HOWELL (Birmingham, All Saints, Lab.) asked the Home Secretary whether he was aware of the practice in hospitals whereby doctors were increasing the charge of a second death certificate necessary for the purposes of cremation from two guineas to four guineas, and the proposal of one hospital in the Midlands to increase the fee to six guineas; and if he would stop this unreasonable increase. Mr. R. A. BUTLER asked him for the information on which the question was based, and said he would be glad to look into it.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending November 9 (No. 45) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of *deaths* and *births* are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1957					1956

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
§ Includes puerperal pyrexia.

Vital Statistics

Influenza

The numbers of deaths from influenza continued to fall in most parts of the country, but a seasonal rise in the deaths from pneumonia was recorded. In the week ending November 16 deaths from influenza reported from the great towns were as follows, with the figures for the previous week in parentheses: England and Wales 102 (149), Scotland 13 (13), Northern Ireland 3 (5), and Eire 14 (10). For the first time for several weeks no town had 10 or more deaths from influenza; the following figures were recorded: London 7, Lancaster 7, Edinburgh 4, Glasgow 3, Belfast 1, and Dublin 8. The total of weekly National Insurance claims in England, Wales, and Scotland again fell from about 222,000 to about 189,000 in the week ending November 12. The latter figure compares with about 159,000 in the corresponding week last year.

The accompanying graph shows numbers of deaths in the 160 great towns in England and Wales from early September to the latest date for which figures are available.

The maps opposite show the numbers of deaths from influenza plus pneumonia as a percentage of the total deaths. These are deaths reported from the great towns for the latest two weeks for which figures are available.

The following table shows the age distribution of deaths from influenza in the 160 great towns of England and Wales.

Week Ending	0-	1-	15-	25-	45-	65+
Sept. 14	1	9	3	4	14	16

Total: Deaths 29, 167, 141, 299, 975, 1,382
% 1, 6, 5, 10, 33, 46

Week Ending November 16

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 550, whooping-cough 472, diphtheria 5, measles 1,695, acute pneumonia 623, acute poliomyelitis 68, dysentery 278, paratyphoid fever 15, typhoid fever 4.

Infectious Diseases

The largest variations in the trends of infectious diseases in England and Wales during the week ending November 9 were decreases of 701 for acute pneumonia, from 1,443 to 742, 66 for dysentery, from 282 to 216, 60 for measles, from 1,736 to 1,676, and 48 for food-poisoning, from 174 to 126; the only increase of any size was 30 for whooping-cough, from 401 to 431.

The largest falls in the incidence of measles were 58 in Kent, from 132 to 74, and 33 in Cheshire, from 65 to 32;

the largest rise was 33 in Southampton, from 45 to 78. Only small variations were recorded in the local trends of whooping-cough. The number of notifications of scarlet fever was 444, the same as in the preceding week, and the largest fluctuation was a rise of 25 in Yorkshire West Riding, from 37 to 62. 4 cases of diphtheria were notified, 1 fewer than in the preceding week. The notification of diphtheria in Cambridgeshire was the first for two years. The incidence

of acute pneumonia fell throughout the country; the largest fall was 81 in Surrey, from 106 to 25.

Four of the 8 cases of typhoid fever were notified in Durham, Bishop Auckland U.D.

The notifications of acute poliomyelitis numbered 61, and these were 2 fewer for paralytic and 3 more for non-paralytic cases than in the preceding week. The largest returns were Kent 9 (Canterbury C.B. 3, Ramsgate M.B. 3), Lancashire 5 (St. Helens C.B. 2, Ormskirk U.D. 2), and Leicestershire 5.

The largest centres of dysentery were Yorkshire West Riding 55 (Huddersfield C.B. 17), Lancashire 28 (Liverpool C.B. 16), London 28, and Durham 26 (Sunderland C.B. 10).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1948-56 are shown thus - - - -, the figures for 1957 thus ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Deaths from influenza plus pneumonia as percentage of deaths from all causes in week ending November 9.

Deaths from influenza plus pneumonia as percentage of deaths from all causes in week ending November 16.

Survival from Cancer

Data for England and Wales obtained in 1945-52 from the National Cancer Registration scheme were published last week by the Registrar-General.¹ Survival rates for cancer at eight sites are tabulated, and the five-year survival rates are given in the following table:

Site	Early Cases Radically Treated %	All Cases %
Female breast	67	37
Cervix uteri	50	35
Prostate	45	24
Stomach	28	5
Intestine	45	17
Rectum	47	18
Lung	14	2
Skin epithelioma	87	78

An analysis of cases of cancer of the female breast showed that a few survived for five years even though they received no treatment. In one case metastases were present when the case was registered; the patient was a woman aged between 75 and 79.

¹ Registrar-General, *Statistical Review of England and Wales for the Year 1952, Supplement on Cancer*. H.M.S.O. 8s. 6d.

Medical News

Television and Medicine.—On November 19 a large team from Guy's Hospital and Medical School gave a comprehensive demonstration in London of the possibilities of colour television in medical teaching. Deliberately chosen to illustrate the medium's versatility, the sixteen demonstrations ranged from experiments illustrating the principles of optical interference (department of physics) and the effect of drugs on the pupil (departments of medicine and pharmacology), to clinical demonstrations of the signs of aortic incompetence (department of medicine) and the function of the long arch of the foot (department of orthopaedic surgery), technical procedures such as the technique of intravenous injection (department of anaesthetics) and the treatment of hirsuties by electrolysis (department of physiotherapy), and a playlet illustrating what a doctor should do when confronted unexpectedly with a corpse (department of forensic medicine). Operative procedures were omitted, as this use of colour television is now fairly familiar. The British Broadcasting Corporation provided the colour television equipment (made in Britain by the Marconi Wireless and Telegraph Company), technical assistance, studio space at Alexandra Palace, and the viewing room in London. The demonstration was arranged and rehearsed by Professor ROGER WARWICK, professor of anatomy at Guy's, with Mr. C. E. ENGEL, of the Guy's department of medical illustration. The demonstrators were members of the various teaching departments. Besides showing the excellent colour rendering of the British equipment, the demonstration made it clear that the many uses for television in a medical school

might well offset the high capital cost of its installation. Another use of the Marconi equipment, recently announced, is for monitoring patients receiving radiotherapy in the telecaesium unit at the Royal Marsden Hospital. Smith Kline and French Laboratories Ltd. also announce that they are replacing the American-made mobile colour television unit which they used this year at the B.M.A. meeting and elsewhere by British equipment.

Rockefeller Grants.—In the third quarter of 1957 major grants were made to the M.R.C. biophysics research unit at King's College, London (£121,000 over three years), and to the department of zoology at Edinburgh (\$25,000 over three years) where research is proceeding on the mechanism of cell division, the functions of cell membrane, and the changes in a cell's immunological properties during its mitotic cycle. At the biophysics research unit, under Professor J. T. RANDALL, F.R.S., x-ray diffraction techniques are being used to study the structure of deoxyribonucleic acid, collagen, and smooth muscle. Among the other grants is one of 14,500 rupees (\$3,160) to the Christian Medical College, Vellore, India, for continuation of their work on a hospital records system; in addition five of the College's staff are given grants to enable them to visit the United States for study. The total grants during the quarter for medical education and public health were over \$300,000, and for biological and medical research \$350,000.

Fulbright Travel Grants (1958-9).—The United States Educational Commission in the United Kingdom announces that, under the provisions of the Fulbright programme, travel grants are available to citizens of the United Kingdom and dependent territories to go to the United States of America for academic or educational purposes, such as study, research, or lecturing. All awards are competitive and are made by the Board of Foreign Scholarships in Washington upon the recommendations of the Commission. Details of the conditions governing the award of these grants may be obtained from the Commission (71, South Audley Street, London, W.1). The closing date for those travelling between June 1 and August 15, 1958, is March 15, 1958; for those travelling between August 16, 1958, and April 1, 1959, the closing date is June 1, 1958.

Hypogammaglobulinaemia.—The Medical Research Council has issued the following statement: "In view of the increasing interest in this comparatively rare clinical condition, arrangements have been made by the Ministry of Health, in consultation with the Medical Research Council, to set aside limited supplies of gamma globulin for the treatment of suitable cases. With this in view a working party of the Medical Research Council has been set up to advise on the allocation of this material and to organize a co-ordinated clinical trial to assess the efficacy of this form of treatment. Medical practitioners with patients in whom a diagnosis of hypogammaglobulinaemia has been made are invited to get into touch with Dr. P. O. WILLIAMS, secretary of the working party on hypogammaglobulinaemia, 38, Old Queen Street, London, S.W.1."

Domville Memorial Gift.—Applications for the Domville memorial gift (£8 per annum for three years) should be submitted by December 16 to the hon. secretary of the fund, R.N. Hospital, Haslar, Gosport, Hants, from whom full details may be obtained. The gift is for necessitous orphans of Naval medical officers.

Otorhinolaryngologists' Dinner.—The joint annual dinner of the medical staff of the Royal National Throat, Nose and Ear Hospital and the academic board of the Institute of Laryngology and Otology was held in the hall of the Royal College of Surgeons on November 22. Dr. STEPHEN COFFIN presided. The toast of the guests was proposed by the CHAIRMAN, and Miss JOSEPHINE COLLIER responded. Lieutenant-General Sir ALEXANDER DRUMMOND proposed the health of the hospital and institute, for whom Mr. ERNEST E. TAYLOR, chairman of the board of governors, replied. Mr. J. C. HOGG proposed the toast of the chairman.

Orbitrons and a Theratron for Cobalt Therapy.—Illustrated below is one of two Metropolitan-Vickers orbitrons for radiotherapy with cobalt-60. One of these instruments has been on show in London this week at the congress of the British Institute of Radiology and is destined for a hospital in Ravenna; the other was recently installed at the South Wales Radiotherapy Centre, Whitechurch Hospital, Cardiff, where it is undergoing its trials. The design of the orbitron is the result of collaboration between the staff of the South Wales Radiotherapy Service and the engineers. Essentially

the instrument consists of a protective container to house the radioactive cobalt and confine its radiation to a single beam, a rotating annulus to which the container is attached, and a mobile treatment table. The cobalt source (up to 2,000 curies) is transferred to its "treatment position" in the annulus by motor, and the annulus itself can then be made to rotate round the patient on the table at speeds varying from one to one-eighth revolution per minute. This motor-driven radial movement is stated to be particularly useful for stationary field treatment. At the Westminster Hospital earlier this month (November 4) the Lord Chancellor, Viscount KILMUIR, commemorated Mr. MICHAEL WIX's recent gift of a theratron cobalt unit to the hospital by unveiling a plaque and opening a new physiotherapy outpatient department there, built partly from Mr. Wix's gift. After the chairman of the board of governors, LORD NATHAN, had received the Lord Chancellor, Sir STANFORD CADE described the work of the radiotherapy department and thanked Mr. and Mrs. Wix for their munificent gift. The LORD CHANCELLOR described their gift as personifying the use of atomic energy for peaceful purposes.

Ban on Windscale Milk Lifted.—On the advice of the Medical Research Council, the MINISTER OF AGRICULTURE, FISHERIES AND FOOD lifted the ban on milk distribution from the restricted area of Cumberland on November 23 (see *Journal*, November 9, p. 1127). Radioactivity in the milk was stated to have fallen to very low levels.

Alleged Misuse of Sex Hormones.—The November 16 issue of the *Pharmaceutical Journal* contains the following notice by the council of the Pharmaceutical Society:

"The council are deeply concerned about reported cases of the misuse by self-medication of stilboestrol by persons who have not sought medical advice. It will be remembered that the council issued a statement on the misuse of sex hormones, which was published in the *Pharmaceutical Journal* of April 16, 1955. In that statement the council advised pharmacists not to supply sex hormones or their preparations unless satisfied that the customer was obtaining them on medical advice, though not necessarily on prescription. From recent information received by the council it would appear that misuse of stilboestrol continues to occur, and the council again urges pharmacists not to supply stilboestrol or any other sex hormones or their preparations, unless they are satisfied that the purchaser is taking the drug under medical supervision."

R.A.F. Medical and Dental Branches Dinner.—The 27th annual dinner was held at the Royal College of Surgeons on November 15. Among the guests was the Chief of the Air Staff, Air Chief Marshal Sir DERMOT BOYLE. The Director-General of R.A.F. Medical Services, Air Marshal P. B. LEE POTTER, outlined the future of the branch in the reorganized Service. The toast of "The Guests" was proposed by Wing Commander R. MORTIMER, and Dr. E. R. BOLAND, dean of Guy's Hospital Medical and Dental School, replied.

B.M.A. Film Library.—A copy of the following film has been presented to the library by its sponsors, William S. Merrell and Co., of New York: "The Doctor Defendant," 16 mm., black-and-white, sound, running time about half an hour. The film was made in co-operation with the American Medical Association and the American Bar Association by Medical Dynamics Inc. Requests for this and other films from the film library should be addressed to the Secretary of the B.M.A.

Scottish Report on Mentally Handicapped.—The Department of Health for Scotland has now made available as a pamphlet the report on "The Welfare Needs of Mentally Handicapped Persons" prepared by a committee of the Scottish Advisory Council on the Welfare of Handicapped Persons (H.M.S.O., price 1s. 3d. net). The report was previously available only in duplicated form to local authorities and voluntary bodies. The report discusses the statutory provisions affecting mental defectives and the mentally ill; their education, training, employment, and accommodation; and the liaison arrangements between official and voluntary organizations concerned with their care.

Sir Geoffrey Keynes unveiled Sir Jacob Epstein's bust of William Blake in Poets' Corner, Westminster Abbey, on November 24. Sir Geoffrey Keynes is chairman of the Blake Trust, which was responsible for this commemoration of the bicentenary of Blake's birth (November 28, 1757).

Mr. Terence Cawthorne, E.N.T. surgeon to King's College Hospital, London, is to be guest lecturer at the Los Angeles Research Study Club's mid-winter convention in January. While in the United States he will also address otorhinolaryngological meetings in Houston and Philadelphia as well as in Los Angeles.

Royal College of Surgeons in Ireland.—Mr. DAVID PALEY, director of surgical studies at the Middlesex Hospital, delivered the College's third Abraham Colles postgraduate lecture on November 11. His subject was "The Treatment of Parotid Tumours Considered in Historical Perspective."

COMING EVENTS

Hospitals' Symphony Orchestra.—Concert including works by Mendelssohn, Liszt, Mozart, Brahms, and Berlioz, November 30, 8 p.m., at the Royal College of Surgeons. Tickets (7s. 6d., 5s., and 3s.) at the door.

Television.—"Experiments on Animals" in the B.B.C. series "Frontiers of Science," December 6, 8.30 p.m.

St. Bartholomew's Hospital.—This year's meeting of the 13th Decennial Club will take the form of a dinner at the Royal College of Surgeons on December 7. Further details may be obtained from the secretaries of the Club.

Royal College of Surgeons.—Annual meeting of fellows and members, December 11, at the College (9.30 a.m. to 5.30 p.m.). Postgraduate lectures on "The Pelvis" (9.30 a.m.) and "The Physiology of Pain" (11.30 a.m.); films and research exhibits; Bradshaw lecture by Sir RUSSELL BROCK, "The Present Position of Cardiac Surgery," at 2.30 p.m., business meeting, 3.30 to 4.15 p.m.

World Medical Association.—First annual meeting of the British Supporting Group will be held on January 9, 1958, at 3 p.m. at B.M.A. House.

NEW ISSUES

SPECIALIST JOURNALS AND ABSTRACTS

All the journals listed below are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Journal of Clinical Pathology.—From 1958, six issues a year (£4 4s. annually). The new issue, Vol. 10, No. 4, includes:

- STERILIZATION OF SYRINGES BY INFRARED RADIATION. E. M. Darmady, K. E. A. Hughes, and W. Tuke.
THE STERILIZATION OF DRESSINGS. V. G. Alder and W. A. Gillespie.
SEMI-SOLID AGAR MEDIA FOR CULTURE AND DRUG SENSITIVITY TESTS OF TUBERCLE BACILLI FROM SPUTUM. R. Knox and G. B. Skinner.
CATALASE ACTIVITY AND ISONIAZID SENSITIVITY OF TUBERCLE BACILLI. A. Beck.
PENICILLINASE PRODUCTION BY STAPHYLOCOCCUS AUREUS STRAINS FROM OUTBREAKS OF FOOD POISONING. M. T. Parker and S. P. Lapage.
A SIMPLE MEDIUM FOR THE RAPID DETECTION OF SALMONELLA-LIKE PARACOLON ORGANISMS. G. H. Lowe and J. H. Evans.
THE USE OF ANCILLARY LABORATORY TESTS IN LEPTOSPIROSIS, WITH PARTICULAR REFERENCE TO THE DIAGNOSIS OF THE MILD CASE. C. R. Robinson.
A CULTURE MEDIUM FOR TRICHOMONAS VAGINALIS DONNÉ AND SPECIES OF CANDIDA. J. G. Feinberg and M. Joan Whittington.
AMINO-ACIDURIA IN COOLEY AND SICKLE CELL ANAEMIAS. C. Choremis, L. Zannos, and B. Basu.
INTRA-ERYTHROCYTIC HAEMOGLOBIN CRYSTALS. J. A. M. Acer and H. Lehmann.
THE TECHNIQUE OF BONE MARROW ASPIRATION IN CHILDREN. John L. Emery.
THE DEGENERATION OF BRAIN THROMBOPLASTIN IN THE PRESENCE OF NORMAL SERUM. C. G. Betty.
THE DETECTION OF A CIRCULATING ANTICOAGULANT ACTIVE AGAINST BLOOD THROMBOPLASTIN FORMATION. D. W. Dawson.
THROMBOSIS AND FACTOR VII ACTIVITY. L. Poller.
LABORATORY CONTROL OF ANTICOAGULANT THERAPY. W. Lewin and B. M. Bloomberg.
THE EFFECT OF ROOM TEMPERATURE ON ERYTHROCYTE SEDIMENTATION RATE AND ITS CORRECTION. Roger W. Manley.
THE INFLUENCE OF ERYTHROCYTE FACTORS ON THEIR SEDIMENTATION RATE. David Phear.
THE PROTEINS OF NORMAL URINE. Gersot H. Grant.
THE ESTIMATION OF THE ORAL HYPOLYCAEMIC AGENT CARBUTAMIDE IN BLOOD. R. H. Thompson.
THE ESTIMATION OF BZ55 AND SULPHONAMIDES IN BLOOD SUGAR FILTRATES. D. G. Moss.
ELECTROPHORETIC ANALYSIS OF SERUM AND URINARY PROTEINS IN THE DIAGNOSIS OF MYELOMATOSIS. J. A. Owen and W. D. Rider.
MICRODETERMINATION OF SERUM CALCIUM USING THE EEL FLAME PHOTOMETER. E. C. Butterworth.
THE ESTIMATION OF CALCIUM IN URINE BY FLAME PHOTOMETRY, WITH A NOTE ON THE ESTIMATION OF SODIUM AND POTASSIUM. W. P. U. Jackson and L. Irwin.
A NOTE ON THE DETERMINATION OF β -GLUCURONIDASE ACTIVITY IN URINE. M. A. M. Abul-Fadi.
THE IDENTIFICATION OF LIVING MALIGNANT CELLS IN EXUDATES. R. J. V. Pulvertaft and L. Weiss.
SIMPLE METHODS FOR MEASURING SERUM LEVELS OF THE GLUTAMIC-OXALACETIC AND GLUTAMIC-PYRUVIC TRANSAMINASES IN ROUTINE LABORATORIES. A. F. Mohun and I. J. Y. Cook.
TECHNICAL METHODS.

Journal of Neurology, Neurosurgery and Psychiatry.—Issued quarterly (£3 annually). The new issue, Vol. 20 (New Series), No. 4, includes:

- ARTERIOVENOUS MALFORMATIONS OF THE BRAIN AND THEIR EFFECT UPON THE CEREBRAL VESSELS. Juan Carrasco-Zanini.
THE LATE SEQUELAE OF PNEUMOCOCCAL MENINGITIS. Honor V. Smith, R. M. Norman, and H. Ulrich.
ELECTRO-ENCEPHALOGRAPHY IN A CASE OF ISLET CELL ADENOMA. John Laidlaw and S. M. Rah.
MANIFESTATIONS OF SUPRARENAL INSUFFICIENCY OCCURRING WITH PITUITARY TUMOURS. Antony Jefferson.
NEUROLOGICAL MANIFESTATIONS IN HAEMANGIOMA OF THE VERTEBRAE. H. Askenasy and A. Behmoaram.
RAPIDLY PROGRESSING DEMENTIA IN DISSEMINATED SCLEROSIS. J. D. Berfin.
FATAL DAMAGE TO THE BRAIN BY EPILEPTIC CONVULSIONS AFTER A TRIVIAL INJURY TO THE HEAD. J. M. Small and A. L. Woolf.
FREQUENCY ANALYSIS OF PHYSIOLOGICAL AND NEUROTIC TREMORS. J. W. T. Redfern.

Abstracts of World Medicine.—Issued in the first week of each month, this journal contains abstracts of important papers selected from the current medical literature of the world. Annual subscription £4 4s.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, December 2

- GUY'S HOSPITAL.—At Physiology Theatre, 4.45 p.m., Endocrine Demonstration: Hypothyroidism. Guest speaker, Dr. D. V. Hubble.
INSTITUTE OF NEUROLOGY.—5 p.m., Academician E. A. Asratyan (Moscow): Compensatory Function of the Brain.
MARLBOROUGH DAY HOSPITAL.—8.15 p.m., Mr. Richard Hauser: New Tools in Dealing with Groups.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. R. I. S. Bayliss: Pathogenesis and Treatment of Oedema: the Clinical Use of Diuretics.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, 5 p.m., public lecture by Dr. H. Harris: Human Biochemical Genetics.

Tuesday, December 3

- BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, W.C., 5.30 p.m., Dr. K. W. Cross: Anoxia of the Newborn.

- INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. H. Meara: Atopy. ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Colonel N. C. Oswald: Pulmonary Changes in some Systemic Diseases.
ST. MARY'S HOSPITAL MEDICAL SCHOOL (WRIGHT-FLEMING INSTITUTE THEATRE).—5 p.m., Dr. M. Lederman: Radiotherapy of Carcinoma of the Cervix.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. Frances D. Bosanquet: Neuropathology.

Wednesday, December 4

- INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Bacterial Flora of Normal Skin.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. K. Robson: Some Observations on the Diagnosis and Treatment of Empyema Thoracis.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., Dr. I. Friedmann, Dr. D. A. Osborn, and Dr. S. Epstein: clinico-pathological conference.
●INSTITUTE OF NEUROLOGY.—5.30 p.m., Mr. K. Till: Trauma.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Dr. A. R. Harrison: Tests of Renal Function.
MANCHESTER MEDICAL SOCIETY: SECTION OF MEDICINE.—At Large Anatomy Theatre, Manchester University, 4 for 4.30 p.m., Dr. W. Robinson: New Therapeutic Methods for Chronic Bronchitis.
MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 8.15 p.m., Mr. J. Leigh Collis: Reflux Oesophagitis.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor G. H. Lath: Bilirubin.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. Marjorie M. Wilson: Cerebral Palsy—Facing the Facts (illustrated).
ROYAL SOCIETY OF ARTS.—2.30 p.m., Dr. Frank Wokes, Ph.D., F.R.I.C.: Some Nutritional Aspects of Vitamin B₁₂.

Thursday, December 5

- BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, W.C., 5.30 p.m., Dr. R. J. W. Rees: Experimental Approach to the Problems of Resistance to Tuberculosis.
CHADWICK TRUST.—At Wright-Fleming Institute, St. Mary's Hospital, 5 p.m., Malcolm Morris Memorial Lecture by Mr. A. J. King: These Dying Diseases—Venereology in Decline?
FACULTY OF HOMOEOPATHY.—5 p.m., discussion: Asian Influenza.
HONYMAN GILLESPIE LECTURES.—At University New Buildings, Teviot Place, Edinburgh, 5 p.m., Dr. M. F. Oliver: Metabolic, Endocrine, and Therapeutic Aspects of Coronary Atherosclerosis.
●INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—4.30 p.m., Dr. G. I. M. Swyer: Intersex.
LIVERPOOL MEDICAL INSTITUTION.—8 p.m., symposium by Dr. C. A. St. Hill and others: Forensic Medicine.
ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: Clinical Application of the Optical Principles of Retinoscopy.
ROYAL SOCIETY.—11 a.m., discussion to be opened by Professor R. E. Peierls, F.R.S.: Parity Conservation.
ROYAL SOCIETY OF ARTS.—5.15 p.m., Professor G. Macdonald: Conquest of Malaria.
SCIENTIFIC FILM ASSOCIATION.—At Royal Photographic Society, 7 p.m., Mr. R. McV. Weston, M.A., F.I.B.P., F.R.P.S.: Photomicrography for the Medical Photographer.

Friday, December 6

- INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. Smart: clinical demonstration.
●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. L. Forman: clinical demonstration.
●INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—2 p.m., Mr. W. R. Kent and Canterbury Hospital.—8 p.m., clinical meeting.
NORTHAMPTON MEDICAL SOCIETY.—At Northampton General Hospital, 8 for 8.30 p.m., Mr. M. P. Ward: Ascent of Everest.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Miss Doreen Nightingale: Treatment of Bronchiectasis. 4 p.m., Sir Geoffrey Jefferson, F.R.S.: A Surgical Neurologist Looks at the Brain.
ROYAL MEDICAL SOCIETY, EDINBURGH.—8 p.m., Dr. R. H. Girdwood: The American Scene—A Photographic Record.
ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—At Royal Faculty of Physicians and Surgeons of Glasgow, 8.30 p.m., short-paper night.
Dr. Wallace Barr: Heartburn in Pregnancy; Dr. W. Buchanan: Sulphonamide Compounds in the Treatment of Diabetes Mellitus; Dr. J. B. McGuinness: Trial of Long-term Antibiotics in Chronic Bronchitis.
WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., joint meeting with East Metropolitan Branch of Pharmaceutical Society. Dr. F. E. Camps: Poisoning: Accident, Suicide, or Murder?

Saturday, December 7

- COLLEGE OF GENERAL PRACTITIONERS: MIDLAND FACULTY.—At Nurses' Recreation Hall, Worcester Royal Infirmary, 8 p.m., Dr. R. Forbes: Medical Litigation.
MIDLAND THORACIC SOCIETY, BIRMINGHAM CHEST CLINIC.—3 p.m., presidential address by Dr. A. Clark Penman: Small-scale Trials.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

- Blend.—On November 13, 1957, at University College Hospital, London, W.C., to Martha (formerly Imerdauer), wife of Dr. David Blend, a brother for Jonathan—Anthony Paul.

DEATHS

- Baird.—On November 3, 1957, Harvey Baird, M.D., of Keena House, Hastings, Sussex.
Dix.—On October 29, 1957, at Gage House, West Moors, Dorset. William Ralph Dix, M.D., aged 90.
Hancock.—On October 25, 1957, at Thatches, Wraybury, Bucks, Frank Thompson Hancock, M.R.C.S., L.R.C.P., aged 76.
Mackenzie.—On October 27, 1957, in hospital, London, Myra Mackenzie, M.B., Ch.B., late of The Lawn, Lincoln.
Silver.—On November 1, 1957, at 3, Porchester Court, Porchester Gardens, London, W. John Payzant Silver, C.B.E., D.S.O., M.B., C.M., Lieutenant-Colonel, R.A.M.C., retired, aged 89.
Thomas.—On October 28, 1957, at the Exmouth Hospital, Robert Stanley Thomas, M.D., J.P., of Farway, Exmouth, Devon, aged 80.
Woods.—On October 27, 1957, at 45, Wick Hall, Hove, Sussex, Frederick Lindsay Woods, M.B., B.Ch., D.P.H., late of Amoy, China.

Any Questions?

Repeated Doses of Polio Vaccine

Q.—What are the "theoretical and practical disadvantages in giving many repeated doses" of poliomyelitis vaccine alluded to in your leading article on the British vaccine?

A.—The practical disadvantages in giving many repeated doses of poliomyelitis vaccine are those which attend any type of inoculation for children which requires to be repeated at intervals. The only theoretical disadvantage lies in the fact that the poliomyelitis vaccine contains a certain amount of monkey kidney antigen, though there is absolutely no evidence that the administration of the very small quantities contained in two or three doses of the vaccine does any harm at all.

Marriage of Cousins

Q.—Some years ago you published an answer on the risks of hereditary defects in the children of "double first cousins." It was stated that a quarter of the genes of such parents would be the same, and from this calculations were made of the risks of transmitting certain hereditary conditions of the risks of transmitting certain hereditary conditions of the unknown incidence. However, the general risk for the appearance of some hereditary defect could not be stated. Have there been any recent studies that make it possible to estimate this general risk in a marriage of double first cousins compared with that where husband and wife are unrelated?

A.—No study has yet been made of the risks to children of double first cousins. But an estimate of the risks to first cousins gives information on the risk to double first cousins. Ordinary single first cousins have on the average 1 in 8 of their genes in common, as compared with 1 in 4 for double first cousins. The risk of recessive abnormalities for double first cousins is then appearing in the offspring of double first cousins is then twice the risk for the offspring of ordinary first cousins.

The best survey yet available on the reproductive performance of first cousins is from Sweden.¹ This is based on 34 first cousin marriages and 32 control marriages, the latter being those of couples in the nearest house or farm. The fertility of the first cousin marriages was no lower than that of the controls. The miscarriage, stillbirth, and infant mortality rates also did not differ appreciably between the cousin and the control marriages. The incidence of physical and mental disability was, however, higher among the children of the first cousins. Taking all conditions in whose causation genetic factors probably play some part, the total morbidity rate for the children of the first cousins was 28% and for the children of the controls 6%. For conditions where there is reason to suppose that genetic determination is recessive, the risks were 16% and 4% respectively. The biggest single risk was for mental deficiency of unknown cause, 9 of 194 children at risk in the cousin marriages, and 2 of 152 control children being affected in this way. In addition there were three children of the cousin marriages and none of the controls with specific genetic spastic oligophrenia. Schizophrenia, deaf-mutism, severe myopia, and club-foot each occurred in 3 or more children of the cousin marriage group.

In the same Swedish population, then, the risk of recessively determined morbidity in the children of double first cousins would be perhaps between 30 and 40%. One should be cautious in applying this risk to the population of Great Britain or other countries, but the risk is probably of the right order, as there is no reason to suppose that the load of deleterious recessive genes is unduly high in Sweden.

Glycerin Suppositories

Q.—What place has the glycerin suppository in modern therapeutics? Can any harm arise from its continual use?

A.—The insertion of a glycerin suppository stimulates the rectal reflex and is a convenient substitute for a small enema, if somewhat less effective. The continual use of such suppositories is as undesirable as the continual use of all artificial measures to cause evacuation of the bowels, but, apart from occasional mild proctitis, is unlikely to have any serious local effects. The frequent use of suppositories is said to have undesirable psychological repercussions in young children.

Familial Variations in Sex Ratio of Children

Q.—(1) What accounts for the marked deviation in certain families over several generations from the usual sex ratio at birth? Is this simply due to chance or do hereditary (or other) factors play a part? (2) Do any factors in an individual couple, such as the mother's age at conception or the sex of her previous children by the same husband, influence the likelihood of their future children being of one sex rather than the other?

A.—(1) There are a few families in which the marked deviation from the usual sex ratio at birth can hardly be due to chance. The explanation is not known. In the fruit-fly some examples are due to abnormal behaviour of the sex chromosomes and germ cell formation, but in human families this appears to apply only in pathological instances.

(2) No factors are known in an individual couple which much affect the likelihood of a subsequent child being a boy or a girl. It is possible that after a run of boys there is a slight increase in the chance that a further child will be a boy, but this does not apply after a run of girls. In addition, mother's age, or more probably father's age, has some slight influence, since the excess of boys born over girls is most marked in young couples and tends to disappear as the parents get older.

Transchoroidal Passage of Drugs into C.S.F.

Q.—What factors influence the transchoroidal passage of such drugs as penicillin and other antibiotics, sulphonamides, arsenicals, barbiturates, and bromide into the C.S.F.?

A.—Transchoroidal passage of drugs is affected by three main factors: protein-binding, which renders the material unavailable for transfer; the molecular characteristics of the drug, which may influence its rate of secretion by the choroid; and the state of the meninges, since inflammation may sometimes facilitate transfer.

Penicillin may be 60% protein-bound; in addition, the molecule does not readily pass the choroid; consequently penicillin concentrations in the C.S.F. are low, even after massive dosage; the levels obtained increase slightly in inflammatory states. Only about one-third of streptomycin is protein-bound, but entry of free streptomycin into C.S.F. is extremely limited; inflammation causes a marked increase in C.S.F. level. The tetracyclines yield poor C.S.F. levels, mainly owing to slow transfer; inflammation has little effect. Chloramphenicol is 60% protein-bound, but the free drug passes readily into the cerebrospinal fluid, so that the C.S.F. level is commonly about half the blood level. Sulphonamides behave similarly; protein binding is variable and more marked with acetylated compounds; an effective C.S.F. level of free sulphonamide is readily achieved. The trivalent arsenicals are rapidly bound after intravenous administration and do not reach the cerebrospinal fluid; pentavalent arsenicals are thought to penetrate more readily.

The extent of protein-binding of barbiturates varies considerably; up to 80% of thiopentone is bound to plasma protein, but the free drug penetrates readily into the cerebrospinal fluid; however, many other barbiturates are much less protein-bound, but the free barbiturate does not usually penetrate readily into the C.S.F., presumably owing to the

relative impermeability of the choroid to these substances. Bromide and chloride ions in the extracellular fluid are treated identically; in the formation of cerebrospinal fluid, however, there appears to be some selection by the choroid in favour of chloride; consequently the bromide level in the C.S.F. is rather lower than the blood level.

Vulval Varicosities

Q.—What treatment is advised for vulval varicosities after the childbearing period? The patient in question is 65 and had bilateral white leg 30 years ago.

A.—The veins of the vulva drain into the long saphenous system. Vulval varicosities are usually therefore due to incompetence of this system, the treatment of which involves Trendelenburg's operation; they are, however, a rare component of this syndrome except in pregnancy, when they usually subside naturally in the puerperium. If large the vulval varicosities can be excised as well. Treatment by injection is contraindicated. Very occasionally vulval varicosities may be traced to an incompetent perforating vein in the thigh.

The fact that this patient has had bilateral white leg is of some importance, as the varicosities here may be secondary to the thrombosis of the deep veins; or, by now, to their recanalization and incompetence, from which she may have other symptoms. The function of the deep veins should be assessed, preferably by a phlebogram. If the femoral vein is patent although incompetent, treatment of the varicosities is as described above. If, however, the femoral vein is blocked so that the varicosities may be acting as collaterals, Trendelenburg's operation should not be done and the varicosities are best left alone. However, if they are huge and threatening to burst they may be removed, though they will probably recur later.

Finally, with vulval varicosities care should be taken to exclude the presence of a pelvic tumour.

Lupus Erythematosus and Sunlight

Q.—What place have anti-sunburn applications in the management of conditions such as chronic lupus erythematosus, where sunlight is thought to be an exacerbating factor? If useful, what preparations are advised?

A.—Many believe that those rays of the sun which cause sunburn may activate lupus erythematosus in exposed skin, and some claim that typical lesions have been produced by radiation from mercury vapour arc-lamps. It is well, therefore, to warn patients with such a disorder to avoid bright sunlight and always to wear a hat that shades the face, ears, and neck. Reflected light, as from water, is, of course, almost as dangerous as direct sunlight.

Anti-sunburn applications form only a small part of the treatment, for unless they are applied so thickly as to be disagreeable they are not entirely effective in preventing the sun's rays from reaching the skin. In women, ordinary face cream followed by liberal use of powder tinted with orange is helpful. Special ointments containing one or more of those substances known to absorb the erythema-producing rays of the sun, such as *para*-aminobenzoic acid, methyl salicylate, tannic acid and esculin (a glycoside from the bark of the horse-chestnut used as a protective against sunburn), 5–10% of each, are most effective, but occasionally lead to contact dermatitis or sensitization. Soft yellow paraffin is also effective, though not entirely satisfactory cosmetically.

NOTES AND COMMENTS

Release Pain as Sign of Peritonitis.—Dr. E. F. BLUMBERG (London, S.W.3) writes: I read with very great interest your answer about release pain ("Any Questions?" November 2, p. 1063). The answer, however, is not correct, as the sign is not produced as originally described. The release pain, or rebound sign, as described by my father, Dr. M. Blumberg, in 1907, depends on the comparison in strength between two different types of pain.^{1,2} Steady pressure is exerted over the suspected area, and while this is being done the patient is asked what kind

of pain he feels. After he has given his answer, pressure suddenly released by lifting the palpating hand abruptly. No the patient is asked again which one of the two pains is stronger. Often the answer can be read in his face. In case the second pain is stronger, peritoneal involvement is certain.

To estimate prognosis and development of a suspected intra-abdominal lesion, as parametritis, appendicitis, cholecystitis, or an abscess, examinations are carried out at intervals of a few hours. If, at first, pressure pain is less than rebound pain, and later on both pains are the same, the lesion is subsiding. In a developing attack, pressure and release pain may be the same to begin with, but the latter will be more pronounced the more time has elapsed. Used in this manner, Blumberg's sign is most reliable, as it excludes the difference between individual thresholds of pain, eliciting two different pains in the same person. Large distending tumours may prevent its use. When used in suspected cholecystitis, an acute inflammation of the pleura must be excluded, as the sign may be found positive in these cases.

OUR EXPERT replies: Dr. M. Blumberg first described "release pain" in 1907,¹ and gave further details of its use as a means of indicating whether peritonitis is spreading or not in his paper on the prognosis and indications for operation in appendicitis and peritonitis in 1910.² What the sign demonstrates is that in peritonitis an abrupt movement of the parietal peritoneum is more painful to the patient than steady pressure. The diagnosis of acute appendicitis with early peritonitis can nearly always be made by gentle palpation without submitting the patient to the additional pain of an abrupt movement. As all cases of acute peritonitis in which there is any doubt whether spreading peritonitis is present or not should be submitted to urgent operative treatment, reliance on a single physical sign may be misleading and if used to indicate a prognosis may give rise to dangerous delay in instituting the proper treatment.

Effect of Adoption on Fertility.—Dr. J. D. BAERYTZ (London, E.9) writes: In answer to a recent query on this subject ("Any Questions?" September 21, p. 719) my own findings may be of interest. Having always been impressed in antenatal clinics by the number of infertile women who conceived shortly after adopting a child, I investigated (not without some difficulty) the incidence of this phenomenon in Auckland, New Zealand. I was surprised to find that only 8% of women conceived after adoption, probably no more than could be expected by chance alone. Coincidentally, this result was identical with that obtained by Hansen and Rock¹ from a similar survey in America.

Correction.—In the paper on "Peripheral Artery Grafting" by Mr. Peter Martin (August 17, p. 371), there were some mistakes in the figures quoted in the section headed "Results and Discussion" (p. 375). In the first paragraph: the later series of cases amounted to 51 (not 31). In the third paragraph: 58 (not 88) by-pass grafts were inserted, and 50 (not 30) of the patients were male. In the fifth paragraph: 47 (not 58) arterial homo-grafts were used, and 37 (not 48) grafts were patent two to eight months after operation.

EXPERIMENTAL APPROACH TO VISUAL INTRACARDIAC SURGERY, USING AN EXTRACORPOREAL CIRCULATION

BY

C. E. DREW, M.V.O., F.R.C.S., P. CLIFFE, Ph.D., M.B., B.Sc., C. F. SCURR, M.V.O., M.B., F.F.A.R.C.S., D. M. FORREST, F.R.C.S., D. J. PEARCE, M.B., F.F.A.R.C.S., P. A. KING, F.R.C.S., H. M. T. COLES, M.D., M.R.C.P., V. M. LEVEAUX, M.D., M.R.C.P., AND JOAN F. ZILVA, M.B., B.Sc., M.R.C.P.

From the Westminster Hospital, London

The possibility of temporary by-pass of the heart to facilitate visual intracardiac surgery has stimulated world-wide interest and investigation during the past twenty years. To achieve this objective it is necessary to continue the functions of the lungs as well as the heart by mechanical means—removing blood as it returns to the right atrium and returning it to the aorta after passage through an oxygenator. Pioneers in this work (Björk, Gibbon, Jongbloed, Dennis, Melrose, Dordill, Dogliotti, and Mustard) devised ingenious but complicated machines, designed to imitate basal cardio-pulmonary function. Despite the use of heparin and pulmonary function. Despite the use of protamine, it was at its subsequent antagonization by protamine, it was at first difficult to achieve adequate oxygenation of the large volumes of blood involved without haemolysis or alteration of the clotting mechanisms. An even greater obstacle was the difficulty of obtaining the expected venous return during cardio-pulmonary by-pass and the consequent inability to obtain normal blood flow and arterial pressure. This problem is still unsolved.

Andreasen (Andreasen and Watson, 1952, 1953a, 1953b), working at the Buckston Browne Farm of the Royal College of Surgeons of England, showed that, if the venae cavae in dogs were temporarily clamped for 30 minutes and venous return to the heart was reduced to that flowing through the vena azygos, survival could be expected. He postulated that during cardiac by-pass it might be possible to obtain satisfactory results with much lower flows than were hitherto thought to be necessary. He confirmed this by donor-circulation experiments in which one animal carried out cardio-pulmonary function on its own behalf and that of a recipient dog undergoing cardiac by-pass. Cohen and Lillehei (1954) later repeated this work, and Warden *et al.* (1954) showed that in dogs a flow rate of three times the vena azygos flow obtained by using donor animals in a cross-circulation study was sufficient to achieve a very high survival rate. As a result of this Lillehei was able to use a similar technique in cases of congenital heart disease in young children, one of the parents providing the donor circulation during cardiac by-pass.

Obvious difficulties arise from a surgical operation carried out on two people in order to benefit one of

them. The next logical step was to devise a pump-oxygenator simple enough to deal with relatively small blood flows. Using a finger-pump already in commercial use and a simple oxygenator in which bubbles of oxygen are passed through a moving column of blood, Lillehei was able to achieve comparable results in the experimental laboratory and in human cases. Although he (personal communication) achieved unqualified success in animal experiments before his apparatus was used in human cases, many groups have used this technique with less satisfactory results. So far little has been published concerning the difficulties encountered in the laboratory. This paper describes the methods we have used and the problems encountered in obtaining animal survivors.

At the beginning of 1956 there were only two types of heart-lung machine available which had proved successful by continued clinical use. The Gibbon (Gibbon *et al.*, 1954) apparatus, used most successfully by Kirklin at the Mayo Clinic, was the only one of its kind available, whereas the Lillehei-DeWall apparatus was easily copied and more simple to use. It was because of this that our own work was directed towards constructing such an apparatus and using it in the experimental laboratory.

Our objectives were twofold. First, to train a team who would later be using an identical apparatus in the treatment of intracardiac lesions in children, and, secondly, to achieve survivals in animals. Although it was known that such an apparatus was being used successfully in human cases it was felt that animal survivals were essential before the technique could be used with confidence in the human.

It was also desirable to obtain as much information as possible about physiological changes which occurred and to obtain experience in the use of apparatus designed to record them.

Apparatus

The apparatus (Fig. 1) has been well described by DeWall *et al.* (1956). Precise details of our version of this apparatus are as follows.

The "sigmamotor" pump is model T-6S with a rated output of 2,000 ml. a minute.

Blood from the venae cavae passes through one pump-head and upwards through a vertical column (48 by 1 in.; 122 by 2.5 cm.) through which oxygen is also bubbled via a single opening $\frac{1}{4}$ in. (6 mm.) internal diameter. The top of this oxygenator joins an inclined debubbler (18 by 2 in.; 46 by 5 cm.), which leads to a reservoir coil (120 by 1 in.; 300 by 2.5 cm.) and then to the arterial line via a filter of stainless-steel gauze. The coil is maintained at 38° C. in a thermostatically controlled water-bath. The coil serves a fourfold purpose: (1) It allows small bubbles to separate from the blood on its spiral descent. (2) It acts as a reservoir. (3) It allows the temperature of the blood to be maintained at approximately body temperature. (4) It acts as a level indicator. During perfusion the pumps are adjusted as required to ensure a constant blood level in the coil. The inflow/outflow balance to the patient is thereby maintained.

The column, debubbler, coil, and arterial and venous lines ($\frac{1}{4}$ in. (6 mm.) internal diameter) are of clear P.V.C. tubing with polished "perspex" connectors. Short tubes passing

FIG. 1.—The apparatus.

through the pump-heads are of translucent rubber ($\frac{1}{4}$ in. (1.3 cm.) internal diameter and $\frac{1}{2}$ in. (1.9 cm.) outside diameter), which gives more satisfactory results than plastic materials in this situation.

The debubbler, pump tubes, and filter are siliconed with an ethereal solution of M 430 (I.C.I.) and allowed to dry before sterilization.

The P.V.C. components are sterilized by autoclaving at a pressure of 5 lb./sq. in. (0.5 kg./sq. cm.) for 30 minutes. The lid of the container is then propped open and the contents are subjected to dry heat for a further 45 minutes. This prevents or reverses opacification due to absorption of water.

The behaviour of the apparatus was investigated before its use in any animal experiments. It was found that the pumps were sensitive to the inflow pressure but substantially independent of the outflow pressure up to 130 mm. Hg. Accordingly, the pumps were calibrated with various paired venous cannulae of different sizes connected to a suitable length of "venous line" tubing. Curves were drawn of the reading of the pump speed control dial against the flow in ml./min. Any required flow for given cannulae could be subsequently set on the pumps and checked at the time if required.

Operation of the Machine

The objects in operating the perfusion apparatus were: (1) To balance the arterial and venous pumps prior to perfusion. (2) To maintain a balance during the perfusion between blood volumes held in the animal and the apparatus. (3) To ensure that any adjustments in flow rate did not reduce the arterial flow below the minimal requirements. (4) To provide adequate oxygenation of the blood.

The dog was weighed before operation and a minimal requirement of 35 ml./kg. body weight/min. was assumed (Warden *et al.*, 1954). The perfusion rates usually ranged between 40 and 65 ml./kg./min., with extremes of 35 and 80 ml./kg./min., the higher flows being used for smaller animals. After circulation of normal saline through the apparatus, about 1,200 ml. of fresh blood (500 ml. containing 18 mg. of heparin in 20 ml. of 5% glucose) was used to prime it.

The end of the arterial line and the cannulae attached to the venous line were inserted into a 100-ml. polythene measuring cylinder. The arterial pump was set at the required rate and the venous pump was adjusted for constant level in the cylinder. During this stage the blood in the machine was oxygenated and the level of blood in the coil was noted.

During perfusion the blood level was maintained constant in the reservoir coil by adjusting the venous pump. Occasionally, if too great a perfusion rate was attempted, the venous pressure would fall and the caeve would tend to be sucked flat. It was then necessary to reduce the arterial flow to effect a balance, but never to less than 35 ml./kg./min. During these adjustments the positive or negative balance need not exceed 50 ml. of blood. The highest total flow rate used has been 900 ml./min.

Oxygenation was obtained by bubbling oxygen directly through a single opening into the bottom of the column and not through multiple tubes or holes. The oxygen/blood flow ratio was 15/1, which, although higher than reported elsewhere, assured oxygenation of 95% or more with acceptable haemolysis.

Coronary Sinus Flow Regulator

This apparatus was designed to allow blood from the open heart (this includes blood from coronary sinus, Thebesian veins, and bronchial circulation) to be returned

FIG. 2.—Coronary sinus flow regulator.

to the machine or to be discarded (Fig. 2). In the latter event an equivalent volume is returned to the venous line from a reservoir of fresh heparinized blood.

Blood is sucked out from the heart via a pump (P). In practice a second rubber tube is inserted through the venous

pump-head. The sinus blood passes to one side of the U-tube (T), and hence to the other side, which contains electrodes A, B, and C. These are connected to a cold cathode trigger device ("Iondex"), which causes the two magnetic valves, M1 and M2, to open when electrodes A and B are bridged by blood. The valves clip around latex rubber tubes, which are closed in the quiescent state. R is a reservoir of fresh blood connected via M2 to the venous line from the patient.

In operation, when blood reaches A the valves M1 and M2 open. Blood then flows from the U-tube until electrode B is uncovered, when the valves M1 and M2 close. The flow through M1 goes to a measuring cylinder, while the equal flow through M2 returns to the machine. Any residual inequalities can be adjusted manually as the volumes entering the cylinder and leaving the reservoir are known.

By the means described an overall balance may be achieved to within about 10 ml. of blood.

The Cannulae

It was felt that both arterial and venous cannulae should have the following characteristics. (1) They should be flexible enough to avoid damage to the vessel being cannulated, yet be rigid enough to avoid kinking or compression.

FIG. 3.—A, venous cannula. B, arterial cannula.

ous cannulae should be large enough to carry the expected venous return without obstructing the veins before starting cardiac by-pass.

Venous Cannulae (Fig. 3 A).—Those designed to meet these requirements are of soft vinyl tubing* about 6 in. (15 cm.) in length, having perspex adapters fused to the proximal end. The distal ends are cut square with four small terminal side holes, to avoid obstruction by the wall of a collapsing vein. Malleable stylets are used during insertion to stiffen the tubing and to allow bending to a convenient shape. Reflux of blood is prevented by the ends of the stylets, which fit into the adapters. After the stylets have been withdrawn the tubes are temporarily clamped by a haemostat whose opposing surfaces are ground flat.

Arterial Cannula (Fig. 3 B).—During arterial cannulation, especially when the artery was small, a soft tube was difficult to insert and was liable to be occluded by the retaining clut. The cannula consists of two parts. The intra-

*"Portex" tubing, manufactured by Portland Plastics Ltd., grade H.D.

arterial portion is of polythene, the proximal end of which is heat-softened and expanded over a conical metal former. This is tied into one end of a short length of vinyl tubing, the other end of which is cemented to a perspex adapter. The arterial end is cut to a short bevel, but there are no side holes. A stylet is passed and the surgeon bends the tube to the appropriate shape. The polythene end is dipped in boiling water and becomes rigid on cooling. The stylet is then removed, when the cannula retains the correct shape and is ready for insertion, a haemostat having been applied to the proximal vinyl portion to prevent reflux. When the carotid artery is used only 1 in. (2.5 cm.) of polythene is required, but the terminal 3 in. (7.5 cm.) should be of this material when the cannulation is made within the chest into the left brachial artery.

Methods

During each experiment, and for a variable time post-operatively, records of the following have been made. (1) Electroencephalograph. (2) Electrocardiograph. (3) Central arterial pressure. (4) Central venous pressure. (5) Venous oxygen saturation. (6) Venous pH. (7) Body temperature. (8) Time.

The E.E.G., E.C.G., arterial and venous pressures, and time are recorded simultaneously and continuously on an Ediswan four-channel pen recorder (Fig. 4).

Electroencephalograph and Electrocardiograph.—In applying the E.E.G. leads the head is shaved unilaterally

FIG. 4.—Simultaneous recordings of E.E.G., E.C.G., and venous and arterial pressures.

and the skin cleaned with ether. Silver electrodes smeared with electrode jelly are held in place with strapping. This is sprayed with "nobecutane" and bandaged into place to prevent drying out and mechanical disturbance. The E.C.G. electrodes are subcutaneous needles which, although satisfactory for a cardiograph, tend to produce polarization effects when used for E.E.G. recording over long periods. E.C.G. standard lead I has been employed routinely in the present work. Difficulty was experienced in the early stages if attempts were made to record the electroencephalogram during diathermy coagulation, as the recorder pens were violently disturbed. Accordingly, the diathermy pedal switch was arranged to operate a relay system which switched the recorder amplifiers to a resistive load at a time 0.2 second prior to the completion of the diathermy circuit by another relay. In this way the pens were switched off during coagulation. On release of the switch pedal the diathermy circuit was broken in less than 0.1 second but the recorder relays were held for several seconds and then switched on the pens. Amplifier blocking was much reduced by this procedure and the pens were automatically protected. To avoid 50 c/s interference the usual mains earth was discarded and all the electrical equipment was connected via a single earth lead to a water-pipe. This includes the neutral leads of the

E.E.G. and E.C.G., the diathermy plate, and the earth leads of the various instruments and motors simultaneously in use.

Arterial and Venous Pressures.—Arterial pressures were recorded through a cardiac catheter inserted via the femoral artery into the thoracic aorta. The catheter is connected to a capacitance manometer (Southern Instruments) through a specially designed system of taps. These provide for a slow pressurized saline or dextrose drip through the catheter, while allowing recalibration of the manometer without interruption of the flow. Blood-clotting in the catheter is thus prevented, whilst accuracy of recording can be checked at will. The venous pressure manometer is of the variable inductance type (New Electronic Products). Errors in pressure scales due to slow drift are less than 0.5 mm./hour arterial and about 0.25 mm./hour venous pressure.

Oxygen Saturation.—This was measured by the Kipp haemoreflexor on the mixed venous blood of the dog during thoracotomy and at three-minute intervals during perfusion. Arterial samples were examined as required.

pH of Blood.—This was determined on the samples withdrawn for oxygen saturation. The necessity for accurate pH values within the restricted range in blood has prompted the use of an electrometer rather than a standard commercial pH meter. A glass-calomel electrode system is connected to a "vibron" electrometer (Electronic Instruments) adjusted so that full-scale deflection corresponds with a pH change from 7 to 8. Further, as facilities are provided to reverse the input, the instrument reads pH 6-7 when the scale is read backwards. Measurements are made at 37° C. and are reproducible to 0.01 pH. There are indications that if enough care is taken with the blood KCl boundary the errors in the method may be reduced to the order of 0.002-3 pH.

Body Temperature.—Rectal temperature was measured with a thermistor thermometer constructed for the purpose. It is read at intervals of 0.1° C.

Anaesthesia

After comparing unpremedicated dogs with those receiving various drug combinations—for example, morphine, pethidine, and chlorpromazine—we found that the best results were achieved by morphine and atropine given intramuscularly one hour before operation. Dogs are tolerant of opiates, and morphine, 16 mg., usually produced effective sedation in a dog of 11 kg. body weight—the average weight in this series. Side-effects of morphine were vomiting, salivation, and defaecation. Atropine, 0.6 mg., was given to diminish secretions.

A 2.5% solution of sodium thiopentone was injected into the anterior subcutaneous vein of the forelimb, the average "sleep-dose" of thiopentone used being 18 mg. per kg. When the jaw was sufficiently relaxed the tongue was pulled out and intubation under vision was performed, using a Magill laryngoscope with an adult blade and a cuffed endotracheal tube. Care was taken to ensure that both sides of the chest were being ventilated.

Many anaesthetic variations have been used: these include thiopentone and air, thiopentone/nitrous-oxide/oxygen, thiopentone/pethidine/nitrous-oxide/oxygen, and thiopentone/nitrous-oxide/oxygen/ether. The most satisfactory results were obtained by thiopentone induction followed by 50:50 nitrous oxide and oxygen with an initial trace of ether, using a Waters canister for carbon dioxide absorption. Following induction spontaneous respiration began after a variable period, and was maintained until the start of operation unless panting occurred. Then the ether was discontinued and anaesthesia maintained with 50:50 nitrous oxide and oxygen and a muscle relaxant. Originally, D-tubocurarine chloride was used, but often this caused a profound fall in blood pressure, presumably due to histamine release or ganglion block. Suxamethonium chloride, however, was free from these side-effects. A dose of 1 mg. may produce apnoea, and throughout operation intermittent doses of 0.45

mg. per kg. were used as required, with controlled respiration. A Guest cannula was inserted into a forelimb vein for the administration of fluids and drugs.

During cardiopulmonary by-pass the lungs were gently inflated with oxygen to diminish post-operative pulmonary collapse and to minimize mediastinal displacement. Extubation was performed only when the endotracheal tube could no longer be tolerated and respirations were adequate. The intravenous drip was maintained for a further 12-18 hours to provide fluids and for the administration of pethidine to control pain and restlessness.

Experimental Procedures and Results

The series includes experiments on 39 dogs, and may be divided into four groups.

Group 1

The purpose of the first eight acute experiments was to gain experience in anaesthesia, surgery, methods of cannulation, operation of the by-pass, and to establish methods of recording data.

Group 2

In this group 21 experiments were carried out with a view to survival.

After shaving and skin preparation, with the animal supine and the forelimbs extended, a trans-sternal bilateral thoracotomy was made in the fourth interspaces (Andreasen and Watson, 1953a, 1953b). The vena azygos was tied or temporarily clamped and the venae cavae were encircled by tapes, avoiding the phrenic nerve. The left brachial artery was mobilized with distal ligation. Heparin (1.5 mg./kg.) was given and the brachial artery cannulated.

The pericardium was opened parallel to the right phrenic nerve. The caval cannulae were inserted through an incision in the right atrial appendage, with temporary control by a Rumel snare. This was removed when the tips of the cannulae were judged to be in the correct position well into the great veins. Bleeding around the cannulae was controlled by two Dunhill haemostats placed between them on the lips of the incision. The arterial line was attached to the arterial cannula with care, so that no air bubbles were included. The venous catheters were then attached to the clamped venous line. Small gas bubbles in this situation are unimportant.

As the pump was started the venous clamp was removed. The caval tapes were tightened around the cannulae to divert returning blood into the oxygenator.

Right atriotomy or ventriculotomy was then performed. Blood from the coronary sinus was removed by suction and discarded or returned to the oxygenator. If discarded an equivalent volume of fresh heparinized blood was automatically provided. After open cardiectomy lasting 15-40 minutes the incision was closed. The caval tapes were released and the venous cannulae removed, with ligation of the atrial appendage. An arterial transfusion was then given if required and the cannula removed, with ligation of the left brachial artery.

Protamine sulphate (3 mg./kg.) was given slowly over a period of 10 minutes, preceded by chlorpheniramine hydrogen maleate ("piriton"), 1-1.5 mg., to lessen the hypotensive effect of histamine release. The pericardium was loosely sutured, drainage tubes were inserted in both pleural cavities, and the chest was closed after complete haemostasis had been achieved.

The predetermined flow rates in these animals varied between 35 and 65 ml./kg.

In this group none failed to survive the period of operation, but all were dead within six hours. During the course of this series certain factors were investigated which may have contributed to the deaths.

Haemorrhage.—Three animals sustained severe haemorrhage, one from a tear at the base of the left brachial artery. In other animals there was enough blood loss to suggest interference with clotting mechanisms. In six

experiments protamine titration was performed (Hurt *et al.*, 1956). This was discontinued for the following reasons: (1) canine blood clot is ill-formed and difficult to recognize, consequently the end-point is sometimes distributed between several tubes; (2) the test took up to 20 minutes at 37° C. at a time when it seemed urgent to antagonize the effect of heparin; (3) on two occasions when the end-point was fairly well defined the clotting-time remained grossly abnormal for several hours. On no occasion was there evidence of fibrinogen lack as judged by the addition of thrombin, which produced immediate clotting. Further experience in human cases as well as animal experiments may modify present practice. On only one occasion were fibrin deposits noticed in the filter.

Sepsis.—Because of reference to fulminating septicaemia with rapid death in a few hours (Nelson, 1951), associated with bacterial contamination in the machine, a clean technique was replaced by a sterile one early in the series. Blood cultures consistently failed to show contamination, so that death from this cause was unlikely.

Anaesthesia.—This underwent frequent modification, as related elsewhere, without apparent effect on mortality.

Lung Complications.—Post-mortem examinations showed pulmonary collapse and haemorrhage of varying degree in many animals in the series, and it seems that the highly elastic lungs of the dog would be more prone to this complication than those in man. Handling of the lungs during the heparinized state and prolonged ventilation during vain attempts at resuscitation were obviously responsible for some of the appearances, and the finding was not constant. Drinker (1945) noted a similar finding in dogs anaesthetized for experimental purposes.

Low pH of Donor Blood.—The pH of blood used to prime the apparatus was constantly 6.8-7. Buffering this acidity with sodium bicarbonate did not achieve survival.

Method of Obtaining Donor Blood.—It seemed that this might have some bearing on our unsatisfactory results. Blood taken by complete exsanguination might contain substances which would prejudice chances of survival after perfusion with it. The result of using several donor animals, each contributing small amounts of blood, was unchanged.

Recirculation of Coronary Sinus Flow.—Replacement of discarded coronary sinus blood did not produce a more successful outcome.

Inadequate Cerebral Blood Flow.—Analysis of the post-operative course demonstrated a fairly constant clinical picture. The animals recommenced spontaneous respiration during the first hour. At first they showed increasing consciousness, but in no case was the improvement maintained. Within a period of two to four hours spontaneous respiration became weaker and gasping in character and eventually ceased, and reflex responses (eyelash, swallowing, tracheal, etc.) which had returned also gradually disappeared. With controlled respiration the blood pressure could in most instances be maintained, and the E.C.G. showed few abnormalities. Just before death occurred twitching movements of the limbs were seen and sometimes generalized convulsions. Evidence of cerebral anoxia was obtained only in the later cases. Having developed the technique already described, we found that the records during perfusion usually showed a rapid and considerable decrease in frequency and amplitude. Occasionally this state was preceded by an increase in amplitude up to 300 μ V with a frequency below 1 cycle per second. Such a change is consistent with a slow onset of anoxia (Wilson, 1957). It was concluded that low flow perfusion via the left brachial artery might not provide an adequate cerebral blood flow, and on this account the animals failed to survive.

Group 3

The surgical approach was modified as follows.

1. Arterial cannulation was carried out via the left carotid artery. The anatomy of the carotid system in the dog differs

from that in man in that both carotid arteries arise from a common trunk, which in turn arises from the aorta. The cannula was inserted proximally along the vessel towards the bifurcation but not past this point. In this way blood flowing along the cannula perfused the right carotid and brachial arteries and the aorta (Fig. 5). It seems probable that cerebral blood flow is greater with this technique than when the left brachial is used.

These observations do not apply to the human, where in a number of cases perfusion via the left subclavian artery has been carried out by us without any evidence of deterioration in the E.E.G. recording or with any clinical evidence of brain damage post-operatively.

2. Only a right-sided thoracotomy was necessary. This resulted in the incision of a much smaller muscle mass, and manipulations were confined to the right pleural cavity.

In this series there were three survivors out of five experiments involving cardiectomy lasting 20-30 minutes. One of the two non-survivors was hypertensive at the beginning of the operation, with a blood pressure ranging from 170/120 to 230/165. It appeared to be an old animal and unlikely to do well. This demonstrates the difficulties which arise from experimental work when the age and fitness of the subjects are unknown quantities. The other non-survivor, although hypertensive (180/125), did not appear to be either old or in bad condition. Haemorrhage persisted post-operatively and insufficient blood was available for transfusion purposes. In spite of the eventual result it regained sufficient consciousness to raise its head and limbs, the clinical picture being that of blood loss rather than cerebral damage. During perfusion the blood pressure varied between 70 and 80 mm. Hg, the E.C.G. recording was satisfactory throughout, and the E.C.G. was normal.

The blood pressure of the survivors returned to normal one to two hours post-operatively. Consciousness was regained over a period of one to four hours, when the drainage tubes were removed. One animal was able to drink water within four and a half hours of insertion of the skin sutures. The survivors were watched continuously for 24 hours post-operatively and pethidine was given to control pain and restlessness. They were encouraged to take water and food, and change of posture was made at frequent intervals. During the period of cardiectomy blood from the beating heart, mainly from the coronary sinus, was aspirated and discarded. An equivalent amount of fresh, heparinized blood was returned to the venous line, using the coronary sinus blood flow regulator. This practice required a large amount of reserve blood. The volume of venous blood returning from the heart muscle during the by-pass was 10-30% of the aortic inflow. During a flow of 500 ml. a minute, suitable for an animal of 9-10 kg. body weight, at least 50 ml. a minute would be lost. During cardiectomy lasting for 30 minutes 1,500 ml. of blood would be discarded, requiring replacement of the same amount of fresh blood. This was one reason why

FIG. 5.—Carotid system in dog and man. Showing surgical approach.

in the next group of experiments it was decided to produce cardiac arrest using potassium citrate (Melrose *et al.*, 1955).

Group 4

This resembled group 3 in all respects except that at the beginning of the by-pass the heart was stopped by means of potassium citrate solution—2 ml. of 25% solution mixed with 18 ml. of blood. Enough of this mixture (7–12 ml.) to produce cardiac arrest was injected between a clamp placed on the ascending aorta and the coronary ostia.

The subsequent cardiectomy period occupied some 20–40 minutes. The ventricular wall was partly repaired, the aortic clamp was removed, and with the restoration of the coronary circulation the heart beat recommenced after a variable period. In some instances this took as long as 10 minutes, after which ventricular suture was completed. Occasional ventricular fibrillation was treated by means of an electrical defibrillator. In each animal of this series the heart eventually regained a normal beat. The E.C.G. showed diverse changes; the main feature in the initial stages of recovery consisted of high T waves.

A further difficulty experienced in the dog was the liability for bleeding to occur from the site of injection in the aorta. In two out of five experiments this was the cause of death, as the bleeding persisted in the post-operative period. Our experience with potassium-induced arrest contrasts sharply with our findings in human cases; in these the heart stopped almost immediately after the potassium injection, and the recommencement of normal rhythm was rapidly re-established at the end of the perfusion. Furthermore, no complications arose from bleeding from the injection site. The wall of the aorta in the dog is thin and sometimes splits on insertion of the needle. Even a small puncture may produce uncontrollable bleeding, often made worse by attempts at suture.

Biochemistry

Apart from the measurements of the pH and oxygen saturation during perfusion, full biochemical investigations have not been carried out for each experiment.

Serum Electrolytes

On several occasions serum or plasma sodium, potassium chloride, and alkali reserve have been estimated during the perfusion and for several hours afterwards. Typical results are shown in Tables I and II. Each refers to a 30-minute perfusion in which the heart was not arrested. Table I refers to a survivor and Table II to an animal which

ultimately died of haemorrhage. Carotid cannulation was used for each experiment. The serum Na and K levels were well maintained for three and a half hours post-perfusion. Haemolysis in canine blood does not produce a significant increase in serum K; this contrasts with human red-cell haemolysis, because K is not concentrated in canine red

cells (Kerr, 1937). However, inadequate perfusion leads to increased serum K levels owing to escape of the intracellular ion.

Typical electrolyte changes in a survivor, in which the heart was arrested with K, are shown in Table III. The plasma K level in the inferior vena cava was only 4.8 mEq/l.

TABLE III

Sample	Time (min.)	pH	Venous O ₂ %	Na (mEq/l.)	K (mEq/l.)	Alkali Reserve (mEq/l.)	Chlorides (mEq/l.)

five minutes after removal of the aortic clamp, although the concentration in the first blood sample from the coronary sinus following arrest was 15.2 mEq/l. The relatively small amount of K injected is itself insufficient to cause any significant change in plasma K when distributed throughout the circulation.

pH of Blood

The pH has been measured serially before and during perfusion in each experiment. The pH and alkali reserve of the donor blood was consistently lower than that of the animal, values being pH 6.8–7.2 and alkali reserve 14–20 mEq/l.

FIG. 6.—Blood pH in surviving dogs.

FIG. 7.—Blood pH in non-surviving dogs.

Typical results during perfusion are shown in Figs. 6 and 7. Fig. 6 shows the variation of pH with time for six survivors. In three of these the heart was arrested and in three it was not. Fig. 7 shows corresponding results for six non-survivors. For all these animals carotid perfusion was employed. The first point on each curve represents a sample from the S.V.C. or I.V.C. at the start of perfusion, while subsequent points represent samples drawn from the venous line. Clearly there is no obvious difference between Figs. 6 and 7. Each curve shows an initial fall in pH, presumably due to the rapid introduction of relatively acid donor blood. As perfusion continues the pH usually remains within about 0.1 pH and the majority of perfusion levels lie between 7 and 7.2. These results appear to be independent of either K arrest or survival. Furthermore, when left brachial perfusion was performed the majority of pH values were within the present range.

However, no attempt has been made to separate the various factors contributing to a given blood pH. It is hoped in future experiments to extend pH measurements to include determination of carbon dioxide tension during perfusion (Astrup, 1956).

Oxygen Saturation

Arterial oxygen saturations have been consistently 95–100% during the perfusion. Venous oxygen saturation levels have shown some variation, but the majority of values were 50–80%, depending on the flow rate per kg. body weight. For the largest animal of the series, 25 kg., the flow rate was 35 ml./kg./min., and the venous oxygen saturation fell from 52 to 33% after 18 minutes' carotid perfusion. This animal made a rapid recovery, and in spite of the low oxygenation the E.E.G. on perfusion was well maintained. In a 10-kg. animal which survived a flow of 50 ml./kg./min. maintained a venous saturation between 70 and 84% during a 30-minute perfusion via the carotid artery. When sub-clavian perfusion was used the E.E.G. showed evidence of cerebral anoxia, even though venous oxygen saturation remained between 65 and 80%.

Other biochemical determinations have included calcium phosphate, urea, and blood sugar. These have shown no significant change from normal.

Summary and Conclusions

This paper describes our experimental approach to the use of an extracorporeal circulation. The Lillehei-DeWall apparatus was chosen because of its simplicity and clinical success. Our version of this, with a coronary and sinus flow regulator, is described in detail together with plastic arterial and venous cannulae which have proved satisfactory.

A description is given of recording apparatus used to observe physiological changes.

In the first group of experiments there were 21 successive deaths when trans-sternal thoracotomy and left brachial perfusion was performed.

Factors which might have been partly or wholly responsible for these failures were investigated. Study of the E.E.G. tracings suggested that low flow perfusion via the left brachial artery gave insufficient cerebral blood flow to achieve survival and was the most important cause of failure. When the left carotid artery was used for perfusion there were three survivors in the next five experiments, and identical results were obtained under similar experimental conditions when cardiac arrest was induced with potassium citrate.

Flow rates ranged between 40 and 65 ml./kg./min., cardiectomy lasted 15–40 minutes, and the largest total flow used was 900 ml. per minute.

The routine and continuous recording of physiological variables was well justified in enabling all stages of each experiment to be carefully monitored and subsequently analysed. The use of the E.E.G. must be especially emphasized, particularly during the period of cardiac bypass when low flows are used. A method of eliminating the effect of electrical interference due to the use of diathermy is described.

It is obvious that success in complex experimental work such as this depends upon a multitude of factors, many small and easily overlooked. From the beginning we have tried to reproduce so far as possible in the laboratory the conditions prevailing in the operating theatre.

Asepsis was observed both in the apparatus and during the experiment, and the post-operative care was intensive and followed similar lines to those in the wards.

Finally, all those who eventually worked together with human patients, including our theatre sister, did so in the laboratory. The transition from experimental to clinical work was carried out with minimal disturbance due to strange apparatus, colleagues, or technique.

It is impossible to thank all those who have helped in this work. Colleagues in many departments at Westminster Hospital have given advice and encouragement, particularly Sir Clement Price Thomas. Dr. K. Goldsmith and Dr. J. Humble have given valuable haematological assistance and Dr. D. Marrack has helped in biochemistry. The work has been facilitated by the technical skill of Mr. J. Goodden in the construction of our apparatus. The presence of our theatre sister, Miss P. Brown, ensured a high standard of surgical technique. One of us (C.E.D.) would particularly thank Dr. Walton C. Lillehei and Dr. John Kirklin for freely given help and advice. Miss P. Dawson and Miss J. Smith have given unstinting secretarial assistance, and Miss Jill Hassell was responsible for the illustrations.

For the third of the Research Defence Society's "Conquest Pamphlets" Dr. W. LANE-PETTER has written an account of the Society's origin and work. The Society was founded by Stephen Paget on January 27, 1908, "to make generally known the facts as to experiments on animals in this country, and the regulations under which they are conducted; the immense importance of such experiments to the welfare of mankind; and the great saving of human and animal life and health which is already due to them." This pamphlet is obtainable from the Research Defence Society, 11, Chandos Street, Cavendish Square, London, W.1, price 6d.

MULTIPLE BRONCHOSTENOSES DUE TO SARCOIDOSIS

REPORT OF TWO CASES

BY

MICHAEL HONEY, M.B., M.R.C.P.

University College Hospital, London;
Formerly Medical Registrar, Brompton Hospital

AND

EWART JEPSON, M.B., M.R.C.P.

Medical Registrar, Westminster Hospital;
Formerly House-Physician, Brompton Hospital

We have recently seen two patients with multiple bronchial stenoses. Bronchoscopic biopsy revealed non-caseating epithelioid follicles, the tuberculin test was negative, and tubercle bacilli were absent from the sputum. We present the case report of these two patients with our reasons for believing them to be suffering from sarcoidosis, discuss the symptoms which led to their investigation, and briefly review previous reports of bronchial sarcoidosis.

Intrathoracic sarcoidosis usually affects the pulmonary parenchyma, where lesions occur mainly in the region of small lymphatics in the peribronchial, perivascular, and subpleural areas (Longcope and Freiman, 1952), and the hilar and paratracheal lymph nodes. In the literature there are few references to bronchial lesions in sarcoidosis. The bronchi may be involved in one of three ways. Firstly, enlarged hilar nodes may compress major bronchi, with resulting atelectasis of lobe or segment (Snapper and Pompen, 1938; Turiaf and Brun, 1955) or bronchiectasis (Cowdell, 1954); this is unusual, and there are no reports of hilar nodes ulcerating through the bronchial wall, as occurs in primary tuberculosis. Secondly, the fibrotic process in the later stages of the disease may constrict bronchi, and fibrosis in the region of the hilum may lead to progressive distortion and narrowing of the major bronchi: a case in which this occurred is described by Longcope and Freiman (1952), who, in their review of 160 cases of sarcoidosis, state that this is not infrequent. Thirdly, sarcoid lesions may occur in the bronchial wall; we have discovered 13 such cases in the literature, characterized by the presence of mucosal abnormalities, bronchial stenoses, or both, and the finding of sarcoid follicles on histological examination of biopsy or necropsy specimens. We believe that the two cases reported here fall into this group.

Case 1

A brewery engineer aged 36 first attended Brompton Hospital in October, 1950. His illness began in July, 1948, with a febrile episode, when a chest radiograph showed an opacity in the anterior segment of the right upper lobe. This opacity cleared in 10 weeks and his symptoms subsided. In 1949 he developed increasing dyspnoea on exertion, wheezing respiration, and a productive cough, and was unable to work. After a second febrile illness he was admitted to hospital in November, 1950.

He was severely ill and febrile, dyspnoeic, and cyanosed; there was no clubbing. Rhonchi and basal rales were widespread. The spleen, liver, and lymph nodes were not enlarged. He had 10-15 oz. (280-420 ml.) of thin mucoid sputum daily, which on culture yielded a mixed growth of organisms; numerous smears and cultures for *Mycobacterium tuberculosis* were negative. A chest radiograph showed patchy consolidation in the right middle and both

lower zones. The tuberculin test was negative at 1/10 O.T. (1,000 T.U.). He was treated with penicillin and triple sulphonamides, but responded slowly. Bronchoscopy showed generalized inflammation of the whole bronchial tree, without ulceration of the mucosa. There was slit-like narrowing of the right upper lobe bronchus.

A biopsy specimen (Fig. 1) from the lower part of the right main bronchus showed multiple discrete epithelioid follicles, with fairly numerous giant cells, one of which contained a typical asteroid inclusion body. There was minimal necrosis of some of the follicles, but no caseation. He was treated as a case of tuberculous bronchitis, with streptomycin, 1 g., and sodium para-aminosalicylate (P.A.S.), 15 g. daily. After six weeks on this treatment there was no clinical improvement. Bronchoscopy on two further occasions (December, 1950, and January, 1951) showed, in addition to the stenosis of the right upper lobe bronchus, considerable narrowing of the left upper lobe bronchus and its divisions. During his stay in hospital his general con-

FIG. 1.—Case 1. Bronchial biopsy in December, 1950. ($\times 70$).
dition and attacks of bronchospasm showed little change, but the sputum volume fell to approximately 5 oz. (140 ml.) daily.

He was discharged home in May, 1951, but the symptoms persisted and he was unable to work. There were several short febrile illnesses, responding to treatment at home. Chest radiographs showed soft opacities in all zones, especially in a contracted right upper lobe. After a course of rehabilitation in 1954 he resumed work in 1955 after six years' unemployment.

The improvement did not last, and, following an increase in his dyspnoea, he was readmitted to hospital in June, 1955. His physical signs were unchanged and a chest radiograph (Fig. 2) showed patchy clouding in the right upper lobe, at the right base, and in the left costophrenic angle. Bronchoscopy showed the slit-like stenosis of the right upper lobe bronchus to be unaltered; the lower part of the right main bronchus and the right lower lobe bronchus were irregular and distorted and mucopurulent secretion was excessive. A bronchogram showed marked stenosis of the right upper lobe, main (lower part), lower lobe, and apical lower bronchi; the anterior and posterior segments of the upper lobe failed to fill and there was poor peripheral filling in the lower lobe. On the left side there were stenoses of the upper division of the upper lobe bronchus and of the superior lingular bronchus, and poor peripheral filling in the upper lobe. There was irregular narrowing and dilatation of the smaller bronchi of both lungs. The tuberculin test was again negative to 1,000 T.U. Serum proteins, liver biopsy, and radiographs of hands and feet were normal. Treatment was started with cortisone, 100 mg., streptomycin, 1 g., and isoniazid, 300 mg., daily. The amount of sputum, which became mucoid, was greatly decreased and the

rhonchi were diminished in all areas. His dyspnoea decreased and the vital capacity rose from 2,700 to 3,800 ml. Cortisone was reduced to a maintenance dose of 50 mg. daily and he was discharged after three months in hospital.

The improvement was not maintained, but an increase in cortisone dosage to 75 mg. daily was effective. Later he again deteriorated; the treatment was temporarily stopped and he was readmitted in December, 1955. Treatment was started again and the dose of cortisone was increased to 175 mg. daily. A fifth bronchoscopy showed that the only part of the right bronchial tree which was not grossly stenosed was the right middle lobe bronchus. The left bronchial tree was less affected, with severe stenosis of the upper division of the upper lobe bronchus, and slight stenosis of the lingular bronchus. He improved on the increased dose of cortisone, but on reducing this to 100 mg. daily his symptoms recurred. Prednisone, 25 mg. daily, was gradually substituted, while continuing with streptomycin, 1 g. thrice weekly, and isoniazid, 400 mg. daily. In addition, 60 units of corticotrophin gel was given once weekly. On discharge in March, 1956, he had again improved, being able to walk upstairs without distress and producing only 1-2 oz. (28-56 ml.) of mucoid sputum. There were only occasional rhonchi.

Since discharge he has been well, and working, apart from one slight exacerbation requiring a temporary increase in the dose of prednisone. A chest radiograph in November, 1956, showed that great clearing had taken place in the right upper lobe, though the horizontal fissure was still raised; the lower zones were clear. Bronchoscopy in January, 1957, showed no significant change in the appearances of the major bronchi on the right side; on the left there was now slight narrowing of the main and lower lobe bronchi, in addition to stenosis of both divisions of the upper lobe bronchus.

Case 2

A housewife aged 53 was admitted to Brompton Hospital in April, 1956. In January, 1950, she had had a febrile illness with productive cough and dyspnoea, which was treated with penicillin. During the subsequent six years she had eight further similar attacks (the last in April, 1956), each of which was treated with a long course of an antibiotic. Between these episodes she had a spasmodic cough, with a trace of mucoid sputum, increasing dyspnoea on exertion, and "wheezing." Antispasmodic inhalations gave little relief and by 1956 she was breathless on very slight exertion.

On admission she looked ill but was afebrile. There was loud stridor, mainly inspiratory, clearly audible from the foot of the bed. The fingers were not clubbed. The heart was displaced to the right; the percussion note was impaired over the front of the right chest and the breath sounds were weak. A few rales were heard at the right apex, but no rhonchi; inspiratory stridor was widely audible. There was no enlargement of spleen, liver, or lymph nodes. A chest radiograph (Fig. 3) showed peaking of the right dome of the diaphragm and displacement of the heart and trachea to the right. There were homogeneous opacities in the right middle zone and at the right base. Some small circular shadows were seen at the right apex and in the right sub-clavicular region, and a few at the left apex. Hilar node enlargement was not apparent. Posterior view and lateral tomographs of the right lung showed a homogeneous opacity, probably pleural, situated anteriorly, a shrunken upper lobe, and bullae and honeycomb shadowing in the apical lower segment. A right bronchogram (Fig. 4) showed gross narrowing of the upper lobe bronchus, distortion of the main bronchus (lower part) and lower lobe bronchus, and gross narrowing of the latter; there was pointed occlusion of the middle lobe bronchus at its origin. There was considerable stenosis of the left main, upper, and lower lobe bronchi.

Bronchoscopy showed that the trachea was slightly compressed. The right main bronchus was displaced laterally and upwards and no trace of the right upper lobe bronchus could be found. Below this, the lumen narrowed rapidly and the middle and lower lobe orifices were seen as small slits; the rigidity of the bronchial tree was extreme. The left main bronchus was displaced upwards, so that an adequate view could not be obtained, but the lower lobe orifice could just be seen and was grossly stenosed. The mucosa everywhere appeared normal. Biopsy (Fig. 5) (from the carina between the middle and lower lobe bronchi) showed squamous metaplasia of the bronchial epithelium; there was one epithelioid follicle with several giant cells, no necrosis or caseation, but much acellular hyaline material. The tuberculin test was negative to 100 T.U. of P.P.D. Sputum culture yielded no pathogens; three specimens and one bronchoscopic trap specimen yielded no *M. tuberculosis* on smear or culture. Serum proteins and liver biopsy were normal.

After admission there was considerable clearing of the basal shadowing, attributed to reabsorption of pleural fluid; the upper zone was unchanged. Loud stridor and severe

FIG. 2

FIG. 3

FIG. 4

FIG. 2.—Case 1. Chest radiograph (June, 1955) before treatment. FIG. 3.—Case 2. Chest radiograph, April, 1956.
FIG. 4.—Case 2. Right bronchogram, May, 1956.

dyspnoea persisted. Treatment was begun with streptomycin, 1 g., isoniazid, 200 mg., and prednisone, 40 mg., daily. One month later the dyspnoea was much less and the stridor barely audible. The vital capacity rose from 1,590 ml. to 2,760 ml. and the maximum breathing capacity from 14 to 31 l./min. Streptomycin was then discontinued and P.A.S. (12 g. daily) started. She was discharged and treatment with P.A.S. and isoniazid continued; the dose of prednisone was reduced to 20 mg. daily.

Improvement continued steadily; a radiograph in November, 1956, showed great clearing of the opacities, but

FIG. 5.—Case 2. Bronchial biopsy in May, 1956. (×125.)

persisting contraction of the right upper lobe with elevation of the right hilum. Bronchoscopy in January, 1957, showed that, though there was still gross narrowing of the right middle and lower lobe bronchi, this was less severe than previously; the right upper lobe orifice could now be seen, though the bronchus narrowed rapidly; a satisfactory view of the left side was not obtained. The improvement in the maximum breathing capacity was maintained (32.2 l./min.).

Discussion

These two cases were found to have multiple bronchostenoses, and bronchoscopic biopsy showed discrete non-casating epithelioid follicles. The sputum contained no tubercle bacilli, the tuberculin test was negative (to 100 or 1,000 T.U.), and there were no pulmonary lesions on the radiograph to suggest tuberculosis. Nevertheless the process in both cases was clearly active, being associated with the presence of cellular follicles on bronchial biopsy in both cases, and with mucosal redness and oedema in Case 1. It is difficult, therefore, to regard either patient as suffering from an ordinary form of tuberculous bronchitis; both have features of sarcoidosis, but are unusual in that the recognizable lesions are bronchial.

The finding of an asteroid inclusion body within a giant cell in an epithelioid follicle seen in a bronchial biopsy from Case 1 also supports the diagnosis of sarcoidosis, as asteroid bodies are not seen in the giant cells of unequivocal tuberculosis. The radiological appearances are consistent with a diagnosis of sarcoidosis, though in neither case had typical bilateral hilar-node enlargement or diffuse pulmonary nodulation been observed. It is quite possible that the early phase of the disease was symptomless and passed unnoticed in our cases, which differ from ordinary pulmonary sarcoidosis in that, in addition to pulmonary fibrosis, there has also been extensive involvement of the bronchi. In both cases there was evidence of endobronchial granulomata and fibrosis, and in Case 2 there was also considerable distortion and rigidity of the main branches of the bronchial tree, as observed bronchoscopically. Bronchography confirmed the widespread distribution of the bronchial lesions, but bronchoscopic biopsy was crucial in suggesting the diagnosis.

The clinical features of these two cases are stridor, recurrent episodes of bronchopulmonary infection, and dyspnoea. In Case 2 stridor was very striking indeed. Before admission, however, this had been regarded as a wheeze indicative of asthmatic bronchospasm. In Case 1 stridor was inconspicuous, being concealed much of the time by wheezing from spasm and the presence of bronchial mucus. However, during treatment with prednisone the stridor was quite evident. Both patients gave histories of recurrent bronchopulmonary infections and both were seen during such an episode. These are to be attributed to infection of lung segments distal to partially occluded bronchi. Though these episodes responded to antibiotics, they did so slowly. Dyspnoea results from the development of large areas of virtually functionless lung and the additional respiratory work required to force air through constricted bronchi.

Both cases were treated with a combination of cortisone (or prednisone or corticotrophin) and antituberculous drugs. Many physicians employ such treatment in cases of sarcoidosis (Hoyle *et al.*, 1955) because of the commonly held belief in this country that many cases of clinical sarcoidosis are the unusual and atypical result of tuberculous infection; furthermore, active sputum-positive tuberculosis is not an uncommon complication of sarcoidosis, whether or not there is any causal relationship between tuberculous infection and sarcoidosis. Both cases responded to this treatment. In Case 1 the main benefit consisted in the relief of bronchospasm, the diminution in the volume of sputum, and the reduction in the number of infective episodes. In Case 2 there was a remarkable improvement in the dyspnoea and stridor, and this was borne out by the results of lung-function tests; there have been no further infective episodes. In both cases considerable radiological improvement occurred, though in neither has the radiograph returned to normal. Disappointingly, there has been little change in the bronchoscopic appearances, Case 1 being slightly worse and Case 2 rather better.

Treatment has been continued for only 18 months in Case 1 and for seven months in Case 2; it is therefore too early to say with confidence that the improvement will be maintained or whether treatment will have to be maintained indefinitely. It is impossible to state with certainty to which of the therapeutic agents the improvement is to be attributed. However, in Case 1 a course of streptomycin and P.A.S. alone (admittedly a short course, lasting only six weeks) was without effect, and an attempt to reduce the dose of cortisone below 125 mg. was followed by deterioration. In Case 2 no such evidence exists. Three of the reported cases of bronchial sarcoidosis (Siltzbach and Som, 1952; Turiaf and Brun, 1955) improved considerably when treated with cortisone or corticotrophin. Experience with the more usual types of sarcoidosis indicates that the best results are likely to be obtained with cortisone, alone or combined with antituberculous chemotherapy, and for this reason it would seem to be rational to use such treatment in cases of this sort. Furthermore, cortisone is believed to be of value in preventing the development of fibrosis following inflammatory or granulomatous lesions.

We have already referred to 13 cases of true bronchial sarcoidosis, previously described in the literature. The main features of these cases are summarized in the accompanying table. In 11 of them bronchoscopy and bronchial biopsy were performed and provided histological evidence of bronchial sarcoid lesions; in the other two bronchial lesions were found at necropsy. Stenosis of one or more major bronchi was seen in six cases; in another six there were visible bronchial mucosal abnormalities but no stenosis, and in one case no details are given. All 13 cases showed changes in the chest radiograph suggestive of sarcoidosis. The sputum (or gastric lavage) was negative for *M. tuberculosis* in all cases. The tuberculin test was negative in 11 cases; in one it was positive at 1 in 100, and in another weak positive to 10 T.U. (1 in 1,000). In seven cases the diagnosis was confirmed during life by other histological evidence (biopsy of subcutaneous nodule in two and lymph-node

Cases of Bronchial Sarcoidosis

Authors	Age and Sex	Hilar Lymph Nodes	Pulmonary Changes	Clinical Features and Extrathoracic Lesions	Sputum for <i>M. tub.</i> (or Gastric Lavage)	Tuberculin Test	Other Investigations	Bronchoscopy and Biopsy	Treatment and Progress
Benedict and Castleman (1941)	20 F	+	Lung fields clear	Cough, night sweats, loss of weight, fever, general lymph-node enlargement, subcutaneous nodules. Respiratory difficulty suggestive of partial tracheal or bronchial obstruction.	—	(1/100)	Biopsy of skin nodule and lymph node showed sarcoid.	Narrowing of both main bronchi; yellowish "bleb-like lesions" (2-3 mm.); Biopsy: many non-casating epithelioid cell follicles with giant cells.	No active treatment. Spontaneous clinical improvement.
Olsen (1946)	47 M	+	Extensive infiltration in R. lung and L.U.Z.	Cough, hoarseness, dysphagia. Cranial nerve palsies (IX and X).	—	(1st and 2nd strengths) (1 mg.)	Lymph-node biopsy: sarcoid. Increased β and γ -globulin. Decalcification and reticulation of two phalanges.	Nodular appearance of lateral wall of R. main bronchus. No stenosis. Biopsy non-casating epithelioid cell follicles.	Gold treatment with little benefit. Later spontaneous clinical and radiological improvement.
Jacobs (1949)	26 M	+	Diffuse nodular foci through both lung fields	Dry cough. Enlarged axillary and cervical lymph nodes. Bone lesions.	—	—	Biopsy of skin nodule: sarcoid. Increased serum globulin.	Lateral compression of L. main bronchus. Red haemorrhagic areas (2-3 mm.) in region of R. "first dorsal" bronchus. Biopsy: non-casating epithelioid cell follicles with giant cells surrounded by collagenous sclerosis.	Streptomycin ineffective. Later regression of hilar nodes, but pulmonary lesions increased.
Vogt (1949)	58 F	+	Diffuse nodular and streaky opacities. Pleural thickening. Bullosa emphysema. Recurrent bronchopneumonia.	Progressive cough, dyspnoea, fever, rigid chest with prolonged expiration, generalized lymph-node enlargement, skin lesions, hepatosplenomegaly, pericardial and block lesions with partial heart-block.	—	—	—	Necropsy: bronchial mucosa dark red and infected; no stenosis. Histology: numerous epithelioid cell follicles with giant cells and calcareous inclusion bodies.	Progressive deterioration. Died.
Siltzbach and Som (1952)	40 M	+	Diffuse nodular and streaky opacities. Pleural thickening. Bullosa emphysema. Recurrent bronchopneumonia.	Cough and purulent sputum, night sweats, loss of weight, wheezing, fever, generalized lymph-node enlargement, splenomegaly, quiet uveitis.	—	(1/100)	Lymph-node biopsy: sarcoid. Increased serum globulin. Bronchiectasis R.M.L.	Stenosis of R. middle lobe bronchus with granular thickened mucosa. Biopsy: non-casating epithelioid cell follicles with giant cells and surrounding inflammatory cells.	Antibiotics ineffective. Cortisone produced great clinical, radiological, and bronchoscopic improvement.
"	35 F	+	Linear opacities both lung fields R.L.Z.	Cough, dyspnoea, wheezing, stridor, prolonged expiration, and rhonchi. Enlarged axillary lymph nodes.	—	(1/100)	Lymph-node biopsy: sarcoid.	Narrowing of L. main bronchus and lower part of R. main bronchus; mucosa of R.M.L. bronchus thickened with narrowing of lumen. Biopsy: numerous non-casating epithelioid cell follicles with giant cells with Schaumann bodies.	No active treatment. Gradual spontaneous clinical and radiological improvement.
Turiaf and Brun (1955) Case 1 (also Brun and Vaillier, 1948, 1950)	39 M	—	Dense infiltration in both mid-zones with bullae	Recurrent febrile episodes with productive cough. Signs of diffuse bronchitis and emphysema, enlarged epirochlear lymph node. Hepatic lesions (necropsy).	—	—	Lymph-node biopsy: sarcoid.	Necropsy: large bronchi invaded by granulomatous tissue with epithelioid cell follicles and giant cells. Bronchioles surrounded, narrowed, and elongated.	Steady downhill course to death. Terminal right spontaneous pneumonia and thorax.
Turiaf and Brun (1955) Case 2 (also Harver <i>et al.</i> , 1950; Turiaf <i>et al.</i> , 1952, 1953)	34 F	+	Segmental opacity of right medial basal segment. Bilateral miliary opacities	Cough, dyspnoea, wheezing. Enlarged cervical lymph nodes, toxic goitre. Later fever, splenomegaly, right spontaneous pneumothorax.	—	(3 mg.) later +	Lymph-node biopsy: sarcoid B.M.R. + 34%.	Mucosa of both main bronchi reddened and thickened. Silt-like coating of R. main bronchus. Biopsy: non-casating epithelioid cell follicles with giant cells.	Streptomycin ineffective. Later spontaneous clinical, radiological, and bronchoscopic improvement and final complete return to normal.
Turiaf and Brun (1955) Case 3 (also Turiaf <i>et al.</i> , 1952, 1953)	25 M	+	Soft infiltration on left and slight reticulation on right	Productive cough, loss of weight, weakness, sweats. Fever, enlarged axillary and epirochlear lymph nodes.	—	(50 T.U.)	Lymph-node biopsy: sarcoid.	Inflammation of L. bronchial tree with irregularity of lip of L. upper lobe orifice. Biopsy: non-casating epithelioid cell follicles with giant cells and inflammatory cells.	Clinical improvement, but persisting radiological abnormality in L.M.Z.
Turiaf and Brun (1955) Case 4 (also Turiaf <i>et al.</i> , 1952, 1953)	28 M	+	Infiltration at R. base and later diffuse nodular lesions through both lung fields	Polyarthritides and erythema nodosum. Fever, weakness, loss of weight. Splenomegaly.	—	(1/100)	Increased serum globulin.	Thickened mucosa at lip of R. upper lobe orifice and of L. lower lobe bronchus. Biopsy: non-casating epithelioid cell follicles with giant cells. Oedema and inflammatory cells.	Progressed in spite of treatment with isoniazid.
Turiaf and Brun (1955) Case 5	52 F	—	Diffuse bilateral nodulation	Dyspnoea. No further clinical details.	—	—	—	Biopsy: non-casating epithelioid cell follicles with giant cells.	No details given.
Turiaf and Brun (1955) Case 6 (also Turiaf <i>et al.</i> , 1952, 1953)	41 M	+	Thickened horizontal fissure and opacity in right costophrenic angle	Pleurisy at 13 years. Pericarditis at 36. Recurrent pulmonary infections with pleurisy and arthralgia. Dyspnoea. Fever, salivary gland enlargement, iridocyclitis.	—	Weak + (1/10)	—	Slight thickening and reddening of mucosa of R. bronchial tree, especially middle-lobe bronchus. Biopsy: numerous non-casating epithelioid cell follicles. No giant cells.	Treatment with corticosteroid and cortisone followed by clinical recovery and radiological improvement.
Turiaf and Brun (1955) Case 7 (also Turiaf <i>et al.</i> , 1952, 1953)	58 F	+	Diffuse pulmonary opacities and reticulation	Dyspnoea, wheezing, and productive cough. Salivary gland enlargement, iridocyclitis, slight enlargement of lymph nodes, splenomegaly.	—	(1/100)	—	Reddening of mucosa of both main bronchi and mucosal thickening of lip of R. upper lobe bronchus, lower part of R. main bronchus, and L. upper lobe bronchus. Mucosa is grossly narrowed. Biopsy: numerous non-casating epithelioid cell follicles.	Progressive deterioration followed by clinical and radiological improvement on cortisone.

Longcope and Freiman (1952) and Cowdell (1954) each refer to one patient in whom the diagnosis of sarcoidosis was made by bronchoscopic biopsy, but give no further details. Turiaf and Brun (1955) refer to seven positive bronchial biopsies, but give details of only six (Cases 2-7 in their monograph).

biopsy in six); in two of these the diagnosis was also confirmed at necropsy. Symptoms and signs of respiratory obstruction, notably stridor or wheezing suggestive of asthma, were recorded in six cases and definite episodes of bronchopulmonary infection in three; productive cough, dyspnoea, and fever occurred in almost all. Improvement following treatment with cortisone or corticotrophin occurred in the three cases in which these agents were used.

Turiaf and Brun (1955) devote a chapter in their monograph on sarcoidosis to the discussion of bronchial involvement and the bronchoscopic findings. After considering extrinsic compression of bronchi by enlarged hilar glands, which is exceptionally rare, Turiaf and Brun proceed to discuss true bronchial sarcoidosis. This may take the form of granulomatous infiltration or of cicatricial stenosis, sometimes with resulting atelectasis, obstructive emphysema, retention and infection of secretions, or bronchiectasis. However, such sequelae are unusual (in contradistinction to tuberculosis) and bronchial sarcoidosis is commonly silent. They state that bronchial lesions are inconstant in the early stages of pulmonary and hilar glandular sarcoidosis, though they do often occur in active cases with fever and visceral manifestations. In such cases these are commonly unassociated with any clinical evidence of bronchial involvement. But in the late ("bullous-emphysematous" and "dense infiltrative") forms of the disease bronchial involvement is invariably present.

They point out that, since bronchial sarcoidosis can occur in the absence of specific symptoms or signs, bronchoscopy and bronchial biopsy are important in the recognition of bronchial involvement. They have seen 15 cases with bronchoscopic abnormalities. In only two was the mucosa grossly abnormal, but in 11 it was inflamed, though the appearances were not distinctive. Stenosis is caused in some cases by warty granulations, and in others by cicatricial fibrosis. Associated with the mucosal inflammation, there may be excessive bronchial secretions, often secondarily infected. Bronchial biopsies were performed in these 15 cases, and in seven the histological examination showed indisputable microscopical sarcoids. They found that, though it is preferable to take the specimen from the parts of the bronchial mucosa which appear most abnormal, there may be typical epithelioid follicles even when the macroscopic changes are inconspicuous.

Cowdell (1954) states: "We have once made a presumptive diagnosis on bronchoscopic biopsy, later confirmed when lymph-node enlargement appeared," but gives no further information about this case. He comments, however, that a biopsy in sarcoidosis should provide a reasonably large portion of tissue, as a small specimen (for example, from needle biopsy of the liver) "may contain only one or very few granulomata and may consequently be insufficient to show the general uniformity of pattern which is one of the most important features."

It is clear that in cases of undoubted sarcoidosis with lesions in well-recognized situations and with histological confirmation, bronchial involvement may occur; this may be associated with the presence of neighbouring hilar-node enlargement and extrinsic bronchial compression, but, on the other hand, the bronchial wall may be affected primarily. Mucosal abnormalities are recognized and stenosis is common.

From this account it can be seen that our cases were similar in their pulmonary and bronchial manifestations to those previously reported cases of sarcoidosis with bronchial involvement. A striking feature, however, is that, whereas these cases usually have had extrathoracic sarcoid lesions, in our cases there were no such manifestations or biochemical abnormalities, and liver biopsy was negative.

Citron (1955) has described a case in many ways similar to our cases under the title of "Multiple tuberculous bronchial stenosis." A man aged 31, with a past history of tuberculous cervical nodes, had recurrent febrile bronchopulmonary infections with pulmonary opacities on the radio-

graph; there were stridor and generalized rhonchi. Bronchography and bronchoscopy showed multiple stenoses of bronchi, and a bronchoscopic biopsy showed "typical tubercles with little caseation." Numerous specimens of sputum yielded no *M. tuberculosis* on culture, but the tuberculin test was positive to 10 T.U. of P.P.D. This patient improved on treatment with cortisone and anti-tuberculous drugs. No reference is made to any extra-thoracic manifestations of the disease.

Summary and Conclusions

Two cases are reported in which multiple bronchial stenoses were associated with a negative tuberculin test and negative sputum; bronchial biopsy revealed non-caseating epithelioid follicles. We regard these as examples of sarcoidosis, predominantly affecting the bronchi.

The main clinical features in our cases were recurrent bronchopulmonary infections, stridor, and progressive dyspnoea. Extrathoracic manifestations of sarcoidosis were absent. The occurrence of these symptoms without adequate explanation calls for bronchoscopy and bronchial biopsy; bronchography may also give useful information.

Preliminary experience suggests that steroid therapy may be helpful, and it is probably wise to combine this with antituberculous chemotherapy.

Bronchial lesions do occur in sarcoidosis, but have hitherto been given little attention in the literature. Thirteen reported cases are reviewed.

We thank Dr. J. L. Livingstone and Dr. N. C. Oswald for permission to publish these cases and for valuable advice during the preparation of this article. We also acknowledge our debt to Dr. J. G. Scadding for drawing our attention to the occurrence of cases of this sort, and to Dr. G. Simon for advice on the radiological interpretation.

ADDENDUM.—Since this article was prepared, Citron and Scadding (*Thorax*, 1957, 12, 10) have reported three cases—one of which is quoted above (Citron, 1955)—closely resembling ours; in one the tuberculin test was positive (to 100 T.U.) and in another the sputum was found on two occasions to contain acid-fast bacilli. They regard their cases as having sarcoidosis of the bronchi, but think that they are all of tuberculous aetiology. Kalbhan (*Thorax*, 1957, 12, 18) describes the bronchoscopic appearances in 11 consecutive cases of pulmonary sarcoidosis (none of more than two years' duration); in four the appearances were virtually normal, in one the only abnormality was distortion of the carina, in five the mucosa was thickened or granular, and in one (Case 9) there was also stenosis of the right middle and lower lobe bronchi. In three cases bronchial biopsy showed non-caseating tubercles and in three others giant cells were seen.

TREATMENT OF POLYCYTHAEMIA VERA WITH RADIOACTIVE PHOSPHORUS

BY

JAMES R. FOUNTAIN, M.D., M.R.C.P.Ed.

Tutor in Medicine, Department of Medicine,
General Infirmary, Leeds

Since the introduction by Lawrence (1940) of radioactive phosphorus (^{32}P) for the treatment of polycythaemia vera, several reports concerning its effectiveness have appeared in the world literature. In the United Kingdom the largest reported series is that of Harman *et al.* (1955), comprising 48 cases, two smaller groups of *et al.* (1955), having previously been described by Bodley Scott (1953) and Abbatt *et al.* (1954).

^{32}P , because of its being chemically indistinguishable from ordinary stable phosphorus, enters into all phases of phosphorus metabolism. After administration it is rapidly concentrated in phosphorus-containing tissues, and Lawrence *et al.* (1940) have demonstrated in animals that the majority becomes localized in bone and marrow, while only slightly smaller quantities become localized in the liver, spleen, and lymph nodes. In leukaemic patients a similar distribution of ^{32}P has been demonstrated (Erf, 1942). According to Reinhard *et al.* (1946) the selective uptake of phosphorus by cells is dependent principally on three factors: (a) total amount of phosphorus in the tissues, (b) rate of turnover of phosphorus in the tissues, and (c) rate at which new tissue is formed. ^{32}P would therefore seem to be a rational and satisfactory approach to the treatment of a myeloproliferative disease such as polycythaemia vera.

^{32}P can be administered orally or intravenously. As about 25% is lost in the stool when given by mouth, it is generally given by the intravenous route as dibasic sodium phosphate. After intravenous injection it is taken up by myeloid tissue during the first 24 hours, and it has been shown that in leukaemic subjects 5–25% of it has been shown that in leukaemic subjects 5–25% of the isotope is excreted, mostly in the urine, during the first six days (Erf and Lawrence, 1941). Patients with polycythaemia vera excrete similar amounts, but in normal subjects 25 to 50% is excreted within the same period. In all cases, however, the rate of excretion falls after the first few days to less than 1% of the injected dose.

Since 1952, 47 patients with polycythaemia vera have been treated with ^{32}P at the Leeds General Infirmary, of which 40 have been followed up for periods longer than three months. The main purpose of this paper is to record the clinical and haematological effects of ^{32}P on this series of patients.

Age and Sex.—All patients were over the age of 40 years when the diagnosis was made, the range being 42 to 74 years (Table I). A slight preponderance (3:2) of females was observed.

TABLE I.—Ages of Patients at Time of Diagnosis

Under 40	40–49	50–59	60–69	Over 70
Nil	11 (23.4%)	24 (51%)	10 (21.3%)	2 (4.3%)

Dosage

The initial dose of ^{32}P recommended by various workers varies from 3 to 7 millicuries (mC.), depending to some extent on body build and the red-cell mass as indicated by blood-volume studies, haematocrit readings, and the height of the red-cell count. In the present series 3 mC. of ^{32}P has been given routinely to all patients as the first dose. Venesections at the outset have been recommended to relieve symptoms and prevent further thrombotic episodes before ^{32}P becomes effective. This has not been done routinely in Leeds, but in 10 patients initial venesection was considered desirable to relieve symptoms. No attempt, however, was made to reduce the red-cell mass to normal by massive venesection as suggested by Harman *et al.* (1955). Patients were treated as out-patients and usually seen at monthly intervals after the first injection. Changes in symptoms and in erythrocyte, leucocyte, and platelet counts were noted on each visit, and, depending on these findings, further doses of 3 mC. of ^{32}P administered when necessary.

In general, a falling red-cell count associated with clinical improvement, or evidence of depression of granulocytopoiesis or platelet production, was an indication against further treatment with ^{32}P . In view of the delayed effect of ^{32}P Lawrence *et al.* (1953) recommended an interval of 10 to 12 weeks before a second injection was given. In their series, however, it was the practice to carry out initial venesection in all cases. In the absence of such a procedure in the present series it has been the rule to give further injections of 3 mC. of ^{32}P during the second and third months after the initial injection if the haematological state warranted them. Experience suggested that such a scheme probably leads to a more rapid control of the disease in the absence of venesections.

The total dose of ^{32}P required to produce a haematological remission, using a red-cell count of 5,500,000 per c.mm. as the upper limit of normal, was variable, but in over half the patients a return of the blood state to normal occurred after a total dose of 3 to 6 mC., and in approximately 90% an initial remission was induced by a total of 9 mC. or less (Fig. 1). Occasional patients required larger doses, and in two cases adequate control was not obtained by ^{32}P therapy alone. In one a total of 34 mC. of ^{32}P was given over a period of two and a half years, and in another 55 mC. in four years, without producing a remission of over three months' duration. These two instances indicate that a small number of patients are resistant to therapeutic doses of ^{32}P , which has been suggested previously by Wiseman *et al.* (1951).

FIG. 1.—Dose of ^{32}P in mC. required to induce an initial remission (38 patients).

Clinical Manifestations before Treatment

The frequency of the various symptoms and signs, together with the complications which occurred, are shown in Table II. All patients were found to have a high colour, while the commonest group of presenting symptoms comprised headache, dizziness, dyspnoea, and increased fatigability. Pruritus occurred in nine patients, and in some was severe and the major complaint; it was generally worse after taking a hot bath. Nine patients complained of dyspeptic symptoms, in four of which a duodenal ulcer was demonstrated radiologically. Two patients had gout, in both for more than five years before polycythaemia was

TABLE II.—Presenting Symptoms and Signs in 47 Patients With Polycythaemia Vera

	No.	%
High colour	47	100
Headache, dizziness, dyspnoea, and fatigability	35	74.5
Hypertension (diastolic over 100 mm. Hg)	30	64
Splenomegaly	25	53
Cardiovascular disease other than hypertension	24	51
Phlebotomias	12	25
Angina pectoris	7	15
Intermittent claudication	5	11
Gangrene	4	8.5
Pulmonary embolism	4	8.5

Cerebral	1	2
Hepatomegaly	15	32
Haemorrhagic phenomena	9	19
Dyspepsia	9	19
Peptic ulcer proved by radiograph	4	8.5
Pruritus	9	19
Gout	2	4

diagnosed. Haemorrhage was not so common as in other reported series (Harman *et al.*, 1955), and was never serious. Cardiovascular disease, and in particular thrombotic phenomena, were common, however, half of the patients giving a history of one or more of the following: phlebotomias, pulmonary embolism, coronary thrombosis, angina pectoris, cerebral thrombosis, intermittent claudication, and gangrene. Hypertension as judged by a diastolic pressure of over 100 mm. Hg was present in about two-thirds of patients. Splenomegaly was present in 25 cases before treatment, but in only a few did the spleen extend further than the umbilicus. The liver edge was palpable in 15 of the 47 patients, but never extended more than two finger-breadths below the costal margin.

Effect of ^{32}P Therapy on Clinical Manifestations

It is generally accepted that most of the common symptoms of polycythaemia vera are due to the increased blood volume consequent upon the red-cell mass. Support for this belief is obtained from observing the effect of treatment, which in most cases results in a disappearance of symptoms as the red-cell count and total red-cell volume fall to normal levels. In this series it was usually found that symptomatic relief was complete before the arbitrary upper limit of normal of 5,500,000 red cells per c.mm. was reached, but in some instances symptoms such as headache, dizziness, and breathlessness persisted after the red-cell count and haematocrit reading had returned to normal. It seems not unlikely that in such cases these symptoms were due to causes other than polycythaemia, such as hypertension and arteriosclerosis, which one would expect in a group of people in this relatively older age group. In 75% of patients, however, headache, dizziness, fatigability, and dyspnoea were completely relieved or substantially improved.

Pruritus was completely relieved in five out of nine patients; in three only partial improvement occurred; while one failed to obtain any relief, although the blood picture returned to normal following treatment. Haemorrhagic phenomena and further thrombotic episodes were not observed after the disease was controlled, but established cardiovascular disease, such as intermittent claudication and angina pectoris, was unaffected by treatment. In the hypertensive patients a consistent fall in the diastolic blood pressure below 100 mm. Hg was observed in only 10 out of 30 patients. This finding indicates that the raised blood pressure in polycythaemia vera is not always due to increased blood volume alone, and in many instances is largely unrelated to the haematological state.

A reduction in the size of the spleen to a greater or lesser extent was observed in all 25 patients in which the spleen was enlarged, and in seven it became palpable. The liver, although never greatly enlarged before treatment, returned to a normal size after treatment apart from one instance. Features common to all—namely, plethora, reddened conjunctiva, and highly coloured palms—disappeared as the red-cell volume diminished with treatment. Dyspeptic symptoms were not significantly affected by treatment, and one patient with gout has required regular treatment for this complaint irrespective of his haematological state.

Haematological Manifestations Before Treatment

The blood findings in the 47 patients at the time of diagnosis and preceding treatment are recorded in Table III.

TABLE III.—Blood Findings in 47 Patients With Polycythaemia Vera at Time of Diagnosis

Range 125,000 to 615,000 per c.mm.	47	100
Below 150,000 " " "	2	4
150,000 to 350,000 " " "	28	60
Over 350,000 " " "	17	36

In most subjects the red-cell count ranged from 6,500,000 to 8,000,000 per c.mm., while the P.C.V. was over 60% in all. Leucocytosis, defined as a white-cell count of over 10,000 per c.mm., was present in 26 patients, but in only three was the leucocyte count higher than 20,000 per c.mm. The differential leucocyte count showed a well-marked preponderance of polymorphonuclear cells in approximately 75% of all patients, but myelocytes and nucleated red cells were observed in the peripheral blood in only five patients (11%). Although thrombocytosis occurs in polycythaemia vera, analysis of the present series suggested that a normal platelet count was more common. If a range of 150,000–350,000 per c.mm. is taken as representing normal, 60% of the patients were found to have platelet counts within this range, while 36% had counts higher than normal.

Thrombocytopenia—that is, less than 150,000 platelets per c.mm.—was detected in only two patients prior to treatment.

Bone-marrow aspiration was carried out in 14 patients. The marrow was found to be hypercellular in all, but no characteristic cellular pattern was observed. Marrow examination is of no diagnostic help in polycythaemia vera, and shows no features that might permit of differentiation from secondary polycythaemia (Lawrence *et al.*, 1953).

Haematological Changes After Therapy

The therapeutic effect of ^{32}P on the blood cannot be evaluated for at least 30 to 60 days, since red cells have a life cycle of 120 days and ^{32}P brings about a reduction of red cells by decreasing their rate of formation. Thus the fall in the red-cell count is slow and not normally apparent for several weeks after treatment.

The time interval between the start of ^{32}P therapy and return of the red-cell count to within the normal range is variable. Of 33 patients in whom accurate analysis was possible, the red-cell count returned to normal within three months in 6, within four months in 15, within five months in 26, and in 7 patients the interval was longer than five months. The delay in return of the red-cell level to normal might be taken as an indication for more liberal use of venesections. In practice, however, symptoms usually disappear before the red-cell count reaches normal, and further thrombotic episodes have not been observed after treatment has been instituted.

Forty patients have been seen regularly for periods of over three months following their initial injection of ^{32}P . In these patients the effect of ^{32}P on the blood can be assessed. In only two have the red cells not been satisfactorily reduced. In the remainder a normal red-cell count has been attained. Severe anaemia has not been observed to follow treatment, but in a few instances the red-cell count has temporarily fallen to a level of 4,000,000 per c.mm.

It is well recognized that ^{32}P not only reduces the red-cell level but also has a profound effect on the leucocyte and platelet counts. Over half the patients in the present series had an initial leucocytosis of over 10,000 per c.mm. After treatment the white cells fell below this level in all cases, together with a return of the differential count to normal. In 15 out of the 40 patients (37.5%) under analysis a transient fall to a leucopenic level (below 4,000 per c.mm.) occurred. In no instance did the leucopenia reach below 3,000 per c.mm. or result in any adverse effect upon the patient. A similar fall in the platelet count was observed to follow treatment, and in 17 patients (42.5%) the platelets fell below 150,000 per c.mm. In one the count fell to 48,000 per c.mm., but in all cases thrombocytopenia was transient, and no instances of spontaneous haemorrhages or purpura were observed. Thrombocytopenia, however, is a potentially dangerous state and may appear before the red-cell count falls. In such circumstances, and similarly when leucopenia is present, it has always been the practice to withhold treatment until the platelets or leucocytes have returned to normal numbers.

Fig. 2 shows graphically the haematological course of events in a woman treated with a total of 6 mC. of ^{32}P . A remission of one year resulted, and following relapse a second course of ^{32}P induced a further remission.

FIG. 2.—Effect of ^{32}P on the blood of a woman aged 58 with polycythaemia vera. (Dotted lines represent upper limits of normal.)

Duration of Remissions

Remissions following initial courses of treatment have been observed in 38 patients. Two were not controlled by ^{32}P , while five have been followed for periods of less than three months. Two others left the district after their first injection and were not seen again. Of 25 patients followed until relapse occurred, 20 (80%) had a first remission of over one year, as calculated from the date the red-cell count fell below 5,500,000 per c.mm., 14 (56%) had remissions longer than 18 months, while in 10 (40%) the initial remission was over two years. The longest remission was 37 months and the shortest two months. In the latter patient a second course of treatment was followed by a prolonged remission. The average length of the first remission in this group of 25 patients was 19 months. In 13 patients the initial remission continues, in 8 being shorter than six months, while in the remainder it ranges from 8 to 36 months.

Remissions followed a second course of therapy in 22 of the 25 patients relapsing after their initial course. Of the other three, two failed to be satisfactorily controlled by ^{32}P a second time, while one left the district. Eleven of this group of 22 patients have since relapsed after second remissions of up to 20 months' duration, while the remaining 11 continue satisfactorily controlled up to 15 months after their second course of treatment. Third and subsequent

remissions of as long as 22 months have occurred in nine patients to date.

Two patients have died. One, a woman aged 67, has been mentioned previously as not responding satisfactorily to ^{32}P therapy. She died of acute myeloblastic leukaemia five years after the diagnosis of polycythaemia vera was made. The other, a woman aged 54, was controlled satisfactorily with ^{32}P until she developed a severe terminal leuco-erythroblastic anaemia.

Comment

Venesection, phenylhydrazine, nitrogen mustard, and external irradiation are all therapeutic methods by which the total red-cell volume can be reduced and hence relieve symptoms in polycythaemia vera. Radioactive phosphorus can likewise effectively reduce the red-cell mass, and on account of the ease of administration, out-patient treatment, and absence of unpleasant side-effects it is now generally regarded as the most satisfactory form of therapy. Under careful supervision prolonged remissions can be expected in most patients and a life expectancy of only a few years under the normal for this age group (Lawrence *et al.*, 1953). The same authors are also of the opinion that the incidence of leukaemia is not higher than in previously reported series treated by other methods, while the incidence of deaths from vascular complications has been reduced by about one-half since the institution of ^{32}P treatment.

^{32}P is, however, not without certain practical disadvantages. Overdose must, of course, be guarded against, and thrombocytopenia and leucopenia, which may precede a fall in the red-cell count, are temporary contraindications to further therapy. Secondly, owing to the rarity of the disease, and the need for skilled technical staff, treatment must be carried out in clinics at the major hospital centres, which entails long journeys for many of the patients. Finally, the relatively long latent period of from 30 to 60 days before the red-cell count begins to fall may necessitate initial venesections to relieve symptoms until the ^{32}P becomes effective.

The excellent results of therapy, however, outweigh any of the disadvantages, and at the present day ^{32}P would seem to be the treatment of choice for patients with polycythaemia vera.

Summary

Forty-seven patients with polycythaemia vera have been treated with radioactive phosphorus (^{32}P).

A description is given of the clinical and haematological findings in this group of patients, and the results of treatment are assessed.

^{32}P was given intravenously in doses of 3 mC. In approximately 90% of patients an initial remission was induced by a total dose of 9 mC. or less.

Of 40 patients who have been observed for more than three months after their initial treatment, all but two developed remissions of up to 37 months' duration. Subsequent remissions usually followed further courses of treatment.

I would like to express my gratitude to Mr. G. W. Reed, senior lecturer, and Miss P. Morris, senior technician, of the Department of Medical Physics, University of Leeds, for their valuable assistance.

WEIGHT IN RELATION TO PREGNANCY TOXAEMIA

BY

CICELY D. WILLIAMS, D.M., F.R.C.P.
D.T.M.&H.

Obstetric Unit, University College Hospital, London

It is probable that pregnancy toxæmias are due to a number of causes, of which some are somatic and some may be social and psychological. Very often the picture is a complicated one.

Of recent years much has been written on the dangers of obesity (*British Medical Journal*, 1953), and there is an admirable summary by Armstrong *et al.* (1951). Kennedy (1955) showed that rats which became obese developed degenerative changes in the kidney at an early age. In fact, "breakdown of function is the result of excessive hypertrophy at any age." Leitner (1955) concluded: "Obesity may thus be regarded as one of the known conditioning factors in the development of essential hypertension." He gave evidence which confirms "the widely accepted clinical observation that weight reduction in the obese is followed by a fall in blood pressure."

In 1957 Elvehjem stated that in experiments on rats nothing is gained by increasing the protein intake over the "minimum optimum." In fact, excess of certain amino-acids may delay growth and increase the fat in the liver. Parry (1955) has recorded large-scale observations with sheep. It is not certain how far "twin lambing disease" (pregnancy toxæmia in ewes) can be compared with pre-eclamptic toxæmia in women, but he is now able to control the disease in large numbers of flocks where his recommendations on diet have been followed. He stated that, though many ewes can become overweight and yet have a normal pregnancy, yet if these obese ewes are subjected to any form of stress they are then liable to develop toxæmia.

There is in effect a great deal of evidence, both with humans and with animals, that obesity in itself is associated with hypertension and with disorders of the kidney, which may be functional or degenerative.

Dieckmann (1952) has shown that pregnant women who develop severe toxæmia begin to put on an undue amount of weight early in pregnancy. He claimed that pre-eclamptic toxæmia never occurred if the weight did not increase by more than 8 lb. (3.6 kg.) in any 10-week period. Hamlin (1953) reported that he had reduced the incidence of eclampsia from 1 in 500 to 1 in 7,000 by strict attention to diet and avoiding undue weight increase. A number of other papers have appeared in the literature. In 1957 Thomson and Billewicz confirmed that the average rate of gain is higher in pre-eclamptic toxæmia than in normal cases. But, as they remark, "there is comparatively little exact numerical information."

Present Investigations

These investigations were started at the request of Professor W. C. W. Nixon, and the material used consists of records from University College Obstetric Hospital, London. From the beginning of the study it appeared that increase in weight during pregnancy was not the only important factor. Women who were already overweight at the time of the first antenatal attendance seemed to produce a large proportion of the toxæmias even in some cases where the observed weight gain during pregnancy was only moderate.

Standard Weight for Height.—It was decided to compare the weights of a group of normal cases with a group of those diagnosed as pre-eclamptic toxæmia, and to use the standard weight for height as a means of comparison. The tables used were those to be found in the Medico-Actuarial Mortality Investigation, vol. 1, New York, 1912. These are almost identical with those at present in common use in this country—for instance, in Burroughs and Wellcome's medical diary. These tables give average weights "after removing the outdoor clothes and shoes." In all the published tables a considerable increase is allowed for age as well as for height. For example, a woman of 5 ft. 5 in. (165 cm.) averages 127 lb. (57.6 kg.) at 19 years and 137 lb. (62.1 kg.) at 33 years. But these are averages and not optima. It was decided, therefore, to take the weight for height at 25 years as a generous optimum and use this as the standard of comparison.

Weight Gain in Pregnancy.—Most of the authorities agree that the permissible gain in weight during pregnancy should be in the region of 20–24 lb. (9.5–10.9 kg.). This gain is made up as follows: products of conception—foetus, placenta, liquor amnii, 11 lb. (5 kg.); maternal gain—uterus, breasts, and other tissues, 13 lb. (6 kg.).

The maternal gain consists of about 3 lb. (1.4 kg.) of extra protein, and 10 lb. (4.5 kg.) of extra water retained in the increased plasma and intracellular and extracellular tissues. This water is quickly lost after parturition (Leitch, 1957). But it was found that many women, when they attend the post-natal clinic, are still above their pre-gravid weight. This more permanent gain is due to fatty and other tissues, and not to increased fluid retention.

Total Weight.—In theory the patient should weigh the standard for her height at the beginning of pregnancy. At term she should weigh an additional 20–24 lb. (9.5–10.9 kg.), and within two weeks after delivery she should return to her pre-gravid weight. If she is lactating she may be permitted an extra pound or two for breast tissue.

Method

There are no records of the pre-gravid weights of the patients, but all the heights are measured at the first antenatal attendance. It is always possible, therefore, to calculate the standard weight for height. The patients are weighed at every attendance. They receive advice on diet as a routine, and special advice on salt and calorie intake, whenever this appears to be indicated.

For some years attention has been paid in this clinic to nutrition and to weight increase. The results of this study are considerably modified by advice and by treatment. However, some patients ignore advice, or develop overweight or toxæmia in spite of it. Many of those who showed signs of toxæmia were admitted to the wards some days or weeks before the onset of labour. Rest in bed and a low-salt diet of 1,200–1,800 calories appeared to be of great benefit in reducing the oedema and the blood pressure. Some patients were also given sedative and hypotensive drugs. Labour was induced if the symptoms did not abate, and in any case before the 42nd week. Because of these antenatal admissions, the average maturity at the final weighing of the toxæmias was rather less than that of the normals, and the interval between the final weighing and the delivery was rather more. Both these factors would tend to show less weight gain in the toxæmias than in the normals, so that the difference may be greater than is indicated in these figures.

The actual weights are used here, although it would have been better to express them as percentages of mean normal weight for height. The computations, however, would have been much more lengthy.

Diagnosis.—Patients have been classified according to the diagnosis made by the registrar, most of which was done before this study began. "Pre-eclampsia" is diagnosed when at least two out of the three following conditions are present: albuminuria in a catheter specimen, oedema,

and a blood pressure of 140/90 or over. "Normal" is diagnosed when delivery and puerperium have been free from complications. It does not exclude certain patients who had deviations from the normal during their pregnancy. For instance, it includes a proportion of patients who at some time had hypertension with oedema but who had responded to treatment before term. Twenty-two of the 50 "normal" patients showed some degree of oedema during pregnancy. None of them had albuminuria.

Selection of Cases.—This study compares 50 normal cases with 50 cases of pre-eclamptic toxæmia. It is confined to primiparae. The records for 1955–6 were examined, and the case sheets of those diagnosed as "pre-eclamptic toxæmia" were requested from the registry. Cases excluded from this survey were as follows: (a) multiparae, multiple pregnancies, abnormal presentations, and hydramnios; (b) essential hypertension, kidney disease, diabetes, and other pre-existing abnormalities such as gross kyphosis; and (c) incomplete or inaccessible records. The 50 normal cases were selected at random by the registry clerks. The only cases excluded were multiparae, multiple pregnancies, and incomplete records.

Results

Initial Weight.—In comparing initial weights, three cases are excluded from each of the two groups. These are all patients whose first attendance was later than the 20th week. The remaining 47 cases in the "normal" group had a mean maturity of 13.4 weeks when first examined, and the pre-eclamptic toxæmia group had a mean maturity of 14.4 weeks. The latter group might therefore be expected to be slightly heavier. To relate the initial weights of the two groups, the comparison should be made between those of the same maturity. However, confining our attention to those patients between 10 and 20 weeks (inclusive) we find that the average increase of weight with maturity over this period (13.4–14.4 weeks) is negligible compared with their variation. Comparing, therefore, the initial weights of the two groups regardless of this slight difference in maturity, we find that the mean initial weight of the normals is 129.1 lb. (58.56 kg.), and that of the toxæmias is 136.4 lb. (61.87 kg.). The overlap is considerable.

FIG. 1.—Initial weight of 47 normal women and 47 with pre-eclamptic toxæmia.

FIG. 2.—Gain in weight per week in 46 normals and 44 toxæmias.

FIG. 3.—Final weight compared with standard weight.

Gain per Week.—The gain in weight, measured by the difference between the weights at the first and last attendance, must depend to some extent on the number of weeks between. In order to make a more valid comparison only those patients observed for 20 weeks are included, and the gain is expressed as average gain per week. In this series 46 normals are compared with 44 toxæmias. The mean gain per week in the 46 normals is 0.912 lb. (0.417 kg.), and in the 44 toxæmias it is 1.156 lb. (0.524 kg.). The difference is statistically highly significant.

Total Gain Over Standard for Height.—In taking standard weight for height we have a baseline which is independent of the number of attendances or the date of the first attendance. In using the final weight as an end-point we depend to some extent on the date of the final weighing in relation to the date of delivery. But most patients showed comparatively small gains in the last three weeks before parturition, and therefore those discrepancies have been ignored. But in Fig. 3 only those are included who were under observation for at least 20 weeks. It appears that when the total weight at the end of pregnancy is compared with the standard weight for height the mean excess in the toxæmic group is higher than in the normals. It will be seen that there is a marked contrast between the two groups. This suggests that the relation to standard weight for height gives a more decisive distinction than either the comparison of initial weights or the gain in weight per week.

Now, if we consider the total of 50 toxæmic patients we find that 48 had either (a) reached more than standard weight +24 lb. (10.9 kg.), or (b) gained more than 24 lb. (10.9 kg.) during the period of observation, which averages 20 weeks, and not the whole period of pregnancy. Of the two remaining cases one had had a nervous breakdown and the other had had an arthrodesis of the hip.

Blood Pressure and Weight Gain.—All those diagnosed as pre-eclamptic toxæmia showed hypertension of 140/90 or more. But many of those who were finally diagnosed as normal also showed an occasional rise in blood pressure. Each case history was examined, and scored for every rise of systolic pressure to 140 or over or a diastolic of 90 or over, and the scores were reduced to a percentage of total observations. The 50 cases were then analysed as follows:

	Blood Pressure Readings Abnormal
15 patients who were more than 30 lb. (13.6 kg.) over standard weight for height at final weighing	11.7%
13 patients who were 20–30 lb. (9.1–13.6 kg.) over standard weight for height at final weighing	4.0%
22 patients who were less than 20 lb. (9.1 kg.) over standard weight for height at final weighing	3%

Of the 50 normal patients, therefore, those who were overweight tended to show occasional signs of hypertension, which was comparatively rare in those who kept in the region of standard weight or underweight.

Discussion

It is obvious that not all cases of pre-eclamptic toxæmia are associated with excess weight or weight gain. For instance, Case 49 of the toxæmic group first attended at 18 weeks weighing 110 lb. (49.9 kg.), which was 11 lb. (5 kg.) less than her standard weight for height. At 36 weeks she weighed only 122 lb. (55.3 kg.), having gained 12 lb. (5.4 kg.) in 18 weeks. She was delivered at 39 weeks by surgical induction of a 7-lb. (3.2-kg.) baby. It is also obvious that many pregnancies appear to remain normal throughout in spite of obesity or weight gain.

Nevertheless, it seems that most cases of pre-eclamptic toxæmia are associated with overweight preceding pregnancy or an excessive gain during pregnancy, or both.

It would seem to be advisable to compare the weight of the antenatal patient with her standard weight for height, as well as to observe the increase during pregnancy. It is important that this should be undertaken as early as possible in pregnancy, if not before.

It may in fact be dangerous to confine observations merely to the rate of increase during pregnancy. For instance, a healthy woman whose actual and standard weight for height is 120 lb. (54.4 kg.) becomes pregnant. As a result of anorexia or vomiting during the first three months she arrives at the antenatal clinic at 14 weeks weighing only 105 lb. (47.6 kg.). She may in fact be in a state of sub-nutrition, which will be overlooked unless reference is made to what, for her, should be normal.

It must be accepted that obesity has become one of the major health hazards in certain countries. Overweight in pregnancy is due to obesity and to increased fluid retention. Both can be controlled by attention to weight and weight increase.

Pregnancy toxæmia is now regarded as one of the primary causes of maternal mortality and morbidity. It is an important cause of prematurity and of perinatal mortality in the more advanced countries.

Theobald (1955) has reported excellent results from careful prenatal supervision from the 24th week, and he advises weekly weighing from this date. The observations at University College Obstetric Hospital indicate that overweight is itself a factor that may increase the risk of toxæmia. A large proportion of patients are already overweight before they become pregnant. It is quite possible for a woman to modify her diet so that she goes through a normal pregnancy with no increase in weight. In fact, obese women have been successfully reduced in weight while pregnant with no damage to the child. The majority of women are on an adequate and even excessive diet before they come to the antenatal clinics. However, it cannot be overemphasized that each patient should be considered separately: some women are badly or inadequately fed and are in need of extra nourishment.

Weight, with reference to height and maturity, must be checked as early as possible in pregnancy. The 24th week may be too late. Signs of malnutrition must not be neglected; but if there is any obesity it should be controlled as early as possible and throughout the antenatal period.

At present a large proportion of antenatal beds are taken up with cases of pre-eclamptic toxæmia, while a great deal of time and attention has to be devoted to observation and to intervention in these cases. It is probable that closer attention to weight in the early weeks would prevent a number of complications. This procedure should be carried out by all who undertake antenatal supervision or treatment. Patients should be urged to attend as early as possible in pregnancy. Each should be measured for height at the first attendance and weighed then and at every subsequent attendance. If there is much deviation from the standard the patient should be seen at weekly intervals. The standard weight for height should be entered on the antenatal card so that this can be referred to throughout pregnancy.

Each antenatal clinic should be equipped with (a) a rod or wall marking for height measurement, (b) adult scales, and (c) a table of standard weights for height at 25 years (the patient's age can then be ignored). The patient's attendance card (the one which she keeps) should have the dates and weights entered on the back so that she herself can remember its importance. Every doctor or midwife who undertakes antenatal care should be sufficiently trained in nutrition and in social medicine to give the appropriate dietetic advice.

It should be remembered that there seems to be a fairly wide margin of safety. Weighing need not be perfectly exact, and dietetic advice need not be too strict except in cases of gross abnormalities. But obesity and excessive gain should be observed, noted, and, if possible, remedied. If a patient comes to the antenatal clinic at 16 weeks already 40 lb. (18 kg.) over her standard weight, it is not advisable to put her on a strict reducing diet. If she is already hypertensive or oedematous she should, of course, be admitted; or she should be advised to restrict salt and calorie intake. She may be able to go to term without any further weight increase and deliver a normal baby. She may even reduce in

weight before term. But it is essential that her reaction to the diet and to the pregnancy should be observed at frequent intervals. It is certainly unwise to delay dietetic advice until a rapid rate of weight increase has been recorded.

Obesity and its complications are serious diseases, and they often start in pregnancy. Not only do they increase the hazards of pregnancy and parturition, they threaten health and well-being in later life. As Kennedy says, "Breakdown in function is the result of excessive hypertrophy at any age."

Obesity is a preventable disease which is not at present sufficiently prevented.

Summary

50 cases of normal pregnancy are compared with 50 cases of pre-eclamptic toxæmia from the records of University College Obstetric Hospital.

The cases of pre-eclamptic toxæmia average higher initial weight, and larger average weekly weight gain than the normals.

When compared with the individual standard weight for height the majority of the normals exceeded this by less than 24 lb. (10.9 kg.) at the end of pregnancy. The majority of the pre-eclampsics exceeded this by more than 24 lb. (10.9 kg.).

The normals who showed excessive weight tended to have more episodes of hypertension than those who did not.

The question of weight and of weight gain in relation to pregnancy and obesity is discussed.

I am grateful to Professor W. C. W. Nixon for initiating this study and for his help. I am also indebted to Mr. N. W. Please for advice and his work on the statistics, and to the staff of the Obstetric and Dietetic Departments of University College Hospital, who have assisted in the collection of information.

The report of the fourth session of F.A.O.'s nutrition committee for South and East Asia is now available through Her Majesty's Stationery Office (price 2s. 6d. net). It is a report of the meeting held in Tokyo from September 25 to October 2, 1956. The meeting was the fourth in a series, the first of which was held in the Philippines in 1948, the second in Burma in 1950, and the third in Indonesia in 1953. At each of these meetings nutrition problems of major importance in the region are considered. The fourth meeting was sponsored jointly by F.A.O. and W.H.O. The report discusses progress in nutrition in the region since 1953, and states that the attention which is being given to the expansion of sea and inland fishing industries is a promising development, since fish is a valuable supplement to diets characteristic of South and East Asia. It also gives information on nutrition and food production, the beriberi problem, improving the nutritive value of rice, and the study and prevention of protein malnutrition. There is a chapter on supplementary feeding and education in nutrition, the latter being regarded as the key to many of the region's nutritional problems.

PRE-ECLAMPTIC TOXAEMIA*

BY

O. VAUGHAN JONES, M.D., F.R.C.S.Ed.
F.R.C.O.G.

St. David's Hospital, Bangor

During the course of this century maternal mortality has fallen from a peak of 7.6 in 1918 to well below 1 per 1,000 births to-day, but nevertheless a study of the Registrar-General's Review (1956-7) reveals that a third of these deaths are still due to toxæmia of pregnancy.

Whilst information of the maternal cause of stillbirths and neonatal deaths is scanty, Baird, Walker, and Thomson (1954), in analysing 1,008 foetal deaths, found that 20% were due to toxæmia and accidental haemorrhage. A total loss of child life in Great Britain, as shown in a report of the Ministry of Health (1949) for all toxæmias, varies between 25 and 40%, while 15 to 20% of all infant losses are associated with toxæmia.

In this paper the theories regarding the aetiology of toxæmia of pregnancy are omitted, as a general treatment of the subject, with particular reference to known clinical facts, is of greater import.

Gemmell, Logan, and Benjamin (1954), in analysing a large series of pregnancies, found that 8.5% of primigravidae and 4.2% of multigravidae developed toxæmia; this is close to the commonly accepted 10% for all pregnancies. The incidence increases in primigravidae over the age of 30 and in multigravidae over 40, whilst it recurs in subsequent pregnancies in 30 to 40% of patients.

Few to-day consider that chronic renal damage is a sequela of toxæmia, and most workers, including Theobald (1933, 1955), Isenhour *et al.* (1942), Barnes and Browne (1945), and Kellar (1950), are agreed that toxæmia does not predispose a patient to chronic hypertension. Light (1948), Gibson (1956), and others believe that the degree of severity and duration of toxæmia do not appear to influence the production of residual hypertension. Browne and Sheumack (1956) conclude that if a patient does not belong to a hypertensive family she will not develop residual hypertension. They also consider that it is probable that in patients who develop hypertension the toxæmia does not cause the hypertension, but simply unmasks the tendency. Primary hypertension therefore appears to predispose a patient to pre-eclamptic toxæmia.

While we may not be able in the course of a pregnancy to cure toxæmia, much can be done to alleviate it. The aetiology is obscure; the treatment must therefore be empirical, and the management of a case should be dependent upon the consideration of the immediate maternal and foetal prognosis, the later prognosis being ignored. This fact should be the basis of our course of action in all phases of this disease. We know that if the pre-eclamptic state increases in intensity there follows a risk of the two major catastrophes of the disease—eclampsia and accidental haemorrhage.

Eclampsia

Eclampsia rarely occurs as a fulminating condition, but almost always follows upon a pre-eclamptic state of varying duration. In our series of 110 cases 90% were of this type, only 10% being of the acute type, presenting no obvious history of previous toxæmia.

The aim of treatment in eclampsia is to stop the convulsions, as the immediate prognosis for both mother and child depends on this. Sedation and hypotensive drugs are used with this end in view. When the condition is under control the pregnancy should be terminated as soon as practicable, preferably by the natural route.

All cases of eclampsia should be removed at once to hospital in view of the special nursing and constant medical supervision that are needed. Even in a rural area such as ours (Caernarvonshire, Anglesey, and Merioneth), I believe this is the best policy. We find that valuable time is lost by the use of the "flying squad," and therefore advocate transfer to hospital, following the administration of morphine, $\frac{1}{2}$ gr. (32 mg.), and atropine sulphate, $\frac{1}{60}$ gr. (1 mg.). In hospital the obstetric team can follow a standardized routine of treatment, and by always using the same course of action assessment becomes easier.

As implied, our method of treatment is that of a modified Stroganoff regime—morphine, chloral, and bromide, supplemented by intravenous magnesium sulphate and calcium gluconate. In cases with marked oliguria 50-100 ml. of 50% dextrose is infused intravenously. A strict time-table is adhered to and sedation closely controlled. Labour is induced as early as possible: in our series of 110 cases only one was subjected to caesarean section because of maternal distress due to eclampsia.

Other effective methods of sedation are the bromethol ("avertin") technique advocated by Dewar and Morris (1947) and that of sodium thiopentone described by O'Donel Browne (1950). Both methods have produced effective lowering of maternal loss, and this is now rivalled by the use of hypotensive treatment ("veratrine") as advocated by Stern and Burnett (1954). Comparison of the statistics relating to the various forms of treatment would be helpful.

From Table I it appears that the outcome of our treatment compares reasonably well with other methods, especially as of the five maternal deaths in our series three occurred in the very early days of the obstetric service in patients who were moribund on admission, and one of whom proved to have bilateral congenital cystic disease of the kidneys. Only two deaths have occurred during the last 15 years. Our method of treatment therefore appears to be suitable for application in our area.

TABLE I.—(Stern and Burnett, 1954)

All Authorities	Total Cases	Maternal Mortality	Recorded No. of Infants	Foetal Loss
Sedation	1,071	7.56%	840	29.17%
Bromethol	149	4.03%	89	32.58%
Veratrine	498	1.81%	123	28.46%
Sedation: St. David's Hospital, 1938-56	110	4.5%	102	28.4%

TABLE II

Method of Treatment	Total Cases	Maternal Mortality	Foetal Loss	Recurrence of Fits after Commencing Treatment
Bromethol: Dewar and Morris (1947)	44	4.5%	30.6%	6.8%
Dewar (1947-53) ..	39	2.5%	15.7%	7.7%
Sodium thiopentone: O'Donel Browne (1950)	18	5.5%	27.2%	22.2%
Rotunda (1950-1) ..	26	7.6%	33.0%	13.5%
Krishna Menon (1953) ..	75	16.0%	40.0%	9.5%
Sedation: St. David's Hospital Dewar and Morris (1939-43) ..	110	4.5%	28.4%	34.0%
	88	20.5%	41.5%	59.3%

*Read at a combined meeting of the Sections of Obstetrics and Gynaecology and of General Practice at the Annual Meeting of the British Medical Association, Newcastle upon Tyne, 1957.

A significant feature is demonstrated in Table II in the low incidence of the recurrence of fits after the beginning of treatment with bromethol as compared with the other series. This reduction in the recurrence of fits should therefore be considered when instituting treatment of the eclamptic patient, as such recurrence increases the danger to mother and child.

The most effective method, however, of reducing fatalities from eclampsia must surely be to reduce the incidence of the disease. In our country area during the last five years (1952-6) 20 cases have been seen as compared with 42 during the five-year period 1942-6.

Accidental Haemorrhage

Accidental haemorrhage is the other acute condition associated with severe toxæmia, and in our experience the concealed accidental haemorrhage which is severe, creating an immediate state of emergency, is a sequela to a fulminating type of toxæmia. The sudden elevation of the blood pressure results in a spasm of the spiral arterioles in the decidua, leading to disruption of the placenta and haemorrhage.

Immediate and full treatment of such cases is essential to relieve shock and to assess the fibrinogen level. Our aim is to deliver the child within six hours of the onset of the disease and if necessary by caesarean section. The intensely toxic state causing the placental disruption and shock causes also a gross renal injury or "renal concussion" that may lead to intractable conditions such as renal cortical necrosis. The work of Sheehan (1955) on this subject is well known, and his more recent suggestions of the use of cortisone in the treatment of renal cortical necrosis may give us a gleam of hope.

Unfortunately, the fulminating toxæmia appears suddenly and unexpectedly, often resulting in this intense emergency and occasionally eclampsia; thus antenatal care fails to give warning and so prophylaxis is uncertain.

More common, however, are the small symptomless haemorrhages and infarcts that occur in established toxæmia, leading by repeated episodes to an accumulative destruction of placental tissue, resulting in placental insufficiency of varying degrees. This latter is likely to happen when the blood pressure rises to 160/100 or more, and is a truly dangerous phase for the infant, leading to intra-uterine anoxia and causing under-development or even death of the foetus *in utero* or during labour, occurrences which, I believe, are avoidable with adequate antenatal care and supervision.

It is a common practice among practitioners to ignore a high first reading of blood pressure, and to take the blood pressure again after a period of rest, and if this is lower to record it as the true level. In our experience this is wrong, for if the blood pressure rises significantly with little excitement it is evidence of an instability that is characteristic of the patient who is either hypertensive or potentially so. We find that such cases, even when at rest in hospital, show distinct variations in the blood-pressure level when this is recorded at intervals each day. These are the patients that need careful watching, for if the blood pressure rises to 160/100, and if the rise is sudden, there is a risk of arteriolar spasm in the renal glomeruli and in the decidua, leading respectively to albuminuria and placental damage. The appearance of albumin in the urine in such cases is therefore a grave warning that the life of the foetus is in danger.

Undoubtedly a high percentage of foetal loss results from this syndrome—a labile hypertension in pregnancy with superimposed toxæmia. It is essential that this condition be recognized early and carefully observed for prolonged periods in hospital. All patients with a blood pressure of 140/90 at the first visit, or who show later in pregnancy a rise above their normal, should be booked for hospital confinement and have the variations in their blood pressure checked as in-patients.

Imminent Eclampsia

Toxæmia may remain static or may gradually deteriorate, leading to a condition bordering on eclampsia—imminent eclampsia. This is characterized by a blood pressure of 160/110, oedema, albumin, oliguria, and symptoms such as headaches, visual changes, and epigastric pain. In such cases our action must be to prevent convulsions developing and to relieve the toxæmic state. Isolation with deep sedation is urgently needed, and if there is no improvement within 48 hours more active measures become necessary. Late in pregnancy this means the surgical induction of labour.

A dilemma arises, however, when this severe toxæmic state occurs before the 36th week of pregnancy. In such cases the foetus may die *in utero* if left too long, and if labour is induced the child will be small and will have to face the hazards of birth. With this degree of toxæmia we have the worst possible material—intense disease and a small immature infant. Even when pregnancy is terminated by caesarean section, various authors have noted a foetal loss of from 20 to 50%. In our experience, when the caesarean section is carried out under local analgesia and thiopentone is administered at the stage of opening the lower segment.

TABLE III

Weight	No. of Infants	Died
3 lb.-4 lb. 6 oz. (1.36-1.98 kg.)	15	2
4 lb. 7 oz.-5 lb. 8 oz. (2.01-2.5 kg.)	13	1
5 lb. 9 oz.-6 lb. (2.52-2.72 kg.)	7	
Total	35	3

the infant's chances of survival are much improved. In our series, extending over the last eight years, 35 patients were delivered in this way by caesarean section because of the severity of the toxæmia. Only three infants (8.5%) succumbed (Table III). In 20 comparable caesarean sections conducted under general anaesthesia the infant loss was 30%.

Discussion

How can we avoid eclampsia, accidental haemorrhage, and imminent eclampsia—those conditions that are responsible for a third of all maternal deaths and a quarter of all foetal wastage?

Workers such as Hamlin (1952), in Australia, and Dawson (1953), in New Zealand, have shown that strict attention to antenatal care leads to a significant lowering of the incidence of eclampsia and to a 50% reduction in foetal loss. To attain this, early detection of toxæmia is essential, together with early admission to hospital for complete and prolonged observation and treatment.

The early recognition of toxæmia is of paramount importance. A patient's usual blood pressure having been ascertained—and before the fifth month it should be below 140/90—any subsequent deviation above this level, however small, must be regarded with the greatest concern. This, with even slight pretibial pitting, warrants strict supervision in hospital. In our scattered antenatal clinics we have not been able to rely on the patient's weight as a guide, but the tightness of the wedding-ring and of the pretibial tissue is a reliable and early sign of fluid retention. Symptoms of headaches and visual disturbances are later indications of toxæmia, whilst albumin in the urine is a real danger signal.

Experience teaches us that under careful hospital supervision toxæmia can be controlled, be it primary or superimposed on hypertension. Our aim in all cases must be to keep the blood pressure below the danger level of 160/100: above that level the risk to both mother and child becomes really serious.

If the incidence of eclampsia is to be lowered and the foetal and maternal deaths from toxæmic causes are to be avoided, it is necessary to maintain a constant watch—with frequent blood-pressure and foetal heart recordings—on all

suspicious cases. This ideal can be attained only by the admission of all such cases to hospital.

The early recognition of toxæmia depends upon a routine antenatal service designed to be comprehensive. In this respect we believe that in our rural area, covering the two counties of Caernarvon and Anglesey, and since 1949 most of Merioneth, such a service has been organized. It is unique, in so far that since the inception of the service in 1938 the obstetric unit, based at St. David's Hospital, Bangor, has been responsible for all the local authority antenatal clinics.

Ten local authority clinic centres, at distances varying from 20 to 50 miles (32 to 80 km.) from the hospital, are administered by the county health departments, through the health visitors and district midwives, but all are conducted by the obstetric unit medical staff. In this way I believe we have achieved not only a continuity of treatment but also, what is equally important, uniformity of assessment of patients throughout a scattered rural area with a population of over 200,000.

In Tables IV and V, Merioneth has been excluded, as Anglesey and Caernarvonshire are true catchment areas and have co-operated fully since 1938.

The development of the obstetric service in the area may be seen from Table IV. An increasing proportion of and mothers have been supervised in the antenatal clinics, and

TABLE IV.—Anglesey and Caernarvonshire

Period	Total Registered Births	First Clinic Attendances as Percentage of Total Births	Hospital Admissions per 100 Total Births		Maternal Deaths from Toxæmia per 1,000 Total Births
			For Toxæmia	For Eclampsia	
1938-41	9,811	20.9	1.8	0.12	2.44
1942-6	14,101	50.6	3.3	0.30	0.64
1947-51	14,248	62.1	4.3	0.25	0.56
1952-6	12,435	68.1	6.3	0.16	0.32

concurrently there has been an increasing resort to hospital admission for cases of toxæmia. This in turn is reflected in a marked lowering in the incidence of eclampsia. (From the early 1940's onwards it is safe to say that very few cases of eclampsia in the area are not admitted to hospital, so that the incidence can with confidence be assessed from the admission rate.)

From Table IV we can see, too, how increasing admission to hospital for toxæmia has resulted not only in fewer cases of eclampsia but also in a marked fall in the maternal mortality of the area from toxæmia and its associated conditions.

TABLE V.—St. David's Hospital

Period	Admissions for Toxæmia	Stillbirths in Hospital to Toxæmic Mothers	Percentage of Toxæmic Admissions Relating to Stillbirths
1938-41	180	43	23.9
1942-6	469	72	15.3
1947-51	610	57	9.3
1952-6	785	56	7.1

Table V gives some indication of the outcome as it affects the infant. The total number of stillbirths of toxæmic origin in the hospital unit has remained static, though in relation to the number of cases of toxæmia admitted there is a gradual fall. In a large proportion of these stillbirths is a gradual fall. In a large proportion of these stillbirths recorded as due to toxæmia the foetus was dead *in utero* on admission, and those cases in which the blood pressure was raised were classified as of toxæmic origin.

However, of the 1,293 toxæmic mothers admitted into hospital during the antenatal period in the nine years 1948-56, a total of 1,491 infants were delivered. Of these, 94 were stillborn and 52 died within the first month—a total of 146 infants lost, a gross percentage of 9.8. This included 15 macerated and 15 abnormal infants. Dawson (1953), in his New Zealand series with 579 infants born of toxæmic mothers, showed an infant wastage of 8.8%. In his most

recent series of 170 infants wastage was 4.1%. Gibson (1954), in a total of 1,516 births, found a gross wastage of 15.9%, and Theobald (1955), in his series, 16.6%.

The average duration of the pregnancies of the 146 infants lost in our series was 35 weeks, which is similar to Dawson's findings.

To some extent the improved outlook for the baby may be due to the fact that an increasing proportion of the toxæmic cases admitted were of the less severe degree. The foetal wastage that is still occurring, including many already dead *in utero* on admission, indicates that in some cases either the patient does not avail herself of the antenatal service or conservative treatment at home is being prolonged beyond the danger point. In the light of our experience we feel that earlier termination of pregnancy would be the means of further reducing the wastage from stillbirths. This appears to be the obvious way to forestall such accidents as intra-uterine death of the foetus: the 35th week of pregnancy appears to be critical for the child in toxæmia.

Conclusions

A comprehensive antenatal service under the supervision of the obstetric unit of an area is advocated as a means of preventing the development of the severe degrees of toxæmia and reducing maternal and foetal mortality.

Booking for hospital confinement is recommended for all patients with an initial blood pressure of 140/90 or over, and admission to hospital for observation at the first sign of a deviation from their normal.

The importance of a regular routine for the treatment of eclampsia is stressed, and it is advocated that those methods giving the greatest reduction of incidence of fits be used.

Caesarean section under local analgesia and thiopentone gives the best prognosis for the immature infants in severe toxæmia.

RADIATION DAMAGE CAUSED BY SHOE-FITTING FLUOROSCOPE

BY

H. KOPP, Cand.Med.

From the Dermatological Department, Finsen Institute, Copenhagen

Within recent years attention has become focused on the potential risk of radiation damage due to fluoroscopic shoe-fitting.^{3,5,7,8,12} However, owing to the long interval between the exposure to radiation and the occurrence of damage, the possible influence of other aetiological factors can very rarely be excluded.

A case of x-ray dermatitis caused by a shoe-fitting fluoroscope is here reported.

Case History

A woman aged 56 gave a history of sciatica in 1950, with pain radiating to the right leg. She has since occasionally had mild lumbar pain on bending forward. In 1952 she had acute anterior poliomyelitis with paralysis of the left leg; paresis of the dorsal flexors of the left foot persisted. In 1953 she had a dislocation fracture of the atlanto-epistropheic articulation after falling on her back down ten stairs. No medullary symptoms were present. In 1954 she had cholecystectomy.

During 1950-1 a few telangiectases occurred on the medial aspect of the right hallux. There has since been slowly progressive exacerbation. The affection has spread laterally across the dorsal surface of the foot, where the skin has become atrophic, with fine scaling, depigmentation, and a network of telangiectases. As the patient had no subjective troubles she did not seek medical advice until 18 months ago, when ulceration occurred medially under the nail of the right second digit, with no tendency to heal under various local treatments.

On examination the skin of the medial and dorsal aspects of the right hallux and, to a decreasing extent, of the dorsal aspects of the second, third, and fourth digits presented cicatricial changes, with keratotic scaling, numerous netlike telangiectases, and depigmentation. The soft tissue of the first and second digits was indurated. The nails of the first, second, and third digits were thickened and partially detached. Medially under the nail of the second digit there was a pea-sized ulceration with pale pus-covered granulations. The skin of the right fifth digit was normal, as was the skin of the left foot. Neurological examination revealed sequelae of acute anterior poliomyelitis with paresis of the dorsal flexors of the left foot. No signs of systematic organic nerve lesions were found (E. Franzen). X-ray examination of the lumbar spine showed degeneration of

FIG. 1.—Typical x-ray dermatitis of right foot.

the disks of the fourth and fifth lumbar vertebrae. X-ray examination of the feet revealed no abnormalities. Oscillometry showed smaller oscillations of the left lower leg than of the right (though both were within normal limits). Blood examination disclosed nothing abnormal.

The clinical picture was one of typical x-ray dermatitis (Fig. 1), but the patient's feet had allegedly never been submitted to radiation treatment or to x-ray examination. On inquiring for other possible chances of exposure to radiation we were informed that the patient had been occupied for about 10 years in a shoe shop where a shoe-fitting fluoroscope was used. The fluoroscope operated by the patient and a similar apparatus in the same firm had been withheld from the compulsory control of the physicist of the Danish Health Directory.

The Shoe-fitting Fluoroscope

Fig. 2 illustrates the shoe-fitting fluoroscope. The x-ray tube (F) is mounted in a box at the floor of the fluoroscope. Except for a field in the roof corresponding to the

FIG. 2.—Lateral and anterior views of shoe-fitting x-ray fluoroscope.

footplate (C), the box is lined with lead sheets 2-mm. thick (B). The customer stands on the footplate (C) during the transillumination. The image appears on the fluorescent screen (A), screened superiorly by a lead-glass plate, 2.1 mm. thick, from which lead sheets 2-mm. thick extend posteriorly and laterally down to the lead sheets lining the box. The fluoroscopic image can be viewed simultaneously by the shop assistant, the customer, and a third person, through three openings above.

In both fluoroscopes the voltage in the tube was rated at 46 kV and the current intensity at 2-3 mA. It could not be elucidated to what extent the primary beam of x rays was filtered. The transillumination time was originally 10 seconds. As, however, this was found to be too short for proper orientation, the time was altered to two minutes. For shorter transillumination the supply of current to the fluoroscope was cut off.

Both fluoroscopes were examined by the physicist of the Danish Health Directory, Mr. P. Rønne-Nielsen, who reported the following results of measurements: In fluoroscope No. 1 the beam intensity at the foot-plate was measured at 9.2 r a minute. In fluoroscope No. 2 the intensity at the corresponding place was 13.2 r a minute. At E (Fig. 2) a defective lead screening was found: one lead sheet adjoined another without overlapping, so that a narrow beam of x rays could penetrate, which, owing to the wooden covering, exposed the shop assistant to strong diffuse irradiation while she was operating the fluoroscope. From the front part of the foot-plate a non-screened cone of rays passed in the direction of the customer's abdomen (Fig. 2 D). The beam intensity was of the order of 1 r a minute in adults, while it might be considerably greater in children, being inversely proportional to the square of the distance from the source of radiation.

Discussion

The present case of x-ray dermatitis with ulceration showed that the patient had in the course of years received very large doses of x rays on the right foot. The chances of exposure to radiation were as follows: (1) The patient operated the shoe-fitting fluoroscope 15 to 20 times daily. While doing this she was standing on the floor to the left of the fluoroscope, where the feet were exposed only a little. However, if, during the transillumination, she supported her right foot on the platform in front of the foot opening it was exposed to intense irradiation. (2) New shoes bought were always fitted by transillumination. (3) If shoes bought were always fitted by transillumination the patient children were afraid of the transillumination to show would now and then put her foot into the apparatus to show that "it did not hurt" (this did not happen every day, however). (3) If there were no customers the shop assistants would occasionally try new shoe models under transillumination.

The site and development of the x-ray dermatitis of the right foot show it to have been due mainly to the first-mentioned chance of exposure.

Preliminary investigation by Stewart *et al.*⁹ have shown that x-ray examination of the abdomen of a pregnant woman may provoke leukaemia or cancer of the foetus. On repeated and possibly prolonged transilluminations in these shoe-fitting fluoroscopes pregnant customers will have received considerable doses of x rays against the abdomen.

The increasing use made of ionizing rays within industries and in medicine will expose a steadily rising number of people to an irradiation of the gonads greatly exceeding that which these receive from the natural background radiation (radiation from radioactive substances in soil and organism, as well as cosmic radiation). Any form of ionizing radiation is mutagenic. There is no lower limit to the dose of rays provoking mutations, and the number of these will ostensibly rise proportionally to the dose received by the gonads.¹¹

To counteract the increasing risk of radiogenic damage thus involved, preliminary investigations have been made to assess to what extent different sources of radiation raise the radiation dose to the gonads. Various writers⁶⁻¹⁰ agree that medical use of ionizing rays is the main factor in this rise.

In the Frederiksberg Hospital¹ 19,000 x-ray examinations are carried out each year, of which 7,578 are grouped round the pelvis. Apart from salpingographies and x-ray examinations in pregnancy and sterility (216 patients), the age incidence shows a maximum for age group 50 to 70 years. In the Roskilde County and City Hospital¹ 7,586 patients were in 1955 submitted to a total of 12,800 x-ray examinations. Only 860 patients under 46 years of age had examinations made involving the gonads. By a good technique the dose can generally be kept as low as 1 or 2 r per examination. Hammer-Jacobsen⁴ has calculated the radiation dose received by the gonads in the Danish population from diagnostic radiology to be 122,313 r a year, corresponding to 29% of the dose received from the natural background radiation.

Roughly 60,000 transilluminations were carried out annually with the two fluoroscopes. The transillumination time was 30 to 45 seconds. During this period a non-screened beam of rays passed from the front part of the foot platform to the direction of the customer's abdomen. In adults the beam intensity was of the order of 1 r a minute, while in children it might be much higher. It is seen that a single defective shoe-fitting fluoroscope will raise the total radiation dose to the gonads much more than even very large radiological units. In assessing the genetic hazards only irradiation of fertile individuals is to be considered. This fact adds still further to the difference, because shoe-fitting fluoroscopes are used chiefly for child customers, whereas x-ray examinations comprise mainly elderly individuals.

The genetic hazards of increased gonad radiation being uncertain, it is necessary to compare the value of the use of each source of radiation with the possibility of increased

risk. Owing to the great danger involved by the use of shoe-fitting fluoroscopes there is reason to examine whether correct measuring and trying on do not fulfil the requirements of exact fitting of shoes, so that these fluoroscopes might be prohibited.

Summary

A case is reported of x-ray dermatitis with ulceration caused by a shoe-fitting fluoroscope.

The physicist's examination of the apparatus revealed that during transillumination of the feet a non-screened beam of x rays passed from the front part of the foot platform in the direction of the customer's abdomen. The rise of the radiation dose to the gonads caused by such a defective fluoroscope is much greater than that from even large radiological units.

ORAL TREATMENT OF DIABETES WITH TOLBUTAMIDE

BY

INDER SINGH, M.B., F.R.F.P.S.; M.R.C.P.Ed.
Lieutenant-Colonel, A.M.C.

Bänder *et al.* (1956) reported the successful therapeutic use of tolbutamide (D.860, "rastinon") in selected diabetic patients. The following clinical study was designed to ascertain the effect of the drug in Indian patients, and covers the period from August, 1956, to June, 1957.

Material

A total of 137 cases of established diabetes mellitus were treated (108 males, and 29 females). The age incidence was 27 to 76 years, excluding a child of 4 years with congenital diabetes. In 30 cases the disease was hereditary. The known duration of the disease ranged from 1 to 27 years. According to the standards set by the Metropolitan Life Insurance Company Statistical Bureau, quoted by Dunlop *et al.* (1953), 10 patients were asthenic, 64 were of ideal weight, and 63 were obese. Of the 105 patients who had symptoms of diabetes of varying severity, 46 had shown evidence of acetoneuria some time or another, but only 17 of them were liable to ketosis within two to seven days of withdrawal of insulin therapy.

The cases were classified as "mild" (28 cases), "severe" (97 cases), and "very severe" (12 cases) on the basis of results of initial glucose-tolerance tests. In the mild cases the highest blood-sugar level was below 250 mg./100 ml., in severe cases it was 250 to 450 mg./100 ml., and in the very severe cases it was over 450 mg./100 ml. 82 cases had been taking insulin regularly.

Methods

Before starting oral antidiabetic therapy clinical examination was made of all patients, and their latest diabetic state was evaluated by means of a glucose-tolerance test after removing all dietetic restrictions and withdrawing

insulin treatment for seven days. During this period the urine was regularly examined for sugar and acetone for evidence of any metabolic breakdown that might have occurred on withdrawal of insulin. In six cases this tendency was very pronounced, and so the glucose-tolerance test was not done, the patients being assessed on the basis of results of blood-sugar levels estimated while fasting and two hours after a meal on withdrawing insulin for only one day. A routine haemogram recorded the pre-treatment haemopoietic state.

To evaluate the hypoglycaemic effect of tolbutamide the blood-sugar level was estimated once a fortnight while fasting and two hours after a meal and after instituting oral therapy. In those who developed hypoglycaemic symptoms more precipitately the blood-sugar estimations were carried out earlier, as indicated. When the results of the blood-sugar tests became more or less static a glucose-tolerance test was repeated during the course of oral treatment at the next follow-up examination to determine the influence of the drug on the actual metabolic pattern. A further follow-up was kept by periodic blood checks. Haemograms were repeated regularly once a month. Urine was examined for sugar, and if necessary for acetone, as often as desired. Liver-function tests were done at the end of six months' continuous treatment.

The patients were given a high-carbohydrate (250-300 g.) low-fat (20-50 g.) diet duly adjusted to individual needs. Tolbutamide was given in the following dosage: initially two tablets (0.5 g. each) twice daily for two days, subsequently the dose was reduced to one tablet twice daily. When adequate response to the drug was obtained maintenance dosage was worked out in each case. If, however, the response was inadequate the morning dose was increased from one tablet to two tablets. The tablets were taken approximately two hours before breakfast and dinner on an empty stomach. In patients subject to ketosis the previous insulin treatment was continued until the oral drug had had a hypoglycaemic effect. In all other cases insulin treatment was discontinued at once.

Most of the patients were already well versed in the routine management of their disease, and so ambulatory treatment was possible. This procedure did not involve any risk. Admission to hospital was not necessary in any of the cases.

Results

The result was considered very satisfactory in 94 cases (68%) and satisfactory in 32 (23%). There were 11 failures (9%). In the very satisfactory cases the patients were rendered aglycosuric, and their blood-sugar values were well within normal; in the satisfactory cases glycosuria was negligible and infrequent, and blood-sugar values showed corresponding improvement, but the glucose-tolerance test still revealed evidence of a mild metabolic deficit. In the failures the response was less marked. No additional advantage was obtained by increasing the dose of the drug if the response to the routine dosage scheme was inadequate or poor, except in the case of the child with congenital diabetes, who could be made completely aglycosuric with three tablets daily but not with two.

The glucose-tolerance tests done during the course of oral therapy at the time of maximum benefit from the drug showed the following patterns: blood-sugar levels that were merely subdued and, after treatment, a curve that was more or less parallel to the pre-treatment curve in 37 cases; a more or less normal curve in 75 cases; a fall, mostly in the fasting sugar level, in 8 cases; a fall, mostly in the latter part of the curve, in 10 cases; a more or less "flat" curve in 5 cases; and no appreciable change in 2 cases.

The renal threshold was lowered in 45 cases, raised in 16, and unaltered in 76 during the course of treatment with the oral antidiabetic drug. Of the 45 cases in which the renal threshold was lowered, 29 were chronic diabetics, and in them the lowering of the renal threshold was part and parcel of the general improvement. The rise in the renal threshold was, however, unaccountable. It was

very striking in one case, which turned out to be a failure. Before oral therapy this patient was slightly glycosuric, with a blood sugar of 218 mg./100 ml. During the course of oral therapy he became aglycosuric and started to complain of weakness. When the fortnightly blood check was done his postprandial blood sugar was 445 mg./100 ml., but there was no glycosuria; the results were confirmed by re-examination.

In 39 cases the highest blood-sugar levels after meals were below 120 mg./100 ml., and gross fluctuations in blood sugar from increases in diet (the equivalent of 200 to 500 calories) or from reasonable intake of free sugar did not occur. The fall in the blood sugar was attended with improvement in general health and increased capacity for physical exertion.

The time taken for a complete response to oral therapy in the 94 very satisfactory cases was two weeks in 58 cases, four weeks in 24, and six weeks in 12. Glycosuria was controlled earlier in about one-seventh to one third of the above periods.

Generally the more complete the response the lower was the maintenance dose. Thus in 39 cases in which the highest blood-sugar levels after meals were below 120 mg./100 ml. (see above) the maintenance dose was one tablet every two days. In 14 of these 39 cases it was subsequently possible to discontinue the drug for one to six weeks before a significant rise in the blood sugar, though still below the highest normal, took place again. So far there has been no definite evidence of drug tolerance in any case.

The drug was generally well tolerated and the incidence of adverse effects was very low. Transitory headache occurred in six cases during the first two days of treatment, when the dose of tolbutamide was 2 g. daily. Seven patients complained of muscular weakness, which was due to low blood sugar and which disappeared when the dose of the drug was reduced. Two elderly patients were extremely susceptible to the drug, and during the first week of treatment they became hypoglycaemic and developed temporary hemiparesis without previous warning. Two patients complained of tingling sensation in the finger-tips, toes, and lips whenever they took tolbutamide. Skin rashes occurred during the first week of treatment in two cases. In one of them the rash was mild and regressed spontaneously, but in the other case the rash was severe and the drug had to be discontinued.

Only minor blood changes were noted. There was no case of permanent platelet depression. In two cases there was an initial fall in the platelet count, but subsequently there was a rise to normal, and in another case the platelet counts showed a progressive increase before becoming stabilized. The changes in the total and differential counts were well within the recognized normal fluctuations. In three cases the leucocytic response was normal during an acute respiratory infection.

Liver-function tests done after six months' oral therapy did not show any abnormality, and there were no adverse effects from the drug in four cases of myocardial infarction during the acute or subsequent stages.

Discussion

The effects of long-term treatment with tolbutamide will not be known for some years. At present the immediate results in the above series indicate that the drug will decrease glycosuria and hyperglycaemia in about 90% of the so-called "adult-onset" diabetics. The success appears to depend on the availability of active insulin. When the metabolic deficit with the glucose-tolerance test was very severe and the patients were liable to prompt ketosis on withdrawal of insulin treatment, the results were significantly poor. Prolonged previous treatment, especially with larger doses of insulin, also adversely affected the results. Thus the result was very satisfactory in 80% of all cases which had been treated with insulin for less than one year, in 56% of cases treated with insulin for two to five years, and in only 6% of cases treated with insulin for more than

AN ASSESSMENT OF BUTHALITONE SODIUM

BY

PETER H. SIMMONS, M.B., B.S., F.F.A.R.C.S.

Senior Registrar, North-east Metropolitan Region; late Registrar, Department of Anaesthetics, Middlesex Hospital

AND

MAY S. BLANSHARD, M.B., Ch.B.
F.F.A.R.C.S.Late Senior Registrar, Department of Anaesthetics,
Middlesex Hospital

There has been a reawakening to the need to have available in anaesthesia an alternative agent to nitrous oxide for short-duration anaesthetics, particularly for out-patients. This can be seen in the recent work of the cyclopropane protagonists (Bourne, 1952) and in the revived interest in ultra-short-acting barbiturates other than thiopentone.

Our investigation and assessment relate to one such barbiturate for which striking claims were made. It was said that the patient need not stay in hospital, and is "strassenfähig" (capable of walking in the street) within half an hour of the administration (Weese and Koss, 1954). It was felt that if this claim were substantiated then anaesthesia for minor operations in casualty or out-patient department could be improved because the anaesthesia disturbed the physiology less.

Pharmacology

Buthalitone sodium is a thiobarbiturate first described in 1936 by Miller *et al.* Chemically it is the sodium salt of 5-allyl-5-(methylpropyl) thiobarbituric acid, with the structural formula:

("Thiamylal": replace ethyl with allyl)

It is a yellow powder which is readily soluble in water, giving, like the other sodium salts of the barbiturates, an extremely alkaline solution. The pH varies with the mode of preparation, ranging from 10.5 in the case of "transithal" to 10.0 in the case of "baytenal" and "ulbreval." The solution is said to be unstable.

The therapeutic index for mice has been shown to be the same as that of thiopentone (K. F. Rivett, 1955, private communication). In dogs it has approximately half the potency of thiopentone (J. A. Anderson, 1955, private communication). Repeated massive administrations in rabbits showed no ill effects on the kidney or haemopoietic tissues (Weese and Koss, 1954). We have found no instance of venous thrombosis in man. Subcutaneous injections of a 5% solution in volunteers gave reactions in all ways indistinguishable from those of thiopentone: an initial burning pain, followed by a transient erythema and swelling, greater than that

five years. It was also very satisfactory in 100% of cases which had received 10 to 20 units of insulin daily, in 75% of those who had 20 to 40 units daily, in 66% of those who had 40 to 60 units daily, in 31% of those who had 60 to 80 units insulin daily, and in none of those who had more than 80 units daily. The experimental work of Haist *et al.* (1940) and Lukens and Dohan (1942) suggests that in the latter cases the stores of endogenous insulin had probably been depleted as a result of prolonged insulin administration. Of the 20 cases on 60 to 100 units of insulin daily, 11 were comparatively insulin-resistant, and this seems to have played a major part in the poor response to oral therapy.

Excluding the effect of insulin deficiency, of whatever origin, and also the effect of insulin resistance, the results did not appear to have been influenced by the current age, in the series, body weight, heredity, duration of the disease, and presence or absence of symptoms. There was, however, a tendency towards a quicker and more satisfactory response in some women. Thus, in five women who had fasting sugars of over 300 mg./100 ml. the response to oral therapy was complete within a week, and in two women with pulmonary tuberculosis and on a liberal diet it was possible to discontinue insulin treatment in favour of oral therapy with tolbutamide without prejudicing the response to antituberculosis treatment in any way. According to Wrenshall and Best (1956), with increasing years of survival after diagnosis of diabetes there is a slow decrease in the average amount of insulin extractable from the pancreas, especially in males. This may partly account for the fact that the women did comparatively better than the men.

There was a case for considering the use of the drug even in patients liable to ketosis on withdrawal of insulin therapy, as about one out of six such cases showed an expected very satisfactory response and in many others the required insulin and the fluctuations in the postprandial blood-sugar levels were significantly reduced. The drug was also effective in the case of congenital diabetes, and the child appeared to tolerate the drug well. Probably, however, in our present state of knowledge oral treatment is not advisable in children.

On account of the low toxicity of tolbutamide, it appears very probable that this drug will have a place in the long-term treatment of selected cases of "adult-onset" diabetes, especially where it may be possible to control the disease with low or intermittent maintenance dosage. It appears that if the drug is given on an empty stomach a smaller dose is required. The drug is also worth trying in cases of severe renal glycosuria, as benefit may accrue from a lowered blood sugar, a raised renal threshold, or both.

Although the mode of action of tolbutamide is still controversial the normal pattern of glucose tolerance obtained during the course of treatment suggests that in many cases the insulin mechanism reverted to the normal in some way or other.

Summary

136 cases of "adult-onset" diabetes mellitus were treated with tolbutamide. The results were very satisfactory in 94 cases (68%), satisfactory in 32 (23%), and there were 11 failures (9%). The result was also satisfactory in one case of congenital diabetes in a child of 4 years. No serious side-reactions were encountered. The factors influencing the action of the drug, and indications for its use, are discussed.

I am grateful to Dr. H. Rodenberg, of Farbwerke Hoechst, for the supplies of rastinon; to Dr. Sarwan Singh Sidhu for carrying out the necessary investigations; and to all the patients for their kind co-operation.

caused by the initial volume of fluid injected. The swelling remained tender for some three weeks and resolved completely in eight weeks.

There is nothing to suggest that distribution via the blood stream to the other body tissues in any way differs from thiopentone, nor its subsequent localization in the body fat. In dogs and rabbits Weese and Koss have shown rapid detoxification, this breakdown, in the dog at least, being hepatic.

Present Trial

The object of the trial was to determine whether by employing buthalitone a patient may be able to "walk the street" sooner than after thiopentone. Some 200 out-patients attending for orthopaedic manipulation or minor surgery formed the main series. Throughout the period of the trial there were only two surgeons and two anaesthetists. The patients were all healthy apart from their surgical complaint. The manipulations comprised manoeuvres for lumbosacral pain and sciatica, joint adhesions, examination under anaesthesia, etc. All these tended to be complete in two to three minutes, but required good muscle relaxation. The minor operations were for various lesions—for example, trigger finger. They lasted longer (10–15 minutes) but required little or no relaxation.

An effectively random allocation of patients was achieved by allotting them alternately to two groups, one treated by each drug. All patients had at least four hours' fasting, and the majority no premedication. Those that received premedication had atropine sulphate, 1/100 gr. (0.6 mg.), only. The drugs were administered intravenously either at the elbow or on the dorsum of the hand. For manipulative procedures—and the majority were of the back—a single-dose technique of the appropriate barbiturate was the method adopted. For the minor operations divided dosage was employed with the inhalation of a nitrous oxide and oxygen mixture comprising 20% oxygen with a high rate of gas flow from a Walton (II) machine. With the beginning of the administration a stopwatch was started and the following periods were timed:

1. Time of injection.
2. Time when rousable, defined as responding in a co-ordinate manner to painful stimuli.
3. Time when "verbally accessible"—namely, perceiving and appreciating the spoken word.
4. Time when "fully conscious, able to sit"—that is, talking freely and able to reach the sitting position unaided.

Many other assessments were made at levels of consciousness nearer normal, but so far these have proved either unsound or impracticable under out-patient conditions. Assessments attempted included: (1) The flicker fusion frequency of a light source. This value diminishes, with cerebral depression amongst other factors (Berg, 1949; Nilsson, 1953). (2) Variations in two-point tactile discrimination. (3) Ability to walk steadily.

The dosage of the drugs was at first adjusted to suit the anaesthetist—namely, the barest minimum of buthalitone was given to keep the patient asleep for the duration of the operation (referred to as Trial Period 1). During this time it was noted that there was not always adequate muscle relaxation with buthalitone and that, while operating, withdrawal movements occurred. In view of this the dosage scheme was readjusted to provide adequate operating or manipulating conditions with both drugs—that is, satisfactory surgical conditions (referred to as Trial Period 2). Further to the controlled series of 208 patients buthalitone was used in 83 in-patients to replace thiopentone and in 12 children as a rectal premedication.

Results

Trial Period 1

The figures in Table I are means $\pm$ standard errors, and the difference in means is also followed by its standard error. The last column shows the probability of obtaining as great a ratio by pure chance as that obtained experi-

mentally with the two drugs. The figure in parentheses gives the total number of observations on which the preceding figure is based. Our findings are shown in Table I. A marked difference between buthalitone and thiopentone is seen. This difference is statistically significant at all three of the measurements, at the 5% level.

TABLE I

	Buthalitone	Thiopentone	Difference in Means	Prob.
Rousing time (min.)	3.7 $\pm$ 0.5 (9)	15.8 $\pm$ 3.6 (14)	12.1 $\pm$ 4.6	0.02
Verbally accessible (min.)	9.0 $\pm$ 1.6 (22)	21.3 $\pm$ 2.8 (21)	12.3 $\pm$ 3.2	0.0004
Fully conscious (min.)	17.2 $\pm$ 2.1 (24)	31.5 $\pm$ 4.0 (21)	14.4 $\pm$ 4.3	0.002

TABLE II

	Buthalitone	Thiopentone	Difference in Means	Prob.
Rousing time (min.)	1.1 $\pm$ 0.4 (9)	11.4 $\pm$ 3.7 (14)	10.3 $\pm$ 4.6	0.04
Verbally accessible (min.)	4.4 $\pm$ 1.2 (22)	17.0 $\pm$ 2.7 (21)	12.6 $\pm$ 2.9	0.0002
Fully conscious (min.)	12.8 $\pm$ 1.7 (24)	26.9 $\pm$ 3.9 (21)	14.0 $\pm$ 4.0	0.002

Times corrected by subtraction of duration of anaesthetic are given in Table II. It was found that correction by subtraction for the duration of the anaesthetic did not materially alter these results.

The comparability of the patients in this trial was confirmed by finding no significant difference in relation to age, sex, weight, or duration of the anaesthetic.

Trial Period 2

In this second trial period the difference in means (Table III, column 3) is diminished or reversed, and there is no significant difference in the time factors between the two drugs. Similarly, the two groups of patients in this trial were found to be comparable. As a further check the dose/weight ratio was calculated for the two groups of patients (Table IV). It was found that this ratio remained more or less constant for thiopentone, showing no statistically significant alteration, whereas in the case of buthalitone the ratio increased and the increase was highly significant. In terms of amount of drugs given for 1 g. of thiopentone, 1.4 g. of buthalitone was administered in Trial Period 1, and 2.1 g.

TABLE III

	Buthalitone	Thiopentone	Difference in Means	Prob.
Rousing time (min.)	7.8 $\pm$ 2.1 (11)	5.2 $\pm$ 1.1 (6) (9.2 $\pm$ 1.7 (27))	-2.7 $\pm$ 3.0	0.40
Verbally accessible (min.)	14.6 $\pm$ 4.3 (13)	16.1 $\pm$ 4.2 (15)	1.5 $\pm$ 6.1	0.60
Fully conscious (min.)	22.0 $\pm$ 4.9 (13)	27.6 $\pm$ 6.8 (14)	5.6 $\pm$ 8.5	0.52

* This figure is misleading—cf. rousing time, thiopentone, in Trial Period 1 (15.8)—because, for a large proportion of patients, the rousing time and time when verbally accessible coincided. A review of this measurement in 27 cases of the series showed thiopentone 9.2, and this mean is not statistically different from 15.8 in trial period 1.

TABLE IV

	Trial Period 1	Trial Period 2	Difference in Means	Prob.
Buthalitone (mg./lb.)	5.72 $\pm$ 0.41	8.19 $\pm$ 0.80	2.46 $\pm$ 0.82	0.006
Thiopentone "	4.23 $\pm$ 0.20	3.93 $\pm$ 0.22	0.31 $\pm$ 0.30	0.32

TABLE V

	Buthalitone	Thiopentone
No. of patients vomiting	11	3
" " coughing	14	15
" " developing hiccup	13	0

in Trial Period 2. Throughout the trial a standard form was employed, and as a result of analysing the 208 cases in the controlled series additional information was available (Table V).

In addition, one patient receiving buthalitone had severe sneezing, and another during recovery showed generalized rigidity and muscle twitchings, especially about the face. Before the episode there had been no hypoxia and there was no history of epilepsy. Return to consciousness was normal. Dose 1.65 g. (12.7 mg./lb.: 28 mg./kg.). In the thiopentone group one patient had a mild laryngeal spasm, one was excessively restless during recovery, one had 10 minutes' apnoea after 0.4 g. (weight 96 lb.: 43.5 kg.), and a fourth noted precordial pain during recovery; the subsequent electrocardiogram was normal.

Careful 30-second serial blood-pressure records were taken from the beginning of the induction until the systolic reading was within 10 mm. Hg of the resting value. No difference was noted between buthalitone and thiopentone in the fall or duration of hypotension. Likewise a careful watch was kept for apnoea or clinical evidence of inadequate ventilation. Again we could detect no difference between buthalitone and thiopentone.

Buthalitone was used in place of thiopentone for 83 in-patient anaesthetics where a quick recovery might be thought to be an advantage—for example, operations about the mouth and nose. Under these circumstances it was found to be satisfactory and comparable with thiopentone. These were selected cases, without controls, and no rate of recovery was assessed. Our impression was that hiccup was a common and annoying concomitant of anaesthesia.

Buthalitone was also administered rectally as a premedicant with atropine for tonsillectomy and/or adenoid curettage in 12 children. Dosage was by weight, 25 mg./lb. (55 mg./kg.), and this worked out as 1 ml. of 5% solution per 2 lb. (1 kg.) body weight. This was administered 45 minutes before operation. On arrival in the anaesthetic room the condition of the child was indistinguishable from one that had had thiopentone 1 g. per 50 lb. (22.7 kg.) body weight, 20 mg./lb. (44 mg./kg.). The course of the anaesthesia was likewise the same. On the other hand recovery was different, being much slower, and the nursing staff noted that they had to feed the younger patients on the first and second post-operative days, and the children were obviously still under the effect of a narcotic agent and sleeping for prolonged periods up to 72 hours, although their general condition gave rise to no anxiety.

Discussion

Clinical experience with buthalitone dates from Weese and Koss, who recorded their findings in 1954. Our work began in the following year. Nobes (1955a) was the first to record his results in this country, and after 11 cases suggested its usefulness for out-patient anaesthesia. Later Nobes (1955b) modified his first impression after a further limited series. He stated that buthalitone is superior to thiopentone and thialbarbitone ("kemithal") as regards rapid recovery, but in the succeeding paragraph remarks that delayed recovery may be a drawback. Other favourable conclusions were reached using buthalitone in psychiatric practice (McColl, 1955) and in general hospital anaesthetic practice (Ruddell, 1955). More recently O'Mullane (1957) has utilized electroencephalographic studies in three volunteers. After comparable depths of anaesthesia he found buthalitone has not as short a recovery time as thiopentone. Henderson and Mackett (1957) suggest buthalitone followed by nitrous oxide and oxygen for out-patients. This technique has been reviewed and demonstrated for dental extractions (Young, 1956). Henderson and Mackett significantly comment that their method has led them to reconsider the position of thiopentone in out-patient anaesthesia, and they feel the need for a comparison to be made. Wylie (1956), reviewing advances in anaesthesia during 1956, states that a final comparison has yet to be made.

The work of Mushin, Henderson, and Mapleson (1955) and of Dundee and Riding (1955) amongst others in the assessment of anaesthetic agents and techniques indicates that no standardized method is as yet available. As so often happens, an initial impression implemented by some animal pharmacology creates an optimism that may not be substantiated. In the case of buthalitone this initial optimism received strong support from our results in Trial Period 1. But in the assessment it became obvious that differing results could be obtained, depending on the criteria against which the agent was judged. In anaesthetic practice the two major considerations are: (1) the well-being of the patient; and (2) the production of good operating conditions. In our Trial Period 1 we began by ignoring the second and achieved results that showed buthalitone to be superior to thiopentone. When due consideration was later given to the operative conditions the picture was altered, and in our assessment of the rate of recovery the difference between buthalitone and thiopentone disappeared.

Thus in attempting to assess the efficacy of a drug it is necessary not only to have a method that satisfactorily measures the properties in question (in our trial, rate of recovery), but one that does so also under the exact circumstances in which the drug is subsequently to be used. If this is not done fallacious results can be produced.

As already suggested, recovery from an anaesthetic is not easy to assess. In our series a simple and relatively crude clinical method was adopted which had the merit of applicability to all cases. It was also objective, and the method was applied by only two observers, thus reducing to a minimum errors due to personal factors. The limitation was that the final stages in the return to fully normal consciousness were not assessed. In out-patient anaesthesia this is important; for in the dangers of street traffic only the acutest perception and highest function in judgment can protect the pedestrian. As is well known, intravenous barbiturates are rapidly redistributed throughout the body, a particularly high concentration being achieved in the fat of the fat depots. The serum level is thus only very slowly reduced, being continually replenished from these depots. Our own results with children suggested this type of slow elimination for buthalitone.

Summary and Conclusion

A new thiobarbiturate, buthalitone, is assessed as an anaesthetic agent for out-patient administration. In 208 cases it is compared with thiopentone.

From the results of this clinical trial it does not appear that buthalitone is an advance in out-patient anaesthesia employed and assessed as described above. The rate of recovery following the administration of buthalitone as compared with thiopentone—when giving equivalent anaesthesia—was found to show no statistically significant difference. In our experience hiccup was a frequent and troublesome sequel to induction. It marred a smooth induction and hampered manipulative surgery. This despite varying techniques of administration—namely, altering the rate of administration. The results with rectal administration to children made us cease after a limited series. Thus buthalitone does not show a more rapid rate of recovery, and also has certain properties which make us prefer the present available techniques and agents.

We thank Dr P. Armitage, of the Statistical Research Unit of the Medical Research Council, for his kindness in dealing with the statistical side of our work and in keeping us from many errors of planning and execution; also Dr H. A. Wilpert, of Farbenfabriken Bayer, Leverkusen, and their London agent, Mr. A. W. Schiff, and Messrs. May and Baker, Dagenham, for supplying the drugs used. We are indebted to Mr. Bernard R. M. Johnson and other members of the department at the Middlesex Hospital for their suggestions and encouragement. We

acknowledge the willing co-operation of the surgical and nursing staffs. Mr. G. J. Lane, superintendent in the department of pharmacology, Bristol University, also helped us in the design of apparatus used in the flicker fusion frequency assessments mentioned above.

RESULTS OF AMNION IMPLANTATION IN PERIPHERAL VASCULAR DISEASE

BY

H. DENDY MOORE, M.C., M.B., F.R.C.S.
F.R.C.S.Ed.

Surgeon, the City and Royal Devon and Exeter Hospitals,
Exeter

Troensegaard-Hansen (1956) states that the implantation of human amnion into the thigh, in patients with peripheral vascular disease with intermittent claudication, brings great improvement—for instance, in 60 cases, 49 had complete cure of the claudication, 7 were much better, and there was 1 failure. The cause for the improvement was obscure. Some of the amnion was prepared by Mr. Troensegaard-Hansen himself, but most was supplied by the research department of Messrs. Smith and Nephew.

Although the rationale of the treatment was obscure, the excellent results quoted and the lack of any other treatment for claudication seemed to justify a trial. The results in seven cases are therefore given. The amnion was prepared locally for the first patient; the remainder was supplied by Messrs. Smith and Nephew. The implants were placed in the thigh of the worst side, deep to the fat, using local analgesia; the patients were not kept in bed at all.

Case Reports

Case 1.—A man aged 65 was seen in August, 1956, complaining of typical intermittent claudication coming on after walking 30 yards, with occasional rest pain in the right calf. The trouble had begun on the right side in 1955, and appeared on the left side in 1956. His feet were cold and clammy and there were no pulses to be felt below the groins. B.P. was 180/100. An arteriogram on the right side showed that the femoral artery was occluded from the profunda to the adductor opening. September 24: Amnion graft implanted. There was no improvement. September 26: Amnion graft repeated. After this the patient stated there was gradual improvement, that his feet were warmer and that he could walk up to one mile, but this did not last. On February 9, 1957, his feet were cold and the distance he could walk was lessening. On February 27 the claudication was at least as bad as before graft; his feet were cold. Next day bilateral lumbar sympathectomy was performed. After this the patient claimed steady improvement in the distance he could walk and in the warmth of his feet. Further progress is awaited with interest.

Case 2.—A woman aged 65 was seen on May 7, 1955, complaining of typical intermittent claudication for two

years, which was becoming gradually more severe and was worse on the right side, the pain beginning after walking 100 yards. Her B.P. was 240/110; her feet were fairly warm, but no pulses were palpable below the femorals. May 10: Left femoral arteriogram showed irregular narrowing and short blocks in the femoral artery as far as the knee, where it was entirely blocked; anterior tibial artery patent at its origin but occluded distally. The other leg vessels were not shown. May 11: Bilateral lumbar sympathectomy. In September claudication was much better. In August, 1956, the claudication was still present, but she said it was better—but difficult to ascertain how much better. Amnion graft implanted in September. June, 1957: Has shown no improvement of any sort following the graft.

Case 3.—A man aged 37 was seen in October, 1956, complaining of aching pain in the left calf when he walked rather less than half a mile; this used to pass off after a few minutes' rest. He had had this for six months, but had had similar trouble in both feet for five years, for which he had been treated with heel lifts, etc., with temporary improvement. November 2: Left arteriogram showed complete block of the femoral artery as far as the adductor opening. Amnion graft implanted. November 14: Patient felt claudication distance had increased up to 1,000 yards or more. December 12: Claudication distance 250/300 yards—not so severe as previously; able to carry on slowly; foot pain absent. February 9, 1957: Walking distance diminished—feet cold and blue. February 27: Bilateral lumbar sympathectomy.

Case 4.—A man aged 60 was seen in November, 1956, complaining of typical intermittent claudication in both legs, but worse on the right side. He had had this trouble since June, 1952. Left lumbar sympathectomy in June, 1954, had given a good result, but operation on the right side had not. His B.P. was 220/140. All the pulses were palpable in the left leg, but only the femoral on the right side. November 30, 1956, arteriograms showed that the right femoral artery was occluded as far as the adductor opening; the left femoral was patent but most irregular in outline. Amnion graft implanted. December 9: Patient stated that his feet were warm for the first time for four years and that there was some improvement in the claudication. February 20, 1957: Patient stated that his feet were warm but claudication was worse. April: Patient stated that the claudication was becoming worse.

Case 5.—A man aged 67 was seen on August 4, 1955, complaining of typical intermittent claudication in the left calf for six months. Walking now reduced to 50 yards. No symptoms in right leg. There was obvious arterial deficiency of the skin of both legs. There were no pulses below the femorals. B.P. 200/120. Heart enlarged. August 23: Bilateral lumbar sympathectomy. November 15: Patient thought his condition was better; but the skin blood supply was obviously most precarious, and he had night pain. January 11, 1956: Patient stated he was much better. June 27: No change. December 19: Right foot satisfactory; left foot still precarious, but no worse. January 3, 1957: Patient stated claudication distance was now 500 yards. January 4: Arteriogram—left—showed that the whole length of the femoral artery was occluded. Amnion graft implanted. February 9: Patient stated claudication definitely better, but skin obviously unchanged. February 23: Patient said he was back to pre-amnion condition. May, 1957: Patient considered there was no improvement—there was certainly no improvement in the skin.

Case 6.—A man aged 59 was seen in May, 1956, with a history of discomfort in the right big toe for two years and discomfort in the right little toe for 18 months, becoming worse. The foot became very cold and he occasionally had discomfort at night. There was no apparent claudication, but it was difficult to be sure, as he could not walk far because of his toes. On examination the right foot was cold and all the toes were rather blue—first and fifth worst. Popliteal and femoral pulses palpable—nil below. Left foot: no symptoms, feet cold, but not abnormally cyanotic,

all pulses palpable except anterior tibial. Right lumbar sympathectomy performed on June 4, 1956. August: Good result—no claudication. January, 1957: Some soreness under big toe and increasing discoloration. February 5: Arteriogram showed localized block at about the adductor opening. Amnion graft carried out. May 18: No improvement at all.

Case 7.—A woman aged 65 was seen in February, 1957, with a history of typical intermittent claudication which had begun in November, 1956, on the left side—the claudication distance was 25 yards. She complained also of cold feet, particularly on the left side. Dyspnoea, orthopnea, and angina also limited walking. B.P. 200/150. On left side only femoral pulse palpable. On right side popliteal and dorsalis pedis pulses could also be felt. Left foot cold. April 5: Left arteriogram showed that the femoral artery was patent as far as the adductor opening, but was grossly irregular, and below this there were only poor collateral vessels. Amnion graft implanted. June 13: No improvement of any sort.

Summary and Conclusions

Seven patients with arterial deficiency of the lower limbs were treated by the implantation of "amnion grafts."

The results of the trial were judged by subjective findings only for the claudication—that is to say, the patient's account of any changes which occurred—and by the effects on the skin, judged clinically.

Some of the patients claimed temporary relief of the claudication, but all returned to their previous state quite soon.

None showed any improvement in the skin.

This trial therefore showed no benefit in any patient as a result of the amnion graft.

Medical Memoranda

Agranulocytosis and Anaemia Associated with Disseminated Tuberculosis

Blood changes associated with disseminated tuberculosis have been reviewed by Fountain (1954), who reported four fatal cases. A further case, presenting with pyrexia, anaemia, and granulocytopenia, and treated with streptomycin, is here reported.

CASE REPORT

A farmer aged 54 was admitted to hospital on July 16, 1954, with a three-weeks history of increasing weakness, lassitude, dizziness, dyspnoea, oedema of the ankles, anorexia, and constipation. There had been slight loss of weight. He had never been ill before and there was no relevant family history.

Examination showed a well-covered man weighing 13 st. 9 lb. (86.6 kg.). The temperature was 101.3° F. (38.5° C.) and pulse 80. He was flushed, sweating, and rather drowsy, with a dirty furred tongue. There was clinical evidence of anaemia and the lower pole of the spleen was palpable 2 in. (5 cm.) below the left costal margin. The liver was also palpable, but there was no adenopathy. No abnormality was found in the cardiovascular, respiratory, and nervous systems.

Investigations.—X-ray examination of the chest on admission showed no evidence of miliary tuberculosis or lung disease. Blood examination was as follows: Hb, 50% (Haldane), 7.4 g. per 100 ml.; red cells, 2,250,000 per c.mm.; C.I., 1.13; P.C.V., 25 vols.%; M.C.V., 113 cubic microns;

reticulocytes, 1%; white cells, 3,200 per c.mm. (neutrophils 33%, lymphocytes 66%, monocytes 1%); bleeding-time, 2 minutes. A blood film showed well-haemoglobinized red cells, macrocytes being prominent. There was a relative lymphocytosis, but no immature cells were seen. Sternal marrow examination revealed intense hypoplasia, the granulocytic series being more seriously affected than the erythroid. Erythropoiesis was normoblastic. A test meal showed the presence of free hydrochloric acid. Red cell fragility was normal and there was no urobilinogen in the urine. Blood cultures were sterile and agglutination reactions negative for *Brucella abortus* and *Leptospira icterohaemorrhagiae*. *Salm. typhi* O and *Salm. paratyphi* B O were positive to a titre of 1/80 and 1/20 respectively. There was no further rise in titre. The stools were repeatedly negative for occult blood and pathogenic organisms.

These investigations did not give any indication of the nature of the underlying disease. The diagnosis was obscure, enteric fever, atypical Hodgkin's disease, aplastic anaemia, aleukaemic leukaemia, and tuberculosis being regarded as possibilities.

The pyrexia continued with a remittent temperature up to 102° F. (38.9° C.), and five days after admission the white cells had fallen to 400 per c.mm., 85% being lymphocytes. There was no appreciable change in the haemoglobin level or red-cell count.

In view of the rapid development of granulocytopenia, treatment with penicillin was started, and blood transfusions were given. There was no response to treatment with penicillin and subsequently chlortetracycline. The patient remained gravely ill, with a persistent pyrexia, anaemia, and granulocytopenia.

Three weeks after admission there was still no firm diagnosis. A further x-ray examination of the chest showed no abnormality, and no choroidal tubercles were visible in the fundus oculi. A blood count showed: Hb, 60% (Haldane); red cells, 2,430,000 per c.mm.; white cells, 400 per c.mm., granulocytes being absent. The patient's condition was critical owing to anaemia, exhaustion, and toxæmia from developing agranulocytic angina.

On suspicion that undiscovered disseminated tuberculosis might be responsible it was decided to start treatment with streptomycin, 1 g. twice daily. Penicillin was restarted at the same time in view of the agranulocytic angina. This treatment, with further blood transfusions, was continued until the patient's death 10 days later.

During the short time that streptomycin was given there was no improvement in the blood picture, the pyrexia, or the patient's condition. Death resulted from toxæmia and terminal bronchopneumonia.

Necropsy Findings and Histology.—The lungs showed terminal oedema and bronchopneumonia. No areas of caseation or follicular reaction were present. The liver showed multiple small areas of caseation with, in some instances, a fibroblastic reaction in the margin. The histological picture was dominated by caseation. The spleen showed very large numbers of tubercles undergoing caseation. Fibrous tissue was present around some of these tubercles, and the lesions varied in age. It was thought that none was older than six weeks. Tubercle bacilli were found in the spleen. The bone marrow showed marked inactivity with greater depression of the granulocytic series than of the erythroid cells. A few tubercles were present, but they showed little caseation and appeared very recent. There was no evidence of tuberculosis in the kidneys or adrenals, and the primary focus of infection was not discovered.

The post-mortem diagnosis was miliary tuberculosis of the liver, spleen, and bone marrow.

COMMENT

The problem presented by this case was largely one of diagnosis, and, with potent chemotherapeutic agents available for the treatment of tuberculosis, early diagnosis is essential.

The case described presented with pyrexia, enlargement of the spleen, and profound depression of both red and white cells. The bone marrow was markedly hypoplastic. There was no clinical or radiological evidence of disseminated tuberculosis, and no glands were available for biopsy. Culture and guinea-pig inoculation of material obtained by bone-marrow aspiration might have confirmed a tuberculous infection during life, as might examination of bone marrow for miliary tubercles (Schleicher, 1946). This case was treated with streptomycin for 10 days without any beneficial effect.

I thank Dr. J. E. Morrison for the histological report.

Plasma-cell Mastitis

Plasma-cell mastitis is a rare disease of the breast, and the purpose of this communication is to record a case.

CASE REPORT

A married woman aged 48 was referred to the surgical out-patient clinic at St. James' Hospital, London, for opinion on a lump in the left breast of four weeks' duration. There was no history of trauma, and she had had no previous trouble with the breasts. There had been only one pregnancy. The lump had been painful and tender for about two weeks. Under observation the pain and tenderness subsided but the lump persisted. Her general health was satisfactory.

Examination revealed a normal right breast and clear axilla. The left breast showed a retracted nipple and dimpled skin over an irregular hard mass in the lower outer quadrant of the breast. The mass was about the size of a golf ball and was fixed to the areola but not to the deeper structures. There was no discharge from the nipple. Small axillary glands were palpable, but were quite mobile.

She was admitted immediately for treatment. In view of the history of an inflammatory episode, it was decided to explore the mass, and on cutting into it puriform material extruded. It was therefore decided to excise the mass and await the histological report, which was as follows: Sections of the breast show areas of stromal inflammation in which plasma cells are the predominant cell; polymorphs, macrophages, and lymphocytes are also present. Periductal infiltration by plasma cells is a marked feature; no giant cells are seen. Some ducts have a hyperplastic epithelial

High-power view of periductal round-cell infiltrate, showing a mainly plasma-cell infiltrate.

lining and the lumen contains desquamated cells, some of which are colostrum cells. In none of the sections is there any evidence of malignancy, and the picture is that of plasma-cell mastitis.

Following the excision, no further treatment was given and the patient made an uninterrupted recovery, being discharged 12 days after admission. A month later she was very well and there was no mass in the breast. She was seen again a year after discharge and nothing untoward was noted.

COMMENT

The rarity of plasma-cell mastitis is evidenced by the fact that in a recent review of the subject Ferrara (1955) was able to collect only 76 cases since 1931. Although the term "plasma-cell mastitis" was first suggested to Cutler by Ewing in 1925, it was not until 1931 that it appeared in the literature in Cheate and Cutler's (1931) book. Adair (1933) reported in detail on the 10 cases included in the above book. He advised local excision and believed the condition to be precancerous. Schultz (1933) emphasized that a clinical diagnosis was possible, and he also believed it to be precancerous.

The aetiology of this condition is undetermined, but most authors subscribe to the view that it is an inflammatory process due to extravasation of the duct contents. It is a condition found in women usually between the ages of 30 and 50 years, with the maximum peak around 40 years. It is almost always seen in non-lactating breasts and in parous women.

The essential feature in the clinical diagnosis of the condition is the occurrence of an inflammatory episode preceding the lump in the breast. While this characteristic history is forthcoming from the vast majority of patients, it is well to remember that in some the episode of previous inflammatory lesion may be absent, as pointed out by Cromar and Dockerty (1941). The initial stages of the disease may be mistaken for a breast abscess and treated as such. The residual stage presents features which suggest a diagnosis of carcinoma, and the surgeon has to be wary here.

The pathological features usually are quite characteristic, and the ultimate onus of an accurate diagnosis lies with the pathologist. He should therefore be given the opportunity of a detailed and satisfactory histological scrutiny. While rapid frozen sections may provide the answer, there are pitfalls, as pointed out by Cutler (1949). The intense epithelial hyperplasia and swollen plasma cells may lead to an erroneous diagnosis of anaplastic carcinoma. Many authors believe that the condition has malignant potentialities. Gaston (1947) suggested two ways in which this could become manifest—namely, either as a malignant epithelial neoplasm from de-differentiation of duct epithelium or as a malignant plasmacytoma. In the present state of our knowledge of plasma-cell mastitis there is no convincing evidence regarding its malignant potentialities.

As regards treatment of the condition, the consensus of opinion favours either simple mastectomy or local excision of the mass as being adequate. Radical mastectomy is unjustifiable.

I thank Mr. J. Burke, consultant surgeon, St. James' Hospital, London, for permission to publish the case. I am also indebted to Dr. G. Allen for the pathological report.

Reviews

ANATOMY OF PULMONARY STENOSIS

The Anatomy of Congenital Pulmonary Stenosis. By Sir Russell Brock, M.S., F.R.C.S., F.A.C.S. (Hon.). (Pp. 114+ xiii; illustrated. 30s.) London: Cassell and Company Ltd. 1957.

The pioneer work carried out by Russell Brock on the subject of pulmonary stenosis is well known, and it is satisfactory to realize that the fruit of his studies is collected into this monograph. The title indicates that this is essentially an anatomical and physiological study rather than a clinical or therapeutic one, and the book gains strength from the study of form and function through the eyes and hands of the practising surgeon. The opening sections, dealing with comparative anatomy and embryology, stress the role of the bulbus cordis in connexion with the whole problem. This distinct part of the embryonic heart becomes incorporated into the ventricular system, and its originally minute channel distends to become the infundibular part of the right ventricle. The right ventricle is virtually separated into the atrial inflow and the infundibular outflow parts by the crista supraventricularis. The infundibulum and the root of the pulmonary artery are the contribution of the bulbus cordis to the final form of the heart, and any abnormality in the chain of development lead to the lesions recognized in pulmonary stenosis, with or without additional complications.

Any classification of the serious forms of abnormality is formidable, for many variations are encountered, and each form must be identified if any attempt at surgical correction is to be undertaken. Stenosis of the pulmonary valve may show a normal aortic root or, as in the case of Fallot's tetralogy, an overriding dextroposed aorta. The stenosis may be located to the infundibulum, the pulmonary artery may be atresic, stenosis may be associated with transposition or with a common ventricle, and so on. Each variety is discussed in detail, and the functional disorder produced by the lesion is clearly brought out to illustrate the rationale of the surgical treatment of individual forms. One important conception of the infundibular action in severe valve stenosis which has considerable bearing on the operative problem is introduced. If the infundibulum is poorly developed the proximal muscle development that has been maintaining the right heart outflow will have distended this area. Removal of the valve stenosis will reduce the pressure in the ventricle and to some extent decompress the infundibulum, thus producing a further possible zone of stenosis. The enormously hypertrophied wall of the right ventricle may practically fill up the outflow track in some cases. In Fallot's tetralogy the author quite dogmatically states that the infundibular obstruction is nearly always short and fibrous or of diaphragm type, and not tubular or long, due to hypertrophied muscle. On this basis a good case can be made out for direct punch or excision operations on the most infundibular stenoses, and the writer claims that the 75% good results that he has had in 168 direct operations on Fallot's tetralogy prove his point. No one would deny the necessity for a direct operation in stenosis associated with a normal root, but the last word on the treatment of Fallot's tetralogy is still awaited.

The final chapter deals with the control exercised by the infundibulum on the right ventricular output. The muscle might be expected to contract *en bloc* in the systolic ejection process, but it would appear that there is a peristaltic form of movement through the infundibulum and a control exercised by muscle tone on the pulmonary valve ring. A sudden increase in pulmonary arterial pressure can easily be followed by regurgitation, which does not occur if the secondary muscular hypertrophy has time to develop.

This monograph cannot just be thumbed through. It must be studied in detail, following the author's closely knit arguments and realizing the amount of knowledge that

he has made available and illustrated so excellently. The experience of the operating surgeon has been added to that of the clinician and anatomist to produce a work that should be in the possession of anyone interested in the heart, and it is a tribute to British publishing and authorship.

T. HOLMES SELLORS.

EXTENSILE EXPOSURE

Extensile Exposure. By Arnold K. Henry, M.B., M.Ch. (Hon.), F.R.C.S.I. Second edition. (Pp. 320+ix; illustrated. 45s.) Edinburgh and London: E. and S. Livingstone Ltd. 1957.

"Books, like songs, should be their own interpreters," writes Professor Henry in his preface to the second edition of this book, and one needs only to open it to realize that here no interpreter is necessary to proclaim its merits. "When the nightingale sings all the other birds are silent lest their feeble notes disturb its song." In an introduction to the author's first book on exposure of the long bones Sir William de Courcy Wheeler wrote, "Exactitude is the outstanding feature of his recommendations." Exactitude could, however, be dry as dust, but not so in this text with its many diversions. Interspersed with the technical parts are many delightful, pithy, and apt quotations and other observations, such as "magnificent commando work but not surgery," "the double gluteal bonnet," and "the huge great sciatic nerve," which Gogarty is cited as calling the one oasis of description which he could find in Cunningham.

Since the appearance of the first edition of the book 12 years ago there have been four reprintings in English and a Spanish translation, so that both its reputation and popularity are already well established. These will be further enhanced by the new edition, which consists of four well-illustrated sections: "The Upper Limb and Neck," "Access at the Second Left Costal Arch," "The Hypogastric Route," and "The Lower Limb." In each of these sections there is much more to be found than surgical exposure, for there is much which adds to both practical and academic anatomy and is thought-provoking as well, causing us, for example, to wonder about the actions of that great slab of muscle the gluteus maximus, with its relatively tiny nerve of supply, and about much else. Not the least interesting also are the small-type footnotes, of which there is an abundance. The distinguished author is to be congratulated on this further development of a masterpiece.

LAMBERT ROGERS.

CLINICAL NEUROPHYSIOLOGY

Fundamentals of Clinical Neurophysiology. By Paul O. Chatfield, M.D. (Pp. 392+xiv; illustrated. 63s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1957.

Most of us in clinical work find it to be almost impossible to keep in touch with the academic background of medicine, or even of our own specialty, and we slowly abandon the struggle to keep up with electronic physiology of all things, important as it is. This field has become so specialized that those working on the nerve cell hardly speak the same language as those interested in the axon hillock, the fibre, or its terminations. Unfortunately for us clinical neurologists, much of the understanding of our subject depends on acquaintance with the mechanisms of conduction along nerves and communication between them; and general physicians cannot afford to neglect the nervous control of their favourite organs either.

Dr. Chatfield has written a readable little book, lucid and as simple as the subject will allow, and freely illustrated. He has plenty of recent references after each chapter for the enthusiast, but the clinicians can find all they need in his very short paragraphs and 20 short chapters. Of necessity most of the book is based on experiments on the cat, to which it is dedicated, but once those who dedicate their work to man have stepped down to that level they can easily translate it to their own needs. It is not nearly obscure enough for the professional physiologist.

DENIS WILLIAMS.

SCIENTIFIC BASIS OF MEDICINE

Lectures on the Scientific Basis of Medicine. Volume 5: 1955-56. (Pp 473+xii; illustrated. 45s.) University of London: The Athlone Press. 1957.

The arrival of this book for review coincided with the news of Hugh Maclean's death, and set one thinking how great has been the change since Maclean thrilled the young men of his generation with his biochemical approach to the problems of diabetes, nephritis, and peptic ulcer. We have gone a long way from the simple estimation of the blood sugar, blood urea, and alkali reserve, and the scientific basis of medicine is now so wide and deep that the present volume of lectures will make stiff reading for most people who are practising medicine or surgery. Indeed, the dilemma of the planners of such a series is to present material which is new and not hackneyed, and yet not to move too far away from their audience. Some of the lectures give the results of the basic study of problems of current clinical interest such as the use of hypothermia in surgery, the effects of anoxia in the foetus, and the changes which occur at birth. Others are the fruits of new techniques such as the interference microscope and the electron microscope. Of general clinical interest is the lecture in which N. H. Martin has collected together the various primary protein deficiencies in the plasma, of which agammaglobulinaemia is the best known, but the 26 lectures reflect so many facets of medicine that it is not possible to mention them all. The contrasts are well shown by the two last lectures, one by Loutit on that most up-to-date of subjects the effects of radiation, the other on the physiology of the nasal circulation, a subject which David Slome shows to have been of considerable interest to Shakespeare.

L. J. WITTS.

THOMAS DOVER

The Quicksilver Doctor: The Life and Times of Thomas Dover, Physician and Adventurer. By Kenneth Dewhurst. (Pp. 192+ix; illustrated. 21s.) Bristol: John Wright and Sons Ltd. 1957.

Medical biographies commonly suffer from several serious handicaps. They are written as a rule neither by practised writers nor by professional historians, and they often concern subjects who, however worthy or picturesque, have left inadequate memorials in the sands of time. Much is therefore written in medical biographies about the times in which the hero lived, more about contemporaries whom he may or may not have met, and too seldom is the subject in the centre of the stage—*Hamlet* without the Prince of Denmark. Dr. Dewhurst has recognized these difficulties and sought to overcome them by diligent and scholarly research, as his interesting bibliography testifies. He has done his best by Thomas Dover—and if the result of his labours has not added to the attraction or importance of his subject he is not to blame.

Dover was an undergraduate at Oxford, but took his medical degree at Cambridge. He was a pupil of Thomas Sydenham's, but never seems to have learnt his master's observational methods. He became an honorary physician at St. Peter's Hospital, Bristol, and in 1702, at the age of 43, began his seafaring career—first as a merchant-captain and then as a privateer, in one of the most famous and successful voyages of all time—described by Woodes Rogers in *A Cruising Voyage round the World*, published in 1712. Dr. Dewhurst protests against Osler's description of "buccaneer" for Dover; but, if the more delicate title of "privateer" fits his activities at sea, there can be no doubt that he was a pirate in medicine. When he practised in London, having been admitted a Licentiate of the College of Physicians, he was deservedly arraigned by the Censors for unprofessional conduct. His medical practice was both good and bad: he practised Sydenham's cooling method for fevers, but he was given to excessive bleeding; he invented the powder which still bears his name—a

valued remedy for 200 years—but he had a monstrous devotion to mercury.

Thomas Dover is—we may be grateful—one subject on whom the last word has now been written; and if not, then any new author must himself commit piracy doing a Dover on Dewhurst.

D. V. HUBBLE.

X-RAY DIAGNOSIS

Röntgendiagnostik: Ergebnisse 1952-1956. Edited by H. R. Schinz, R. Glauner, and E. Uehlinger. (Pp. 590+xii; illustrated. D.M. 139.) Stuttgart: Georg Thieme. 1957.

The use of x rays in clinical diagnosis now extends over so vast a field that no one individual can hope to cover more than a very small area, whilst its advance is so rapid that only by repeated communications can we keep contact with its progress. In this volume are collected short accounts of the advances made in one short period. Each is presented by an expert in that particular area, and they have this in common, that each is obviously the work of a master. It is only possible to glance at a very few. Zdansky presents a most original article on the function of the adult heart in various disorders of the valves and of the muscle. Admirably illustrated, it gives in a clear form information which could not be obtained in any other way. Janker gives a most impressive description of congenital abnormalities of the heart, illustrated by instantaneous photographs of great beauty. Wellauer presents a great study of the abdominal aorta and its branches and of the great vessels, concluding with a fascinating study of the portal system. Prevot presents a study of cholangiography with "biligrafin" as the contrast material which is of the very first importance. Walter Hess follows with a most original article on cholangiography during operation. The whole volume is a very great contribution to a subject of interest and importance to us all. It is superbly produced and illustrated and full bibliographies are provided. It should be accessible to all.

HENRY SOUTTAR.

The second edition of *World Directory of Medical Schools*, published by the World Health Organization, contains much more information than the first, which appeared in 1953. The directory lists institutions of medical education in over 80 countries. Under each country are recorded such data as the number of medical schools, of doctors, and of medical graduates qualifying each year, and the ratio of doctors and medical schools to the population. Annexes summarize these data and give world totals. There are 638 medical schools and 1,235,799 qualified doctors in the world. The ratio of doctors to population varies from 1:434 in Israel to 1:74,640 in Nepal, the average being 1:2,147. An outline of the general educational system and a brief description of undergraduate medical education (including conditions of admission, curriculum, examinations, and qualifications) in each country are given. The name and address of the medical schools are given, together with the ownership, year of foundation, number of teaching staff, total and annual enrolment, number of graduates, and annual tuition fees. In general, such data refer to the academic year 1954-5. In its present form the *Directory* is a valuable source of information on world medical education. It is obtainable from the World Health Organization, Geneva, from H.M. Stationery Office, London, W.C.2, or from the national agents for W.H.O. publications throughout the world (price 25s., \$5, or 15 Swiss francs). A French edition is in preparation.

The lack of a general history of Australian medicine has prompted Dr. B. Gandevia to compile *An Annotated Bibliography of the History of Medicine in Australia* (pp. 140; £A.1 15s.). The book, which provides a widely representative rather than an exhaustive list, covers medico-historical articles, but not original papers of historical interest; it should prove a valuable starting-point for those studying the medical history of Australia. It appropriately forms Number 1 of the series of Monographs of the Federal Council of the B.M.A. in Australia and may be obtained from the Australasian Medical Publishing Co. Ltd., Seamer and Arundel Streets, Glebe, Sydney.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY DECEMBER 7 1957

DIURETIC THERAPY

The advent of a new and potent oral diuretic, chlorothiazide, is of considerable clinical importance, but its value must be assessed against the background of present-day diuretic therapy. It is now more than thirty years since a medical student first observed that an organic mercurial compound, originally synthesized in 1917 as a treatment for syphilis, induced a profound diuresis in a patient with congestive cardiac failure. This chance observation led to the development of such organo-mercurial compounds as mersalyl which have been of inestimable value to oedematous patients for more than a quarter of a century. Though toxic and other undesirable effects have been attributed to them, organo-mercurials have, in relation to their widespread use, been outstandingly free of trouble. In only some 30 cases has sudden death been reported following an injection and always the injection has been intravenous; hence the preference for intramuscular administration. Although unresponsiveness to mersalyl has been observed for many years, only recently have the mechanisms for this been elucidated.¹ In some instances the glomerular filtration rate is so low that the renal tubules reabsorb virtually all the sodium chloride filtered, and mersalyl, which acts by impairing the tubular reabsorption of chloride, fails to increase significantly its elimination. In others, resistance to mersalyl is due to drug-induced electrolyte imbalances.^{2,3} The commonest is a low serum chloride level (hypochloreaemic alkalosis), which develops if proportionately more chloride than sodium is excreted. This state can be corrected with ammonium chloride, which replenishes the lost

chloride and hence increases the chloride load to the renal tubules. Furthermore, ammonium chloride has a synergistic effect on the diuretic action of mersalyl,⁴ probably by increasing the acidity of the urine and so enhancing the local release of mercuric ions within the renal tubule. Another cause of electrolyte imbalance is reduction in the serum level of both sodium and chloride. This "low-salt" syndrome is particularly likely to develop in patients on rigid salt restriction and leads to weakness, apathy, anorexia, mental confusion, and uraemia. Mersalyl may also increase the urinary loss of potassium⁵ and cause potassium depletion, with enhanced liability to intolerance of digitalis.⁶ To improve the effect of mersalyl and to prevent hypochloreaemia, hypokalaemia, and the emergence of refractoriness, it is good practice to give 1 g. ammonium chloride and 1 g. potassium chloride in enteric-coated capsules two hours before each injection of mersalyl. But the great disadvantage of the organo-mercurials is that they must be given by injection. This is unpleasant for the patient, and if painful a change should be made to another preparation. It is also inconvenient for the doctor, and district nurses spend much valuable time visiting patients to give once or twice weekly injections.

The need for an effective oral diuretic is urgent, and in recent years several compounds have been developed. Such compounds must be devoid of toxicity, immediately and continuingly effective, and be at least as powerful as mersalyl. Oral organo-mercurial compounds have been in use for some time, but even the most recent preparations, such as chloromerodrin, are less potent than mersalyl and are apt, if the dose is increased, to induce nausea, vomiting, intestinal colic, and diarrhoea.

A pharmacologically original step was to follow up the observation that certain sulphonamides are carbonic anhydrase inhibitors,⁷ and this led to the introduction of acetazolamide. The effect of this compound is to inhibit the tubular reabsorption of bicarbonate, which is excreted with sodium and an isosmotic equivalent of water. Unfortunately, on continued administration acetazolamide loses its effectiveness, and this self-limiting action is due to the development of a metabolic acidosis with a reduction in the amount of bicarbonate presented to the tubules.⁸ Excretion of potassium is also enhanced,⁹ and hypokalaemia may develop. Acetazolamide is less potent than mersalyl, and is of little or no clinical value in the treatment of severe congestive cardiac failure.^{10,11} Nor can it be relied upon to keep free of oedema convalescent cardiac patients hitherto controlled with weekly injections of mersalyl. Amino-metradine is also a non-mercurial oral diuretic, but

the maximum response is not obtained for several days and it is inferior to mersalyl.¹² Anorexia, nausea, and vomiting are apt to develop, particularly if the dose is increased to fully effective amounts, and the drug may have to be abandoned in as many as one-third of patients because of these side-effects.¹³

Chlorothiazide ("saluric") is the latest and most potent oral diuretic to be developed (see p. 1363). Chemically it is a benzothiadiazine dioxide (6-chloro-7 sulphamyl - 1,2,4 - benzothiadiazine - 1,1 - dioxide), which was first synthesized by F. C. Novello and J. M. Sprague.¹⁴ This chemical structure, with a free SO_2NH_2 group, suggested its action would be that of a carbonic anhydrase inhibitor, and this effect is demonstrable *in vitro*¹⁵ and to some extent in its diuretic action in the dog.¹⁶ In man, however, it produces diuresis by enhancing the excretion of chloride, which is accompanied by an almost equimolar loss of sodium.¹⁷ Thus it resembles organo-mercurials in its action. Chlorothiazide induces within two hours a diuresis which is maximum in 4-8 hours and wanes in 10-12 hours. The maximum effective dosage range lies between 1.0 and 2.0 g., though as little as 0.5 g. is active, and larger doses have been given without the development of toxic effects; indeed, a striking finding is the apparent absence of toxicity at any dosage level. Chlorothiazide is certainly more potent than other oral diuretics, and in its power to enhance sodium excretion it is equal to organo-mercurials given parenterally. Thus 1 g. chlorothiazide is equivalent to 1 ml. meralluride intramuscularly, and 0.7 g. to 1 ml. mercaptomerin subcutaneously.¹⁸ About 0.5 g. chlorothiazide produces a loss of sodium equal to that following four tablets of chlormerodin orally, and this dose is also twice as potent as the maximum effective dose of acetazolamide.¹⁸ Chlorothiazide is continually effective and is most potent when given in two divided doses at 12-hour intervals.

Chlorothiazide and mersalyl given together have an additive effect which may be of value in severe refractory cases of cardiac failure. Also of importance is the finding that chlorothiazide is often effective in patients who fail to respond to mersalyl. In severe cases of oedema the effective dose is 1 g. twice daily, and in less severely ill patients and those who show a rapid improvement 1 to 1.5 g. daily in divided doses is sufficient. In mild cases 0.5 to 1 g. daily may be adequate, and for maintenance therapy 0.5 to 1.5 g. given on only three to four consecutive days each week is usually sufficient. Like other potent diuretics, chlorothiazide increases the urinary excretion of potassium, and if given continuously over a prolonged period may induce hypokalaemia. This is

particularly likely to happen in chronically ill patients taking daily doses of 2 g. Under these circumstances a supplement of potassium chloride in enteric-coated capsules is recommended. The exact amount depends on the individual patient and how well he is eating, but the range lies within 2 to 6 g. potassium chloride daily. In patients eating well who respond quickly and are taking 1.5 g. chlorothiazide or less daily, or are on intermittent maintenance therapy, a potassium supplement is rarely necessary.

CORTICOSTEROIDS AND TUBERCULOSIS

A preliminary report of the first controlled trial of the use of corticosteroids as an adjunct to chemotherapy in pulmonary tuberculosis recently appeared in this *Journal*.¹ The investigation, which was by the Research Committee of the Tuberculosis Society of Scotland, is much to be welcomed, for even though its results are in many respects inconclusive they provide some factual data on a question about which there have been and are great divergences of opinion. When corticosteroids first came into clinical use, reports of exacerbations of inactive tuberculosis in a few patients with rheumatoid arthritis and other diseases during prolonged treatment with them appeared to indicate that the deleterious effect on resistance to tuberculosis which had been reported in experimental animals might operate also in man and contraindicate their use in the presence of active tuberculosis. But it was soon found that during effective chemotherapy these hormones might be given safely to patients with pulmonary tuberculosis. L. E. Houghton² first used corticotropin in patients with severe pulmonary tuberculosis in order to control hypersensitivity reactions to antibacterial drugs. Not only were the hypersensitivity reactions controlled but the patients showed immediate clinical improvement, with lowering of temperature and sedimentation rate, greatly improved sense of well-being, and, in some cases, improvement in radiographic appearances in the lungs. Experience of this sort has led to a general agreement that corticotropin and corticosteroids are certainly of use in enabling effective antibacterial treatment to be continued in face of hypersensitivity reactions, without the long delays often occasioned by the usual procedure of desensitization; and that, even if the long-term results of the administration of the hormones with antibacterial drugs prove no better than those to be obtained with the drugs alone, the use of the hormones at the begin-

¹ Report by the Research Committee of the Tuberculosis Society of Scotland *Brit. med. J.*, 1957, 2, 1131.

³ Citron, K. M., and Scadding, J. G., *Quart. J. Med.*, 1957, 26, 277.
⁴ Pyke, D. A., and Scadding, J. G., *Brit. med. J.*, 1952, 2, 1126.
⁵ Truelove, L. H., *ibid.*, 1957, 2, 1135.

ing of the treatment of patients with severe acute forms of pulmonary tuberculosis would be fully justified by the immediate relief of symptoms. But patients who react to antibacterial drugs by hypersensitivity reactions which are difficult to control and patients with very acute forms of tuberculosis are a minority.

The important questions are whether the results of prolonged antibacterial treatment of more ordinary types of pulmonary tuberculosis can be improved by the concurrent administration of corticotropin or corticosteroids; and, if so, whether the degree of such improvement is sufficient to offset the possible side-effects of the use of these powerful hormones. The difficulty of answering these questions is greatly increased by the general effectiveness of accepted regimes of chemotherapy for patients whose tubercle bacilli are sensitive to the three commonly used drugs. Because of this, any effect of the hormones on the final result of treatment must be expected to be small, and to be detectable only by a properly designed controlled trial, probably requiring large numbers of patients.

The Scottish trial included 90 patients, after some had been excluded for various reasons. All received accepted combinations of antibacterial drugs, 46 without other treatment, and 44 with the addition during the first three months of prednisolone 20 mg. daily together with A.C.T.H. gel, 30 units intramuscularly on two successive days every fortnight. The patients treated with prednisolone, especially those more acutely ill, showed a more rapid clinical improvement and fall of sedimentation rate during the earlier months. However, after the prednisolone was stopped, the sedimentation rate increased in this group, while it continued to fall in the control group, so that at six months the control group showed an advantage in this respect. Radiologically, the prednisolone group showed a distinct advantage over the control group in the earlier months. When prednisolone was stopped, about one-sixth of the patients showed some radiographic deterioration; but they thereafter improved, so that at the end of six months the group on prednisolone still showed a slight advantage in the radiological assessment. In the prednisolone group 85% of cavities had closed at the end of six months, compared with 72% in the control group, but this difference is not significant. It may be of importance that the proportion of patients with acute disease was higher in the prednisolone group (93.2%) than in the control group (78.3%). This might well favour the prednisolone group in a trial of this nature, since acute disease is likely to respond more completely to chemotherapy

than chronic disease with recent spread, the type of disease which constituted the rest of the two groups.

Toxic effects attributed to chemotherapy were observed in 16% of the control group and 11% of the prednisolone group. Rashes were observed in three control and two prednisolone patients; the dose of prednisolone used was less than equivalent to the doses of cortisone or corticotropin generally found necessary to suppress sensitivity reactions to antibacterial drugs. Three patients on prednisolone suffered mild gastro-intestinal symptoms. In two patients, prednisolone was stopped because the blood pressure reached a diastolic level of 140 mm. Hg. In 17 patients skin rashes appeared after the withdrawal of prednisolone. On the whole, therefore, the complications of treatment were more numerous in the prednisolone than the control group. At present the results of the trial provide no clear indication for the use of prednisolone in patients who appear likely to do well with chemotherapy alone; but they do show that prednisolone may safely be given if, in the individual patient receiving effective chemotherapy, it appears desirable to suppress severe constitutional symptoms at the beginning or troublesome drug sensitivity during the course of treatment.

The mode of action of corticosteroids used as an adjunct to the chemotherapy of tuberculosis is undoubtedly complex, but suppression of the allergic hypersensitivity which underlies the inflammatory phenomena of acute forms of tuberculosis is one of the possibly useful effects. Although skin sensitivity to tuberculin is an imperfect index of general tissue sensitivity, study of the effects of corticosteroids on tuberculin reactions in the skin may throw some light upon what happens when corticosteroids are administered to patients with tuberculosis. Early reports appeared somewhat contradictory; reactions to intradermal injection of tuberculin were variously reported to be inhibited or diminished, unchanged, or even enhanced during administration of cortisone or corticotropin.

K. M. Citron and J. G. Scadding³ showed that the effect of cortisone mixed with the tuberculin used in intradermal tests in patients with pulmonary tuberculosis varied with the level of tuberculin sensitivity. Reactions to small doses of tuberculin in highly sensitive patients were diminished or inhibited; reactions to large doses of tuberculin in patients with low sensitivity were on the whole unaffected; while, in a small group of patients who had been desensitized to tuberculin, most showed reactions when cortisone was injected with tuberculin. They also confirmed previous observations⁴ that some patients with sarcoidosis whose skin fails to react to tuberculin produce

tuberculin reactions under the influence of cortisone. Now L. H. Truelove has reported⁵ a group of patients with various diseases in whom, after the administration of cortisone or prednisolone in moderate or low dosage, the skin, previously insensitive, reacted to tuberculin. Patients admitted to acute medical wards and thought likely to receive corticosteroid treatment were routinely Mantoux-tested, and 24 who were found to be "negative" were retested at variable intervals after corticosteroid treatment had been started. Twenty of them then gave "positive" reactions. Fourteen of the patients were over the age of 60 years, and several of them showed evidence of suppression of suprarenal cortical function. Truelove suggests the generalization that corticosteroids in low dosage may restore a tuberculin reaction which has been suppressed by age, infection, or suprarenal deficiency.

Further investigation of this suggestion is needed. Tuberculin skin-reactions cannot be divided precisely into "negative" and "positive," and it is desirable to state their results in terms of the size of the area of induration produced after a stated interval, a procedure which has the additional advantage of facilitating statistical treatment of the data. Repeated tests on similar patients not receiving corticosteroid treatment seem desirable as controls, since, as Truelove remarks, clinical recovery from severe illness might account for restoration of tuberculin sensitivity. For various reasons he rejects this explanation. Whatever the explanation of the change in skin sensitivity to tuberculin in his cases, it seems likely to be different from that of the similar change reported in some patients with sarcoidosis, since the latter are usually neither ill nor old. Many fundamental problems will have to be solved before the action of corticosteroids on the complex processes of tuberculous infection will be understood.

AIR POLLUTION

Exactly five years ago Greater London was enveloped in a fog of exceptional density and duration. This great "smog," by no means the first in London's history, was accompanied by an immediate and sudden rise in both morbidity and mortality.¹ During the first three weeks of December, 1952, there were 4,000 more deaths than would have been expected and it is reasonable to attribute these to the smog.^{2,3} The effects on the health of the people who breathed that filth and survived are incalculable and might be more serious than was once

thought. The conviction with which an increasing number of patients ascribe the onset of their chronic bronchitis to the 1952 smog is striking and will be attested to by many chest physicians.

Studies have shown that urban air pollution differs widely from time to time in quality as well as in quantity, and the recognition of various types of pollution makes possible a rational approach to the investigation of their clinical effects. Smog is not a distinct physical entity but should be regarded as the acute form of air pollution which occurs in towns during temperature inversions; it varies greatly in composition. Usually the weather is cold, so that the contribution from domestic chimneys is great, and fog is often persistent. Acute pollution has acute effects, which are well documented but ill understood. Research on acute pollution is concerned to discover specific pollutants, so that their emission may be urgently suppressed. Equally important is the need to develop devices for protecting susceptible patients.

In winter pollution often reaches high levels for short periods and escapes general notice. Mortality statistics are too crude an indicator of the effect of these short episodes, but it is becoming increasingly apparent that the clinical condition of patients with chronic bronchitis is closely related to them. The ordinary daily pollution of the air merits closest attention because it is strongly suspect as a cause of chronic bronchitis and lung cancer.⁴ Proof of the effects of chronic pollution is difficult to obtain, since many other attributes of town life are also strongly suspect, and these factors are generally too closely associated with air pollution to allow their separate effects to be assessed. The establishment of smokeless zones may offer an opportunity to observe the effect of the removal of one pollutant, but hopes of success may be tempered by the fact that these chronic diseases probably require for their development long exposure to the causal agent, so that any consequence of the removal of a factor such as air pollution will probably not be apparent for many years. The Beaver Committee, whose work was so largely responsible for the Clean Air Act, put these problems into perspective when it wrote in its interim report: "What happened in London in December, 1952, emphasized the immediate danger to health from an abnormal concentration of air pollution. The effects on health and welfare of the continuing air pollution to which many town dwellers are regularly exposed are also serious. This is one of the most urgent problems to-day in the field of environmental hygiene."

THE EUGENICS SOCIETY

While the word eugenics was invented by Galton as late as 1883, the ideas that it connotes have seized man's interest back to earliest recorded times. Much early saga poetry shows a striking—almost interminable—preoccupation with genealogy, and family trees are a conspicuous feature of some of the Old Testament books. Until recent times marriages were arranged in many civilized countries partly on what were judged to

be eugenic grounds, since social power and material assets were held to be probable signs of good breeding. Moreover, traditions and experiments as old as the sagas had given man insight into the principles of improving plants and animals by selective breeding. It was therefore natural for his thoughts to turn, under the impact of Darwin's theories on the interaction between environment and organism, to improving the human race. No longer a unique creation, man now seemed susceptible of conscious betterment. Hence Galton defined eugenics¹ as "the study of agencies under social control which may improve or impair the racial qualities of future generations either physically or mentally."

The idea has since had its vicissitudes. It was born into a society most of whose members would have felt able to point unhesitatingly to what are and what are not improvements in racial qualities. There was a general belief, too, that man, having recognized how he could improve the race, would be eager to set about doing so. To-day we are more cautious, and not only because of the racial crimes of sterilization and extermination that made Germany infamous under Hitler. One of the difficulties is to detect desirable or undesirable qualities, even if agreement could be obtained on what they are. Another difficulty is so to order society that breeding tends to improve the good qualities and diminish the bad, for, as moralists have noticed, man does not inevitably prefer the good when given a choice. Aware that there were many problems of this kind worth studying, a small group of people got together in 1907 and founded the Eugenics Society. Its first president was Galton, who also founded the eugenics laboratory at University College, London, from which much fundamental work on genetics has flowed. Several medical men have been among the distinguished people who have since held that office—Sir J. Crichton-Browne, Sir Humphry Rolleston, and Lord Horder. The society's fiftieth anniversary was celebrated at a dinner last Wednesday under the presidency of Sir Charles Darwin, F.R.S., a grandson of the great biologist.

The society's aims are²: "To study the influences that may modify inborn human qualities; to formulate and support policies for developing these qualities to the utmost advantage; to promote research on eugenic problems; to foster a responsible attitude to parenthood; to guide public opinion on these matters." Being endowed with substantial funds, it is able to carry out its aims by publishing a quarterly journal, the *Eugenics Review*, holding lectures open to the public, and financing research. Under the last head a particularly interesting project is at present under way—an attempt to identify families likely to be exceptionally valuable to the community. It is a natural corollary of the society's previous work on the identification of problem families, and "its aim is that steps should be taken to encourage and such promising families to have more children."² It comes into the category of positive eugenics, which is

apt to be a less controversial category than negative eugenics: this implies restricting the fertility of people who wish to restrict it or are deemed to be in need of having it restricted for one reason or another. Most medical men would agree with the society's support of research into methods of birth control suitable for people of diverse religious convictions. The need for voluntary limitation of fertility is particularly evident when one of the parents transmits a disease by a dominant gene—for instance, Huntington's chorea, of which M. J. Pleydell has given a notable account.^{3,4} But the society's advocacy of voluntary sterilization and termination of pregnancy on, admittedly restricted, eugenic grounds is more controversial.

As increasing urbanization continues to break down traditional breeding patterns, the need for new thought to replace the old myths is likely to grow. The Eugenics Society has a part to play in encouraging the emergence of "a community which provides good prospects for the future welfare of children," and of parents who "produce, by intention and design, a family large enough for replacement and provide for it a happy and healthy home."⁵

THE N.H.S. IN 1956

The Annual Report¹ (Part I) of the Ministry of Health contains as usual a mass of information about the National Health Service. It records, for instance, that over 1,200 speaking-tubes, auricles, ear-trumpets, and other non-electric hearing-aids were issued in 1956, and that out of 1,107 senior registrars 6 were working in the specialty of venereology and 4 in that of infectious diseases. The total cost of the Service in England and Wales was £535m., about £40m. more than in 1955. The Exchequer met nearly 80% of the bill, and less than 5% came from direct payments by persons using the Service. The cost of the hospital and specialist services went up in 1956 by £27m., but there has been increased "production." The number of patients treated rose by 87,000 (an increase of 2.4% over 1955), and the waiting-list has gone down to 431,000—the lowest figure since the Service began. The improvement appeared to be due to a reduction in the length of stay in hospital. The hospitals employed 6,739 consultants in 1956, 89 more than in the previous year. Of these consultants, 269 received "A" distinction awards, 673 "B" awards, and 1,347 "C" awards.

The figures relating to general practice show that the number of principals has again risen—from 18,783 to 19,082—and the number of single-handed practitioners has fallen from 6,715 to 6,568. Over 65% of principals are now working in partnerships. The report comments that "these figures reflect gradual changes in the pattern of general practice such as the development of group practice and an appreciation of the advantages which partnership offers." In 1952 only 20 million of the population were living in "adequately doctored" areas; the

figure is now 35 million. A more even distribution of patients is also being achieved, though slowly: between 1954 and 1956 the proportion of patients on lists of 3,000 and over fell from 29% to 25%. The assistants employed in general practice numbered 1,546, and 125 of these had been working in that capacity since before July 1, 1949.

Once again the report records an increase in the cost of providing patients with medicines. The average cost of a prescription was just short of 5s. in 1956, but went up to over 5s. 6d. in December, when the revised prescription charges came in and larger quantities of medicines began to be prescribed. There was, however, a fairly steep fall in the number of prescriptions dispensed in December. Over the country as a whole there were wide differences in the average annual cost of pharmaceutical services for persons on doctors' lists—the two extremes being Wigan with £2 0s. 4d. and Huntingdonshire with 16s. 2d. The report attributes some of the increased cost of prescriptions in 1956 to the release of restrictions on the supply of cortisone and hydrocortisone in December, 1955. Regional medical officers visited 692 doctors during the year in order to discuss their prescribing, and to most of these, as well as to some others who had not been visited, a letter was sent drawing attention to their prescribing costs and asking them to do their best to reduce them without detriment to the treatment of their patients. The Minister of Health can ask the local medical committee to investigate "if, *prima facie*, the costs of a doctor's prescribing was more than was reasonably necessary for proper treatment." The machinery necessary to keep the Minister informed about these matters is elaborate, but only thirteen cases were referred to local medical committees during the year, and in only two of these had the committees decided that there was excess cost.

OPTICIANS BILL

The Opticians Bill, which is to have its second reading in the House of Commons on December 6, is a private member's Bill supported by, among others, Mr. H. A. Marquand, a former Minister of Health in a Labour Government, and Mr. R. H. Turton, a former Minister of Health in the present Government. The relationship between the medical profession and ophthalmic opticians has never been an easy one, but five years ago, with the publication of the report¹ of the Crook Committee, it looked as if some of the old-standing difficulties could be surmounted. As we said at the time,² "At least an attempt should be made to approach the matter in an unbiased fashion, and both sides should cease to harbour dark suspicions of each other." Unfortunately the Bill now before Parliament is likely to arouse suspicions rather than lull them. In providing for the establishment of a General Optical Council, "with the general object of promoting high standards of professional education and professional conduct among opticians," the Bill follows the report of the Crook Committee.

¹ Report of the Interdepartmental Committee on the Statutory Registration of Opticians, 1952, H.M.S.O., London.
² Brit. med. J., 1952, 1, 1074.

It is on registration that the Bill departs from the recommendations of the Committee, which advised the establishment of three separate registers of opticians—those who test sight and dispense spectacles, those who only dispense spectacles, and those who only test sight. Eventually, the Committee believed, sight-testing opticians, by ceasing to sell spectacles, "might one day achieve complete professional status." When that stage was reached the second and third registers only would exist. The present Bill cuts clean across this obviously desirable development by establishing two registers only, one of ophthalmic opticians "qualified to test sight and to fit and supply optical appliances," and the other of dispensing opticians "qualified to fit and supply optical appliances." The Ophthalmic Group Committee of the B.M.A. believes that the Bill's failure to secure the separation of sight testing from the dispensing and sale of glasses is a fundamental omission and contrary to the intentions of the Crook Committee.

In other respects, too, the Bill is most unsatisfactory. The medical profession is to have only 5 representatives on the General Optical Council out of 23 members. The importance of having adequate medical representation can be judged from the fact that the Council "may make rules prohibiting or regulating" the administration of drugs and the practice of orthoptics by registered opticians. The Crook Committee carefully defined the functions of the ophthalmic opticians and the dispensing opticians, but the Bill gives no precise definitions, nor does it seek to prevent the sale of spectacles by unqualified persons.

DOCTORS' QUESTIONARY

During this and next week, between a third and a quarter of all doctors in contract with executive councils, regional hospital boards, and boards of governors will receive from the Royal Commission on Doctors' and Dentists' Remuneration a questionnaire on their professional earnings. Their names, about 9,000 in all, have been randomly selected. The completed forms will not be seen by the Commission, which will be given a statistical analysis of the returns, and there will be no disclosure of confidential information. Sir Harry Pilkington points out that part of the duties of the Commission, of which he is chairman, is to compare remuneration in the medical and other professions. The questionnaire is a means to this end and similar inquiries are being sent to members of other professions. Accompanying the questionnaire is a statement, which we published last week,¹ from Sir Russell Brain and Dr. S. Wand, chairmen respectively of the Joint Consultants Committee and the Council of the B.M.A. It asks recipients to fill in the form and return it promptly, since it is desirable that the Commission issues its report, acceptable or not to the profession, as early as possible. However, the chairmen make it clear that they had not necessarily accepted the questionnaire as being useful or appropriate, nor had they abandoned the right to criticize any conclusions or recommendations that might result from it.

THE PRICE OF FREEDOM*

BY

Sir FRANCIS WALSHE, M.D., F.R.C.P., F.R.S.

I am honoured that you should invite me, who am not of your Fellowship, to address this annual meeting, though I am not sure that your officers fully realized what they were about when they made me free of this rostrum.

I have ventured to choose the words "the price of freedom" as the title of my remarks this afternoon, because, gazing upon the medical scene as a somewhat detached spectator who clung to his amateur status in 1948, and who is neither follower nor followed, I have a strong impression that there are in our profession those who are not very interested in the notion of freedom, and that, of those who are interested, not all appreciate what must be done to keep it.

Diversity of Outlooks

Wise men have said that liberty can be preserved only by the united and the vigilant, but even in our most complacent moods we can hardly say of our profession that we are either vigilant or united in its regard. There are, of course, many excuses we may give ourselves for this state of affairs. Firstly, we may have different ideas of what constitutes freedom for our profession, and, secondly, we have diverse outlooks upon medicine itself.

The inevitable differentiation of roles which have been forced upon us by the increasingly complex nature of medicine has created many and varied ways of life for doctors. Some of these ways are extremely remote from the care of individual human persons, or even from contact with those healthy members of the community whose welfare by preventive medicine we seek to promote. On the other hand, many of us spend our working lives wholly or predominantly in contact with those who seek our aid.

Of all of us, the general practitioner is most deeply and continuously immersed in what I shall call the human situation, coping not merely with illness but with all the complications that may surround the lives of the sick, raising issues far beyond the merely clinical. The specialist and consultant is, of course, less deeply involved here, while still less so is the doctor who works exclusively in hospitals. I always think of these last favoured individuals as the florists of medicine, who get their clinical flowers cut, neatly tied up, with the dead leaves cut off and the earwigs shaken off.

In contrast to them is the general practitioner, a real gardener who has to deal with the entire plant in its native soil, with all its weeds, parasites, domesticities, muck, and mud, and with no one to do his fatigues for him. It is he who has over the generations built up the ideal of the doctor-patient relationship that we have inherited but that we now begin to see replaced in some quarters by a mere business relationship, under the influences of a National Health Service.

Such then being the varied circumstances of the doctor's life, it is not surprising that there should be amongst us different notions about professional freedom, and that the achievement of a general agreement amongst us of the optimal relation between the State and the doctor should be hard to come by.

Thrice Defeated

Surely, in an old, learned, and humane profession, with the most ancient code of professional ethics in the

*An address given to the Annual General Meeting of the Fellowship for Freedom in Medicine on November 23. A report of the meeting is published at page 187 in this week's Supplement.

world, there should be sufficient generality of understanding for us to be able to harmonize our sectional loyalties with our first loyalty to medicine as a whole. Yet, if we are to be realist, we must admit that nothing is plainer than that, in peacetime at least, we have proved unable to achieve a generally accepted synthesis of ideals. Thrice within my own professional life has our profession vigorously, even vociferously, stood out for a while against certain Government proposals designed to bring us within a narrower framework and one more subordinated to the State. Yet each time in the end we have fallen back, disunited, disgruntled, defeated, but acquiescent.

The present year has seen the latest of these unimpressive spectacles of instability and disunion: a negotiating committee with no real solidarity of aim among its disparate elements, each of these with different measures of freedom to negotiate, swearing that it would ne'er consent to a Royal Commission, and then, man by man, consenting, not having thought out before they began the consequences of a single one of their proposed actions, whether of advance or of retreat.

Lessons of History

Now I suppose none would dispute that some form of National Health Service is inevitable under modern conditions, but this is not to say that we can regard the present hastily imposed, over-centralized organization of lay civil servants that regulates the details of the doctor's life in ever increasing degree as reasonable in its structure, or as compatible with the greatest usefulness and the optimal development of British medicine as a constantly growing science.

I think that at this turning point in the history of our profession we should give some thought to its constitution. We are a corporation set up by statute—namely, by the Medical Acts of the last century. Under these Acts we have our own governing body, the General Medical Council, which exercises disciplinary powers over our professional lives, sets the standards of our training according to advances in knowledge, and sees to it that our educational institutions conform to those standards. This governing body within its range of authority gives equality to all doctors, and does not interfere with the details of our work.

There is another learned profession in a like situation—namely, the profession of the law. This also has its own government, though one not identical in form with our own. The Inns of Court, those ancient universities of the lawyers, and the Law Society exercise functions comparable with those of the General Medical Council.

There was a third learned profession—namely, the clergy of the Established Church—which in 1533, by a formal "Act of Submission," handed over to Henry VIII absolute control of its theological and ecclesiastical beliefs and activities, and the confusions of authority which this submission entailed are with us to-day. This should be a lesson to us to yield up none of our freedoms to the State.

I do not apologize for this incursion into history, for if we will not learn the lessons of history we are doomed.

Permanent Official in Command

Hitherto, the civil service as we have had it during the past century has never had detailed control over a learned profession. Its structure and its patterns of administration have been devised for quite other activities, and an administrative regime that might well, in its laborious fashion, be adequate for the Board of Trade, or the Ministry of Supply, or the Office of Works is on the face of it hardly likely to be appropriate to the organization of a profession the members of which, still in a majority of their number, enter into close human relationships with those whom they serve. We deal with men and women at their most helpless, their most anxious, their most emotional, even perhaps their most unreasonable. It is our tradition not only to provide them with the best that the science and art of medicine can provide, but also to treat them as human beings whose

confidences we receive and whose individual interests are our first responsibility.

In brief, ours is both a learned and a humane profession, one which makes great demands upon judgment of human issues as well as upon strictly technical issues, which calls for the exercise of discretion and for qualities not only of sympathy but on occasion for firmness and control.

Who in his senses could have supposed that the reach-me-down, or ready-made, pattern of ordinary civil service administration could contain, without strangling, such a situation? In 1948 there did not exist a single Minister or lay civil servant in any way qualified to set up a rational structure for a National Health Service, and the ensuing decade has done nothing to encourage us to believe that the civil servant has learned anything. He is not there to learn, but to force us into the Procrustean bed of his administration and to impose his will upon us. And what opportunities he has had! The troubled sequence of ephemeral Parliamentary figures that have held the office of Minister of Health has flitted too rapidly across the scene to have had any influence upon events. This Ministry is a sort of Parliamentary Didcot Junction, where the hopeful aspirant to Cabinet rank waits in the chill breeze until the train arrives to carry him on to the city of his dreaming spires, his political Oxford.

In effect, the permanent official is in command, and for the first time in the history of his Service he has got his claws well into a learned profession and he will not willingly let go.

In No Way Qualified

Hitherto, then, the seat of order and government lay within our profession, in the hands of men who were themselves doctors and thus best placed to understand the nature of medicine and the conditions of its healthy life and growth and its adaptation to the needs of the community.

Our situation is now changed for the worse, and the head and centre of the organization of our activities has moved to Whitehall and fallen into the hands of a lay bureaucracy, to whom medicine is nothing more than a body of men and women, of activities and institutions there to be regulated according to a civil service pattern the details of which are not within our control.

It is Whitehall that now decides how doctors shall be graded, like fat stock, how many of this and that kind of hospital officer and registrar there shall be, to what specialties they shall be allotted, and where they may be allowed to go. In modern jargon, the Ministry sets all our "ceilings," and if—as must and does happen—its decisions are not always compatible with optimal medical needs, or even with common sense, then some person or persons have to bombard Whitehall by post, or go hat in hand to some permanent official to beg, persuade, or bully him to increase the allotment of this or that human or material item in the system, or to send it here or there—and all this with results that are wholly unpredictable and may bear no relation whatever to the medical needs of the situation.

Thus the centre of gravity of our profession has moved out of its proper orbit, and swings precariously, ineffectively, and—need I add—extravagantly, according to the decisions of a body of men in no way qualified to pronounce upon any question involving the applications of the art and science of medicine to the best interests of the community.

Shadow Looms

Now, I venture to say that if the State is to subsidize medical services this could have been done without the minute and detailed control of the doctors' activities and of hospital administration that we find. The universities are not supported in this crazy fashion, nor is that remarkable medical organization the Medical Research Council, with its large medical and scientific staff and its many units, so infiltrated with fussy and futile interference. None of them could function if it were so.

Nor dare we hope that we have reached the limit of imprisonment within this fantastic administrative machine, for the shadow of a fully paid State medical service looms over us, with all that it implies of helotry for us and of the dehumanizing of medicine for our patients.

It is ominous that at this juncture a President of the Royal College of Physicians should have reminded us in April of last year in the columns of the *British Medical Journal** that the policy of the College is one of firm and consistent co-operation with the Government of the day. In this unqualified form the statement must give us ground for disquiet. Does it mean that if a Government introduced a Bill to impose a whole-time State-paid medical service the College would co-operate to this end, or would acquiesce in any other scheme a Government might propose in our regard? And if it does not mean this, what precisely does it mean? Is it no more than an historical note on past policy, with no reference to present or future, or is it the ill-omened offer of yet another "Act of Submission" by a learned profession to the State?

I have to confess that I was surprised that such a statement evoked no comment or protest from your Fellowship, for I know that no such submissive attitude informs it, that your Fellowship has as its prime interest the fullest freedom for medicine, and that it has drafted an alternative plan for a national medical service to avoid the ineptitudes of the Service we have.

Overdue Task

This last task, of course, I venture to think is one that the British Medical Association should have initiated nine years ago. There should have been set up and kept in being a standing study group to observe the workings of the Service in all its aspects, so that at the expiration of a decade it should have had a report ready embodying a comprehensive survey and a series of practical suggestions for reform where these seemed indicated.

I cannot help feeling that, if the Association had had the foresight and political sense the situation required, its negotiators would not have marched their heterogeneous army up the hill and down again last summer, with nothing in its brief but a request for pecuniary adjustments in a Service that the Association perfectly well knows needs far more than this done to it. Why give colour to the jibe that we are interested in nothing else than remuneration?

The price of freedom is greater than we have shown any corporate signs of recognizing. It does not allow these recurrent manifestations of instability and disunion, this failure to provide ourselves with the exhaustive and ordered analysis of the working of the National Health Service that we must have if we are to put any brake upon the slow progress of events towards a full-time State-paid medical service or to make reasoned constructive suggestions.

I venture also to suggest that, if our purely academic corporations confined their intervention in respect of the improvement of the present Service to professional and scientific questions, their recommendations to the Government would benefit immensely in strength and prestige by the absence of claims or recommendations upon questions of remuneration. Let these be the task of other organizations best fitted to cope with them. In short, let us have some differentiation of function, for this is of the very essence of organization.

*Brain, W. R., *Brit. med. J.*, 1956, 1, 857.

Men, Steel, and Technical Change (H.M.S.O., price 2s. net) is the first of a series of booklets sponsored by the Department of Scientific and Industrial Research on the results of research into problems connected with industrial progress. Among the problems discussed are those arising from automation and problems of management and human relations. The booklets will be either "industrial versions" of research reports or short reviews on research.

RESEARCH DEFENCE SOCIETY LORD COHEN OF BIRKENHEAD ON ANIMAL EXPERIMENTATION

LORD COHEN OF BIRKENHEAD delivered the 26th Stephen Paget memorial lecture to the Research Defence Society in London on November 28. His title was "Some Reflections on Animal Experiments."

This lecture, said Lord Cohen, had been delivered by our foremost physiologists, pathologists, veterinarians, leaders in tropical medicine and public health, and even by three surgeons. He was the first physician to be chosen for this distinction, and yet the triumphs of animal experiment were exemplified perhaps more clearly in the daily work of the physician, which brought him into intimate contact with personal suffering, and no one could appreciate more fully the contribution animal experiment had made to the prevention, cure, and alleviation of disease.

Three Questions

From his reading of the literature on antivivisection Lord Cohen had found that three aspects of the problem tended to be confused. First, had animal experimentation contributed to our understanding of disease, its cause, prevention, cure, and alleviation? Secondly, was every step being taken by legislation to ensure that needless suffering was prevented? And, thirdly, whatever victories over disease might be clearly demonstrable, was it ethically or morally defensible to seek to lessen or eradicate human suffering by animal experiment? The second of these questions had recently been the subject of a debate in the House of Lords, where though general charges of cruelty had been made no specific indictment was laid, despite full opportunity. The third question—the ethical or moral defensibility of animal experiment—like all such questions, did not lend itself to objective, rational assessment; it must be answered by the individual, though it might not be without significance that the results of a questionnaire sent eight years ago to the religious heads of our community suggested that they accepted, by an overwhelming majority, the case for animal experimentation.

Those who opposed animal experiment asserted that knowledge gained from it was useless, or, if useful, such knowledge was already known through clinical observation; that any alleged benefits from animal experiments could have been achieved by other methods; and that, as the final experiment must be on man, this was the only valid one and everything that preceded it was indecisive and often misleading. It was important at the outset, said Lord Cohen, to make clear that no one claimed that animal experiment was the exclusive method of investigating disease; "though it is typical of the misrepresentation of the antivivisectionists," he went on, "that, having stated in a recent speech that 'I do not regard animal experiment as the exclusive method of medical investigation, but it is quite indispensable,' it was repeated in their journal that I claimed 'that able,' it was repeated in their journal that I claimed 'that brain functions have been made known only by animal experiment.'"

Insulin and Vaccines

The answer to the question, How valuable is animal experiment in medicine? was best given by a few specific examples. The discovery of insulin was *par excellence* a triumph of animal experiment. Before insulin the expectation of life of a diabetic child of 10 was about 15 months, and of an adult of 30 four to six years; now the expectation of life for the child was over 45 years and for the adult only a little short of the normal average. In the light of the rising incidence of diabetes mellitus—in Great Britain there were now more than 200,000 diabetics—these facts gave some measure of the life saved by one therapeutic agent. And besides the prolongation of life there were also the reduction of mortality in diabetic coma from 50% to 3%, the great fall in maternal and foetal mortality, and the recognition of the syndrome due to an islet-cell tumour.

What was the antivivisectionists' answer to the triumphs of insulin therapy? They said that insulin was not a cure for diabetes, but no one would doubt that insulin "controlled" diabetes.

Lord Cohen took as other examples vaccines and sera, for whose production and virulence and potency testing not even the most convinced antivivisectionist denied that animal experiment was needed. Lord Cohen instanced the reduction in morbidity and mortality from typhoid fever and diphtheria since the introduction of prophylactic immunization, and rebutted arguments that sought to explain away these dramatic changes simply as examples of a general fall in the incidence of infectious disease, due to better housing and nutrition and improved general hygiene. He then discussed the sulphonamides and antibiotics.

Extrapolation to Man

What of the last allegation, that only the final experiment in man was valid? No one denied that animals differed in many respects from man, but the similarities were more striking than the differences, and the investigator selected the animal best suited to his purpose. That had been the method used by all physiologists, including Harvey. It was by these preliminary animal experiments that we were able to define whether the results were applicable to man, and also the conditions of maximum safety for human experiment.

For the rest of his lecture Lord Cohen of Birkenhead illustrated by examples from antivivisectionist literature the shortcomings of their arguments. "I do not claim," said Lord Cohen, "that fallacious inferences, unscientific analysis of data, and unfounded assertions are confined to the literature of antivivisectionists, but in extensive reading in many fields I have yet to find anything comparable to the antivivisectionists' errors in these respects."

CHLOROTHIAZIDE AND OTHER DIURETIC AGENTS

CONFERENCE IN NEW YORK

[FROM A SPECIAL CORRESPONDENT]

An all-day conference to discuss chlorothiazide and other diuretic agents was held at the Academy of Sciences, New York, on November 8, under the general chairmanship of Dr. ROBERT F. PITTS (Cornell University). The morning session was opened by Dr. ROBERT W. BERLINER (National Heart Institute, Bethesda), who discussed the renal transport of electrolytes. Dr. JAMES SPRAGUE (Merck, Sharp, & Dohme Research Laboratories), who originally discovered chlorothiazide, then surveyed the chemistry of this and other diuretics.

Action of Diuretics

Dr. GILBERT H. MUDGE (Johns Hopkins University) discussed the mode of action of mercurial and xanthine diuretics, and produced evidence that organomercurials act by the local release of mercuric ions within the renal tubule.

The mechanism of action of carbonic-anhydrase inhibitors was described by Dr. A. GILMAN (Albert Einstein College of Medicine), who showed how acetazolamide inhibits the tubular secretion of hydrogen ions and thereby depresses the reabsorption of bicarbonate ions, which are excreted in company with sodium and potassium cations. Dr. KARL H. BEYER (Merck, Sharp, & Dohme Research Laboratories), who was responsible for the original pharmacological studies of chlorothiazide, said that although chlorothiazide had the structure of a carbonic-anhydrase inhibitor its diuretic action was due to enhanced excretion of sodium and chloride in a manner similar to the organomercurials. In contrast to most carbonic-anhydrase inhibitors, chlorothiazide caused an almost equivalent excretion of sodium and chloride with little enhancement of potassium or bicarbonate loss. Nor did it produce a self-limiting metabolic acidosis as does

acetazolamide. Chlorothiazide was equally effective by mouth or intravenously; its action was uninfluenced by either acidosis or alkalosis, and was of rapid onset. Acute and chronic experiments in animals had shown it to have very low toxicity.

Therapeutic Trials of Chlorothiazide

In the afternoon the diuretic therapy of congestive heart failure, liver disease, and chronic renal disease was discussed. Dr. RALPH FORD (Houston) had found that in congestive heart failure chlorothiazide produced a diuresis in two hours which lasted for about 12 hours. The drug maintained its effectiveness when administered daily, was devoid of toxic effects, but had a tendency to induce hypokalaemic alkalosis. A maximum effect was produced by 2 g., given in two daily doses. A dose of 1 g. orally was equivalent in effect to 1 ml. meralluride given intramuscularly, and a dose of 2 g. was more potent than either 250 mg. acetazolamide or 80 mg. chlormerodrin.

Dr. JOHN LARAGH (Columbia University) described his experience with chlorothiazide in more than 100 oedematous patients, of whom 32 had been subjects of metabolic studies. Satisfactory clinical responses had been obtained in about two-thirds; in some patients supplements of potassium chloride were required to correct hypokalaemic alkalosis. Nine cirrhotic patients with ascites and a daily urinary sodium excretion of less than 1 mEq had been treated. Three had responded well and six had shown a temporary improvement. He reported that chlorothiazide might elevate the serum uric acid, and that the clearance of free water was greater with mersalyl than with chlorothiazide. Dr. GEORGE SCHREINER (Georgetown University) described the value of chlorothiazide in 19 patients with nephrosis due to a variety of causes (of whom 12 responded) and in other renal conditions. He concluded that chlorothiazide was a potent, safe, and effective adjunct in the treatment of renal disorders associated with oedema.

Effect on Potassium Balance

In the subsequent discussion Dr. SHEILA SHERLOCK (Postgraduate Medical School, London) reported that in cirrhotic patients with ascites chlorothiazide might induce hepatic coma and electro-encephalographic abnormalities, which were due, not to the chlorothiazide *per se*, but to potassium depletion, and could be corrected by giving potassium even when chlorothiazide was continued. Dr. MACKIE (Boston) reported similar observations, but had found the coma could be prevented by giving intestinal antibiotics, and doubted whether potassium depletion was the whole explanation. Other workers reported on the use of chlorothiazide in pre-eclamptic toxæmia of pregnancy; 1-g. doses induced a satisfactory diuresis and caused a fall in blood pressure.

During the evening session Dr. R. I. S. BAYLISS (Westminster Hospital, London) described his experience with chlorothiazide in acute experiments and in oedematous patients. He confirmed that chlorothiazide had a predominant action on sodium and chloride excretion, with an insignificant and inconstant effect on bicarbonate excretion. On a daily sodium intake of 22 mEq or more, no instances of hypochloræmic alkalosis had been encountered, but potassium excretion was increased, and there was a tendency for the serum potassium level to fall particularly in refractory patients requiring prolonged treatment. Chlorothiazide had often proved effective in patients who responded poorly or not at all to mersalyl, and mersalyl given in combination with chlorothiazide to mersalyl-resistant patients induced a greater diuresis than chlorothiazide alone.

Role in Treatment of Hypertension

Finally there was a panel discussion by Dr. EDWARD FREIS (Georgetown University), Dr. JOHN H. MOYER (Hahnemann Medical College), and Dr. ROBERT WILKINS (Massachusetts General Hospital) on the recently discovered antihypertensive action of chlorothiazide. This action is not seen in normotensive subjects, but is particularly marked in

patients receiving rauwolfia or ganglionic blocking agents. Insufficient data is available as yet to assess the value of chlorothiazide in this field, but it may prove a useful adjunct to antihypertensive treatment, and reduce the unpleasant side-effects of ganglionic blocking agents by allowing a substantial reduction in their dosage.

Motoring News

BEATING THE WINTER

With the advent of December, winter in earnest may descend on us at any moment, and often enough motorists are quite unprepared for it unless they are country dwellers who face this season and its attendant hazards with resigned nonchalance. During the winter months the comfort and reliability of the doctor's car are really put to the test, and there are many up-to-date accessories which will be of help.

Turning to interior luxury first, we find many firms making heaters for individual makes of car and for universal fitting to any make. A rear-seat heater is a comparatively recent innovation, being mounted beneath the rear seat; it costs £16. Independent petrol-driven heaters are being marketed by two concerns in this country. These units, however, are not easily fitted to private cars on account of their size, being primarily intended for coaches, though a model is available for Volkswagens. When the engine of the air-cooled car is stopped the heater becomes immediately ineffective; hence the introduction of this petrol unit. Another worthwhile addition to winter comfort is a set of seat covers, which make the conventional leather-upholstered car very much cosier. A windscreen defroster has its uses if no provision is made for screen demisting in the heater system; a steering-wheel glove, a special stick-on window for preventing mist on the rear window, and a heated seat pad are further items of value. For the country practitioner rubber link mats are essential in a new car, for they save mud and dirt being ground into the carpets.

It is often a wise plan to check the windscreen wiper blades and renew them if they have a tendency to smear. A windscreen washer unit is a useful accessory for all the year-round motoring, but it is especially handy in fog or when the screen has iced up after the car has been left standing for some time. As to driving-lamps, a bewildering array generally confront the motorist at every garage, but one good lamp carefully mounted is a great asset. The law requires a white lamp to be mounted with its centre 2 ft. from the ground, but a yellow fog lamp may be mounted anywhere. It is therefore a good policy to obtain one which can be raised or lowered on a sliding arm, and lamps with interchangeable yellow and white glasses or front-mounted bulb holders for changing bulbs quickly are invaluable. Another item which is convenient for doctors is the spotlight, normally fitted on the windscreen pillar for spotting street names and house numbers. The latest types are now being made of plastic and fix inside the windscreen, being operated from inside the car.

To help the engine a very popular fitment is a radiator blind. These can now be obtained for nearly every type of car; they are mounted in front of the radiator core and controlled by a small chain under the dashboard. Superseeding the old-fashioned radiator muff, which had to be rolled up and down by hand, for which the driver had to stop, these blinds allow the engine to warm up quickly, stop cold winds from icing up the radiator when the car is left for long periods in the open, and enable the interior heater to operate more efficiently. Keeping the engine warm at night is a problem which can be largely solved by fitting a small electrically operated immersion heater into the lower water hose. It is connected to the mains when the car is garaged. Electric and paraffin sump heaters are still sold in large numbers, and for those cars which have bonnets that are awkward to open they are convenient and can be left

burning all week if necessary, since their fuel consumption is so low.

Apart from the normal heavy-duty tyres which are offered by all the manufacturers and which are excellent in icy weather, many country doctors who have to motor considerable distances on ice and snow have found that tyres with a special tread for this purpose are worth fitting. These in conjunction with rubber criss-cross snow chains or rubber grips will defy any weather in which it is possible to use a car at all. Battery chargers are also desirable things for the winter motorist, because the poor battery often has too much to do when many demands are made upon it by electrical accessories, especially if no long journeys are made to charge it up again. Finally, for keeping the exterior of the car in good trim, a transparent protective for chromium plate can be obtained, and a de-icer in plastic squeeze bottles is a handy item for guarding against frozen-up windcreens.

Use and Abuse of Blood

SIR.—For several years I myself have been worried by the steady increase in the use of blood in my hospital, and for that reason I have watched my clinical colleagues (especially the younger ones) with a very critical eye. When the demand reached 4,000 bottles a year, or 550 bottles per 100 occupied beds, I became so alarmed that I invited the regional transfusion director to visit the hospital and see what was happening. After his visit he told me that in his opinion I had resisted demand too much, and that I should at once arrange for at least a 10% increase in use. My hospital serves a population of between 200,000 and 250,000—that is, between 1/250 and 1/200 of the population; so if my hospital's demand is optimal, the country, as a whole, should need between 800,000 and 1,000,000 bottles of blood each year—considerably more than is now available.

When preparing for the symposium on blood transfusion held in Sheffield last month, I asked a number of my colleagues to complete a questionnaire. From their replies it appears that, of 27 hospitals, 12 used less than 300 bottles per 100 beds, 10 between 400 and 700, and 2, both teaching hospitals, more than 1,000 bottles. It was clear that the demand for blood was greatest near university centres. As enthusiasm for the use of blood to combat shock—whether due to accident or to surgery—spreads, and as young and enthusiastic surgeons leave university centres for the more distant hospitals, so in those peripheral hospitals will the demand for blood increase—and in my opinion rightly so. Wastage seems to me inevitable when the transfusion service has to supply hospitals in small towns where there is only an occasional emergency; it is easy enough to avoid waste in cities, not so easy to keep emergency stores available in rural areas without waste.

I am not certain that the pathologists of the S.W. Metropolitan area were altogether wise in rejecting pilot bottles. I started transfusion work without pilot bottles, and accepted them with many of the misgivings which Dr. Stark Murray expresses (November 23, p. 1239); but now, after a few years' experience, I would object vehemently were I asked to abandon them. The old objection that they could be separated from the main bottle, be confused, or broken is completely overcome by the Sheffield system or the modification used in the north London area, and although occasionally one meets an empty pilot bottle, or one with little in it, one can then enter the bottle. What is important is that pilot bottles do allow one to hold really adequate cover for a potential haemorrhage without waste—and that is my chief worry. I have not heard of a single case in the north London area in which dependence on a pilot tube resulted

in harm to the patient, and I believe that no such trouble has occurred in the Sheffield region either. Surely the proof of the pudding is in the eating—or, if one is to be elegant, one might say that, in the world of phenomena, conclusions drawn *a posteriori* are more reliable than those made *a priori*.—I am, etc.,

London, N.W.10.

GEORGE DISCOMBE.

SIR.—It is disturbing to read in Dr. M. S. Beare's letter (*Journal*, November 2, p. 1046) that blood may still be wasted because it has been cross-matched by sampling the bottle and then not transfused within a specific time. It is agreed that the answer is the use of pilot tubes, but these are not used in some centres because they may become detached from the parent bottle, or they may be broken.

The National Blood Transfusion Association of Ireland uses two tubes, one of which is used as the pilot tube and the other as a transfusion centre sample. Both tubes, the bottle, and the donor registration form bear identical serially numbered adhesive labels, which are applied while the donation is being taken. Since one donor attendant is allocated to each donor for the duration of the donation, confusion in the application of identification labels does not arise. The tubes may thus be separated from the bottle with impunity.

When blood is issued the pilot tube is carried in a pocket in the combined instruction and report card attached to each bottle, and is thus well protected. Broken pilot tubes are a rarity. We consider the only disadvantage of this method is that the degree of infection may become excessive if the pilot tube is not returned promptly to the blood bank refrigerator. This disadvantage may be minimized by the incorporation of a suitable antibiotic in the tube. To ensure the sterility of the bottle of blood itself a special aluminium "pilfer-proof" sealed cap is applied by machine immediately after the receipt of each donation. It will thus be appreciated that blood surplus to a hospital's requirements may be returned to us and reissued or used for dried plasma production with confidence.

It is felt that criticisms of the pilot tube system mentioned by Dr. Beare are largely answered by our method. That this is so is, we feel, borne out by the fact that, in so far as we are aware, no accident due to confusion of pilot tubes has occurred since the introduction of this system in 1950.—We are, etc.,

J. P. O'RIORDAN.
G. FUTERS.

Dublin.

SIR.—As some of my remarks at the recent meeting of the Consultant Pathologists Group are quoted in the *Supplement* of November 9 (p. 146) without their full context, may I be allowed to comment briefly, if only to reiterate some of the points Dr. D. Stark Murray makes in his letter (*Journal*, November 23, p. 1239)?

Most pathologists, I believe, agree that no hard-and-fast rules should be laid down in such matters as cross-matching techniques or type of bottle. Much argument has centred around the use of pilot bottles, and I think I made it clear at the meeting that, so far as the South-western Metropolitan Region (eastern division) is concerned, this matter was discussed at length at the regional committee of pathologists on several occasions, and each time an almost unanimous vote was cast in favour of continuing the "pilotless" bottle. This decision was never influenced, incidentally, by the director of the regional transfusion service; on the contrary, he was willing to introduce pilot tubes should the meeting so decide. Perhaps the simplest way of putting the argument (so familiar to pathologists) is that, by testing a bottle for compatibility without a pilot tube, one examines a sample of the blood which the patient ultimately receives.

In this laboratory, through the co-operation of my colleagues in all departments, we seldom have to re-cross-match bottles of blood, and the overall wastage is negligible. Obviously conditions vary between different types of hospitals, but where close contact between ward and laboratory exists little difficulty arises. Certain simple procedures of maintaining sterility, familiar to bacteriologists, must, of course,

be observed, but similar precautions are necessary when puncturing a pilot bottle, with the disadvantage that the technician tends to be less careful in his technique when using the latter.

Finally, may I say that, having used both methods, I admit neither to be ideal. I understand a plastic bottle with an attached tube to overcome the sampling difficulties has been developed, but is proving too expensive to be generally introduced in this country.—I am, etc.,

Steyning, Sussex.

K. S. RODAN.

Combined Prophylactics

SIR,—I found the paper by Drs. Guy Bousfield and L. B. Holt (*Journal*, November 23, p. 1213) on this subject most interesting, but should like to raise a few points arising from it. In part two of the first investigation, where they compared the Schick conversion rates achieved by 30 Lf of diphtheria toxoid in the presence of different amounts of tetanus toxoid, they conclude that an increase from 12 Lf of tetanus toxoid to 25 Lf diminishes the response. The superiority of the results with 12 Lf is significantly better than the control at the 5% level. Since there would be a 5% chance of any of the groups, which were of equal size, showing a difference of this order, and four groups were tested in addition to the control, the chance that such a difference might occur in one (unspecified) of them would be only 1 in 5. For this reason the 5% level of significance is not adequate here. If this result is discounted the Schick conversion rates in all the other groups do not differ appreciably. These results may be interpreted, therefore, as meaning that the presence of tetanus toxoid does not affect the results of the diphtheria toxoid.

In the later investigations Drs. Bousfield and Holt show that the Schick conversion rates achieved by the triple antigen are inferior to those achieved by diphtheria-pertussis antigen. It should be borne in mind, however, that the conversion rates achieved are still far superior to those attained with diphtheria toxoid alone, and F.T. is accepted as a satisfactory antigen. What is being lost is merely a little of the augmenting effect of the pertussis vaccine. What matters is not the proportion who are Schick-negative after one dose, but what proportion are immune for some time after a course. Provided the results are not inferior to those attained when F.T. is used alone they should be considered satisfactory.

Parents do not like their children to receive too many injections. A quadruple antigen which was accepted by 90% of parents, even if it was only effective in 60% of the cases, would be of more value than separate vaccines if less than 45% of parents were willing to subject their children to the large number of injections involved. By all means do trials of quadruple antigen, but measure what matters—antibody levels of all components after the full course. By setting too high a standard let us not discard what may be the most effective course of action.—I am, etc.,

Barton-on-Humber, Lincs.

J. S. ROBERTSON.

Collateral Circulation after Subclavian Ligation

SIR,—It must be rare to be able to investigate the collateral circulation after ligation of the subclavian artery, and the comment by Major A. M. Wiley and Captain G. M. Boyes (*Journal*, November 16, p. 1160) prompts us to write about our findings in a case where this operation had been performed by one of us in April, 1936, and which was investigated *post mortem* in May, 1955. It was found that the intercostal arteries, through the thoracic branches of the axillary artery, and the arteries to the brachial plexus were as important in maintaining the circulation of the upper limb as the scapular anastomosis, which is usually so much emphasized. A full report of this case appeared in *Guy's Hospital Reports* (1955, 104, 380).—We are, etc.,

H. J. B. ATKINS.

J. JOSEPH.

London, S.E.1.

Anaphylactoid Reaction to Penicillin V

SIR,—Penicillin V (phenoxymethyl penicillin) has now been in general use in this country for nearly two years and to date no serious reactions have been reported, although a recent annotation (*Journal*, March 30, p. 757) drew attention to the clinical picture as described in the United States.¹ Levin² quotes a further case from recent American literature³ in his review of side reactions to oral penicillin.

I was urgently summoned to see a 59-year-old male Pole who had suddenly collapsed. The patient, who is of pyknic habitus, was pale, bloated, sweating, cyanosed, very wheezy, and restless. The first thing that sprang to mind was that the patient had sustained a myocardial infarction. He was unable to give a history, but his sister displayed a bottle containing 250 mg. penicillin V capsules and stated that the patient had taken one with a cup of tea ten minutes before he collapsed. He apparently became very flushed, and then went pale and complained of difficulty in seeing, was seen to be having difficulty with breathing, and then collapsed on the floor although he did not lose consciousness. When first examined, about 20 minutes after he collapsed, his blood pressure was not recordable. He was given 3 ml. of 1 in 1,000 adrenaline subcutaneously over a period of 20 minutes with marked relief. At the end of this period his blood pressure was 110/70 mm. Hg. and he was able to corroborate his sister's story. He stated that he had taken the capsules three weeks previously for a boil on his forehead and that he had taken another one because he felt he had another boil coming. The patient was put to bed and given 1 ml. of hyperdural adrenaline and 2 ml. of antazoline by intramuscular injection, and three hours later was feeling quite well; his chest was clear and his blood pressure was 110/80. Next morning he was quite normal and the following day went to work as usual, although he agreed to attend medical out-patients two days later. At this attendance no abnormality was found on clinical, radiographic, cardiographic, or haematological examination.

The patient had never had asthma or any other allergic condition. He had penicillin in large quantities for bronchopneumonia in hospital in 1951, with no untoward effects. He was unwilling to take part in any further tests which might involve the use of penicillin and which might have elucidated whether he was sensitive to other types of penicillin or had been recently sensitized to penicillin V.

I wish to thank Dr. A. Leese for his helpful discussion of this case and for arranging the investigations.—I am, etc.,

Leeds.

"Nomen Proprium"

SIR,—The Association of Teaching Hospital Pharmacists, comprising the chief pharmacists of the undergraduate teaching hospitals of England and Wales, has discussed in recent meetings the growing practice by prescribers of disclosing to patients the identity of prescribed medicines. Correspondence on this subject has appeared in the columns of the medical and pharmaceutical press during the past few years in which the points in favour of this practice have been advanced. It is realized that in some instances there are no objections; indeed, there may be advantages to be gained, but this association believes that there are also disadvantages and risks which should be recognized.

A dispensed medicine is intended for the use of the patient for whom it is prescribed for a definite period of time, and by disclosing its identity on the label these objects may well be defeated. Once the name of a drug is known to a patient, further supplies (other than certain poisons and substances controlled by law) may be obtained indefinitely by direct purchase without further reference to the prescriber. Not only may the patient indulge in self-medication, he may also recommend to others presenting "similar" symptoms the use of a drug by name. Recently, leaflets giving details of clinical uses, contraindications, and the technique of laboratory control of dosage of a drug have come into the hands

DEC. 7, 1957

CORRESPONDENCE

of patients, to the embarrassment of the physician concerned. Such leaflets may be included in the original containers of drugs acquired by direct purchase. Present-day patients are reputed frequently to demand a particular drug or preparation from their physicians. This method of labelling will surely increase the frequency of these demands and in certain instances may be an indication of the disease being treated. Further, the use of this method as an *aide-memoire* in repeating prescriptions is not one which this association would advocate when other proper systems of recording patients' treatments are available.

Perhaps the most serious risk is the use of a drug left over from a previous occasion which has been stored long after its useful life in the household medicine cupboard. The anonymity of a dispensed drug is the one factor which makes it unlikely to be used by sensible patients at a later date. A named drug is more likely to be used and will be assumed to be active and safe. It may be neither. On prolonged storage in unsuitable conditions a drug may become inert or, more rarely, toxic. Further risks arise with supplies of drugs of different strengths, or with similar names, which may be mixed by the patient and subsequently used.

For these reasons we believe that the disclosure of drug treatment to patients should not be done routinely and that the initiative remains with the prescriber as a matter of individual decision. If it is decided to let the patient know the name of the drug with which he is being treated, the prescription should be marked "N.P." (*nomen proprium*) and the pharmacist will then label the drug by name. Without such instruction the pharmacist will continue to maintain the secrecy which we believe he has always done in the past.—We are, etc.,

C. WILSON PECK,
Chairman.G. BRYAN,
Hon. Secretary.

Post-tuberculous Pyonephrosis in One Kidney

SIR,—This unpleasant state of affairs is usually avoidable because of the effectiveness of modern therapeutic agents when proper supervision is given to the case. The following is generally the course of events when it does occur: (1) One kidney has been removed for tuberculosis, perhaps years before. (2) The other kidney insidiously becomes the seat of the infection. (3) In spite of the fact that the tuberculous infection in the solitary kidney is apparently ultimately cured, gross pyuria persists and is completely responsive to medication. Contemplation of such features can point a useful finger in the direction that our management of the case should take.

The eventual evidence of infection in the remaining kidney, delayed though it often is, merely demonstrates the well-established fact that in the majority of cases renal tuberculosis becomes bilateral. It is unfortunate when the infection develops in the solitary kidney without the usual chronic increased frequency of micturition; for the absence of this warning is likely to delay an early attack on the disease by effective medication—thus the opportunity of keeping cavitation at a minimum is reduced. Nephrectomy in bilateral renal tuberculosis is justified for the worse in the kidney when the urine shows no gross infection in the kidney when the urine shows no gross infection in the kidney. Dramatic improvement in general health is the quick evidence of benefit from nephrectomy in these circumstances. When there is a "silent" infection in the solitary kidney, simple haematuria, perhaps with pyrexia, is the local sign which most commonly reveals the remaining kidney with the disease already well established there, sometimes unhappily in an advanced degree. Such a demonstration is a sharp reminder of the insidious progress which this infection can make over the years; even through the whole genitourinary apparatus. Hence the need for a well-organized and indefinite follow-up of genital and urinary tuberculosis and, particularly in young patients. The following are the relevant facts concerning a case of this kind.

A married woman, aged 43, the mother of one child aged 12, had her right kidney removed for tuberculosis about 23 years ago. Subsequently she had no urinary symptoms until fourteen years later, when she began a persistent pyrexia and painless haematuria. Penicillin injections controlled these symptoms. At this time, however, tuberculosis bacilli were found frequently in the urine. A nine-weeks course of streptomycin injections was given, after which tuberculosis bacilli could no longer be found in the urine, although pyuria was still a striking feature. Since that time, over the past six years, all the commonplace organisms except tuberculosis bacilli—in spite of many searches—have appeared intermittently in the urine, and the deposit of pus has slowly increased in spite of a great variety of antiseptic medication, so that at present there is about $\frac{1}{2}$ in. (19 mm.) of pus in the bottom of the conical urine glass containing the morning specimen. A comparison of the intravenous urogram of 1950 with that of 1957 shows three main areas of renal damage in the early films and merely the outline of an enlarged kidney in the later one. There has never been any appreciable increase in the frequency of micturition.

The most striking feature in the course of this case has been the occurrence of several attacks a year of oliguria, with raised blood urea and an occasional vomit during the attack, which has always responded to a short course of intramuscular saline administration. I have always been afraid of using the intravenous route because of the danger of adding a further burden to the already congested kidney. The last attack was within the last few weeks when the blood urea went up to 144.9% and later, after treatment, settled to 83%. Over a period up to a year ago she had several attacks of haematuria. These were generally controlled by a blood transfusion.

It remains an academic point whether or not active tuberculosis bacilli are still present in the kidney in spite of a six-year intermittent search. Whatever the answer is, the lesson from this case is clear: follow up all cases in young people indefinitely, so that treatment can be given before excavation of a kidney has reached any important degree.—I am, etc.,

London, W.1.

H. P. WINSBURY-WHITE.

Smoking Habits of Doctors

SIR,—When we completed the original questionnaire prepared by Professor A. Bradford Hill and Dr. Richard Doll the macabre thought that we were preparing our habit obituaries in advance did not then probably occur to us, but such was the case, and the fullest co-operation should be given in regard to the new appeal.

The new form states the original smoking habit as given previously, in my own case 10–20 cigarettes per day, and it is interesting to me to find I now smoke a maximum of 5–10 cigarettes per day. I am still an addict in the strict sense of the word, but I keep easily within this limit by not smoking during the working day until after tea, and not indulging in social smoking of any sort. In some large measure I am certain this is the result of conscious and unconscious perception of the probable significance of the work being done, and it would be intensely interesting if Professor Bradford Hill and Dr. Doll would publish what change, if any, in doctors' smoking habits emerges from the new survey.

We are told smoking in general is increasing, but if the results of the new questionnaire show a definite decrease in cigarette smoking by doctors, those proposing active propaganda to discourage, as distinct from forbidding, smoking may well feel persuaded to go ahead with their plans. The very title of the circular letter sent to doctors constitutes propaganda of a sort, though of course not intended as such, but if it is too successful Professor Bradford Hill and Dr. Doll may well be left with a most disconcerting mass of material to evaluate.—I am, etc.,

London, S.W.1.

ROBERT CUTLER.

Description of Cholera Stools

SIR,—Regarding the description of "rice-water" stools in cholera, Dr. B. J. Bouché (*Journal*, November 9, p. 1111) states: "I have wondered, in a long experience of cholera both in peace and war, when this totally untrue and ill-fitting description of a cholera stool would disappear." He

describes it as more typically like barley-water, and to support his contention he quotes MacCallum's *Pathology*.¹ MacCallum, in saying that rice-water is a poor description and that the stool seems more viscid, turbid, and mucoid than that could be, does not mean that it in any way resembles barley-water. From my own experience as a junior hospital medical officer at the City Fever Hospital, Bombay, during a cholera epidemic in 1953, I would say emphatically that the stools bear more resemblance to rice-water than to barley-water. To support my statement, I would like to quote the following authors. Sir Neil Hamilton Fairley,² in Price's *Textbook of Medicine*, states: "The stools now resemble rice-water and contain flakes of epithelium." Boyd³ states: "As a result of constant passage of these watery stools (rice-water stools) the patient becomes extremely dehydrated." Herbert French⁴ writes: "In cholera, diarrhoea is extreme to the extent of producing 'rice-water' stools." The War Office memorandum⁵ says: "The motions, at first faeculent and bile stained, quickly assume the typical rice-water appearance, there being small white flocculi of intestinal epithelium in a slightly opaque fluid."—I am, etc.,

Accrington.

Binding of Haemoglobin

SIR,—Your leading article (*Journal*, November 16, p. 1164) and the paper by Dr. A. C. Allison and Mr. W. ap Rees (p. 1137) on haemoglobin-binding by plasma proteins prompts us to comment. We are specially interested in this subject, because over the past two years we have studied the form of attachment of haemoglobin to serum proteins in 30 normal individuals and in 24 patients suffering from megaloblastic anaemia, haemolytic anaemia of varying aetiology, and also in other miscellaneous pathological conditions in which haemolysis was not suspect.

In our experimental technique we employed as complementary tests (1) paper electrophoresis of serum to which haemoglobin had been deliberately added, followed by benzidine staining; and (2) addition of ammonium sulphide, as in the Schumm reaction, to such mixtures of serum and haemoglobin with subsequent spectroscopic examination. Our results led us to the conclusion that serum proteins capable of combining with haemoglobin are compulsorily lost in the process of clearing the latter from the circulation. These conclusions are further substantiated by the changes which occur in the sera of patients with megaloblastic anaemia due to vitamin B₁₂ or folic acid deficiency in response to appropriate therapy, and in other haemolytic states in which remission occurs. On the basis of these observations we have felt it possible to advocate the use of these tests as a means of demonstrating intravascular haemolysis, which they can do even when other more commonly used tests are negative or equivocal.

In brief, we find that by simple paper electrophoresis it can be shown that a normal serum will bind haemoglobin to alpha₂-globulin (haptoglobin of Jayle),^{1,2} to a beta₂-globulin (which is not transferrin), and to albumin, in that order of preference as the concentration of haemoglobin is increased. According to the severity of the episode, sera from patients experiencing haemolysis are denuded of haptoglobin and haemoglobin-combining beta₂-globulin, again in that order. On remission, haemoglobin-combining proteins return in reverse order to their disappearance, i.e., beta₂-globulin first, followed by the alpha₂ component.

Sera which are deficient in alpha₂ haptoglobin, and to which haemoglobin is added, are found to give, under the influence of ammonium sulphide, a haemochromogen with an absorption band of 558 mμ which differs from that given by methaemalbumin in possessing but a single band and being for a while reversibly oxidized by air to oxyhaemoglobin. This haemochromogen appears to derive from the beta₂-globulin-haemoglobin complex, as it only occurs when there is insufficient haptoglobin

to combine with all the haemoglobin present in the specimen. This simple chemical test provides a ready means for showing a deficiency of haptoglobin, and, we believe, of demonstrating that haemolysis is occurring or has recently taken place.

The beta₂-globulin differs from the alpha₂-haptoglobin in being able to combine with haematin. This can occur as strongly as combination between haematin and albumin, bearing in mind the quantitatively greater amount of the latter in serum. We do not think, however, that the presence of benzidine-positive material associated with albumin demonstrable after haemoglobin addition to normal serum followed by electrophoresis indicates the formation of methaemalbumin. Direct spectroscopic examination fails to show any characteristic band at 623 mμ, and the haemochromogen we have described above is not attributable to the presence of haematin in the serum. Moreover, investigation of urine from patients suffering from the nephrotic syndrome has shown that an albumin-haemoglobin complex may be formed without the subsequent production of a haemochromogen if the beta₂-globulin component is not also present; a similar result can be demonstrated by employing an albumin transfusion preparation which contains mainly albumin and the iron-binding beta₂-globulin, which latter does not combine with haemoglobin.

The two tests have been found to give consistently parallel results, and it is largely a matter of convenience, according to the adequacy of the serum sample, which of them is used. We consider that an addition of haemoglobin to a concentration of 0.3 mg. per ml. of test serum can be critical in determining whether intravascular haemolysis is present or has recently occurred. Under the latter circumstances serum will give a secondary acceptance pattern at this haemoglobin concentration, as there is insufficient of the prime haemoglobin binder, haptoglobin; it will also give a haemochromogen spectrum on treatment with ammonium sulphide. Our findings in the application of these tests to the series of cases mentioned above have been submitted in full for publication elsewhere, but we felt it was of interest to point out that it now appears possible to ascertain, with appreciably more delicacy than before, whether a haemolytic process is operative in any given case.—We are, etc.,

Mongolism in a Twin

SIR,—With reference to Dr. J. V. Morris's medical memorandum on mongolism in a twin (*Journal*, November 2, p. 1038), and subsequent letters on this subject, I wish to record a further case, which occurred in our practice.

The parents had a normal son in 1941, and in April, 1945, twins were born one month prematurely at the patient's home. The mother was aged 35 at this time, and she has not had a subsequent pregnancy. Delivery was normal, both babies being vertex presentation; the first was a boy weighing 4 lb. 13 oz. (2.1 kg.), and the second, a girl weighing 4 lb. 11 oz. (2 kg.), was born 20 minutes later. The girl was noted to be a typical mongol at the age of 7 months, and this was confirmed by a paediatrician. She is now at a colony for mentally defective children, and her mother states that she is very healthy and able to talk.—I am, etc.,

Bridford-on-Avon,
Warwickshire.

A. H. H. GUILBRIDE.

SIR,—The article on mongolism in a twin, by Dr. J. V. Morris, in your issue of November 2 (p. 1038) and its apparent rarity prompt me to put on record a case which I have at the moment.

The father, aged 40, is a steel erector. The mother is aged 38. Both are perfectly healthy, and both seem of average intelligence. There is one other child, born in 1946, who is a normal, healthy boy. There was one girl born prematurely in 1947 weighing 6 lb. (2.7 kg.), and who died at 3 weeks from "convulsions." This was before I attended the family and I know nothing of the circumstances. The mother assures me that both of these pregnancies and confinements were normal.

The wife's mother, aged 68, is also a patient of mine, as also is her brother (unmarried), and her sister (married with two normal children). All these are healthy. The wife's father died 15 years ago, aged 53, from "heart failure and asthma." The husband's parents live in Lancashire and are not known to me. Both are 65 years of age and healthy. They have one other child, a daughter, aged 42, married with three healthy children. There are no twins in the wife's family, but the husband seems to remember vaguely twins way back in the family somewhere.

I attended the wife for pregnancy in 1954. Her estimated date of delivery was October 14. I note from her record card that she had treatment for vitamin-B deficiency in July, 1954. X-ray in early September confirmed the presence of twins, both presenting by the vertex. At this time she had a blood pressure of 170/100 mm. Hg, with a slight trace of albuminuria. Her blood group was O Rh negative, and Hb at that time was 76%. On September 22 she was admitted to hospital as an emergency in labour, her admission having been prearranged. She had a normal delivery first of a normal female, weight 3 lb. 12 oz. (1.7 kg.) and then of a male mongol weight 4 lb. 6 oz. (2 kg.).

The child is now aged 3 years 2 months. He is a typical mongol. His behaviour and toilet habits are those of a child of 18 months. Since he is only just walking and very unsteady on his legs he spends a large amount of his time in a play-pen. He has a habit of banging his head on the side of this. He behaves in a somewhat cantankerous manner towards his sister, who is a perfectly normal, healthy child.—I am, etc.,

JOHN LEWIS.

Swansea.

Preparation of Skin for Electrocardiography

SIR,—I would like to endorse Dr. James Maxwell's discovery (*Journal*, October 19, p. 942) that a special jelly is not essential in the preparation of the skin. About six months ago my stock of special jelly supplied by the makers of the electrocardiograph ran out. Initially I tried ordinary "K-Y jelly" with completely comparable results, and later experimented with a cotton-wool swab soaked in soap-water. This, if anything, gave even better results with considerably less rubbing compared with both the K-Y and special electrode jelly. I now use soap and water routinely, but find K-Y jelly very useful for the chest leads in hairy-but, unlike Dr. Maxwell, I find the saving in cost at 7s. per tube, plus packing, postage, and customs charges, far from negligible.—I am, etc.,

DONALD WHITFIELD.

Ndola, N. Rhodesia.

Drug Firm Representatives

SIR,—I cannot entirely agree with Dr. D. J. Adderley (*Journal*, November 23, p. 1243) about these gentlemen. Sometimes, when they are "only detaining me for a minute" (which drags on to five or more), they provide small pieces of useful information, and their samples are often useful, though I have cupboards full of those which are not.

What I complain about is the complete ignorance of psychology in advertising. Every post produces a spate of proprietary literature, some of it too large to go through the letter-box, so that the door must be opened. I have the misfortune to appear twice on some firms' mailing list, so that I receive their publications in duplicate. They may be differentiated into: (1) Pretty pictures useful for scrapbooks, the rest for W.P.B. (2) Pseudo-scientific, as presented to the public, with anatomical diagrams showing what is apt to happen if the drug is not taken. These are for the W.P.B. (3) Tremendously scientific, with case notes, references, and proofs of superiority to comparable preparations. These either clutter up one's desk until there is time to glance through them or the pile becomes so big that it falls over. In any case—W.P.B.

We have to contend daily with the suggestion that every firm's iron, sedative, antibiotic, cortisone, and the rest is better than any other, whereas, in fact, in our simplicity, we learn one name, and if the preparation is efficacious we stick to it. St. Barbe Baker once told us how many square miles of forest were destroyed to produce paper for one edition of the *New York Sunday Times*. Several acres must have been delivered to my house, ultimately to produce smog, in more than one sense. So the new world continues to redress the balance of the old.—I am, etc.,

Ipswich.

D. W. FRYER.

SIR,—With reference to the letter from Dr. D. J. Adderley (*Journal*, November 23, p. 1243), I would like to add my own opinion. I often derive more information, which is sometimes more up to date, from a representative than from his firm's literature. I have also found them willing to obtain additional information from their scientific department at very short notice. They can often inform me of other doctors' experiences concerning their new drugs, and are willing to consider my own comments. Provided that the representative is competent and the interview is brief, I would appreciate just two visits a year from him.—I am, etc.,

Harrow.

CHARLES ROBERTS.

SIR,—With reference to Dr. D. J. Adderley's letter (*Journal*, November 23, p. 1243), it is felt that only one side of the problem—although undoubtedly an important one—has been presented. Reports received from our representatives have often stressed that the general practitioner of the present day has not the time to read all the literature on new drugs and preparations which is sent to him. He therefore often prefers a verbal discussion because this gives him an opportunity of asking questions which he would not have the time to put in writing to the medical information department of the manufacturer.—I am, etc.,

London, W.C.1.

G. A. SCHMEIDLER,
General Manager, Camden Chemical Co. Ltd.

Drug Addiction

SIR,—I am rather concerned at the increased use of the morphine-like drugs, such as methadone and pethidine, for non-malignant chronic conditions and wonder whether practitioners are fully aware of the danger of addiction to these drugs. While it is possible that any adequate analgesic may produce addiction, it is amply proved that a few weeks' medication with pethidine, especially, often leads to addiction, as shown by significant withdrawal symptoms on discontinuing the drug. From personal experience, and that of colleagues and intelligent patients, I can state that the particular effects of pethidine, which produce, apart from analgesia, a marked degree of euphoria followed by a state of "hang-over" or depression, are such as to encourage repeated doses leading to addiction.

This all applies particularly to arthritic patients, who are prone to keep asking for something new for their pain. These patients go on for many years, but their symptoms usually wax and wane even without treatment, and it is urged that they should never be given an addicting drug, but should be given carefully regulated doses of analgesics known to help joint pain, such as phenylbutazone or the compounds of codeine and aspirin. Newer codeine salts, such as dihydrocodeine, have an analgesic action comparable with the morphine-type of drugs without their addicting qualities, so far as can be ascertained, and these are worthy of trial.

It may seem strange that this warning should be necessary, but it has been prompted by recent experience with patients sent to hospital for radiotherapy and with dying cancer patients, whose last weeks would have been much more easily passed had they not become accustomed, not to say addicted, to increasing doses of opiates.—I am, etc.,

Hove, 3.

E. MILLINGTON.

Hospital Confinement

SIR,—I was much interested by Mrs. A. M. C. Miller's comments (*Journal*, November 23, p. 1238) on the occurrence of breast abscess in hospital and domiciliary obstetric practice. I can remember an occasion when there were three doctors' wives with breast abscesses in the obstetric ward of a first-class hospital. While accurate statistics on this subject are hard to come by in general practice, it is likely that the research committee of the College of General Practitioners would be able to help. As a general surgeon I have been struck by the apparently lower incidence of breast abscess in domiciliary practice, even allowing for the smaller proportion of women confined at home, and it would be valuable to know if this is borne out by careful investigation.

One cannot but agree with Mrs. Miller that the feeding regime in hospital is frequently too rigid. I intend no disrespect to those who staff our hospital obstetric departments when I say that "factory" conditions are not conducive to easy establishment of breast-feeding. By contrast, the woman who is confined at home under the care of a good family doctor is likely to enjoy more sympathetic supervision and less exposure to noxious bacteria. Furthermore, even if such a woman should develop a sore nipple, it is far less likely that pathogenic organisms will invade the breast.

The points raised by Mrs. Miller are of great importance. It does seem quite wrong that, when home conditions are suitable, so little encouragement is given to mothers to have their babies at home. The general practitioner should be given every facility and encouragement to undertake domiciliary obstetrics. Lest I should appear to be an armchair theorist, and in answer to Dr. J. P. O'Dwyer's inquiry (*Journal*, April 20, p. 947), may I say that my wife has had five children delivered at home by our family doctor.—I am, etc.,

Radlett, Herts.

REGINALD S. MURLEY.

Medical Training and Research in India

SIR,—I am most appreciative of the article on medical training and research in India to-day by Professor A. W. Woodruff in the *Journal* of September 7 (p. 537). May I, however, point out that I was not a little surprised to note that the name of the School of Tropical Medicine, Calcutta, a premier research institution of international reputation, has not been mentioned anywhere in the article? Established in 1922, the school has to its credit outstanding contributions in the fields of postgraduate teaching and research in tropical medicine and allied sciences. It is affiliated to the Calcutta University for a nine months' diploma course in tropical medicine and hygiene. The school also provides courses for the diploma in clinical pathology for nine months and licentiate in tropical medicine for three months. It has fourteen special departments as well as a 150-bedded hospital.—I am, etc.,

Stoke-on-Trent.

J. E. M. SMITH.

Knock-knee in Children

SIR,—While Dr. A. J. M. Morley's paper (*Journal*, October 26, p. 976) confirms many clinical impressions, the whole research has been based on a wrong premise. Knock-knee is not a static deformity. Measurement of the inter-malleolar separation whether lying or standing can only be a rough guide; it is far more important to see the child walk barefooted, and no one yet has succeeded in any method of recording the effect produced.

Knock-knee, while having its characteristic bone conformation, is the result of poor muscle function and co-ordination; it is accompanied by a lateral rotation of the tibia at the knee joint. If a child is stood or laid down with its feet pointing forward, the tibial rotation is corrected and the general limb outline is improved. Wedging of the heels of the shoes assists muscle function in maintaining this more normal use of the limb.

The implications of this view of the cause and nature of knock-knee indicate that the condition is treatable and

should be treated. It is a fallacy that the condition always disappears. How many surgeons have looked at the knees of adults for a cause of chronic backache which is postural in origin? Most people who suffer this chronic backache put up with it and do not ask for specialist assistance.

As to treatment, I am sure that a valgus heel wedge is corrective, bearing in mind always the cases with inverted forefoot which need an accompanying varus sole wedge. Night splints are of value in severe degrees of knock-knee and will almost always eliminate any need for operative correction.

Since Dr. Morley's paper comes from such an authoritative source, it is essential that another point of view should be stated. Knock-knee is not a simple abnormality; it is a very complex mixture of bone structure and muscle function, as are most orthopaedic conditions in children. Function is the most important factor.—I am, etc.,

Newcastle upon Tyne, 3.

MICHAEL JAMES.

Traffic Delays

SIR,—Traffic in and around London has become so thick of recent years that one is finding it more and more difficult to answer an urgent call urgently. Usually, of course, fifteen to twenty minutes added on to one's normal time for the journey does not make much difference. However, one very often cannot know this at the time. If one tries to overtake the traffic, people think one is impatient, and do their best to hug the centre of the road as a sign of their disapproval, thus making things worse than ever. I should be interested to know if other doctors have complained of this, and whether they have any ideas on how to cope with this problem. I have often wondered whether a card on the windscreen saying "On urgent call" might help; but is this allowed?—I am, etc.,

S. Croydon, Surrey.

C. W. COOLE.

Some Paediatric Problems of Uganda

SIR,—Dr. Joseph Luder's paper on some paediatric problems of Uganda (*Journal*, November 16, p. 1143) interested me greatly. He mentions marasmus and the problem of treatment when the illness has reached the point of no return. He says, "No matter how large the calorie intake, many will not gain weight significantly, and frequently die, after a long battle, of a secondary infection."

In the pre-antibiotic era of 30 years ago, marasmus claimed many infant lives in this country. It followed such illnesses as pneumonia and enterocolitis, and neither modifications of diet nor drugs was of any avail. A colleague and I, both R.M.O.s at Alder Hey Children's Hospital, Liverpool, decided to try blood transfusions on these desperately ill babies. Our series was small—12 in all, of whom only 2 survived. But these two made complete recoveries, and we did feel that the blood transfusions had miraculously saved them. Our results were published.—I am, etc.,

Topsam, Devon.

Neuropsychiatric Sequelae of Lightning Stroke

SIR,—In carrying out a survey of institutionalized epileptics at Runwell Hospital, under the auspices of the Mental Health Research Fund (with moneys provided by the Dowager Lady Peel Trust), we have found what appears to be a genuine case of epilepsy following lightning stroke, and wonder if other people have come across similar cases. We have not been able to find any such described in a provisional survey of the literature, and we were stimulated to make this preliminary communication in view of the interesting article by Drs. D. Shaw and M. E. York-Moore (*Journal*, November 16, p. 1152), and also your annotation, in neither of which, however, does epilepsy find specific mention.

Our patient gives a negative personal and family history in respect of epilepsy (she was the fourth out of a family of

16 children) prior to the age of 5. She states that at this age she was struck by lightning while walking on Wandsworth Common in company with her two cousins and one brother. The cousins were killed and the brother rendered a cripple, while she herself was "knocked unconscious." Her first fit came on in the same year but some months following the lightning stroke. Her present fit pattern is that of focal cortical epilepsy, and appropriate electroencephalographic correlates were demonstrated during sleep but not in the primary waking trace. There are, however, other abnormalities present in the waking E.E.G., the interpretation of which is uncertain.

Some of the sequelae of lightning stroke described by Drs. Shaw and York-Moore might conceivably be related to focal cortical abnormality, though they are careful to point out that loss of consciousness never occurred as a late (six months after the lightning stroke) sequel. It will be very interesting to see whether follow-up studies carried out over a longer period will bring to light the development of frank epilepsy in any of their cases, as also whether, in this event, the symptoms of which such patients presently complain will become incorporated in their definitive auras.—I am, etc.,

Wickford, Essex.

JAMES H. MARGERISON.

Acute Inversion of Uterus

SIR,—From the clinical experiences recounted in your columns, it appears fairly certain that shock occurring with acute inversion of the uterus can be overcome if there is no acute inversion of the uterus; and that if this fails to be brought about at an early stage shock continues, requiring to be countered before the hazards of reduction can be safely faced.

There is an experimental explanation of these happenings and certain therapeutic procedures based on the accompanying renal ischaemia that may prove of practical value when reduction has been delayed. Professor E. C. Amoroso¹ compressed the conceptus between thumb and fingers in pregnant rabbits at about mid-term and demonstrated that as the compression mounted the kidney surface became progressively paler. The degree of cortical pallor and its onset were commensurate with the pressure applied; and a dramatic and profound surface renal ischaemia could be occasioned. Removal of the stimulus abolished its renal effects. These experimental findings have a strict parallel with Dr. B. P. Bhattacharya's clinical experiences (*Journal*, November 16, p. 1174), and I would contend that in the latter there are analogous renal changes as well, pointing to the utero-renal reflex as underlying the observed phenomenon, as in both the uterus is exposed to considerable trauma.

Renal ischaemia can produce both shock and anuria. It has been shown that the diminished oxygen consumption by the tissues produced by chlorpromazine—e.g., the lytic cocktail or hypothermia—can reduce shock and the risk of subsequent cortical necrosis,^{2,3} and that splanchnic block can be safely employed in the most severe degrees of shock when it can stave off cortical necrosis as well in cases of concealed accidental haemorrhage.⁴ It may be of therapeutic import to bear both hypothermia and splanchnic blocking in mind when faced with a prolonged unreduced uterine inversion, especially in countries where the incidence of this occurrence is high, as in the East.—I am, etc.,

JOHN SOPHIAN.

SIR,—We have read with interest Dr. B. P. Bhattacharya's letter (*Journal*, November 16, p. 1174) and original article¹ on the subject of inversion of the uterus. None of his seven cases had any oxytocic drug administered before uterine inversion occurred. If such a drug had in those days been given, perhaps the four who died might have survived, for the best way of preventing inversion is routine administra-

tion of ergometrine with the delivery of the infant's head or anterior shoulder.

Oxytocics are no more likely to cause inversion than some of the other factors mentioned by Dr. Bhattacharya—such as hypoadrenalinaemia or neurosis. We challenge him to quote a single case of inversion after the administration of oxytocics. None has occurred at University College Obstetric Hospital during the last nine years in more than 14,000 deliveries, during which ergometrine was routinely administered at the end of the second stage of labour.—We are, etc.,

W. G. MACGREGOR.

Minor Derangement of the Temporomandibular Joint

SIR,—The comments on "Clicking Jaw" (*Journal* November 9, p. 1130) prompt me to raise an allied problem. Not infrequently in general practice a patient comes complaining of pain and stiffness in one temporomandibular joint for which no particular reason can be found. The trouble usually comes on suddenly and in most cases subsides within a few days. In the past I have been a bit vague about the cause of these attacks, and if pressed for an explanation have usually fallen back on a suggestion of slight trauma or "a touch of rheumatism" in the joint.

I recently had a similar attack myself. It is always instructive for a doctor to become a patient, and my experience on this occasion led me to consider another possible explanation that I had not previously thought of or seen mentioned. One morning at breakfast I found I could not quite close my jaw and it hurt on the left side if I attempted to do so. Other movements at that time were painless and the head of the mandible seemed to be properly in its socket. Subjectively it felt as if the meniscus was slightly swollen and became squeezed when I tried to clench my teeth. Active and passive manipulations made no difference, as they might have done if a synovial fringe had been caught between the articular surfaces.

I got through the day without much discomfort, but when I went to bed that night there was an unexpected rather severe pain in the left temporomandibular joint as I put the right side of my face on the pillow. I had not realized until that moment how far one's jaw can be displaced sideways when one rests one's face on the edge of a pillow, and it was this movement that now caused the pain which disappeared when I quickly raised my head again. I often go to sleep lying on my front with my head turned sharply to the left, but I noticed that in this position the pressure on the side of the jaw is much greater than if one lies on one's side. It occurred to me that by lying asleep for several hours, with the head of the mandible pushed laterally to its full extent, some slight trauma might take place, resulting possibly in some swelling of the meniscus. In other words it might be that the head of the mandible does not like being pushed sideways too far for too long. It was not the side on which I lay that became painful, the side where the head of the bone was pushed medially, but the side that was uppermost, where there was lateral displacement—a kind of *contre-coup*. And so I turned over and went to sleep on my back. Next morning I was 80% recovered, and 100% on the following day. Perhaps, when faced with a case of this kind, in addition to considering other possible forms of trauma one should inquire into the position assumed by the patient during sleep.—I am, etc.,

Jersey.

NORMAN A. SPROTT.

POINTS FROM LETTERS**Interleaved Cotton-wool**

Dr. R. P. ROBERTSON (Morpeh, Northumberland) writes: Is it not extraordinary that in these days when one can hardly dispose of the quantities of paper that come unasked into the house, it is not possible to obtain interleaved cotton-wool in 1 lb. packages such as was a commonplace before the war?

Obituary

JANET C. BLACK, M.B., Ch.B.

Dr. Janet C. Black, the vice-chairman of the East Ham Local Medical Committee, was killed when the flying-boat in which she was a passenger crashed near Newport, Isle of Wight, on November 15. She was 57 years of age.

Janet Cook Wallace was born at Arbroath, Angus, on July 21, 1900, and studied medicine at St. Andrews University, originally with a view to becoming a medical missionary. She graduated M.B., Ch.B. in 1925. While acting as an assistant to a doctor in West Ham she met her future husband, Dr. Alfred Black. Together they built up a large general practice in East Ham, where she was a very popular member of the local community. Earlier this year she was elected vice-chairman of the East Ham Local Medical Committee, and was chairman-elect for 1958-9. Apart from her practice responsibilities and her membership of the local medical committee, she took an active interest in local affairs, being an honorary member of the Inner Wheel of the Rotary Club of East Ham, and a loyal member of the East Ham Presbyterian church. She will be greatly missed by her patients, friends, and colleagues.

S.T. writes: The community and the medical profession of East Ham have suffered a very great loss by the tragic death of Dr. Janet Black. It was in 1931 that Dr. Janet Black, on her marriage, joined her husband, Dr. A. Black, who was then an established and well-known general practitioner. She soon became a most valuable member of the firm by providing the area with what it always needs, a sound and responsible woman doctor. It was not just her ability which attracted, but her extreme kindness and true interest in the problems of her patients. The exigencies of a very busy practice did not, however, prevent her from entering into a full and happy family life, and to her husband and three sons she was a devoted wife and mother. Of a somewhat shy and retiring disposition, it was only recently that she was persuaded to enter into committee work, and she had agreed in the forthcoming year to accept the chairmanship of the local medical committee, a decision which caused very great pleasure to all her colleagues. Her untimely death is mourned by countless patients and friends, who will so miss her kindly humour and unfailing good nature and generosity. Her lively presence will indeed be missed and her place hard to fill. Our deepest sympathy goes out to her husband, her three sons, and other relatives in their irreparable loss.

JAY McLEAN, M.D.

Dr. Jay McLean, who discovered heparin in 1916, died on November 14 at his home in Savannah, Ga. He was 67.

Jay McLean was born in San Francisco and graduated in science from the University of California in 1914. Two years later his discovery of heparin was recorded in the *American Journal of Physiology*. He extracted from dog liver a substance which retarded blood coagulation *in vitro* and which was later named heparin after further work by Howell and Holt. For a time during the first world war McLean served in the medical corps of the French Army, and on his return to the United States he graduated M.D. at Johns Hopkins University. For the next three years he worked as assistant resident surgeon at Johns Hopkins Hospital. He held a number of posts as a teacher of surgery at Columbia and other universities, and in later

years worked as a radiotherapist. He had been at Savannah as a director of the tumour clinic there since 1949.

W. E. G. DUTHIE, M.B., D.P.H.

The death occurred at his home at Saxonwold, Johannesburg, on November 15, of Dr. Ewart Duthie, aged 37, probably one of the oldest graduates in medicine in South Africa.

William Ewart Gladstone Duthie came from Aberdeenshire, and was educated at the Woodside Public School, at Aberdeen Grammar School, and at Aberdeen University. He graduated M.B., C.M. in 1894, and took the D.P.H. two years later. After a period of practice in the United Kingdom he went to South Africa before the Boer War, and during that war served as railway medical officer to the Imperial Forces. Subsequently, after holding appointments as railway medical officer at Trompsburg and Edenburg in the Orange Free State, he settled in Kroonstad, where he was railway medical officer, district surgeon, and medical officer of health. In 1925 he moved to Johannesburg and practised in the southern suburbs and in Orange Grove. A cardiac illness in 1934 cut short his professional activities, and he lived a life of retirement, devoting himself largely to gardening and racing, of which he was a keen follower. His later years were clouded by ill-health, and he died after a few months' illness.

Dr. Duthie was a product of the Aberdeen School, taught by such men as Professor Sir Alexander Ogston (surgery) and Professor D. J. Hamilton (pathology), and throughout his career exemplified the practical, common-sense approach to medical practice which is so characteristic of Aberdeen teaching. He was twice married, and leaves a widow. He is also survived by his elder son (the younger having died suddenly in 1955), daughter-in-law, and three grandchildren.

J. W. RUTHERFORD, F.R.C.S.I.

Dr. J. W. Rutherford died at his home at Killiney, Co. Dublin, on August 9.

James Whigham Rutherford was the eldest of the seven children of the late Dr. William Rutherford, at one time a very eminent practitioner in the west of Ireland. Of these seven children, five later qualified in medicine and the only daughter married a doctor—a family achievement worthy of record. J. W. Rutherford qualified by taking the Irish Conjoint diploma in 1904, and then held a number of house appointments at Dublin hospitals. Having obtained his F.R.C.S.I. in 1909, he joined the staff of the Somerset and Bath Mental Hospital, Cotford, where he soon became the senior assistant. Later, on his father's death in 1911, he returned to Ireland to take over the practice in Ballinasloe, Co. Galway, where he remained until 1922. He then moved to Dublin, where he succeeded Dr. J. J. Purser in Rathgar. He was later appointed assistant physician at Dr. Stevens' Hospital. On the death of his brother, Dr. H. R. C. Rutherford, who for many years had been one of the leading psychiatrists in Dublin, he took over Farnham House private mental hospital and remained there until his retirement in 1956. He married Miss Mabel Henderson, and is survived by his widow, two sons (the younger of whom is in practice in Folkestone), and two daughters.

W. A. GILMOUR, C.B.E., M.D., F.R.A.C.P., D.P.H.

Dr. Walter Gilmour, one of New Zealand's leading pathologists, died at Remuera, Auckland, on November 18. He was 71 years of age.

Walter Allison Gilmour studied medicine at Glasgow University, graduating M.B., Ch.B. in 1908. He proceeded to the M.D., with honours, in 1912, being awarded a Bellahouston gold medal for his thesis on the Wassermann reaction, and took the Oxford D.P.H. in 1914. After

graduation he became assistant to the professor of pathology at Glasgow, and later held the appointment of pathologist at the Gartloch Mental Hospital. During the first world war he served in the R.A.M.C. as a pathologist and bacteriologist in Malta, Salonika, and Italy. On demobilization he returned to Glasgow, where he was appointed assistant medical officer of health and assistant tuberculosis officer. In 1920 Dr. Gilmour left Scotland to become pathologist to the Auckland Hospital, in New Zealand, an appointment he held until recently. Chairman of the Auckland Division of the B.M.A. in 1935-6, he was elected a Fellow of the Royal Australasian College of Physicians in 1947 and appointed C.B.E. in the following year. Dr. Gilmour, who had been ill for some time, is survived by his widow and by one son.

A. C. WILSON, M.R.C.S., L.R.C.P.

The obituary of Dr. A. C. Wilson was printed in the *Journal* of November 16 (p. 1182).

M. N. W. writes: May I add to the admirable obituary notices of Dr. A. C. Wilson? I write as a pupil, colleague, and friend. Dr. Wilson's most outstanding characteristics seemed to me to be his absolute lack of pettiness and his extreme generosity. I do not mean in material matters, though in this way he was as liberal as he could be. He encouraged others in their endeavours to the utmost, and was without jealousy or envy. His was a really fine personality and he possessed the highest sense of integrity imaginable.

F. R. CAWTHORN, O.B.E., M.B., B.S.

The obituary of Colonel F. R. Cawthorn was printed in the *Journal* of November 23 (p. 1244).

Lieutenant-General Sir TREFFRY THOMPSON writes: Colonel Cawthorn served with me through some of the most difficult years of the fighting on the Burma front. I formed a high opinion of his ability and admiration for his character. He was one of those who always managed to get things done—even to producing and running a full-sized general hospital under most difficult conditions and an apparent shortage of all desirable amenities. Always cheerful, full of energy, with much medical experience to back his judgment, he was a fine colleague to whom many hundreds of sick and wounded owed a great debt. Lucky were we to have a group of such fine officers.

Medico-Legal

SHOCK AND THE LAW

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

In 1901 the first English case¹ occurred in which a plaintiff recovered damages for personal injuries produced by nervous shock. The plaintiff was a barmaid, and the occasion of her shock was the appearance of the defendant's horses and van being driven into her bar. In that case the three components of a valid cause of action in negligence were present. First, the defendant in the circumstances had a duty to take reasonable care for the safety of the plaintiff, for a van driver must appreciate that people within his sphere of operation, such as passers-by on the footpath or barmaids in bars adjoining the highway, will be affected by the quality of his driving. Secondly, there was a breach of his duty to take care, for the reasonably careful driver does not find his horses drawing his van into the bar of a wayside public house. Thirdly, the medical evidence was that

the barmaid had suffered damage by reason of nervous shock caused by the defendant's breach of duty. Mr. Justice Kennedy, therefore, did not hesitate to decide that she was entitled to compensation by way of damages for the injury which the defendant had caused her through the medium of shock—just as though she had received an injury by being kicked by one of the horses.

Since then the principle that nervous shock is a medium through which damage can be caused as readily as through physical injury has been consistently observed in English law, though certain difficulties have arisen in relation to the causes of the shock; these have recently been the subject of comprehensive analysis by J. Havard in the *Modern Law Review*.² The difficulties have arisen from that part of the judgment in *Dulieu v. White* in which Mr. Justice Kennedy observed that it was not every nervous shock occasioned by negligence and producing physical injury which would give a cause of action: the shock to give a cause of action must arise from reasonable fear of immediate personal injury to the plaintiff himself. Havard points out the medical difficulty of deciding whether and to what extent shock in any particular instance has been caused by fear for self, for property, or for the safety of loved ones. In *Hambrook Bros. v. Stokes*³ a mother who knew that her daughter was on her way to school saw a lorry running out of control down the street by which the child had just gone and in which the mother was standing. The lorry ran into a house and stopped before it reached her, but she ran up the street, and, on being told that a little girl answering her daughter's description had been injured, had a hysterical attack. She discovered that her daughter had not reached school, and found her in hospital seriously injured. As a result of the shock the mother, who was pregnant, had a haemorrhage and ultimately died. The Court of Appeal held that, though her fear had been primarily for her child, the owners of the lorry were liable. It might have been very difficult to say what proportion of shock was caused by fear for herself, and what by fear for her child.

After reviewing the authorities, and in particular the House of Lords decision in *Bourhill v. Young*,⁴ Havard suggests a solution to these difficulties. It appears to be that Mr. Justice Kennedy's limitation of liability to circumstances in which there is fear of danger to self applies not to the third element required to establish liability—that is, the causation of the shock which constitutes the injury—but to the first element alone. If the defendant ought to have in mind the possibility that he might make someone scared about his own safety, then he has a duty towards that person; if the possibility is that the person would be scared not for his own safety but for someone else or something else, then no such duty arises.

If this solution is correct, no difficulties of medical evidence really arise. It is a matter for the judge without the help of medical evidence to say whether or not the circumstances were such that the duty existed. It is for the doctors to say whether the plaintiff suffered injury through the medium of shock arising out of the accident. It does not matter what was the precise cause which medically gave rise to the shock.

ABNORMALLY THIN SKULL

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On September 14, 1957, William Henry Evans, aged 46, who had been avoiding arrest for non-payment of a fine of £20, spent the evening in a Coventry public house, where he drank four or five pints of beer. When he left at closing-time he showed no signs of illness and was walking quite normally. At about 11 p.m. he knocked at the door of his home in Coventry, and was let in by his wife, who told him she was going to fetch the police.

His wife saw that he had been drinking, and she heard him trip. He was staggering. Meanwhile his 19-year-old son Roy had come home, and he went outside to his father,

² Havard, J., *Modern Law Review*, 1956, 478.

³ 1925, 1 K.B. 141.

⁴ 1943, A.C. 92.

who he recognized had been drinking, and told him he had better go, as he knew the police were after him and he would get his mother into trouble. His father took his coat and tie off and went to hit him, and Roy in self-defence hit him in the right eye with his fist and turned away.

This was seen by a neighbour, who went over to Evans as he lay on his back in the road, "out." The neighbour gave him some water, and after a few seconds Evans came round. He had a slight cut on the right eye, which was bleeding. After a cup of tea with the neighbour he left and went to his sister-in-law's for a short time. On emerging from there he fell heavily face down in the road. He was picked up by another neighbour, who found him conscious but obviously having "had a drink." He said he wanted to go to the hostel, so the neighbour put him in a taxi and gave him a pound.

At 12.45 a.m. on September 15 Evans was refused admission to the Salvation Army Hostel. At 7.45 p.m. on that day he came to the casualty department at the Coventry and Warwickshire Hospital with a history of having been knocked down by his son on the previous night and a small cut on the right eyebrow.

An x-ray photograph was taken of his head and no fracture of the skull was found. The wound was treated with penicillin, anti-tetanus serum was given, and, as there was no apparent symptom of concussion, he was discharged.

He remained in casualty, however, and at about 9.30 p.m. Sergeant Orange, of the Coventry City Police, came to the hospital for him. After he had explained to the staff nurse that, if Evans was arrested, he would be detained in the police station overnight and taken to prison next day, Sergeant Orange was told Evans was fit for discharge, so he arrested him and took him to the station by car. On the way Evans kept on saying, "Oh, my neck," but, apart from that, Sergeant Orange would not have known either from his speech or from his general condition that there was anything the matter with him. Still complaining of pain in the neck Evans was handed over to the night duty inspector and put in a cell for the night.

When Sergeant Bennett came on duty at 5.50 a.m. on September 16 there was vomit on the floor of the cell and Evans was sitting upright on his bed aimlessly clapping and unclapping his hands. He seemed to be mentally ill, and at 8.15 a.m. refused breakfast. At 9.30 a.m., when Sergeant Bennett left for the Magistrates' Court, he was standing up in the corner of his cell, and when the sergeant returned at 12.5 p.m. he was picking his face, clutching the front of his jacket, and leaning back on to the wall at the back of his bed. Sergeant Bennett asked him how he was, but could get no reply, and, thinking he was pretty ill, sent for the police surgeon.

The police surgeon when he arrived at 1.10 p.m. found Evans in a stuporous condition, pallid, and slightly cyanosed. He had a slightly bounding pulse, and his reflexes and reactions were very sluggish, especially the pupils. He thought he would get adequate attention at the prison hospital, and so Evans was sent to Winson Green Prison. He was admitted to the hospital block directly on admission, and seen by the senior medical officer at 4.15 p.m. Clinical examination showed that he was obviously suffering from some cerebral damage, for his central nervous system showed abnormal response of the left great toe, no reaction to light of the pupils, and absence of knee jerks. Permission was immediately secured to transfer him to the Dudley Road Hospital, where he arrived at 5.50 p.m. unconscious. At 9 p.m. when seen in consultation by the consultant physician, he was seriously ill, in coma, and struggling. A lumbar puncture was made which showed the presence of meningitis of a particularly virulent type, and in spite of treatment with penicillin and intramuscular chloramphenicol he died at 5.45 p.m. next day.

At the inquest held at the Birmingham Coroner's Court on September 19 Dr. F. E. D. Griffiths, Home Office pathologist, who carried out the necropsy, found that, in addition to the meningitis and bronchopneumonia which were the prime causes of death, Evans had a crack fracture of the skull on the right side extending from the upper border of the temporal muscle to the base, and the dura beneath showed haemorrhage. His skull was abnormally thin, and less than $\frac{1}{8}$ in. (1.6 mm.) thick at the site of the fracture. On the other side of the skull there was a contrecoup subdural haemorrhage. In his view death was accelerated by this injury to the skull and brain, though he had had pneumonia for at least five days and probably already had meningitis at the time of the injury.

DEATH AFTER SELF-INJECTION

The death of a doctor aged 36 after he had injected himself with penicillin was the subject of an inquest at Wakefield on November 29.¹ He was Dr. J. E. Fahy, an assistant M.O.H. in Yorkshire West Riding, who qualified in Dublin in 1952. Dr. David Price, Home Office pathologist, who carried out the post-mortem examination, said that the cause of death was anaphylactic shock. He had found signs of early acute bronchitis, and it was possible that Dr. Fahy had taken penicillin for that condition, a normal thing for a medical man to do. An empty phial found in his room had contained penicillin, and there was a hypodermic mark on the thigh. Mrs. K. Leedal, at whose home the doctor had rooms, said that on the evening of November 20 she heard him calling to get Dr. Spatz. She telephoned him and meanwhile gave Dr. Fahy a drink of water at his request. On his arrival Dr. O. Spatz found that Dr. Fahy was unconscious: he died in spite of efforts to revive him. A verdict of death by misadventure was recorded.

Medical Notes in Parliament

CHRONIC SICK AND ELDERLY

The first private members' day of the current session found the Commons discussing on November 29 the social as much as the medical needs of the chronic sick and elderly. The motion which began the debate, introduced by a Government supporter who had the luck of the draw in the first ballot, welcomed the initiative of the Government in organizing a nation-wide survey of services available to the chronic sick and elderly; approved the steps taken by the Minister of Health to make known to hospital and local health authorities the best and most effective practice, as revealed by the survey; and called on those who were not doing so to implement the Minister's advice.

That was the theme. Its development became a recital of shortcomings and unfulfilled needs, and the constant reiteration of a single remedy—co-ordination of services in a national plan. Mr. LESLIE THOMAS (Canterbury, Con.) said both the Phillips and the Guillebaud Reports had revealed gaps in the health and welfare services. A few weeks ago the Minister of Health in Circular 14/57 defined the separate responsibilities of the two services, and in doing so had done much to bring about the degree of closer liaison and co-operation that was essential. This had been followed by a circular issued the previous day by the Minister of Housing and Local Government emphasizing the need for greater attention to the needs of old people in the provision of housing accommodation. (While he was enlarging on this Mr. Thomas was interrupted by a voice from the Opposition side—"What do they use for money?") Mr. Thomas urged among other things the closest liaison between the general practitioner, the health visitor, and the hospital. The medical officer of health should have from the National Assistance authorities the names and details of those applying for assistance, since poverty was one of the main causes of the problem. It should also be part of the duty of the general practitioner to advise the M.O.H. of the slightest sign of deterioration in the condition of an old person—for which he should have proper facilities. The local authority could produce a comprehensive list by keeping in touch with the voluntary bodies and services. On this basis an efficient and economic service could be built.

Dr. DONALD JOHNSON (Carlisle, Con.) commented that the Minister's circular came under the well-worn description "Too little and too late." The most uncomfortable fact that had to be faced was that too many old people, because there was nowhere else to dispose of them, were being certified and sent into mental hospitals. Doctors and relatives got stranded perhaps with a seedy old person whose mind

was wandering a little owing to physical causes, and who became trying to look after. There was nowhere to dispose of these people except to have them certified, which made admission to hospital compulsory. When the question of improper certification was raised denials sprang automatically from the lips of Ministers. The evidence did not come from deluded, paranoiac, or hallucinated people.

The fundamental cause of the "evil" lay in the division of powers between local authorities and hospitals. Local authorities had this easy way of putting their responsibilities on to the hospitals. "It is like a rat trap: there is no easy way back once the people are in the hospitals." Local authorities had permissive powers to provide such a service, but the great majority had not taken action. The Minister should seek to obtain integration not only of services but also of finance.

Chiropody Service

Mr. F. ALLAN (Salford, East, Lab.) set out in 12 points the Labour Party's views on the establishment of a chiropody service. It should be a national scheme based on medical need, limited to such categories as sepsis and infection, medical or surgical disorders which substantially affected the feet, and gross deformities. Treatment should be on pre-fee, and gross deformities. Cases of the service and consideration for public funds. Cases referred to the chiropodist by the general medical practitioner. Those needing hospital treatment should be referred back with the chiropodist's recommendation to the general medical practitioner, who would decide on the disposal of the case. The services of chiropodists in private practice should be utilized for cases that did not merit hospital treatment. Wherever practicable, treatment should be given in the chiropodist's surgery, and he should bear all the cost of the treatment, being reimbursed partly by the patient and partly by the Government. Patients should have the right to select their own chiropodists from an approved list in the possession of general medical practitioners.

Mr. SOMERVILLE HASTINGS (Barking, Lab.) added his demand for something to be done for the foot needs of old people, some 70% of whom required treatment; and went on to plead the cause of the young chronic sick, for whom he thought small wards in hospitals offered the best care.

Mr. M. ORBACH (Willesden, East, Lab.) advocated the creation by every local authority of an old people's health clinic, staffed by a medical officer, a health visitor, and an almoner. Mr. N. DODDS (Erith and Crayford, Lab.) enlarged on the topic of persons who were not insane being certified "in a terrifying way," and committed to mental institutions or hospitals "as a matter of expediency" because of the failure to provide other treatment or accommodation for them.

Deployment of Resources

When the MINISTER OF HEALTH came to answer all this he began with the general economic context: it would of course be agreeable to be able to say that in services so necessary and deserving as health they could ignore the economic factor and proceed regardless of cost, but it would be unrealistic, untrue, and indeed unhelpful. It had been with the object of securing the best deployment of resources that the survey was undertaken to discover the size and nature of the need, how well it was being met, and whether changes in emphasis were required. Two fundamental points emerged from consideration of the survey were: (1) more effective liaison was required between the various agencies providing the services; (2) the key to problems stemming from an ageing population lay with the preventive and home services, for the extension of communal accommodation could never of itself be enough. From this he embarked on a detailed review of available facilities.

On the question of certification, he agreed that more accommodation in welfare homes and hospitals for the chronic sick would make it possible to discharge some old people sooner from mental hospitals. Mr. DODDS interrupted:

"The Minister cannot get away with that. Is he denying that there is overwhelming evidence to indicate that large numbers of old people are certified and taken to mental institutions?" Mr. WALKER-SMITH replied that the Royal Commission did not accept the allegations of wrong certification. Commenting on the figure given by Mr. Dodds suggesting that 80% of people in mental institutions should not be there, he said that in 1954 a survey indicated that there were some 10,000 old people in mental hospitals who might be capable of being treated elsewhere. The total number of old people over 65 in designated mental hospitals was about 45,000, so the percentage was something very different.

The survey had brought to light clearly examples of insufficient co-operation between local health and welfare authorities and hospitals, and even between different departments of a single authority. The need for better liaison was particularly marked in the use made of chronic sick beds. The survey showed 4,500 patients in chronic sick wards who no longer needed hospital treatment, and at the same time 1,900 residents in welfare homes who were needing hospital care. His circulars had therefore stressed the need for close and constant liaison so that accommodation could be used for people for whom it was most suitable, and for quick and easy interchange between welfare home and hospital ward to take account of changes in the physical condition of the people concerned. There must be as well first-class liaison between the various departments of local authorities, particularly where the health and welfare departments were separate.

The motion was agreed to.

Coastal Sewage Pollution

Mr. N. DODDS (Erith and Crayford, Lab.) on November 26 asked the Minister of Housing and Local Government, in view of the danger to health arising from the contamination of the sea and rivers where bathing took place by the discharge of untreated sewage, what consideration was being given to the matter with the object of producing a national programme to deal with the menace. Mr. J. R. BEVINS, the Parliamentary Secretary, told him it was for the local authorities concerned to provide a remedy where these problems existed locally.

Mr. DODDS suggested that samples of sea water should be analysed regularly and the results displayed alongside the sunshine and rainfall records on seaside promenades.

Dr. R. BENNETT (Gosport and Fareham, Con.) said that 15 years ago two Americans, Paul and Trask, isolated poliomyelitis virus from sewage in great dilution, and were able to prove that it was conveyed one-eighth of a mile, and even had strong reason to believe that it could be conveyed several miles. In view of the almost overwhelming presumptive evidence that there was spreading of the disease by this means, would the Minister ask his officials not to increase the already strong tendency to inertia among some local authorities by advising that there was no risk worth bothering about? Mr. BEVINS said that, while he was not prepared to accept as gospel what Dr. Bennett said about the danger to health, since the end of the war schemes to the value of £200m. had been approved—all but £30m. since 1950.

Tuberculosis Treatment in Prisons

Mrs. LENA JEGGER (Holborn and St. Pancras South, Lab.) asked the Home Secretary on November 28 what arrangements were made for mass radiography of prisoners, on reception and during their sentences, and what was Home Office policy on treatment. Mr. R. A. BUTLER told her that all prisoners were medically examined on reception, and any prisoner suspected of having active tuberculosis (whether on reception or at a later date) was sent for an x-ray examination. The mass radiography units of the regional hospital boards were invited to visit prisons when in the neighbourhood, and in 1956 some 7,000 prisoners were examined in

this way. Any prisoner found to be suffering from tuberculosis or any other disease was given the treatment he required, either in prison or in an outside hospital, usually in consultation with a local chest physician.

Hereditary Changes in Population

Mr. R. MASON (Barnsley, Lab.) asked on November 28 for what reason it was necessary for the Medical Research Council to form a research team to watch the hereditary changes in the population; and which area was to be the subject of their study. Mr. WALKER-SMITH replied that the Medical Research Council had, for a number of years, taken an active part in developing research in genetics. As part of this general policy they had decided to establish a research unit to study population genetics; the location in which the unit would work was still under discussion.

Doctors in Private Practice

Mr. JOHN HALL (Wychcombe, Con.) asked the Minister of Health on December 2 how many general practitioners were engaged solely in private practice; and what would be the additional cost if those doctors registered for the treatment of Health Service patients. Mr. WALKER-SMITH said the number of general practitioners engaged solely in private practice was not known precisely, but was believed to be about 600 in England and Wales. It was not possible to make any exact estimate of the additional cost to the Exchequer in the hypothetical event of all these doctors joining the Health Service.

Mental Hospital Staffs.—The estimated shortages of male and female nursing staff in mental hospitals at March 3, 1957, were 2,450 and 4,000 respectively. The comparable figures at December 31, 1955, were 3,100 and 5,150; and at September 30, 1956, 2,900 and 4,500.

Welfare Milk.—The total quantity of welfare milk, both liquid and dried, supplied during September, 1957, is estimated at 13.49 million gallons—compared with 13.51 million gallons in September, 1956.

Universities and Colleges

UNIVERSITY OF OXFORD

In Congregation on November 2 the degree of D.M. was conferred on G. E. Honey and A. L. Jacobs.

UNIVERSITY OF CAMBRIDGE

Professor A. Leslie Banks, M.D., F.R.C.P., professor of human ecology in the University, has been elected a member of the General Medical Council for five years from October 22, 1957.

The Senate has approved a proposal to confer the degree of M.A. on Dr. R. T. Sims and Dr. J. G. Cruickshank, University Demonstrators in the Department of Anatomy and Pathology respectively.

The following degrees were conferred on October 19:

M.A.—R. T. Sims, M.B., B.S.
M.B., B.Chir.—S. G. Sutton, H. J. Hoyland, K. A. A. Mourin, R. C. Brodie.
M.B.—S. F. Kuvin, *Enid Wheldon, C. C. Cory.

Sir Ronald Fisher, Sc.D., F.R.S., formerly Arthur Balfour Professor of Genetics, has been elected into a supernumerary Fellowship of Gonville and Caius College for life.

In Congregation on November 2 the following degrees were conferred:

M.D.—J. E. Blundell, I. J. Carré, E. W. P. Jones.
M.B.—J. V. F. Catto (by proxy), R. O. S. Sims.

*By proxy.

UNIVERSITY OF ABERDEEN

At a graduation ceremony on October 30 the degree of M.D. was conferred on W. M. Davidson (with honours) and on John McKenzie (with commendation).

UNIVERSITY OF DURHAM

In Congregation on September 28 the degree of M.B., B.S. (*in absentia*) was conferred upon Phyllis M. Fleury.

UNIVERSITY OF LONDON

The degree of M.D. was awarded by the Senate on October 23 to Gwendolen M. G. Barton and M. J. Craft.

The degree of Ph.D. was awarded in October to Pamela C. B. Mackinnon, M.B., B.S., and Donald Stewart McLaren, M.D., D.T.M.&H.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the College held on October 16 with Sir Walter Mercer, President, in the chair, the following candidates, having passed the requisite examinations, were admitted Fellows of the College:

J. J. Adendorff, R. G. Azizkhan, K. S. Baichwal, B. O. Barry, J. R. Boulic, M. Brukin, R. Campbell, E. W. Carr, W. Chancin, C. G. Clark, P. H. Corkery, F. V. Cosentino, A. J. Dark, A. C. W. Mosbergen Da Rosa, W. J. Garrett, W. E. Gillies, L. R. H. Gracey, I. H. Greer, S. Guergawi, S. Gupta, E. K. Handal, T. M. Hannigan, C. A. Holborow, R. L. Huckstep, P. B. Humphris, I. M. Jassim, T. Joseph, J. N. Joshi, I. Kaplan, S. D. Khandwala, J. D. L. Kirshtein, L. Klenerman, J. Kohari, D. R. Lee, P. A. Limbers, A. Litton, G. M. McFadden, D. O. N. McIntyre, G. P. McNair, P. Narendran, Maung Aung Nyunt, W. B. Saunders, J. N. McM. Schofield, Li Jin Seow, R. L. Shah, A. R. Shepherd, D. Singh, D. Smyth, H. Srinivasan, K. J. W. Stump, R. D. Suckling, L. Symon, G. N. Takla, P. K. Tamaskar, R. M. Varma, P. Virmani, F. E. Wheeler, J. H. Williams, W. Wilson, M. N. Zaman.

ROYAL AUSTRALASIAN COLLEGE OF PHYSICIANS

At a meeting of the Council of the College held at Sydney on October 15 the following candidates, who were successful at an examination by the Australian Board of Censors, were admitted to Membership of the College:

W. G. Grigor, D. A. Handley, B. R. M. Hurt, J. McRae, and R. A. Mellick, of New South Wales; G. W. Crock, D. J. Fone, N. B. Pinkus, B. A. Smithurst, and G. R. Wagner, of Victoria; B. T. Emmerson, G. A. Hocker, and K. J. Murphy, of Queensland; P. R. Hodge and S. Posen, of South Australia; H. J. H. Colebatch and A. M. Rankin, of Western Australia; J. C. H. Morris, of Tasmania. R. W. Hawker, of Queensland, was admitted under the special provisions of Article 37.

Vital Statistics

Influenza Resurgent

Influenza is again spreading throughout Japan, according to reports from the World Health Organization. All specimens of virus isolated so far are of the Asian type. The clinical character of the disease is the same as during the spring outbreak. A few patients are catching the disease a second time.

In Great Britain the death rate from influenza continued to decline, though in Eire it increased slightly. In the week ending November 23 deaths from influenza reported in the great towns were as follows, with the figures for the previous week in parentheses: England and Wales 70 (102), Scotland 11 (13), Northern Ireland 3 (3), and Eire 16 (14). The numbers of deaths recorded in certain cities were as follows: London 6, Edinburgh 3, Glasgow 2, Belfast 2, Dublin 11, Liverpool 4, and Salford 4.

The following table shows the age distribution of deaths from influenza in the 160 great towns of England and Wales. The total of deaths recorded in the table is 3,063.

Week Ending	0—	1—	15—	25—	45—	65+

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in October was 108, compared with 98 in the previous month and 96 in October, 1956.

The number of cases of industrial diseases in the United Kingdom reported during October, 1957, were as follows: lead poisoning 4, phosphorus poisoning 1, arsenical poisoning 1, anthrax 3, epitheliomatous ulceration 4, chrome ulceration 12; total 25. There was one death from anthrax.—*Ministry of Labour Gazette*, November, 1957.

Accidents in Mines

Record low levels were recorded in 1956 for both the death rate and the reportable-injury rate per 100,000 man-shifts worked underground in the coal-mines, according to the report of H.M. Chief Inspector of Mines for 1954-6. The Chief Inspector reports that the majority of deaths and injuries are caused by individual accidents, not by the major disasters which strike the headlines. He says there is no room for complacency, and draws attention to the fact that many accidents appear to have been caused by illegal smoking. Another frequent cause is failure to maintain adequate ventilation.

Week Ending November 23

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 610, whooping-cough 615, diphtheria 4, measles 1,960, acute pneumonia 499, acute poliomyelitis 67, dysentery 433, paratyphoid fever 4, typhoid fever 2.

Infectious Diseases

The chief variations in the trends of the notifications of infectious diseases in England and Wales during the week ending November 9 were increases of 106 for scarlet fever, from 444 to 550, 62 for dysentery, from 216 to 278, and 41 for whooping-cough, from 431 to 472, and a decrease of 119 for acute pneumonia, from 742 to 623.

The notifications of measles numbered 1,695 and were 19 more than in the preceding week; the largest variations in the local trends were an increase of 64 in Glamorganshire, from 130 to 194, and a fall of 50 in Lancashire, from 300 to 250. A small increase in the incidence of scarlet fever was reported from most regions; the largest rise was 32 in Lancashire, from 48 to 80. Only small variations were recorded in the local trends of whooping-cough. 5 cases of diphtheria were notified, being 1 more than in the preceding week; 2 cases were notified in Middlesex, Edmonton M.B., and in Warwickshire, Birmingham C.B. A further fall in the number of notifications of acute pneumonia occurred in the south and the midlands, but in the northern section of the country the decline was arrested; in the north-west, Yorkshire, and the north there were 171 notifications compared with 155 in the preceding week.

The notifications of acute poliomyelitis numbered 68, and these were 4 more for paralytic and 3 more for non-paralytic cases than in the preceding week. The largest returns were London 6, Kent 5 (Ramsgate M.B. 2, East Ashford R.D. 2), Berkshire 5 (Reading C.B. 4), Essex 5 (Southend on Sea C.B. 3), and Durham 5 (Blaydon U.D. 3).

The rise in the incidence of dysentery was mainly due to a rise of 40 in Yorkshire West Riding and 22 in Lancashire. The largest returns were Yorkshire West Riding 95 (Leeds C.B. 22, Huddersfield C.B. 17, Sheffield C.B. 13, Bradford C.B. 12), Lancashire 50 (Liverpool C.B. 31), London 29, and Leicestershire 26 (Leicester C.B. 26).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1948-56 are shown thus - - - -, the figures for 1957 thus —. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending November 16 (No. 46) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Medical News

Scientific Exhibition.—The closing date for entries for the scientific exhibition at next year's B.M.A. Annual Meeting is December 31. The meeting is in Birmingham, and the scientific exhibition will be open from July 14 to 18. Application forms for space at the exhibition are obtainable from the Secretary of the B.M.A.

Royal Society Council.—At the anniversary meeting on November 30, Sir CYRIL HINSHELWOOD was re-elected President. Sir LINDOR BROWN, Jodrell professor of physiology at University College, London, was re-elected biological secretary, and among those elected to the council were Brigadier J. S. K. BOVD, lately director of the Wellcome Laboratories of Tropical Medicine, Sir CHARLES DODDS, Courtauld professor of biochemistry, London University, Sir BRYAN MATTHEWS, professor of physiology, Cambridge University, and Professor W. T. J. MORGAN, deputy director of the Lister Institute and professor of biochemistry, London University.

Nigeria's Teaching Hospital.—On November 20 the PRINCESS ROYAL opened University College Hospital, Ibadan, the teaching hospital of Nigeria's university college at Ibadan. The hospital, which is stated to have cost nearly £5m., is regarded as unique in West Africa. At present about half of its 500 beds are occupied, and the remainder are expected to be in use by the end of next year. University College, Ibadan, is in "special relation" with London University, its students taking the London degrees, but until this year the University College's medical students had to complete their studies abroad. Recently London University has accorded provisional recognition to the clinical course at University College Hospital, so the medical course can now be completed in Nigeria. The opening ceremony was attended by over 5,000 people, including the Prime Minister of the Federation of Nigeria, the Premier of the Western Region, the Federal Ministers of Health and Education, the Governor-General of Nigeria, and the Vice-Chancellor of London University. After expressing her happiness at being present and being able to see for herself something of the achievement in Nigeria to which the Queen had drawn attention after her visit the year before, the PRINCESS ROYAL warmly congratulated all those whose planning and hard work had made the hospital possible. "A modern hospital," she said, "is a complex organization and requires for the achievement of its purposes the highest degree of harmonious collaboration between the many varied departments and services which constitute it." Before calling on the Princess Royal to declare the hospital open, the Governor-General, Sir JAMES ROBERTSON, referred to the great speed with which the hospital building had been completed. "It is appropriate," he continued, "that this ceremony should take place within a few weeks of the entry of clinical students into the hospital; for the training of Nigerian doctors, though by no means the only reason for this institution, was its original purpose." Earlier the Federal Prime Minister, ALHAJI ABUBAKAR TAFAWA BALEWA, had described the teaching hospital as the most expensive project which Nigeria had so far undertaken. He looked forward to the day when its medical school would have a widespread reputation as a centre of research. The chairman of the hospital's board of management, Sir SYDNEY PHILLIPSON, thanked on behalf of the board all those men and women, authorities, institutions, and firms, both in Nigeria and in the United Kingdom, who had contributed to the present achievement. After messages of congratulation had been read from the Chancellor of London University, the Secretary of State for the Colonies, the chairman of the Inter-University Council for Higher Education Overseas, and the presidents of the three Royal Colleges, the PRINCESS ROYAL was conducted round the wards of the hospital by Sir SYDNEY PHILLIPSON, Sir KOFO ABAYOMI,

deputy chairman of the board of management, and Brigadier N. B. BRADING, the house governor. To conclude the proceedings the PRINCESS ROYAL was entertained at a cocktail party.

Royal Society of Medicine.—PRINCESS MARGARET is attending a council meeting of the Royal Society of Medicine on December 11 to receive a diploma of honorary fellowship.

Medical Faculty at Cambridge.—The plans of the new Regius professor of physic, Professor J. S. MITCHELL, F.R.S., for the development of the postgraduate medical school and for the departments of medicine and radiotherapeutics at Cambridge are discussed in a recent report of the general board of the faculties. The board recommends, in order to provide some relief for Professor Mitchell, the creation of the posts of dean of the postgraduate medical school—for which it proposes Dr. LESLIE COLE—and clinical research assistant to the Regius professor. The proposal is that the dean's appointment, which would date from October, 1957, should, in the first instance, be personal to Dr. Cole. The board also agrees that there is a "very urgent need" for a building near the radiotherapeutic centre of Addenbrooke's Hospital to house the departments of medicine and radiotherapeutics, both still in temporary huts, and to accommodate the School of Postgraduate Teaching and Clinical Research. The board states that it has reported this need to the council of the Senate, but as neither site nor funds for a building are available no detailed proposals can be made.

Association of Industrial Medical Officers.—At the annual general meeting on November 8, Dr. W. E. CHESMAN, Treasury medical adviser and lecturer in industrial medicine at St. George's Hospital, London, was elected president. Dr. R. A. GORDON SMITH, medical officer to Carreras, Ltd., became hon. secretary, and Dr. P. A. B. RAFFLE, senior medical officer to the London Transport Executive, hon. treasurer. The association's office is now at 47, Lincoln's Inn Fields, London, W.C.2.

Enham-Alamein Village Settlement.—The facilities at Enham-Alamein Village Settlement, Andover, for the rehabilitation and vocational training of registered disabled men have now been extended. Men will be accepted for training who are handicapped by chronic bronchitis, emphysema, asthma, pneumoconiosis, and arrested tuberculosis. To start with, priority of admission will be given to men with these disabilities, but the scheme is also open to men with locomotor disabilities from conditions such as rheumatoid arthritis, spondylitis, poliomyelitis, or limb injuries. Later it is hoped to admit women also. During the preliminary experimental stage of the scheme the average period of training is expected to be 12 months. Further information about the admission of cases and the financial and medical arrangements may be obtained from the Village Centres for Curative Treatment and Training Council, 16, Grosvenor Place, London, S.W.1.

Cancer of the Rectum.—The proceedings of a recent symposium on carcinoma of the rectum, held by the Section of Proctology of the Royal Society of Medicine, are available as a pamphlet (price 2s. 6d., post free). The speakers were Dr. CUTHBERT DUKES, Mr. LAWRENCE ABEL, Mr. W. B. GABRIEL, Mr. O. V. LLOYD-DAVIES, and Mr. C. NAUNTON MORGAN. Copies of the pamphlet may be obtained from the editorial office, Royal Society of Medicine, 1, Wimpole Street, London, W.1.

Royal College of Obstetricians and Gynaecologists.—At the council meeting on November 23, William Blair-Bell memorial lectures for 1958 were awarded to Dr. J. M. CRAWFORD, of Lanark, and Dr. J. S. SCOTT, obstetric tutor at Liverpool University. Mr. V. B. GREEN-ARMYtage was awarded next year's Green-Armaytage Anglo-American sterility lecture.

Royal Society of Health.—The Minister of Health, Mr. DEREK WALKER-SMITH, has accepted the presidency of the

Society's annual Health Congress next year. The Congress is being held at Eastbourne from April 28 to May 2.

Edinburgh University.—Next year's Lewis Cameron postgraduate prize (value about £45) is offered for the best published or unpublished original papers, by an Edinburgh graduate of not more than five years' standing, on the diagnosis of disease. The papers must be lodged with the dean of the faculty of medicine by April 5, 1958.

Dr. J. N. Morris, director of the Medical Research Council's social medicine research unit, London Hospital, is in the United States as visiting professor of epidemiology at Yale University School of Medicine till the spring.

COMING EVENTS

FitzPatrick Lectures.—Dr. TERENCE EAST will lecture at the Royal College of Physicians on December 10 and 12 at 5 p.m. His subject will be "Some Aspects of the History of Cardiology."

B.B.C. Television.—A visit to the Burden Neurological Institute, Bristol, in the series "Eye on Research," December 12, 10.35-11 p.m.

Heberden Society.—Scientific sessions and annual general meeting, December 13 and 14, at the Wellcome Foundation, Euston Road, London, N.W.1. Dinner at the Apothecaries' Hall on December 13. Details from the secretary of the Society, the London Hospital, Turner Street, London, E.1.

"Children Going into Hospital."—One-day conference arranged by the Central Council for Health Education, January 23, 1958, at B.M.A. House. Details from the Council, Tavistock House North, Tavistock Square, London, W.C.1.

Italian Society of Cancerology.—First national congress, April 8 and 9, 1958, in Milan. Mammary and oesophageal cancer will be discussed. Details from Dr. U. Veronesi, 22, Piazzale Gorina, Milan.

Association of Surgeons of Great Britain and Ireland.—Annual meeting, April 10-12, 1958, in Belfast. Details from hon. secretary, 47, Lincoln's Inn Fields, London, W.C.2.

International Congress of Internal Medicine.—Fifth Congress, April 23-26, 1958, at Philadelphia, U.S.A. Details from the secretary-general, Dr. E. R. LOVELAND, 4200 Pine Street, Philadelphia, Pennsylvania, U.S.A.

European Academy of Allergy.—Course and symposium on occupational allergy organized by the Netherlands Society of Allergy, May 14-24, 1958, The Hague. Details from Dr. W. J. Q. VAN UFFORD, 17, Emmalaan, Utrecht, Holland.

British Association of Urological Surgeons.—Annual meeting, London, June 19-21. Details from the hon. secretary, 47, Lincoln's Inn Fields, London, W.C.2.

International Federation of Gynaecology and Obstetrics.—Second World Congress, June 22-28, 1958, in Montreal: "Current Trends in Gynaecology and Obstetrics." Details from Montreal Committee, Suite 220, 1414, Drummond Street, Montreal, 25.

National Association for Maternal and Child Welfare.—Annual conference, June 25-27, 1958, in Glasgow. Details from the National Association, Tavistock House North, Tavistock Square, London, W.C.1.

British Congress of Obstetrics and Gynaecology.—The fifteenth Congress will be held in Cardiff, July 14-16, 1959. The subjects for discussion include the effects of factors in pregnancy and labour on the future development of the child, psychosomatic gynaecology, ovarian malignant disease, oestrogen metabolism, and oxytocic drugs. Details from the hon. secretaries of the Congress, Maternity Hospital, Glossop Terrace, Cardiff.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, December 9

●INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—4.30 p.m., Sir Arthur Gemmell: Phaeochromocytoma Complicating Pregnancy.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, 5 p.m., public lecture by Dr. H. Harris: Human Biochemical Genetics.

Tuesday, December 10

CHELSEA CLINICAL SOCIETY.—At Rembrandt Hotel, S.W., 8.30 p.m., discussion to be opened by Mr. William Redpath: Skeletal Finds at St. Brides Church, Fleet Street.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. B. Russell: Pyogenic Infections of Skin.
INSTITUTE OF NEUROLOGY.—5.30 p.m., Professor A. Asenjo (Chile): Classification of the Surgical Vascular Diseases of the Brain.
●INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—4.30 p.m., Mr. W. Hawksworth: Utero-Vaginal Prolapse.
MANCHESTER MEDICAL SOCIETY: SECTION OF SURGERY.—At Large Theatre, Clinical Sciences Building, York Place, 5 p.m., Mr. Selwyn Taylor: The Solitary Thyroid Nodule.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Professor M. L. Rosenheim: Sensitivity Reaction to Drugs.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., FitzPatrick Lecture by Dr. C. F. T. East: Some Aspects of the History of Cardiology—Lessons of the Deadhouse.
ST. MARY'S HOSPITAL MEDICAL SCHOOL (WRIGHT-FLEMING INSTITUTE THEATRE).—5 p.m., Mr. A. W. Bourne: Uterine Inertia in Labour.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Mr. L. C. Oliver: Post-traumatic Space-occupying Lesions.

Wednesday, December 11

EUGENICS SOCIETY.—At Rooms of Royal Society, Burlington House, W., 5.30 a.m., Dr. J. S. Weiner: Settlement of Europeans in Extreme Climates.
●INSTITUTE FOR THE STUDY AND TREATMENT OF DELINQUENCY.—At St. George's Institute, 7.30 p.m., Miss Marjorie Cooke: Educational Possibilities.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. C. Hoyle: Natural History of Pulmonary Sarcoidosis.
●INSTITUTE OF NEUROLOGY.—5.30 p.m., Dr. John Marshall: Disorders of Muscle.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. H. G. Hanley: Urological Problems in Pregnancy.
MANCHESTER MEDICAL SOCIETY: SECTION OF PATHOLOGY.—At Large Anatomy Theatre, 4.30 p.m., Professor H. B. Maitland: How Do Viruses Grow?
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. H. Harris: Biochemical Genetics.
ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—3.30 p.m., Dr. C. E. Dukes: Precancerous Conditions of the Colon and Rectum.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—2.30 p.m., Bradshaw Lecture by Sir Russell Brock: Present Position of Cardiac Surgery.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. Henry Yellowlees: Cause of Juvenile Delinquency.
ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION, PSYCHOTHERAPY AND SOCIAL PSYCHIATRY SECTION.—At 11, Chandos Street, W., 8 p.m., Nurse Emily Meir: The Role of the Student Nurse in a Mental Hospital.

Thursday, December 12

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, W., 8 p.m., Dr. T. M. Linr: Some Emotional Effects of Illness.
HONYMAN GILLESPIE LECTURES.—At University New Buildings, Teviot Place, Edinburgh, 5 p.m., Mr. G. L. Alexander: Foramen Magnum and High Cervical Syndromes.
●INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—12 noon, Professor W. C. W. Nixon: Modern Views on Disordered Uterine Action.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., FitzPatrick Lecture by Dr. C. F. T. East: Some Aspects of the History of Cardiology—Heart Failure and Treatment.
ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: Some Factors in the Formation of the Images.
ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—7.30 p.m., Dr. J. F. B. Edeson: Experimental Transmission of *Wuchereria malayi* from Man to Various Animals in Malaya. A discussion will follow.
WEST OF ENGLAND CHILD HEALTH GROUP.—At Department of Child Health Lecture Theatre, Bristol Royal Hospital for Sick Children, 5.30 p.m., Dr. K. Laybourn, Ph.D., M.Sc.: Selection of Children for Secondary Education.

Friday, December 13

BIOCHEMICAL SOCIETY.—At Institute of Basic Medical Sciences, Royal College of Surgeons of England, 11.30 a.m., 368th meeting.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. Smart: clinical demonstration.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—(1) 3.30 p.m., clinical discussion for general practitioners by Mr. W. S. McKenzie: Surgical Treatment of Deafness. (2) 5.30 p.m., clinical lecture by Mr. K. G. Rotter: Tumours of the Nose.
PLYMOUTH MEDICAL SOCIETY.—At Freedom Fields, 8.30 p.m., symposium: Relief of Pain. Introduced by Dr. R. E. Angel, Dr. Neil Beaton, Dr. H. A. W. Forbes, Dr. J. M. Gilroy, and Mr. G. J. Lillie.
ROYAL VICTORIA HOSPITAL TUBERCULOSIS TRUST.—At Royal College of Physicians of Edinburgh, 5 p.m. Memorial Lecture by Dr. C. W. Clayton to mark centenary of the birth of the late Sir Robert W. Philip.

Saturday, December 14

KENT PEDIATRIC AND CHILD HEALTH SOCIETY.—At Farnborough Hospital, 3 p.m., symposium: Adoption. Speakers, Miss M. Kornitzer and Dr. D. G. Leys.

Sunday, December 15

MANCHESTER UNIVERSITY: FACULTY OF MEDICINE.—At Theatre I, Clinical Sciences Building, York Place, 11 a.m., in conjunction with North-western for general practitioners. Professor J. H. Kellgren and Mr. J. Charnley: Backache.

APPOINTMENTS

LIVERPOOL REGIONAL HOSPITAL BOARD.—R. H. Martlew, M.D., D.P.M., Whole-time Resident Consultant Psychiatrist and Deputy Medical Superintendent at Rainhill Hospital; G. M. Edington, M.D., D.C.P., D.T.M.&H., Consultant Pathologist, giving maximum part-time sessions to Whiston and Rainhill Hospitals; S. E. Keidan, M.B., Ch.B., M.R.C.P., D.C.H., Consultant Paediatrician, giving three sessions to the Royal Liverpool Children's Hospital, Myrtle Street, and one session to Broadgreen Hospital; T. R. Littler, M.D., M.R.C.P., Consultant Physician, giving one session to Birkenhead General Hospital; Irene P. Rowlands, F.R.F.P.S., M.R.C.P., M.R.C.P.Ed., D.P.M., Consultant Physician in Geriatrics, giving maximum part-time sessions to the Chester and Warrington areas; D. P. Hennessy, M.B., B.Ch., D.P.M., Whole-time Resident Consultant Psychiatrist and Deputy Medical Superintendent at Winwick Hospital; J. K. Wilson, M.D., M.R.C.O.G., Part-time Consultant Obstetrician and Gynaecologist to North Wirral and Birkenhead Groups of Hospitals; Marie J. Bouton, M.D., Whole-time Assistant Pathologist to Liverpool Region Children's Hospital Management Committee Group.

NORTH-WEST METROPOLITAN REGIONAL HOSPITAL BOARD.—B. L. Day, B.M., B.Ch., F.F.A.R.C.S., Consultant Anaesthetist, King Edward Memorial Hospital, Ealing; G. L. Buntton, M.Chir., F.R.C.S., Consultant Surgeon, Northwood, Pinner and District Hospital; J. I. Wand-Tetley, M.B., B.S., M.R.C.P., D.Phys.Med., Consultant Physician in Physical Medicine, Edgware General Hospital; J. W. Lewis, M.B., B.S., F.F.A.R.C.S., Consultant Anaesthetist, Thoracic Surgical Unit, Clare Hall Hospital; R. J. H. Smith, M.S., F.R.C.S., D.O., Consultant Ophthalmic Surgeon, Paddington General Hospital and Western Ophthalmic Hospital; S. Tischler, M.R.C.S., L.R.C.P., D.P.M., Consultant Psychiatrist to High Wick, Tyttenhanger, St. Albans; K. Owen, M.S., F.R.C.S., Consultant Surgeon, Royal Northern Hospital; M. W. J. Grummitt, M.B., B.S., F.F.A.R.C.S., Consultant Anaesthetist, West Herts Hospital and Watford Hospitals; S. M. Smith, M.B., B.Ch., D.M.R., Consultant Radiologist, Finchley Memorial Hospital and Friern Hospital; C. S. Lindsay, M.B., B.Ch., D.P.M., Assistant Psychiatrist (S.H.M.O.), St. Bernard's Hospital.

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—J. H. Price, M.B., B.S., Senior Psychiatric Registrar at Moorhaven Hospital, Ivybridge; W. J. H. Collins, M.B., B.Ch., D.P.M., Senior Psychiatric Registrar at Tone Vale Hospital, near Taunton; A. Cumin, M.B., B.Ch., M.R.C.P., Registrar to Bristol Chest Clinic and associated hospitals; Jill M. Evans, M.B., B.Ch., D.Obst.R.C.O.G., Registrar in Obstetrics and Gynaecology at Royal Devon and Exeter Hospital, Exeter; H. T. John, M.B., B.S., F.R.C.S., Senior Surgical Registrar at Royal Devon and Exeter Hospital, Exeter, and W. J. Gall, M.B., Ch.B., F.R.C.S., Senior Surgical Registrar at Southmead Hospital, Bristol (joint appointments with the United Bristol Devon and East Cornwall Hospital, Plymouth); Joze Jancar, M.B., B.Ch., D.P.M., Assistant Psychiatrist to Stoke Park Hospital Group, Bristol; J. W. Warboys, M.D., D.P.M., Consultant Psychiatrist at Tone Vale Hospital, near Taunton.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Cambridge.—On November 25, 1957, at Leeds Maternity Hospital, to Dr. Joyce (formerly Harrison), wife of Dr. Geoffrey Cambridge, a son—Nicolas Adam.
Gibb.—On November 24, 1957, at St. Bartholomew's Hospital, London, E.C., to Mary (formerly Feetham), wife of Dr. W. E. Gibb, F.R.C.P., a son.
Probert.—On October 30, 1957, at Cardiff Maternity Hospital, to Jane, wife of W. R. Probert, M.Chir., F.R.C.S., a son—Timothy Charles Edward.

MARRIAGES

Sayers—Hay.—On October 26, 1957, at Murrayfield Parish Church, Edinburgh, W. J. Hastings Sayers, L.R.C.P.&S.Ed., of 148, Eastern Road, Brighton, and Co. Antrim, to Mary Marguerite Hay, L.R.C.P.&S.Ed., of 133, Saughtonhall Drive, Edinburgh.

DEATHS

Blachford.—On November 11, 1957, James Vincent Blachford, C.B.E., M.D., of Long Ashton, near Bristol, aged 91.
Black.—On November 15, 1957, the result of an air crash, Janet Cook Black, M.B., Ch.B.
Campbell.—On November 18, 1957, at his home, The Rylands, Wickford, Essex, John Craig Campbell, M.B., Ch.B.
Clapham.—On November 6, 1957, at his home, 17, Sollerhott West, Letchworth, Herts, Howard Dennis Clapham, M.R.C.S., L.R.C.P., L.D.S., aged 75.
Duguid.—On November 8, 1957, in hospital, Henry Duguid, M.D., D.P.H., of 6, Halstead Grove, Gatley, Cheshire.
Dunning.—On November 8, 1957, John Beatson Dunning, M.C., M.B., B.S., of 36, Redcliffe Square, London, S.W.
Easton.—On November 8, 1957, at Sunningdale, London Road, Reigate, Surrey, Wilfred Angel Easton, M.R.C.S., L.R.C.P., L.D.S.
Fyfe.—On November 11, 1957, at 12, Royal Terrace, Glasgow, David Fyfe, M.D., F.R.C.S.Ed., F.R.F.P.S., D.P.H., L.D.S.
Heldt.—On November 18, 1957, Hans Rudi Heldt, M.D., of 25, Hillside Court, Finchley Road, London, N.W., and 49, Queen Anne Street, London, W.
Henderson.—On November 3, 1957, at Orewa, New Zealand, Douglas Campbell Henderson, M.B., Ch.B., late of Lydd, Kent, and Steyning, Sussex.
Holdsworth.—On November 19, 1957, at Whin Brow, Cloughton, Scarborough, Yorks, Charles Dyson Holdsworth, M.D., aged 77.
Hughes.—On November 7, 1957, at The Old School House, Avington, near Winchester, Hants, Audrey Margaret Hughes, M.B., B.S., D.P.H., aged 57.
Meadows.—On November 6, 1957, at Falkland House, Long Melford, Suffolk, Sydney Manvers Woolner Meadows, D.S.O., M.R.C.S., L.R.C.P., Colonel, A.M.S. (retired), aged 81.
Milner.—On November 4, 1957, Alan Milner, M.B., Ch.B., of The Elm, Nafferton, Yorks.
Moore.—On November 13, 1957, at his home, New Place, Sunningdale, Ascot, Berks, Charles Gordon Holland Moore, C.V.O., M.B., B.Ch., J.P., aged 72.
Smith.—On November 5, 1957, at Romaldkirk, Barnard Castle, Co. Durham, Alan Ayre Smith, M.D., late of Sunderland, aged 81.
Teuten.—On November 9, 1957, at 53, Tring Avenue, London, W., Aubrey Clifford Teuten, M.R.C.S., L.R.C.P.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Surgery in Those on Corticosteroids

Q.—An increasing number of patients presenting themselves for surgery are on courses of cortisone, prednisone, or other corticosteroids for some concomitant condition—e.g., rheumatoid arthritis, cutaneous periarthritis nodosum, and asthma, to mention three encountered in the last two months. What are the dangers of anaesthesia and operation in these patients, and what steps should be taken to avoid them?

A.—Case reports are now accumulating emphasizing the ease with which death from circulatory failure occurs in these circumstances, even when the anaesthesia or the surgery may by ordinary standards be judged trivial. It is naturally difficult to estimate which patients on cortisone therapy are going to present this hazard. Atrophy of the adrenal cortex with suppression of its hormones may occur with any daily dose of cortisone in excess of normal requirements—that is, about 20 mg. a day, and this dose might be enough to cause such suppression. It is advised that any patient who has been having doses of this sort for three months or longer should be specially prepared for any operation. At least two doses of cortisone are given, each of 100 mg. and the last an hour before the operation. During operation the greatest care should be taken to replace any blood lost. Reports indicate that these patients stand blood loss badly. Post-operatively, a regime of cortisone is instilled in which the dose gradually tails off to the usual daily dose. In general, hypnotic and anaesthetic drugs may produce an exaggerated effect in these patients and should therefore be given in reduced dosage and with caution. Evidence of circulatory depression during operation may indicate an insufficient amount of cortical adrenal hormone, and preparations of hydrocortisone should be available for intravenous use. The usual vasopressors and transfusion material must also be kept in readiness.

Breast Milk and Immunity to Smallpox

Q.—Is passive immunity to smallpox conferred on the baby in breast-milk? I vaccinated on the same day a mother and her breast-fed 5-months-old son. The mother had been vaccinated several times before, and reacted with an accelerated immune response. The child showed reddening of the pressure marks of my needle in 24 hours, and the ing of the pressure marks of my needle later I re-vaccinated him from the same batch of lymph, which had been near the bottom of my kitchen refrigerator in the meantime. This time, on the fourth day the needle marks reappeared, and became confluent on the fifth; no true pock was formed and the reaction had disappeared by the tenth day. It may be that his first inoculation was spoiled by a secondary infection, and that his second inoculation was atypical because the lymph had deteriorated. But the second inoculation produced too rapid a reaction for primary vaxcinia and too slow for a secondary infection. Could the baby have been affected by his mother's anamnesis?

A.—It is very unlikely that the failure of vaccination reported could have been due to simultaneous revaccination of the mother, who was breast-feeding her 5-months-old son at the time. Even if the mother's antibody rose sufficiently early and appeared in the milk the infant's gut would have been impermeable to it at this age. Younger infants under 3 months old have sometimes failed to respond to vaccination in those rare instances where the mother developed

smallpox or was successfully vaccinated shortly before birth, presumably owing to transplacental passage of antibody.¹ In other instances failure to respond in these early months has been attributed to natural immunity. From the third month on, however, it is wise to assume that all previously unvaccinated infants are susceptible, and they should therefore be revaccinated repeatedly until a primary response occurs. Your correspondent wisely attempted revaccination, but the same lymph was used, and, as he points out, it may have deteriorated in storage, or may even have been defective in the first place, thus accounting for the original failure to take. The next step is to revaccinate the infant with fresh lymph.

Adiposis Dolorosa

Q.—What accounts for the pain in adiposis dolorosa (Dercum's disease)? Have there been any recent advances in its treatment?

A.—Generalized tenderness of excessive fat, or adiposis dolorosa, was thought for a long time after its description by Dercum to be due to hormonal disturbance. No such hormonal imbalance has been established, and present-day opinion is that the tenderness and the obesity are for the most part both of psychogenic origin. There are no pathological changes, although, as in normal people, occasional herniae of fatty tissue through fascial planes may be painful if traumatized—especially in the sacral region. Psychological and emotional difficulties should be investigated and help given if possible. A rigid reducing diet with or without amphetamine should also be instituted.

Bequeathing Corneas

Q.—What steps should a patient take who wishes to leave her corneas to a hospital for grafting purposes?

A.—The patient's wishes should be made known to her relatives, her executor, her doctor, and, should she be admitted to hospital at any time, to the hospital authorities. She should also sign a simple statement such as, "I (name in full) request that after my death my eyes may be used for therapeutic purposes," and hand this to one of her relatives or to the person with whom she resides. The person responsible for the burial arrangements is not bound to carry out these wishes; but, should he be willing to do so, he should ask the advice of the doctor in attendance during the last illness, who can then make arrangements for the eyes to be removed by a representative of the nearest hospital with appropriate staff. The sooner after death the eyes are removed the better, though successful grafts have been obtained from eyes taken as long as ten hours after death.

Riedel's Lobe

Q.—What is Riedel's lobe of the liver, and what accounts for its presence? Is it the result of some abnormal process of development, or should it be regarded as a normal structure? Does comparative anatomy shed any light on its origin and function?

A.—Riedel's lobe is a tongue-like downwards extension of the anterior margin of the right lobe of the liver. It is usually to the right of the fundus of the gall-bladder, but the hepatic tissue round this structure may be involved. The lobe is found more frequently in women, and tight lacing has been advanced as its cause. The condition, however, is occasionally associated with cholecystitis or with adhesions to other abdominal viscera; there is, however, no clear evidence of a causal relationship, either way, between the presence of the lobe and pathological conditions of the biliary tract. An extreme form of the abnormality, in which the lobe is joined to the main mass of the liver by a fibrous pedicle, has been described and may result in altered hepatic or gall-bladder function.

The presence of Riedel's lobe in normal men, and in women who have never been tightly corseted, suggests that at least in some cases the anomaly has a developmental basis, but there is no evidence to my knowledge indicating positively that the condition is inherited. Comparative anatomy throws no real light on the problem; though it is true that the liver in the great apes (especially the gorilla) and monkeys is more lobulated than in man. There is no evidence to suggest that Riedel's lobe possesses a function other than that of hepatic tissue in general.

Apart from its possible association with pathological changes the presence of Riedel's lobe may cause diagnostic problems owing to the ease with which it may be palpated.

Streptomycin and Visual Disturbance

Q.—What is the significance of difficulty of visual accommodation in patients on streptomycin? Does this call for the cessation of streptomycin therapy and the use of another antibiotic?

A.—Streptomycin can lead to blurring of vision, especially if given in large doses. The blurring is usually transient and does not call for cessation of the treatment unless other neurological signs, particularly eighth-nerve involvement, are observed.

How streptomycin causes the blurring is not fully understood, but it is believed to be by a toxic effect on the optic nerve.

I know of no case where a permanent optic atrophy has resulted from streptomycin therapy.

Skin Sutures

Q.—Why is it traditional to use non-absorbable materials such as horsehair, silkworm gut, and synthetic materials for skin sutures? Recently I have been using absorbable catgut for suturing skin wounds, with good results. The advantages are less tendency for knots to slip and no need to remove after healing.

A.—More than tradition makes non-absorbable sutures such as horsehair, silkworm gut, and synthetic materials more suitable for skin sutures than catgut. They are much less irritating to the tissues, and, being non-capillary, do not attract infection from the surface into the depth of the wound. The resultant scar is therefore much less obvious. The scars when catgut is used tend to be keloid, however, owing to infection and the severe foreign-body reaction produced by the presence of the absorbable suture.

Of the three suture materials mentioned in this question, silkworm gut is probably the one most generally used, although fine stainless steel wire or specially prepared silk has many advocates. With silkworm gut there is no tendency whatever for knots to slip as with horsehair and nylon products.

Glyceryl Trinitrate in Angina

Q.—A middle-aged man who suffers from angina of effort has for years been taking pills containing glyceryl trinitrate gr. 1/200 (0.32 mg.) and caffeine gr. 1/2 (22 mg.), and often exceeds the stated dose of ten pills in 24 hours. What are the possible effects, toxic or otherwise, of taking fairly large doses of these pills?

A.—The action of glyceryl trinitrate is transitory, but the immediate effects of taking several tablets in rapid succession may be troublesome and consist in a sensation of flushing, headache, and tachycardia (resulting from the fall in blood pressure). Faintness or even syncope may occur, especially if the patient is in the upright position. In the instance quoted, the dose of glyceryl trinitrate is not large, and, provided several tablets are not taken in rapid succession, there is no objection to exceeding the stated ten pills in 24 hours. Tolerance is said to occur, however, and, if enormous

doses are taken in an attempt to overcome this, methaemoglobinemia might occur, but this is quite exceptional in therapeutic dosage. Progressive increase in severity of anginal pain and loss of effectiveness in nitrites may, however, be due to a further coronary artery occlusion. It is worth paying some attention to the mode of administration. The speed of action of glyceryl trinitrate is much retarded if the tablet is swallowed rather than dissolved in the mouth, since it is then not absorbed until it reaches the small intestine. The dose of glyceryl trinitrate required may sometimes be reduced by adding a long-acting nitrate such as pentaerythritol tetranitrate three or four times daily before meals.

The dose of caffeine in each pill is very small, the B.P. dose being 0.3–0.6 g. (4–8 gr.), and is therefore unlikely to have any appreciable effect. In effective dosage caffeine is probably best avoided in patients with coronary artery disease, in view of its stimulant effect on the higher centres.

NOTES AND COMMENTS

Angular Stomatitis.—Mr. D. G. LYON, F.D.S.R.C.S., and Mr. A. O. CHICK, Ph.D., M.D.S. (Bristol), write: "With reference to the question concerning angular stomatitis ('Any Questions?' October 26, p. 1007), may we add a note to your expert's answer on this subject? In addition to the cause of this condition listed, i.e., nutritional deficiency, iron-deficiency anaemia, achlorhydria, and avitaminosis B complex, we would draw your attention to the possibility of *Candida* infection associated with dentures.¹ The questioner states that the patient's teeth were healthy; but, in our experience, a seemingly healthy mouth with a small partial denture can be associated with a quite heavy *Candida* infection. This infection, characterized by a raised, congested area outlining the denture, can often be missed unless one is specifically looking for it, especially if there is a high palate. In the paper referred to above, a higher incidence of angular stomatitis was found in cases of denture sore mouth due to *Candida* infection than in normal amongst denture wearers. Waisman² drew attention to the number of cases of thrush showing angular stomatitis and says it is regrettable that the lesion should be considered a symbol of avitaminosis. All the cases that exhibited angular stomatitis in our series of denture sore mouth due to *Candida* cleared up when the intra-oral fungus infection was successfully treated. We would suggest, therefore, that, should your questioner's patient be wearing a denture, this should be immersed in a weak solution of 'savlon' each night and 'caprygel' or 'pruvagol cream' applied to the denture-bearing area three times a day. A simple analgesic ointment applied to the corners of the mouth was found to be helpful in some cases in conjunction with the fungicidal treatment in the mouth.

Incompetence of the tricuspid valve is commonly noted in clinical practice, often in association with heart failure, and has been recently intensively studied (Müller and Shillingford, 1954, 1955; Korner and Shillingford, 1954, 1957; McMichael and Shillingford, 1957). The distinction between functional tricuspid insufficiency in heart failure and that due to organic disease of the valve presents considerable difficulty. The criteria for the diagnosis of tricuspid stenosis have been well documented by Gibson and Wood (1955), Whitaker (1955), and Yu *et al.* (1956), but, since many of the diagnostic signs are frequently obscured by other cardiac lesions, the diagnosis is often missed. We are therefore presenting a combined clinical, haemodynamic, and pathological study of 21 proved cases in order to draw attention to the wide spectrum of organic tricuspid valve disease and to clarify the diagnosis in cases complicated by other lesions.

Case Material and Methods

Twenty-one cases (15 female and 6 male) of organic tricuspid valve disease have been studied. Thirteen were observed clinically, and in these the diagnosis was confirmed by haemodynamic studies in seven (two of which also came to necropsy), and by necropsy alone in the remaining six. A further eight cases were studied retrospectively by examining the necropsy and case records of 190 consecutive cases of rheumatic heart disease over a period of 10 years. The total necropsy incidence was therefore 8.4%.

All the cases had associated mitral valve disease, and 12 had aortic disease also. The severity of the associated valve lesions and of pulmonary hypertension varied widely.

Criteria for Inclusion in the Series.—All the cases coming to necropsy had definite narrowing of the valve, with fusion of the cusps and thickening and shortening of the chordae. Minor thickening of the cusps without narrowing of the valve orifice was not accepted. In life the diagnosis was regarded as proved if there was a diastolic gradient of 5 mm. Hg or more across the tricuspid valve. The gradient was measured in presystole in cases with sinus rhythm, and early diastole if atrial fibrillation was present.

*Present address: Cardiac Station, Denver General Hospital, Denver, Colorado, U.S.A.

Radiological Criteria: Assessment of Right Atrial Size.—The maximum distance of the right atrial border from the midline in a 6-ft. (1.8-metre) postero-anterior radiograph was measured, and enlargement was graded as follows: grade 1 (slight), up to 50 mm.; grade 2 (moderate), 51–70 mm.; grade 3 (considerable), 71–90 mm.; grade 4 (aneurysmal), over 90 mm. Attention was also paid to the size of the ventricles and left atrium and to signs of pulmonary hypertension (Davies *et al.*, 1953).

Cardiographic Criteria.—Right ventricular hypertrophy was graded as follows: Grade 0, no evidence of right ventricular hypertrophy. Grade 1, dominant R wave in Lead V4R only; and/or dominant S in V5 with normal V1; and/or dominant R in VR with normal V1. Grade 2, dominant R (less than 5 mm.) in V1. Grade 3, dominant R of 5 mm. or more in V1. Grade 4, qR pattern in V4R and V1 with inverted T in V4R, V1, V2, and V3; dominant S in V5 and dominant R in VR. P waves which were pointed and 2–2.5 mm. or more in height were regarded as evidence of right atrial enlargement (right atrial P waves). The P–R interval was considered prolonged if it exceeded 0.2 sec. Attention was also paid to evidence of left ventricular hypertrophy and to atrial fibrillation.

History and Symptoms

Rheumatic Fever.—Histories of rheumatic fever were given by 15 patients, and six of these had suffered more than one attack. One patient had a history of rheumatoid arthritis.

Duration of Symptoms.—The time interval between the first attack and the onset of symptoms in the personally observed cases was very variable. In two cases symptoms followed immediately upon the attack, while the maximum period before the onset of symptoms was 33 years. Six patients developed symptoms less than 10 years after rheumatic fever. The duration of symptoms from onset to death was less than 10 years in all but two patients (aged 20 and 26 years). The range (apart from these two cases) was 6 months to 11 years.

Pulmonary Congestive Manifestations.—Dyspnoea on effort was present in all cases, and in 11 was severe (grade 3 or 4 according to the American Heart Association Classification, 1939). Paroxysmal dyspnoea or

pulmonary oedema occurred in six patients and bronchitis in 13. Haemoptysis occurred in five and pulmonary infarction in seven. This infarction may have been embolic in origin in two cases, since thrombus was found in the right atrium. Three patients with infarction had thrombosis of a large pulmonary artery. When a history of swelling of the ankles was obtained it was always associated with dyspnoea. Substernal pain on effort was noted in six patients, and pain due to hepatic congestion simulated angina in some cases. In general, the history did not suggest tricuspid involvement.

Physical Examination

Many of the physical findings were attributable to associated valve lesions, and only those abnormalities which appear relevant to the diagnosis of the tricuspid lesions are described.

Mitral Facies.—Cyanotic malar flush (mitral facies) was observed in five cases.

Jugular Venous Pulse.—Only the personally observed group is discussed here. Six patients had sinus rhythm, and the presystolic ("a") wave was prominent in all, reaching "giant" proportions (10–15 cm. above sternal angle) in two. The time interval between the "a" wave and the carotid pulse was increased in six cases owing to prolongation of the P-R interval. In seven of the eight patients with atrial fibrillation there was a large systolic wave suggestive of tricuspid incompetence. The mean venous pressure was raised, and in four cases the systolic wave reached the angle of the jaw when the patient was semi-recumbent at 45 degrees. In the remaining patient the jugular venous pressure was normal. In one patient (Case A 10) a giant "a" wave was replaced by a large systolic pulsation when atrial fibrillation occurred (Fig. 1).

FIG. 1.—Jugular phlebogram and cardiogram in Case A 10 during atrial fibrillation. The phlebogram shows the large positive wave (S), indicating regurgitation of blood back through the tricuspid valve in systole. The "y" descent is not sharp, suggesting some obstruction to right ventricular inflow.

normal. In one patient (Case A 10) a giant "a" wave was replaced by a large systolic pulsation when atrial fibrillation occurred (Fig. 1).

FIG. 2.—Six-foot (1.8-metre) postero-anterior radiograph of Case C 6, showing aneurysmal right atrium (measurement 105 mm.).

Arterial Pulse.—This was of small volume in all cases, and its quality was determined by the associated valve lesions.

Rhythm.—Of the total series, 13 had atrial fibrillation and eight were in sinus rhythm.

Pulsation of Right Parasternal Region.—In 2 of the 13 personally observed cases pulsation in the left parasternal region, conventionally attributable to right ventricular enlargement, extended to the right of the sternum and was even felt in the right mid-clavicular line (Case C 6). The right atrium was greatly enlarged radiologically (Fig. 2), and it was thought that the pulsation might represent systolic expansion of that chamber. In one case there was dullness but no pulsation to the right of the sternum. One patient had a normal left ventricular impulse, five had left parasternal lift, and seven had combined right and left ventricular enlargement due to associated valve lesions.

Auscultatory Signs.—Ten of the 13 personally observed cases had a presystolic murmur at the tricuspid area, which increased on inspiration in five. In eight cases there was a mid-diastolic murmur or presystolic murmur, which in six increased with inspiration (Fig. 3). A sharp sound in early diastole, thought to be the opening snap of the tricuspid valve (Kossmann, 1955) and increasing on inspiration, was noted in three. An atrial sound at the left sternal border was present in three of the cases with sinus rhythm. In those with pulmonary hypertension the pulmonary component of the second heart sound was accentuated.

Hepatic enlargement was present in 9 of the 13 personally observed cases and in 7 of the 8 retrospective cases. It was gross (6 cm. or more below the costal margin) in 12. In three of the cases with sinus rhythm there was presystolic pulsation, while systolic pulsation occurred in six of those with atrial fibrillation.

FIG. 3.—Phonocardiogram of Case C 3 showing increase in tricuspid presystolic and mid-diastolic murmurs on inspiration.

FIG. 4.—Six-foot (1.8-metre) postero-anterior radiograph of Case A 10, showing large right atrium (measurement 95 mm.). There is also pulmonary venous and arterial hypertension.

Splenic enlargement occurred in 5 of the 21 cases. **Peripheral oedema** occurred in 11 of the 21 cases, and was gross in five.

Ascites was present in four cases, and jaundice (due to cardiac cirrhosis or pulmonary infarction) in six.

Radiology

Teleradiograms were available in 13 cases. The dominant feature was right atrial enlargement (Figs. 2 and 4) which was outside the normal range in nearly all, and greater than that found in rheumatic heart disease without tricuspid stenosis in half (Fig. 5). Right ventricular hypertrophy could not be reliably assessed in the presence of marked right atrial enlargement, which often prevented assessment of vascular changes also. Accordingly we have tabulated the radiological grade of right atrial enlargement, the cardiographic grade of right ventricular hypertrophy, and the P-R interval (Table I). Although aneurysmal dilatation of the left atrium can interfere with measurement of the right atrium, it did not do so in this series.

It will be seen that right atrial enlargement was often considerable or gross when right ventricular hypertrophy was absent or slight. It was found that the cardiogram provided the best index of right ventricular dominance and the x-ray film of right atrial size. The association of appreciable right atrial enlargement but little right ventricular hypertrophy on the cardiogram is particularly characteristic of tricuspid stenosis.

Atrial Fibrillation.—This was present or developed in 13 of the 21 cases. The presence of fibrillation appeared to be related directly to right atrial size (Table II).

The P Wave and P-R Interval.—Eleven cases showed sinus rhythm at some stage, and in five of them pointed P waves exceeding 2 mm. or more in height suggested right atrial enlargement (Fig. 6). In 6 of the 11 cases the P-R interval exceeded 0.20 sec. (Fig. 7), in four it was

Case	X-ray Film R.A. (Grade)	Cardiogram R.V. (Grade)	E.C.G.	
			P-R Interval (sec.)	
C 1	1	0	0.30	
C 2	2	1	0.26	
C 3	3	2	0.24	
C 5	1	0	0.20	
C 6	4	3	—	
C 7	2	0	0.26	
A 6	3	0	0.20 A.F. later	
A 8	4	0	0.20 A.F. later	
A 9	3	0	—	
A 10	4	1	—	
A 13	3	R.B.B.B.	—	
A 14	4	1	—	
A 15	2	1	—	

A.F. = Atrial fibrillation. R.B.B.B. = Right bundle-branch block.

vided the best index of right ventricular dominance and the x-ray film of right atrial size. The association of appreciable right atrial enlargement but little right ventricular hypertrophy on the cardiogram is particularly characteristic of tricuspid stenosis.

Cardiology

Atrial Fibrillation.—This was present or developed in 13 of the 21 cases. The presence of fibrillation appeared to be related directly to right atrial size (Table II).

The P Wave and P-R Interval.—Eleven cases showed sinus rhythm at some stage, and in five of them pointed P waves exceeding 2 mm. or more in height suggested right atrial enlargement (Fig. 6). In 6 of the 11 cases the P-R interval exceeded 0.20 sec. (Fig. 7), in four it was

TABLE II.—Right Atrial Size and Rhythm in 13 Personally Observed Cases

Size of Right Atrium on X-ray Film	Total No. of Patients	Cases with Atrial Fibrillation
Grade 1	2	0
" 2	3	2
" 3	4	2
" 4	4	4

FIG. 6.—Cardiogram of Case C 1. There is sinus rhythm, P waves are 3 mm. in height in lead V5, and the P-R interval is 0.36 second. There is normal ventricular balance.

0.20 sec., and in one it was 0.18 sec. A comparison between the P-R interval in tricuspid disease and rheumatic heart disease without tricuspid disease is shown in Fig. 7. It will be seen that a significantly greater proportion of cases of tricuspid disease have a prolonged P-R interval (see also Table I). Active rheumatic carditis which might prolong the P-R interval was absent in all cases. Thus a prolonged P-R interval supports the diagnosis of tricuspid stenosis, and one of less than 0.16 sec. is against it.

Right Ventricular Hypertrophy.—This was usually either absent or slight and never gross (Table III). Table I shows the discrepancy between the degree of right atrial and right ventricular hypertrophy. The association of a

right atrial enlargement but little right ventricular hypertrophy on the cardiogram is particularly characteristic of tricuspid stenosis.

TABLE III.—Cardiographic Signs of Ventricular Hypertrophy

No. of patients	R.V.H. Grade					L.V.H.	L.B.B.B.	R.B.B.B.	R & L.V.H.
	0	1	2	3	4				
5	9	1	2	0	1	1	1	1	1

R.V.H. = Right ventricular hypertrophy. L.V.H. = Left ventricular hypertrophy. R.B.B.B. = Right bundle-branch block. L.B.B.B. = Left bundle-branch block.

FIG. 8.—Cardiogram of Case C 3. There is sinus rhythm. The P waves are 3–4 mm. in height in V1, and the P-R interval is 0.26–0.28 second. There is evidence of modest grade 2 right ventricular dominance, V4R and V1 showing a dominant R wave.

Man aged 43. Increasing dyspnoea on exertion for two years (grade 2-3). Congestive heart failure six months. *Physical signs.*—Arterial pulse normal; regular. B.P. 150/110. Cardiac impulse, marked right ventricular hypertrophy P2 accentuated; narrow split. Jugular venous pulse; large "a" wave and systolic wave (subsequently atrial fibrillation and systolic wave only). Tricuspid presystolic and systolic murmurs. Faint mitral diastolic murmur. Mitral systolic murmur. Mitral first sound only slightly accentuated. Opening snap poor. Early diastolic murmur at left sternal edge (Fig. 1). *Cardiography.*—Atrial fibrillation. Right ventricular hypertrophy (grade 1). *Radiology.*—Right atrium grossly enlarged. Right ventricle enlarged. Heavy calcification of mitral valve (Fig. 4). *Clinical diagnosis.*—Mitral stenosis and incompetence. ? Tricuspid stenosis. Pulmonary hypertension. *Haemodynamic studies.*—Systolic wave in right atrial pulse. Right ventricle not entered with catheter. *Conclusion.*—Tricuspid stenosis and incompetence. Mitral stenosis and incompetence. Pulmonary hypertension. Tricuspid disease suspected because of tricuspid murmurs and very large right atrium.

Treatment and Progress.—Atrial fibrillation occurred while awaiting admission to hospital. Repeated pulmonary thromboembolism treated with anticoagulants. Mitral valvotomy not advised in view of heavy calcification of mitral valve and mitral incompetence.

Necropsy.—Severe mitral stenosis and incompetence. Moderate tricuspid stenosis (circumference 110 mm.) and incompetence. Thrombosis of pulmonary artery to right lower lobe.

Case A 9: Tricuspid Stenosis Associated with Severe Aortic Stenosis, Critical Mitral Stenosis, Atrial Fibrillation, and Slight Pulmonary Arterial Hypertension

Woman aged 42. Dyspnoea on exertion and paroxysmal nocturnal dyspnoea for many years. **Physical signs.**—Cyanosed. Arterial pulse small. Atrial fibrillation. B.P. 120/90. Jugular venous pulse: initially 2–3 cm. systolic wave—subsequently normal. Signs of severe aortic stenosis, mitral stenosis, and ? incompetence.

FIG. 14.—Six-foot (1.8-metre) postero-anterior radiograph of Case A 9. Right atrium grossly enlarged (80 mm.) and strikingly at variance with the normal pulmonary arterial pattern and minimal pulmonary hypertension.

of signs of pulmonary hypertension. **Haemodynamic studies.**—Small gradient across tricuspid valve in diastole (5 mm.). Normal right ventricular pressure.

Conclusion.—Severe aortic stenosis. Mitral stenosis and incompetence. Mild tricuspid stenosis. Signs of tricuspid stenosis totally obscured by atrial fibrillation and other valve lesions. Diagnosis suspected on radiological grounds alone.

Treatment.—Aortic and mitral valvotomy. Death from cerebral embolism immediately after operation.

Necropsy.—Slight tricuspid stenosis (circumference 100 mm.) (Fig. 13). Severe aortic and mitral stenosis.

Discussion and Conclusions

The incidence of appreciable tricuspid valve disease found at necropsy in this series approximates closely to that described by Smith and Levine (1942), who found an incidence of 9.4% in a series of 340 cases of rheumatic heart disease coming to necropsy, and of Cooke and White (1941), who noted 14% in 217 cases of rheumatic heart disease. Associated valve disease was present in all the cases, and was severe in most. Mitral valve disease was present in all, and aortic disease in 75%.

Diagnosis

In one of our cases (C 1) mitral valve disease was clinically insignificant, and in this type of case the presence of a large presystolic wave in the jugular venous pulse, a tricuspid valve murmur, and an enlargement of the right atrium, without evidence of right ventricular hypertrophy, makes clinical diagnosis easy. Usually, however, the signs of tricuspid valve disease are obscured by those of associated

mitral valve disease. Tricuspid murmurs may become louder during inspiration (Gibson and Wood, 1955; Yu *et al.*, 1956; Hollman, 1956), and this sometimes enables them to be distinguished from mitral murmurs which do not. Even in cases where this distinction cannot be made with certainty, tricuspid disease can nevertheless be strongly suspected if the degree of right atrial enlargement is disproportionate to the degree of pulmonary hypertension and right ventricular hypertrophy. The present study also suggests that when the right atrium is considerably enlarged (over 70 mm. from the midline) in cases of rheumatic heart disease, the diagnosis of tricuspid involvement can be made with confidence, particularly if the P-R interval exceeds 0.20 sec. in the absence of active carditis.

The importance of prolongation of the P-R interval in the diagnosis of tricuspid disease has not been mentioned in previous studies (Ferrer *et al.*, 1953; Whitaker, 1955; Gibson and Wood, 1955; Yu *et al.*, 1956; Hollman, 1956; Pantridge and Marshall, 1957), although Trace *et al.* (1954) described it in their own case. Dalla Volta and Forattini (1957) described three cases of tricuspid stenosis in which the P-R interval appeared to exceed 0.20 sec. in the published cardiograms, but the timing of the cardiograph paper was not mentioned.

The most difficult differential diagnosis is from functional tricuspid incompetence, which may produce identical signs. Such incompetence is usually due to pulmonary hypertension from mitral stenosis, and differentiation depends on the proportion between the hypertension and right atrial size, as already mentioned. When, however, mitral incompetence is present there may be a raised venous pressure without much pulmonary hypertension (Gibson and Wood, 1955). However, prolongation of the P-R interval does not seem to occur in these cases, and, if present, may suggest the correct diagnosis. When mitral incompetence is severe and the left atrium aneurysmal, atrial fibrillation is always present and tricuspid incompetence frequently so. Under these circumstances the differentiation becomes clinically impossible. Final proof depends on the demonstration of a considerable pressure gradient across the tricuspid valve, for a slight gradient may be present in functional incompetence (Yu *et al.*, 1956). This may be due to a very high stroke volume.

Effect of Tricuspid Disease on Symptoms of Rheumatic Heart Disease

It has been suggested that tricuspid stenosis modifies the symptoms of pulmonary congestion due to left-sided valvular lesions (Thompson and Levine, 1937), but the findings in our series do not support this; for all patients were dyspnoeic, and pulmonary oedema or paroxysmal dyspnoea occurred in nearly one-third of them. Orthopnoea and paroxysmal dyspnoea occurred in three of Gibson and Wood's 14 rheumatic cases, and orthopnoea in 7 of the 13 cases of Reale *et al.* (1956). The most severe case of tricuspid stenosis in our series (Case C 2) had marked dyspnoea on effort and repeated attacks of paroxysmal dyspnoea and orthopnoea, attributable to gross mitral disease. Thus even gross tricuspid disease will not modify the symptoms of mitral disease if the latter is severe enough, but may do so if the mitral disease is slighter.

Haemodynamic Data

Our haemodynamic studies are similar to those published by Ferrer *et al.* (1953), Gibson and Wood (1955), Whitaker (1955), Hollman (1956), Yu *et al.* (1956), and Pantridge and Marshall (1957), and demonstrate the gradient in diastole across the tricuspid valve. In the cases with sinus rhythm, the atrial systolic pressure is not transmitted to the venous tricle, and the height of the "a" wave in the atrial pulse as compared with the right ventricular systolic pressure is striking. The slow "y" descent is also noteworthy. It is of interest that patient C 10, who had a large "a" wave in the jugular venous pulse when in sinus rhythm, developed gross tricuspid insufficiency at the onset of atrial fibrillation

(Fig. 1), and at necropsy his tricuspid valve was thought to be incompetent as well as stenosed. A similar case, but without proof at necropsy, is reported by Ferrer *et al.* (1953).

Association of Incompetence with Stenosis

The development of signs of tricuspid insufficiency in all patients with tricuspid stenosis who developed atrial fibrillation led us to suppose that the organically stenosed and obstructed valve is probably always incompetent to some degree. The findings of Ferrer *et al.* (1953), McCord *et al.* (1954), Whitaker (1955), and Hollman (1956, 1957), in general support this contention. However, Reale *et al.* (1956) doubt whether a marked systolic wave in the right atrial pulse necessarily indicates tricuspid incompetence, and they suggest that if the atrium is filled and stretched at the very time of ventricular systole the regurgitation of even a very small amount of blood might produce a considerable systolic wave. Ten of their 13 cases came to operation, and "significant" regurgitation was detected in only one. A low cardiac output at the time of palpation of the valve, however, may obscure a regurgitant jet. Pantridge and Marshall (1957) reported incompetence in one of two cases of tricuspid stenosis at operation for tricuspid valvotomy.

However, the work of Müller and Shillingford (1954) and Korner and Shillingford (1957) suggests that a large positive systolic wave is in fact associated with a considerable volume of reflux estimated by the dye-dilution technique. Such a wave was regularly seen in our patients with atrial fibrillation, and at necropsy it seemed probable that the valves had been incompetent. The absence of this wave in sinus rhythm may have been partly due to better emptying of the atrium, which is then able to accept a regurgitant flow without conspicuous rise of pressure.

We believe, therefore, that incompetence is a very common accompaniment of stenosis, but is not necessarily in the variable. This point has an important bearing on the surgical treatment of tricuspid stenosis, since valvotomy is unlikely to be wholly successful if appreciable incompetence is present, for it may be increased by valvotomy (Hollman, 1956), to the detriment of the patient. At the present time, tricuspid valvotomy is a well-recognized though uncommon operation (Brofman, 1953; Chesterman and Whitaker, 1954; Krook *et al.*, 1955; O'Neill *et al.*, 1954; Trace *et al.*, 1954; Bailey, 1955; Swan *et al.*, 1955; Gibson and Wood, 1955; Pantridge and Marshall, 1957; Dalla Volta and Forattini, 1957). But, as Hollman (1956) points out, the risk of increasing incompetence is appreciable. We have no personal experience of tricuspid valvotomy, but we believe that the general applicability of the operation is small, and that the difficulties of selecting the suitable case are considerable. The operation should probably be reserved for patients whose symptoms are urgent and unrelieved by medical means.

Summary

Twenty-one proved cases of organic disease of the tricuspid valve have been presented. The diagnosis is discussed, with special reference to the modification in the clinical picture produced by other valve lesions. Clinical, haemodynamic, and pathological data are discussed. Special emphasis is laid upon enlargement of the right atrium, and a method of radiological measurement is presented. The importance of right atrial P waves in the absence of evidence of right ventricular hypertrophy on the cardiogram is stressed. Prolongation of the P-R interval is underlined as a valuable diagnostic pointer.

Reasons are given for concluding that tricuspid incompetence usually accompanies tricuspid stenosis, and the surgical implications of this are mentioned.

We are indebted to Mrs. Birbeck and the department of medical photography for the illustrations.

EFFECT OF TEMPERATURE ON SURVIVAL OF BACTERIA IN BLOOD FOR TRANSFUSION

WITH A NOTE ON CONTAMINATION BY COLD-GROWING ORGANISMS

BY

J. D. JAMES, M.R.C.S., L.R.C.P.

Director, North London Blood Transfusion Service

AND

E. JOAN STOKES, M.B., M.R.C.P.

Bacteriologist, University College Hospital, London

From 1946 to 1949 the practice in the North London Blood Transfusion Centre was to transport blood collected at the donor sessions to the centre in vans without refrigeration. Thus, at the most outlying sessions, the first donor's blood was unrefrigerated for about eight hours before reaching the cold room at the centre; approximately 210,000 bottles of blood were so treated. In 1949 transport by refrigerator vehicles was considered.

When fresh blood is kept for four days at room temperature the red cells do not survive well on subsequent storage (Gibson *et al.*, 1947), but if it is allowed to cool slowly for a few hours before refrigeration it is unlikely to suffer, and, since the phagocytic and bacteriolytic processes in the blood are most active at body temperature, such treatment might even have definite advantages (James, 1954).

It was decided that a complete change to refrigerator transport should be delayed until evidence of its value could be obtained. In the meantime two refrigerator vans were employed in conjunction with five non-refrigerators. In fact, owing to the inconvenient size of the new vans when negotiating the narrow streets of London and some provincial towns, the approximate ratio in which they were used was 2:11.

During the period when both types of van were in use about 700,000 bottles of blood were collected and one death from infected blood was recorded, this bottle having been carried in a non-refrigerator van, but the

TABLE II

Exp.	No. of Donors	Strain	Ability to Grow at 4° C.	Time Stored at 4° C. Before Final Incubation	Inoculum per Bottle 250 ml.	No. of Bottles Found Sterile	
						Treated for 3-6 Hours at 37° C.	Refrigerated Immediately
1	27	BP1	+		14-50	6/27	0/37
2	9	BP1	+		14-59	2 hrs. at 37° C.	0/9
3	80	BP2	+		12-30	4/9	0/80
4	50	<i>Staph. pyogenes</i>	—	15 days	14	1/80	5/50
5	50	<i>Bact. coli</i>	—	21 "	7-14	23/50	49/50
6	50	" "	—	4 "	50-100	50/50	50/50

receive no bacteria. A small proportion of the incubator-treated samples may of course also be sterile by chance, but it cannot account for sterilization of nearly half of them.

In experiments 4, 5, and 6 a time had to be chosen to test survival by incubation, and the results might have been different if the blood had been stored for either a longer or a shorter period. In experiment 4, 15 days was chosen as a time when many bottles of blood are used. When in experiment 5 the bacilli survived in only one of 100 bottles, it was thought possible that prolonged storage (21 days) might have contributed to their death, but in experiment 6 the result was similar in samples seeded much more heavily after storage for only four days.

After treatment one of the pseudomonas was killed much more easily than the other, which suggests that different strains of this organism may have different degrees of resistance to the action of blood.

A marked difference in survival was found between the two human pathogens tested. In experiment 4 the *Staph. pyogenes* survived in 45 of 50 untreated samples, seeded with an average of 14 viable organisms per 250 ml. of blood, whereas in experiment 6 the *Bact. coli* (selected for its ability to grow from small inocula in small volumes of stored blood) died out in all of 50 untreated samples when seeded with 50-100 viable organisms per 250 ml. This may be due to killing by phagocytin (Hirsch, 1956), which was found to be much more active against Gram-negative than against Gram-positive organisms. The effect is different from and completely overshadows the bactericidal action, which depends on temperature. Gram-negative organisms susceptible to it are unlikely to survive in blood at any temperature once the phagocytin has been released.

One further point of interest was that in experiment 3 some samples of the blood which had been incubator-treated yielded growth on storage slightly earlier than the untreated controls. Blood from 30 of the 80 donors which was subcultured almost daily yielded growth on the seventh day from 25/30 of the incubator-treated samples and only 16/30 controls; on the eighth day the figures were respectively 29/30 and 20/30, and by the tenth day growth was found in all bottles.

If many more strains of cold-growing pseudomonas were tested the majority might prove, like BP2, to be resistant to killing by blood. Since it is clear that in any case the method can never be completely effective, further experiments which would involve large quantities of blood are thought to be unjustifiable. If at some later date incubation treatment of blood should seem desirable for other reasons—for example, to activate chemicals added to blood to prolong cell life—further work might be worth while.

4. Effect of Slow Cooling at Room Temperature on the Survival of Contaminating Bacteria

In the preliminary experiments, using small volumes of blood (3 ml.) and the cold-growing pseudomonas BP1, it seemed that on the whole slow cooling was to be preferred to immediate refrigeration after bleeding (Table I). The

test was repeated, using slightly larger volumes of blood (5 ml.), the other pseudomonas (BP2), and one strain of *Staph. pyogenes*. The blood was allowed to remain at room temperature for eight hours before refrigeration, because that is the maximal time likely to elapse between bleeding and storage when the donor session is held at a distance from the centre and there is no refrigerator transport.

Estimation of Growth in Heavily Contaminated Blood During Slow Cooling at Room Temperature

The first method described above (Section 3) was employed. In each case the number of bacteria recovered after eight hours at room temperature (18-23° C) was compared with the number found in a duplicate 5-ml. sample of the same donor's blood which had been refrigerated immediately after inoculation.

One strain of *Staph. pyogenes* did not multiply during this time, but BP2 was able to increase approximately fourfold in fresh blood under these conditions. It would appear from these results that blood infected with BP2 is best refrigerated soon after bleeding; but the conditions of the test differ from those in accidental contamination, as already discussed, in that the blood volumes were small and the inoculum heavy.

The fate of small inocula of both strains of pseudomonas were therefore tested in large volumes (approximately 250 ml.) of blood. The second method described in Section 3 was employed. Half the bottles were left at room temperature for eight hours before refrigeration, and their duplicates were refrigerated as soon as possible, in no case later than 30 minutes after bleeding.

The stored blood was subcultured at intervals for 28 days. Those samples which remained sterile were then subcultured again after 48 hours' "incubation" at room temperature as a further test of sterility.

The two sterile samples were blood from the same donor which was presumably particularly active against BP1.

TABLE III

No. of Donors	Strain	Inoculum per Bottle (250 ml.)	No. of Bottles Found Sterile	
			Treated 18-23° C. for 8 hrs.	Refrigerated 4° C. Immediately
18	BP1	9-46	1/18	1/18
20	BP2	12-30	0/20	0/20

It seems from the results (Table III) that there is little point in early refrigeration, but it was noticed that growth appeared a few days earlier in some of the bottles which had not been immediately refrigerated. Thus, in the first test (BP1) blood from seven donors yielded growth first in the bottles treated at room temperature; blood from one donor yielded it first in the immediately refrigerated bottles; there was no difference in four, and in four the time of growth could not be assessed. In experiment 2 (BP2) the blood from 15 donors yielded growth first in the bottle treated at room temperature, none grew first in the immediately refrigerated bottle, and in five the time of growth could not be assessed. The most frequent difference in time was two to three days, and the maximum noted was four days.

It may appear from this that if growth in some samples can be delayed for a few days, refrigeration might be worth while, but in practice the difference between full bottles refrigerated immediately in a van and those left at room temperature during transport is not as great as in these experiments. The volume of blood was of necessity half a bottle instead of a full bottle, and it was refrigerated in a large cold-room. At a donor session many full bottles are packed into a small refrigerator in the van, and it was found that during transport to the centre they can raise the refrigerator temperature from 4 to 12° C. Probably the advantage of rapid refrigeration in these conditions is so slight as to be negligible.

Inquiries at regional transfusion centres in this country revealed a diversity of practice in that, while centres conveyed blood mainly in refrigerator vans, the time which elapsed between filling the bottle and placing it in the van varied, so that in practice the blood was often allowed to cool slowly for periods up to two hours at room temperature.

Effect of Temperature on Red-cell Survival.—The percentage red-cell survival of incubator-treated and immediately refrigerated blood after 28 days' storage at 4° C. was estimated in four donors using the method of radioactive isotope tagging described by Reeve and Veall (1949) and Mollison and Veall (1955). The results showed a slightly reduced percentage survival time after incubation treatment in all four tests. This is not necessarily a contraindication for incubator treatment, because the test was made late in storage when the percentage survival time is falling rapidly and when, for this and other reasons, blood is very seldom given. If it were tested at 21 days, which is the maximal time blood is normally stored before transfusion, the effect of incubation would probably be negligible.

5. Contamination by Cold-growing Bacteria

It is agreed that bacteria which are able to multiply in stored blood at 4° C. are the most dangerous contaminants (Pittman, 1953; McEntegart, 1956). In Britain during the last ten years approximately 4,400,000 bottles of blood were given and there have been eight deaths thought to be due to contaminated blood (W. d'A. Maycock, 1957, personal communication). Cold-growers were isolated from all of them, and two of these strains were employed in the experiments here recorded.

It was hoped that incubation immediately after blood is withdrawn would effectively kill cold-growers, especially as they are barely capable of growth at 37° C. Although these expectations were fulfilled in some cases, the action of blood is not constant enough to be relied on, and other methods must be sought to prevent contamination or to sterilize the blood.

It has been suggested that the addition of small doses of tetracycline to blood would prevent growth and do no harm to the recipient (Braude *et al.*, 1955). We are not in favour of this, because it is doubtful if all strains of cold-growers are sensitive to any one drug; moreover, antibiotics are not stable, and would therefore have to be added to the bottle after autoclaving, and they are themselves sometimes considered harmful, because they may kill a person who is hypersensitive.

McEntegart (1956) has suggested that danger could be avoided if blood were never stored longer than a week, because his cold-growing strains were not apparent in blood until the second week of storage. Both our strains of pseudomonas, however, yielded heavy growth from small inocula in some samples at six days, and if more had been tested it would probably have occasionally appeared even earlier. By the tenth day heavy growth in all lightly seeded samples was the rule. There is no doubt, however, that the shorter the storage the less chance there is of danger from cold-growers. We also found that if growth had not appeared by the sixteenth day the sample would prove to be sterile.

Prevention of Contamination

We have succeeded in cultivating cold-growing bacilli similar to, but not identical with, BP1 and BP2 from the air, from dust, from swabs of unwashed skin, and in large numbers from fluid in which plastic caps used to cover transfusion bottles are delivered from the manufacturer. The closed techniques in common use could be improved to prevent their entry in the following ways. The bottle should be autoclaved, with the aluminium cap loose, to prevent the formation of a vacuum, and with the holes in the cap covered by adhesive strapping. The strapping should be

removed at the donation session immediately before bleeding and the cap should not be touched before the airway needle (attached to an air-filter tube) and the taking-set needle are plunged through it. When the bottle is full the needles should be removed, still taking care not to touch the cap, which can now be wiped, if necessary, with dry sterile cotton-wool or gauze. The holes should then be sealed with sterile waterproof strapping and the cap covered with an autoclaved plastic cap. The provision of a paper dust-cap over the top of the bottle is not essential, but may be added as a refinement.

There seems to be no reliable way of recognizing infected blood before transfusion. During 1952 to 1955 one London teaching hospital carried out routine stained-film examination of every bottle transfused (15,000), and they came to the conclusion that the risk of infection was so slight (conjectured at 1 in 7,500) that the practice was stopped. Moreover, although the cold-growing bacilli can be seen among the debris when blood is known to be infected and a careful search is made, their presence might well be missed even by experienced workers in a routine examination when blood is urgently needed.

6. Examination of Blood for Infection after Transfusion

Deaths reported after transfusion of infected blood are rapid, and are almost certainly due to foreign substances produced in the blood as a result of bacterial growth rather than to infection by the bacterium. Unless blood is grossly mishandled significant infection by human pathogens which grow at 37° C. but not in the refrigerator is very unlikely. The few staphylococci and diphtheroids which may be introduced from the donor will either die during storage or will remain in very small numbers unless they are given a chance to grow by prolonged incubation or storage at room temperature.

If contamination of blood before transfusion is to be prevented it is important to be able to recognize it when it has occurred. It has become clear to us that revision of culture methods for this purpose is required. Bottles are often taken down at the end of transfusion by someone unskilled in bacteriological technique who is not at the time expecting the remains of the blood in the bottle to be cultured: contamination at this stage is therefore likely. It is necessary to know more about the ability of blood to support the growth of different species of bacteria and the rate at which small numbers of contaminating organisms will grow in it before the most suitable culture methods can be devised and the results of culture can be properly assessed.

Comparison of Undiluted Transfusion Blood and Peptone Water as Culture Media

Comparison of Blood and Peptone Water to Support Growth of Small Inocula.—Growth of 10 to 50 viable organisms in 5 ml. of the two fluids was compared, using a freshly isolated *Staph. pyogenes*, the two cold-growing pseudomonas BP1 and BP2, and stored blood from four donors. In all cases growth appeared earlier and more abundantly in the peptone water. Two further points of interest were noted. The *Staph. pyogenes* grew more readily in old than in fresh blood, and, although the cold-growers flourish at about 20° C. in peptone water, in blood at this temperature their growth is comparatively poor. Small inocula of BP1 died out in some samples of blood at 20° C., although they grew in the same blood at 4° C., almost as well as in the peptone-water controls. Presumably they, like other Gram-negative organisms, are affected by an inhibitor which is active at room temperature and at 37° C., but not in refrigerated blood.

Rate of Growth of Air Contaminants in Blood and Peptone Water at Room Temperature.—Stored blood between 3 and 20 days old from four donors was distributed in 5-ml. amounts in 1-oz. (28-ml.) screw-capped bottles having mouths 1.8 cm. in diameter (transfusion bottles have mouths

2.2 cm. in diameter). An equal number of similar bottles each containing 5 ml. of peptone water were placed in the same racks as controls. Twelve bottles and controls were exposed to air in a ward for seven hours; this included bed-making time, when the air would be very heavily contaminated. A similar set of bottles were exposed for seven hours in the laboratory passage during a time of heavy traffic. After exposure the bottles were closed with sterile caps and left overnight on the bench. The next day and subsequently they were well shaken and subcultured on to two blood-agar plates which were incubated for 48 hours, one at room temperature and the other at 37° C. The results are seen in Table IV.

TABLE IV

	No. of Bottles Yielding Growth at Intervals After Exposure to Air for Seven Hours		
	1st Day	2nd Day	3rd Day
Blood	3/24	8/24	22/24
Peptone water	21/24	24/24	24/24

Culture of Blood in Bottles Returned to the Laboratory after Transfusion

Over a period of one month the remains of blood in all transfusion bottles returned to the laboratory were cultured; no transfusion reactions were reported during this time.

The bottles had been sealed after collection and were not opened until used for transfusion. Immediately before use the cap was replaced by the sterile filter and rubber bung of the giving set; blood was not warmed in the bottle. When the transfusion was over, the giving set, which has no air filter, was removed and the cap, which had been exposed to the ward air, was replaced and the bottles were returned to the laboratory, where, for lack of refrigerator space, they stood in the laboratory passage.

The culture method recommended below was employed, but "incubation" at 4° C. and multiple seeding on blood agar were omitted.

Altogether 141 blood residues were cultured between six hours and five days after transfusion. Sterile cultures were obtained from 105 samples, growth in one liquid culture only from eight; growth in both liquid cultures from 17, and growth in all cultures from 10.

The 10 heavily contaminated samples were cultured between one and five days after transfusion. Four of them had been left for one or more days uncapped. (Five of the sterile samples had also remained uncapped for six hours to two days.) One of the remaining six bottles, which was cultured three days after transfusion, yielded a cold-growing bacillus similar to, but not identical with, BP1 and BP2. The others yielded *Staph. albus* (one), *Staph. pyogenes* (two), an aerobic spore-bearing bacillus (one), and one bottle two days old yielded a mixed growth of a spore-bearer and a Gram-negative cocco-bacillus, not a cold-grower. All bottles (16) cultured less than one day after transfusion were sterile.

Other species isolated in liquid culture only were a diphtheroid, a micrococcus, a cold-growing bacillus not identical with BP1 and BP2, a haemolytic streptococcus (not belonging to groups A, B, C, D, or G), and a non-haemolytic streptococcus.

In the light of these results the following method is recommended for the examination of blood when infection is suspected.

Method of Examination of Blood for Infection after Transfusion

After transfusion the used bottles should be capped and returned to the laboratory refrigerator, where they should be kept for at least 24 hours in case investigation is required. When infection is suspected the dregs from the bottles should be cultured even if they have inadvertently remained exposed at room temperature for many hours, because there is a good chance that if the blood was not originally infected it will still be sterile or very lightly contaminated.

The procedure is as follows. Mix the blood well and examine a Gram-stained film for bacteria. Inoculate three blood-agar plates with six separate loopfuls each of the blood and incubate one at 37° C. for two days, one at room temperature (20–25° C.) for one week, and the third at 4° C. for at least as long as the blood had been stored in the refrigerator. (This method of seeding gives a rough estimate of the number of bacteria in the blood. One or two colonies resulting from one loopful might occur by chance, but when each of six loopfuls yields a small number of colonies the blood must be moderately heavily contaminated.)

Inoculate three tubes, containing at least 2 ml. of peptone water or nutrient broth, with five drops each of blood. Incubate one at 37° C., one in the dark at room temperature for a week, and the third at 4° C. for at least as long as the blood had been stored in the refrigerator before the transfusion was given. Return the remainder of the blood to the refrigerator.

Examine the liquid cultures daily, and when growth appears subculture to blood agar and incubate at the appropriate temperature. If after a week there is no evidence of growth, subculture the liquid cultures to blood agar before discarding them and treat the subcultures as already described for the original plate cultures. When growth occurs in only one of the liquid cultures, transfer the others to the favourable temperature to see if they are also infected with the same organism before they are discarded. If no further growth is obtained, make further cultures from the blood which has been kept in the refrigerator, because growth in a single liquid culture may be due to laboratory contamination.

This method is delicate enough to recognize contamination of the order of 5,000 viable organisms per full bottle. When a cold-growing organism is found in profusion—that is, growth on the original blood-agar culture—and damage to the patient can be attributed to no other cause, it should be considered guilty until it can be proved harmless, even if the blood has remained in an uncapped bottle in the ward for 12 hours, because nothing short of injecting a culture into the blood after the transfusion could produce such a heavy growth of this kind of organism in so short a time.

When routine cultures are made of unopened bottles to check aseptic technique during collection it is reasonable to cultivate larger volumes of blood. Since bacteria which contaminate blood are also apt to contaminate cultures in the laboratory, too much weight should not be attached to growth from single liquid cultures. Laboratory technique can be controlled either by making all cultures from the same bottle in triplicate and disregarding less than a two-thirds positive result, or bottles of sterilized nutrient medium can be sampled on every occasion in parallel with the bottles of blood and the infection rate assessed statistically from a large number of cultures.

Discussion

Although some samples of fresh blood incubated for two hours immediately after donation can kill small numbers of contaminating organisms, routine incubator treatment cannot be recommended without further extensive investigation. If it were shown that cold-growing bacilli similar to BP1 were the most likely contaminants during collection and no means could be found to exclude them, routine incubation for a short period would be worth while, because some contaminated bottles would be sterilized and the lives of patients receiving this blood would not be endangered. Most contaminants, however, may be resistant to killing by blood, and if it is collected by the closed method recommended contamination by cold-growers would probably be exceedingly rare. In these circumstances the benefits of incubation might be outweighed by slight damage to the red cells in the numerous uncontaminated samples. In practice, incubator treatment would not be easy to carry out, because some means of automatic refrigeration after two hours would be required.

It has been shown that in practice the transport of blood in non-refrigerator vehicles between donor session and centre was satisfactory, in that over a period of seven years about 500,000 bottles have been so collected with only one fatality due to infection that was caused by an organism which grows in blood at 4° C. Blood contaminated with cold-growers which caused the other seven deaths reported in England and Wales during the last ten years was collected by services which employ refrigerator transport between donor session and centre.

In spite of experimental evidence that some samples of blood contaminated with these organisms will yield growth slightly earlier during storage if not immediately refrigerated, the remoteness of this hazard in practice explains the good results obtained with non-refrigerator vehicles.

Provided that blood can be refrigerated within eight hours of collection there would appear to be no evidence that refrigeration at the collecting session or during transport is essential in temperate climates. Experimental incubation of blood for two hours immediately after collection suggests that in the tropics it will come to no harm if left for at least two hours unrefrigerated.

It seems that one reason why accidents from infected blood are not more common may be that blood for transfusion is a poor culture medium.

Summary

The problem of contamination of blood for transfusion was investigated, particularly with regard to the effect of temperature after collection on contaminating organisms.

Bacteria which grow at 37° C. and two strains isolated from infected blood which grow at 4° C. were inoculated into samples of freshly drawn blood in an attempt to reproduce the actual mode of infection during donation.

It was demonstrated that, although experimentally there are slight advantages in refrigerating blood within 30 minutes of collection, in practice refrigeration in temperate climates is not essential until at least eight hours after collection.

Some samples of blood held at 37° C. for two hours immediately after donation killed small numbers of contaminating bacteria; none of the strains tested multiplied in blood during this time.

Prevention of contamination by cold-growing bacteria is discussed and a method is recommended for the examination of blood suspected of infection.

We wish to thank first the blood donors who volunteered for these experiments, without whom the work could not have been done. Acknowledgments are due to Professor Wilson Smith for his encouragement and advice, to Dr. P. L. Mollison for the estimation of red-cell survival, to the staff of the North London Blood Transfusion Centre, particularly Dr. P. B. Booth and Dr. G. Plaut, and to Mr. T. D. Whittet for the pathogenicity and pyrogen tests in rabbits.

ADDENDUM.—Since this paper was completed, results of experiments on the survival and growth of bacteria in bank blood incubated at 37° C. for short periods before refrigeration have been published by Geller, P., Chandler, L., and Jawetz, E., *J. Lab. clin. Med.*, 1957, 49, 573. So far as the results can be compared, they are in agreement.

SPLENECTOMY IN ACQUIRED GENERALIZED MYELOSCLEROSIS

BY

N. K. SHINTON, M.B., M.R.C.P.

Senior Registrar in Clinical Pathology, Queen Elizabeth Hospital Birmingham

Acquired generalized myelosclerosis with associated myeloid metaplasia is an uncommon but well-recognized disorder which has been described under a variety of names, including osteosclerotic anaemia, myelophthisic anaemia, megakaryocytic myelosis, and agnogenic myeloid metaplasia. It is regarded as distinct from the hereditary osteopetrosis or marble bone disease of Albers-Schönberg, which occurs in childhood and young adults. Acquired myelosclerosis is not familial, and is seen in patients of both sexes more commonly after the age of 40. The clinical features are an insidious progressive anaemia, usually of leuco-erythroblastic type, and gross splenomegaly. The anaemia may later show a haemolytic component or may be associated with neutropenia or thrombocytopenia. Radiographs of the bones sometimes show mottled rarefaction or irregular condensations in the cortical portions and splintering or elevations of the periosteum (Rosenthal and Erf, 1943). The prognosis is poor, death occurring usually within five years from cardiac failure, intercurrent infection, or haemorrhage. At necropsy there is replacement of the bone marrow by fibrous or osseous tissue and extramedullary haemopoiesis, myeloid metaplasia occurring in the spleen, in the liver, and sometimes in the kidneys and lymph nodes.

Aetiology

The cause of the condition remains uncertain, but in a few cases it has been reported in association with carcinomatous deposits in the marrow, myeloma, Hodgkin's disease, and diffuse tuberculous infection. Wyatt and Sommers (1950) reviewed a group in which they suggested that the changes were a result of intoxication by various organic chemicals. Donhauser (1908) was the first to regard the myeloid metaplasia as a compensatory extramedullary haemopoiesis and the spleen as the most important source of red cells, granulocytes, and platelets. If this is a correct hypothesis, splenectomy would be clearly contraindicated (Scott, 1949; Wintrobe, 1951; Learmonth, 1951; Chatterjee, Meza Arrau, and Dameshek, 1952; Hickling, 1953).

An alternative hypothesis supported by Vaughan and Harrison (1939), Dameshek (1951), Hutt, Pinniger, and Wetherley-Mein (1953), and Richardson and Pinniger (1953) regards the myelosclerosis and the myeloid metaplasia as part of a proliferative disorder of mesenchymal tissue, in response to an as yet unknown stimulus. As the mesenchymal cell is multipotential and may differentiate into a fibroblast, erythroblast, myeloblast, or megakaryoblast, the clinical and haematological pattern depends upon the predominant cell group and the stage of development involved. Myelosclerosis has been described in association with polycythaemia vera in a number of cases reviewed by Beattie and Withey (1953), since when further reports have been added by Robson (1953) and Korst, Clatanoff, and Schilling (1956). Cases of myeloid leukaemia with myelosclerosis have been reported by Hutt *et al.* (1953) and Richardson and Pinniger (1953).

Richardson and Pinniger (1953), Croft (1956), and Asher (personal communication) describe cases where the features of myelosclerosis, polycythaemia vera, and leukaemia have occurred in the same patient at different times, as has also megaloblastic anaemia in the case described by Croft (1956). According to this myeloproliferative theory, the myeloid

metaplasia in the spleen is not a compensatory mechanism, and in fact splenic hyperactivity may contribute to the pancytopenia, neutropenia, thrombocytopenia, and haemolytic anaemia which may develop in this condition. Splenectomy, by this hypothesis, is not contraindicated, and has now been reported in at least 23 histologically proved cases of acquired generalized myelosclerosis (Hirschfeld, 1914; Mettler and Rusk, 1937; Waitz and Warter, 1938; Carpenter and Flory, 1941; Reich and Rumsey, 1942; Dustin, 1947; Engell, 1947; Heller, Lewisohn, and Palin, 1947; Edwards, 1951, 1955; Andersen and Sorensen, 1952; Franks and Richardson, 1952, and personal communication; Green, Conley, Ashburn, and Peters, 1953; Merskey and Budz-Olsen, 1953; Nelson, 1954; Asher, 1955, and personal communication; Croft, 1956; Linman and Bethell, 1957).

FIG. 1.—Rib marrow from Case 1 showing fibrosis (reticulin). (×230.)

Against this background four further cases of acquired myelosclerosis are reported in which splenectomy was performed.

Case 1

A 59-year-old man was admitted to hospital in March, 1951, with dyspnoea and hepato-splenomegaly. Haematological examination showed a normocytic normochromic anaemia with erythroblast-
aemia, neutropenia, and thrombocytopenia (red cells, 3,260,000 per c.mm.; Hb, 8.5 g. per 100 ml.; M.C.V., 83 cubic microns; M.C.H.C., 30%; reticulocytes, 2.6%; normoblasts, 500 per c.mm.; white cells, 1,850 per c.mm. (700 neutrophil polymorphs, 15 eosinophils, 15 basophils,

250 myelocytes, 700 lymphocytes, and 170 monocytes); platelets, 73,000 per c.mm.). Radiographs revealed no bone changes. On sternal puncture no marrow was obtained, but on histological examination a rib biopsy showed osseous trabeculae in the medullary cavity, between which were numerous collagen and reticulin fibres (Fig. 1); cells of the erythroid and myeloid series and megakaryocytes were present in normal or possibly increased numbers. The patient was treated by blood transfusions, but after 12 months these failed to maintain his haemoglobin above 7 g. per 100 ml. (Fig. 2). During this time his serum bilirubin was always less than 0.5 mg. per 100 ml., and the direct Coombs test was negative. In September, 1952, a course of corticotrophin (20–40 mg. a day intravenously) was administered over 22 days (total 680 mg.) without benefit.

In view of the persistent pancytopenia and failure of repeated blood transfusions it was decided in October, 1952, to perform a splenectomy. At operation the spleen was found to be grossly enlarged, weighing 2,000 g., and on histological examination showed foci of erythroid and myeloid haemopoiesis but very few megakaryocytes; macrophages in the pulp contained a moderate amount of haemosiderin. A rib biopsy taken at the operation showed changes similar to those seen 18 months before. After splenectomy there was a marked erythroblast-
aemia, a rapid rise of platelets to 200,000 per c.mm. and of neutrophil polymorphs to 3,300 per c.mm.; the haemoglobin level became stationary around 10 g. per 100 ml. Two months later the patient returned to work, continuing until May, 1953, when he developed haemorrhagic pericarditis, the cause of which was never satisfactorily explained. In view of the fall in haemoglobin at this time a further transfusion was given.

He remained well until April, 1954, when he developed epigastric pain followed by recurrent haematemesis. A barium study showed the presence of a duodenal ulcer. This did not respond to medical treatment, and further severe haematemesis necessitated partial gastrectomy in October, 1954. Shortly after the operation he developed cardiac failure and died.

Necropsy (Dr. J. G. Jackson).—Both lungs showed pulmonary oedema, and the heart (375 g.) had a pale friable myocardium with interstitial fibrosis, the coronary arteries and aorta showing slight atheroma. The liver (2,500 g.) was enlarged, and showed erythroid and myeloid metaplasia with occasional megakaryocytes. The femora contained soft red marrow throughout the length of each shaft, but the sternum, ribs, and vertebrae showed a moderate increase of laminated bony trabeculae in the medullary cavity with an increase of collagen and reticulin fibres. The bone marrow from each site showed many foci of erythroid and myeloid cells, but no increase in megakaryocytes.

Case 2

A 71-year-old housewife was admitted to hospital in September, 1955, with gross splenomegaly accompanied by severe abdominal pain. Haematological examination

FIG. 2.—Blood levels in Case 1.

showed: red cells, 4,460,000 per c.mm.; haemoglobin, 12.3 g. per 100 ml.; P.C.V., 38%; M.C.V., 84 cubic microns; M.C.H.C., 35%; reticulocytes, 8.6%; white cells, 32,000 per c.mm. (21,000 neutrophil polymorphs, 7,800 myelocytes, 2,300 lymphocytes, and 350 monocytes); platelets, 157,000 per c.mm. Puncture of the sternum and iliac crest was easily carried out, but no true marrow was obtained, a finding very suggestive of myelosclerosis.

In view of the patient's persistent pain and of her extreme difficulty in walking due to the abdominal swelling, it was decided to perform a splenectomy. The spleen was grossly enlarged, weighing 5,440 g. Histological examination showed the pulp to contain large numbers of erythroid and myeloid cells and megakaryocytes (Fig. 3). The evening following

FIG. 3.—Spleen from Case 2 showing erythroid and myeloid metaplasia with megakaryocytes. (H.E. ×560.)

operation the patient became hypotensive, and an emergency laparotomy revealed bleeding from the small vessels under the diaphragm which could not be controlled. She died of the diaphragm which could not be controlled. She died of peripheral circulatory failure 48 hours after splenectomy.

Necropsy.—There was a large blood clot beneath the left diaphragm but no other evidence of haemorrhage throughout the body. The liver (2,770 g.) was enlarged, showing scattered white nodules of erythroid and myeloid cells with in the hepatic lobules and along the portal tracts. The ribs, sternum, and femora showed a general increase of laminated bony trabeculae and a patchy increase of collagen and reticulin fibres associated with foci of erythroid and myeloid cells, but without increase in megakaryocytes.

Case 3

A 58-year-old man was admitted in January, 1956, with a three-months history of pallor and dyspnoea on exertion. No abnormal physical signs were detected. His blood values were: red cells, 2,030,000 per c.mm.; haemoglobin, 5.3 g. per 100 ml.; M.C.V., 79 cubic microns; M.C.H.C., 33%; reticulocytes, 3.8%; white cells, 4,000 per c.mm. (3,500 neutrophil polymorphs); platelets, 182,000 per c.mm.; a small number of normoblasts; red cell osmotic fragility normal;

direct Coombs test negative; and serum bilirubin less than 0.5 mg. per 100 ml. Radiographs of the long bones showed no abnormality. Bone-marrow puncture at different sites on three separate occasions was carried out with difficulty and poor specimens of hypocellular marrow were obtained. A provisional diagnosis of myelosclerosis was made and the patient given monthly blood transfusions.

Over the next three months the spleen became palpable and gradually increased in size; myelocytes began to appear in the peripheral blood; urinary and faecal urobilinogen was raised, but the serum bilirubin was never above 0.6 mg. per 100 ml. By August blood transfusions failed to raise the haemoglobin above 6 g. per 100 ml. (Fig. 4), and it was therefore decided to perform a splenectomy. The spleen was enlarged, weighing 1,350 g., and showed marked hyperplasia of the sinusoids, the pulp containing large numbers of macrophages laden with haemosiderin. A very small number of erythroid and myeloid cells with a few megakaryocytes were present. A rib biopsy at the time of operation showed the marrow to be almost completely replaced by fibrous and osseous tissue; a few foci of erythroid and myeloid cells were present and megakaryocytes were increased.

The post-operative course was uneventful, but the haemoglobin level gradually fell during the next few weeks, becoming stationary around 7 g. per 100 ml. three months later when the patient again had some dyspnoea on exertion. Over the past year he has required blood transfusions on two occasions only, when the haemoglobin fell below 6 g. per 100 ml.

Case 4

A 62-year-old housewife was admitted to hospital in July, 1954, with gross splenomegaly and moderate hepatomegaly. The blood values were: red cells, 4,930,000 per c.mm.; haemoglobin, 11.1 g. per 100 ml.; M.C.V., 86 cubic microns; M.C.H.C., 26%; white cells, 17,900 per c.mm. (13,200 neutrophil polymorphs, 800 eosinophils, 400 basophils, 100 myelocytes, 900 metamyelocytes, 2,300 lymphocytes, and 200 monocytes); occasional myeloblasts and normoblasts were seen. Occult blood was present in the stools and a subsequent barium study showed a diaphragmatic hiatus hernia.

FIG. 4.—Blood levels in Case 3.

first decade (0-10 years) 51% had non-vegetative urethritis and 10% had vegetative urethritis, hillocks only—that is, no actual polypi. Moreover, it is significant that, of the 34 children under 16 years of age with frequency, 79% had enuresis. Occasional cases without frequency or enuresis had such symptoms as terminal dysuria, holding the water for long periods, and even acute retention. Thus we see

FIG. 2.—Urethral contractions in relation to age groups in 65 cases of cystitis in women.

FIG. 3.—Residual urine in relation to age groups in 65 cases of cystitis in women.

FIG. 4.—Vegetative urethritis in relation to age groups in 65 cases of cystitis in women.

FIG. 5.—Incidence of hillocks and polypi in relation to age groups in 65 cases of cystitis in women.

1956), an increasing incidence of urethral contractions (Fig. 2) and residual urine (Fig. 3) in relation to age.

In the cystitis cases the incidence of vegetative forms of urethral inflammation is seen to be broadly more common in older patients (Fig. 4), the polypi being more in evidence than the hillocks (Fig. 5), although these often occur together in adult cases. They are both found in the posterior urethra; these two types of vegetations were

described long ago (Winsbury-White, 1948). The urethral caruncle which arises in the anterior urethra is much less in evidence.

The non-vegetative forms of urethral inflammation in the older patients are usually apparent as fibrotic changes—producing rigidity of the internal urinary meatus and a raised and irregular posterior margin of this structure—or as the urethral contractions already referred to. A rare type shows pus oozing from numerous points in the urethral wall.

In 1956 I pointed out that 88% of 274 cases showed inflammatory urethral involvement. In the present 65 cases of cystitis there was an even greater incidence (94%); this is not surprising if we are to regard these cases as broadly representing a further stage of the same disease.

In considering the data I have presented it is difficult to believe that cystitis and frequency do not represent varying clinical states of the same pathological condition. Particularly is this conclusion justified when we see how, in a clinical sense, the two groups merge into each other.

Cervix Uteri.—The importance of a pathological condition of the cervix here should never be overlooked. Clinically, it is impossible to clear up the bladder neck if a cervical erosion is neglected. The experimental work which I carried out many years ago (Winsbury-White, 1933) emphasizes this point. An intact hymen must never be regarded as an assurance of a non-eroded cervix. Of my 65 patients aged 21-60, 7% had cervical erosion which needed attention. As urethral fulguration is often necessary in the same case, the urologist must be ready to deal with the cervix at the same time.

Gland Structures in the Posterior Urethra

According to Nelson *et al.* (1957), it appears that centuries before microscopy was available disease of the bladder neck in females causing obstruction was proclaimed by Ambroise Paré (1575) and De Groot (1672). Microscopical aid in due course brought pronouncements from Virchow (1853), Von Brunn (1883), Tourneau (1881), and Albarran (1909) pointing to the theory that glandular hyperplasia, in some respects resembling prostatic hypertrophy, caused obstruction at the bladder neck in women. A particular point to be emphasized in relation to prostatic obstruction is the common incidence of inflammatory changes found in the removed prostate even when hypertrophy is the dominating feature (Franks, personal communication). The common incidence of inflammatory phenomena in the posterior urethra of women, as seen with the urethroscope, points to the same tendency in the female—namely, that the glandular tissue there encourages inflammation.

Felix (1912) stated that in the female urethra the glandular ducts may atrophy and disappear, or may be present. Other writers have described the glandular tissue in the urethra adjacent to the internal urinary meatus. Folsom and O'Brien (1945) reproduced a photomicrograph of glands in this situation in the female foetus. Huffman (1948) presented wax models of the gland ducts of the female urethra which show these structures in close proximity to the internal meatus on both the anterior and the posterior aspect of the channel. Folsom and O'Brien agree with me that it is in the posterior urethra, and not the anterior, where vegetative phenomena are common. Fig. 6 shows the gland structure in the tissue of a bladder neck, including the adjacent part of the posterior urethra, which I excised for a woman aged 58.

Even in female children with chronic disturbances of micturition, including enuresis, and involving persisting small amounts of residual urine, the excised bladder neck shows abundant evidence of chronic inflammation. I call to mind two such children, each with enuresis and frequency, with amounts of residual urine varying from 1 to 3 oz. (28 to 85 ml.); one aged 7 years was cured 18 months ago, and the other, aged 13, is a more recent case; both after suprapubic bladder-neck excision.

In noting that vegetative urethritis occurs in the posterior and not in the anterior urethra one recalls that this is what happens in the male in relation to urethritis generally.

In searching for aetiological factors, it is to be noted that posterior urethritis in the male either is accompanied by a non-vegetative anterior urethritis or there is evidence that inflammation has occurred in the anterior urethra in the past. In the female, signs of non-vegetative anterior urethritis always accompany the posterior urethral changes mentioned. Also there is the fact that, in the first five years of life, simple vulvitis is a very frequent incident in connexion with urethritis. These two separate pieces of evidence suggest that the posterior inflammation is secondary to an anterior one.

FIG. 6.—Section of bladder neck excised transvesically from a woman aged 58, showing a vertical cleft or pit, with a gland space on the left and a focal aggregation of chronic inflammatory cells on the right. There is some irregular hyperplasia of the surface epithelium. (H. and E. $\times 115$.)

General Survey of Cystoscopic Appearances in Cystitis

As chronic frequency is so commonly due to chronic inflammation in the lower urinary tract, in a general way, and as my purpose is to discuss inflammation in the bladder, these matters may wisely be considered together. Because it is unusual to carry out cystoscopy during an attack of acute cystitis, the appearances described below do not include this condition.

Speaking generally of the cases of chronic frequency, it can be said that cystoscopic evidence of cystitis is more common in the younger than in the older children. This is common in the first five years compared with the second five so in the first five years compared with the period of late years. In adolescence, which embraces the period of relative inactivity of disturbances of micturition, of whatever origin, the signs of inflammation are nearly always confined to the posterior urethra. In the third decade, and before to the posterior urethra. A sudden onset of frequency, or an attack of cystitis which clears completely or quiescence, or an attack of cystitis which clears completely or quiescence, or an attack of cystitis which clears completely or quiescence, is a familiar event. It is resolved into chronic frequency, is a familiar event. It is resolved into chronic frequency, is a familiar event. It is resolved into chronic frequency, is a familiar event.

Unfortunately there is a widespread belief that in the absence of residual urine in the bladder the lower urinary tract can be absolved from causing symptoms in the upper

urinary tract, and this idea is often a sufficient reason for not making a complete investigation of the lower urinary tract. In certain cases of cystitis the infection seems to begin in the kidneys, and in a definite small proportion of cases full investigation shows that the primary cause of the bladder symptoms certainly lies in the kidneys. It is important to realize, however, that the renal symptoms of bladder-neck origin may completely overshadow vesical symptoms; thus treatment can be wrongly directed. Also minor renal symptoms, particularly in the nature of a recurring aching pain, can be made to disappear by finding and treating a posterior urethral lesion. I have often wondered whether the successes claimed for dilating strictures of the ureters were not due, at least in part, to the urethral dilatation which inevitably occurred at the same time. On the other hand, it cannot be expected that a prolonged renal attack from a long-continued urethral lesion will not produce permanent changes in the kidneys.

To put it in another way, when trying to influence renal symptoms by treatment of a bladder-neck urethral lesion it must not be forgotten that this may become all the more difficult to do according to the degree of change that has already taken place in the kidneys.

Intravenous urography, as most of us are aware, can give detailed information not only about striking renal changes but about minor ones as well when a series of films from an individual case are studied.

Treatment

The follow-up work done by Garrod *et al.* (1954) has shown that there has been too ready a tendency to claim a cure from internal antiseptics and antibiotics. For these workers have demonstrated that the more time that is allowed to pass before tests for relapse of infection are made the fewer are the cases found free of infection. Moreover, the fact that they proved that a clinical type that recurs is one that has a past history of urinary infection points to the likelihood of a latent urinary infective focus.

All persisting polypi of hillocks must be fulgurated. Urethroscopy must be carried out later if symptoms continue or return. Cases which react badly to treatment must be carefully tested for residual urine. Those with several ounces of residual urine require bladder-neck resection. Some cases without residual urine react badly to treatment, especially those that take sedatives regularly. Gentleness is the watchword for treatment of all cases.

The improvement which often follows the first examination draws attention to the benefit from simple urethral dilatation. This benefit is most likely due to the improved drainage which results from the dilating effect on glandular and adventitious orifices in the urethra. Doing this too often, and using coarsely graded dilators—all uterine dilators—are common faults in technique. Wyndham Powell dilators should always be used.

Uncertain Value of Urine Reports

I hesitate to put forward figures on urine reports in support of claims, because these can vary so much in relation to varying circumstances of the examination. But, for what they are worth, the single reports on urines taken in the 65 cases at the first visit are compared with single reports at varying times from 2 to 12 years after one form of instrumental treatment or another had been carried out; these show that 66% of urines were bacteriologically negative before treatment, compared with 77% after treatment.

The inconspicuous feature of the presence of pus cells noted in the urine reports is emphasized; only 7% of these merited one plus or more.

The value of urine reports, bacteriologically, may be summarized as follows: (1) In a high proportion of cases the urine reports are negative, although endoscopic and symptomatic evidence of an infective urinary tract focus exists.

(2) In spite of clinical improvement it is uncertain that evidence of complete cures from any form of treatment will be found.

Summary

The bladder neck, including the posterior urethra, is considered in some detail as a potential focus of chronic infection in recurring cystitis in women.

Some practical points in relation to urethroscopy are discussed.

There are common patterns of incidence and pathology in decades for cases of chronic frequency and cystitis.

The cervix uteri is considered.

Attention is called to the occurrence of gland structures resembling prostatic tissue in the posterior urethra of females.

A general survey of cystoscopic appearances in frequency and cystitis is made.

The efficacy of local treatment is based on the need to provide the best possible drainage from the infected focus. Residual urine which resists other forms of treatment sometimes calls for bladder-neck resection.

The uncertain value of urine reports is discussed.

LYMPHOGRANULOMA VENEREUM

BY

H.-J. B. GALBRAITH, M.D., M.R.C.P.
Senior Medical Registrar

C. W. GRAHAM-STEWART, F.R.C.S.
Resident Assistant Surgeon

AND

C. S. NICOL, M.D., M.R.C.P.

Physician in Charge of the Department of Venereal Diseases
St. Thomas's Hospital, London

Lymphogranuloma venereum is a venereal disease, usually acquired in tropical or subtropical regions, caused by a filterable virus which is related morphologically and antigenically to the virus of psittacosis. There are even more descriptive synonyms for the condition than is usual, including lymphopathia venereum, lymphogranuloma inguinale, poradenitis venerea, climatic bubo, and Nicolas-Favre disease. It should be distinguished from granuloma inguinale (venereum), an infection by the Gram-negative pleomorphic organism *Donovania granulomatis*.

Although some of the classical studies of the disease were published in Britain (Stannus, 1933; Findlay, 1933; Hanschell, 1938), the number of cases diagnosed in this country is not high; thus new patients seen in special treatment centres in the five years 1951 to 1955 inclusive and enumerated in the annual reports of the chief medical officer of the Ministry of Health total only 363.

Stannus (1933), who suggested that John Hunter in 1786 and William Wallace, of Dublin, in 1833 may have

described cases of the bubonic form of lymphogranuloma venereum, thought that the scarcity of reports of infection in Great Britain was due to the lack of recognition of the disease by the medical profession. The experience of King *et al.* (1956) supports this view. Frei tests were performed on all patients attending the venereal diseases clinic of the London Hospital during a 13-months period. Active infection with lymphogranuloma venereum, as shown by a positive skin test and a complement-fixation test positive at a serum dilution of 1 in 32 or more, was found in 23 out of 1,119 patients (2%). Almost half of the patients with positive reactions had clinical evidence of infection. However, in spite of a more widespread appreciation of the clinical features of the disease, and in spite of the greater facility with which complement-fixation and skin tests for the disease can be carried out, there were, until the above-mentioned report, fewer than 20 instances in the literature of patients who have acquired the infection in this country and in whom the diagnosis is indubitable (see Subsidiary References).

Hanschell (1938), who had a considerable experience of the disease, reported that in 19 years of observation in a London dockside hospital he had seen no cases of indigenous infection. The disease is apparently transmitted in exudates from ulcerated lesions which in the male are usually present for only a short time. Males constitute the bulk of travellers from the tropical and subtropical areas where lymphogranuloma venereum is endemic, and the short incubation and infectious phases will often be completed during the journey to this country. It has been suggested that the infectious phase is for practical purposes further curtailed by the fact that the man is rendered *hors de combat* for much of this time by the concomitant painful buboes (Stannus, 1933). It is probable, therefore, that hitherto infectious cases have rarely reached this country and that "reservoirs" of infection have not developed here. With the increasing use of air travel and with the influx of immigrants from the West Indies, where lymphogranuloma venereum is extremely common, this situation may be altered.

In this paper the cases of two patients who acquired lymphogranuloma venereum in this country and who presented in the immediate post-primary stage are reported, together with details of four other cases which also attended this hospital during a recent period of four months and which illustrate other syndromes of the disease.

Case 1

A West Indian negro aged 39 while in his early teens had had swellings in the left groin which had discharged and healed, leaving some linear scars. He admitted several sex contacts before this. Since coming to this country three years ago he had been treated on two occasions for acute gonorrhoea. Three weeks before admission he had intercourse with a coloured West Indian woman whom he met casually. About ten days later he developed an itching blister on the glans penis. The blister was broken by scratching, but healed within a few days, at which time bilateral inguinal swellings developed; these increased in size and became painful. He came to hospital complaining of the painful groin swellings and of headache.

On admission he had an intermittent fever to 100.6° F. (38.1° C.) with a pulse rate of 70-84 a minute. There was no neck stiffness. On the dorsum of the glans penis adjacent to the corona there was a depigmented area indicating the site of the recent lesion. There were tender enlarged glands in both groins above and below the inguinal ligaments, with oedema and induration of the surrounding subcutaneous

1403

tissue and overlying skin. Each swelling was divided by a deep skin groove (see Fig.). The changes were more obvious on the right side, where the external iliac glands were also palpable and slightly tender. A few small glands were palpable in both axillae. The scar of a recently healed boil was present on the right wrist and there was a small discharging pustule in the left suprapubic region. Proctoscopy demonstrated mucopus lying on an inflamed rectal mucous membrane. The Frei skin test was positive: an area of induration 8 mm. in diameter was present at 48 hours.

Case 1. Note groove in bubo and pigmented area on glans penis.

A complement-fixation test for lymphogranuloma venereum was positive at a serum dilution of 1 in 16, the titre falling to 1 in 8 12 days later. Other investigations showed: haemoglobin, 10.6%; white blood cells, 5,100 per c.mm. (neutrophils 80%), E.S.R. 41 mm. in one hour (Westergren); total serum proteins, 7.9 g./100 ml. (albumin 4.8 g., globulin 3.1 g.); electrophoresis of serum proteins showed prominent alpha-2 and gamma-globulin bands; after two weeks the serum globulin had risen to 3.7 g./100 ml. Serum Wassermann and Price precipitation reactions were negative, and the chest radiograph was normal. The episode of inguinal suppuration in this case was thought to be due to a chancre-adolescence in this case was confirmed by a positive crocid bubo; this suspicion was confirmed by a positive dmelcos skin test for infection with *Haemophilus ducreyi*.

Forty-eight hours after treatment was started with tetracycline, 500 mg. every six hours by mouth, some reduction in the swelling and tenderness in the groins was apparent. On the fourth day of treatment the patient became, and subsequently remained, afebrile. Tenderness had disappeared within six days of starting treatment, and after 14 days there remained only slight inguinal-gland enlargement without apparent periadenitis. The dosage of tetracycline was reduced to 250 mg. every six hours after five days and to 250 mg. every 12 hours after a further eight days; the anti-biotic was stopped on the nineteenth day after a total of 20 g. had been given.

Between the times of his extramarital exposure and of the appearance of symptoms the patient had had intercourse with his wife. Her Frei test and lymphogranuloma venereum fixation test were normal three weeks after this coitus. She failed to attend subsequently for the tests to be repeated.

Case 2

A male West Indian negro aged 31 was referred to the department of venereal diseases with tender enlarged glands in the groin. Two years previously he had been treated for acute gonorrhoea. He had suffered from bouts of mild central abdominal pain for some years and from a cough for about one year. Since his arrival in England some six months earlier he had had night sweats. His weight had not changed. Eleven days before admission he had felt feverish and a tender swelling had appeared in the right groin. He became constipated and complained of headache and dysuria. Four days later a swelling developed in the left groin. On the day before admission he coughed up some blood-stained sputum.

On examination he had an irregular intermittent fever to 103° F. (39.4° C.) without comparable tachycardia (pulse rate 80-100 a minute). A few glands were palpable in all areas, including both epitrochlear regions. Lying below and parallel to the right inguinal ligament was a chain of enlarged, slightly tender lymph nodes, the most medial of which showed periadenitis with adherence to the skin. A smaller but similar chain of glands was palpable in the left groin, and the right external iliac glands were also enlarged. There was a mild urethritis with no gonococci demonstrable on examination of the urethral discharge by smear and culture. The rectal mucosa was normal on proctoscopy. The Frei test was positive, with an area of induration 10 mm. in diameter after 48 hours. The complement-fixation test for lymphogranuloma venereum was positive at a serum dilution of 1 in 32.

Other investigations showed: haemoglobin, 10.6%; white blood cells, 6,000 per c.mm. (neutrophils 49%, lymphocytes 34%, monocytes 9%, eosinophils 8%); E.S.R., 15 mm. in one hour (Westergren); total serum proteins, 8.4 g./100 ml. (albumin 5.8 g., globulin 2.6 g.); electrophoresis of serum proteins showed a prominent gamma-globulin band. Dmelcos skin test was positive. Serum Wassermann and Price precipitation reactions were negative and the chest radiograph was normal. Tetracycline was given in the same dosage pattern as in Case 1. After 72 hours the patient was afebrile and had no headache; the right external iliac glands were no longer palpable and the tenderness of the inguinal glands had disappeared. Before the patient defaulted nine days later, the groin glands were becoming smaller and more mobile.

Case 3

A coloured West Indian woman aged 32 had for three months, since shortly after her arrival in England, been the regular consort of the previous patient (Case 2). Her attendance at hospital for investigation as a contact was therefore arranged and she was subsequently admitted. She had given birth to a child a year before and since delivery had had leucorrhoea. There were no symptoms suggestive of infection with lymphogranuloma venereum, but for four months she had suffered from a cough. Two weeks before admission there had been pain in the right chest and on one occasion she had produced blood-streaked sputum.

On examination she had a fever to 99.6° F. (37.6° C.). There were a few palpable but not very large glands in the axillae and groins. A small irregular punched-out ulcer was present on the inner surface of the right labium minus. Proctoscopy revealed a slight purulent proctitis. The Frei test was positive, with an area of induration 12 mm. in diameter. The complement-fixation test for lymphogranuloma venereum was positive at a serum dilution of 1 in 256. Examination of her blood showed: haemoglobin, 96%; white cells, 7,700 per c.mm. (neutrophils 38%, lymphocytes 34%, monocytes 10%, eosinophils 17%); E.S.R., 28 mm. in one hour (Westergren); total serum proteins, 8.6 g./100 ml. (albumin 4.8 g., globulin 3.8 g.); electrophoresis of serum proteins showed a prominent gamma-globulin band. A radiograph of the chest showed slight shadowing of doubtful significance at the extreme left apex. The sputum was negative for tubercle bacilli on smear and contained no ova or mites.

Before investigation or treatment could be completed the patient took her own discharge because her consort failed to visit her in the ward. She had then received 10 g. of tetracycline during five days and the vulval ulcer had almost healed.

Case 4

For about one week before his admission, while travelling from Jamaica, a male negro aged 48 was treated in the ship's hospital for central abdominal pain and diarrhoea. A more accurate history was unobtainable owing to the patient's low

intelligence. His temperature was 98.4° F. (36.9° C.) and his pulse rate 80 a minute. Tenderness and guarding were present in the right iliac fossa. On rectal examination there was tenderness on the right side of the pelvis. A scar was present in the right groin.

Acute appendicitis was suspected and appendicectomy was performed through a McBurney incision. The appendix was firm and pale. There was at least 5 oz. (140 ml.) of clear straw-coloured fluid in the peritoneal cavity. A Meckel's diverticulum was sought but not found. There were some slightly enlarged mesenteric glands. Macroscopic section of the appendix showed thickening of the submucosa, and microscopically there were the changes of mild chronic inflammation. The ascitic fluid contained no acid-fast bacilli on smear, and a Löwenstein culture was negative.

Post-operatively the patient had an irregular intermittent fever to 102° F. (38.9° C.), and in view of the indefinite changes found at operation further investigations were made: haemoglobin, 108%; white blood cells, 4,100 per c.mm. (neutrophils 85%); E.S.R., 18 mm. in one hour (Westergren). The serum Wassermann and Price precipitation reactions were negative. On the sixth post-operative day he complained of suprapubic pain; albumin and pus cells were found in the urine and a course of sulphadimidine (21 g. over six days) was given. A mid-stream specimen of urine, obtained before this treatment started, was later reported to contain no albumin, only a few white blood cells and epithelial cells, and to be sterile on culture. He was then found to have bilateral moderately enlarged and slightly tender inguinal glands with some tenderness over the right external iliac glands. On proctoscopy a small piece of mucus was seen on the anterior rectal wall. A Frei test was positive. Complement fixation test for lymphogranuloma venereum was positive at a serum dilution of 1 in 16.

Fifteen days after admission the E.S.R. had risen to 35 mm. in one hour (Westergren); the total serum proteins were 7.8 g./100 ml. (albumin 4.3 g., globulin 3.5 g.); electrophoresis of serum proteins showed increased gamma-globulin. Tetracycline, 250 mg. every six hours, was given for the next five days, during which time the affected glands became smaller and less tender. A fortnight after finishing this treatment the glands were no longer palpable.

Case 5

A male Jamaican aged 27, who had lived in the United Kingdom for one year, was admitted to hospital with abdominal pain. This had been present for three days accompanied by anorexia, occasional vomiting, constipation, and fever. At first the pain had been of an aching character and had been situated in the lower abdomen, but it had gradually become more severe and had spread over the whole abdomen.

On examination the patient lay with his knees drawn up; his temperature was 103.2° F. (39.6° C.) and pulse rate 104. There was diffuse abdominal tenderness, maximal in the right iliac fossa, with guarding and rigidity. There was no tenderness on rectal examination. A small ulcerated papule was present on the prepuce dorsally, adjacent to the coronal sulcus, and the inguinal lymph nodes on both sides were enlarged and firm but not tender. He admitted having had a sore on the penis about three weeks before.

Laparotomy was performed through a right lower paramedian incision. There was no ascitic fluid, and no localized lesion was found other than injection of the peritoneal coat of the whole of the small gut. The appendix, which appeared normal, was removed. The fever settled by lysis during the next three days. The Frei test was negative, but the complement-fixation test for lymphogranuloma venereum was positive at a serum dilution of 1 in 128. Two days after operation the E.S.R. was 70 mm. in one hour (Westergren); total serum proteins were 7.8 g./100 ml. (albumin 4.2 g., globulin 3.6 g.); electrophoretic pattern—increased alpha-2 and gamma-globulins.

Case 6

A married white woman first attended hospital in 1937 at the age of 35, shortly after her arrival from Barbados, where she was born. She complained of rectal discomfort with a slight rectal discharge and of difficulty in defaecation for the previous eight years. She was found to have rectal strictures at 2 and 5 in. (5 and 12.5 cm.) from the anus; these required dilatation by the passage of rectal bougies every few weeks. For about six years she suffered repeated attacks of arthritis in her knees. In 1944 a Frei test was positive.

She now (1957) complains of urgency of defaecation with slight faecal incontinence, although there is little evidence of rectal stenosis; her complement-fixation test for lymphogranuloma venereum is positive at a serum dilution of 1 in 16.

Discussion

The clinical picture in Case 1 is typical of the early stages of lymphogranuloma venereum in the male, while Case 2 provides a similar but less complete example of the syndrome. The primary lesion is usually described as a herpetiform vesicle or ulcer, often situated in the region of the coronal sulcus. The lesion, which is painless and often unnoticed by the patient, appears between 3 and 21 days after the infecting coitus and disappears spontaneously in a few days. No palpable scar is produced, but an area of discoloration may result, as in Case 1. The inguinal bubo appears usually between 7 and 30 days, although occasionally months, after infection. These buboes, which are bilateral in a quarter to a third of the cases, have several unusual features which together form an almost pathognomonic picture. Lymph nodes in all sections of the superficial inguinal group are involved, and soon periadenitis with inflammatory obstruction of adjacent lymphatic vessels produces induration of the subcutaneous tissue and of the overlying skin, which may become discoloured. The resulting elongated swelling has its long axis parallel to the inguinal ligament, and is typically grooved in this axis. The principal groove appears to be due to enlargement of lymph nodes above and below the groin fold, which persists owing to the normal adherence here of the superficial fascia to the inguinal ligament. Lesser grooves are due to inflammatory attachment of the skin to deeper structures.

If untreated the bubo begins to fluctuate at several sites owing to patchy suppuration and necrosis. Finally, multiple sinuses without inflamed or ulcerated orifices appear. The external iliac glands often become palpable but do not break down. Constitutional symptoms such as fever and headache are not infrequent. Splenomegaly, arthritis, iridocyclitis, meningitis, or a typhoidal state may occur. Acute abdominal episodes form another rare but well-recognized group of manifestations of systemic involvement (Longmire, 1944). The symptoms may be those of diffuse pelvic peritonitis, or the pain and clinical signs may be more intense in the right upper or lower abdominal quadrants. A local granulomatous lesion may be found at laparotomy, but often only a serous effusion is discovered. Cases 4 and 5 would seem to be examples of this condition. Law (1943) believes that the syndrome which mimics acute appendicitis may occur when the deep iliac and lumbar glands are extensively involved.

Anorectal disease is not as common in the male as in the female, and if present may be due to direct infection following homosexual contact. This does not seem likely in Case 1, in which the infection presumably reached the rectal mucosa via the pelvic lymphatics. Such spread is the rule rather than the exception in the female, for the primary lesions are commonly situated in the upper vagina or on the cervix; as a result of this, pelvic rather than inguinal lymph vessels and nodes become involved in the post-primary stage. This anatomical distribution of the lesions probably accounts for the fact that the early stages of the disease are often symptomless in women. Our Case 3 had no symptoms likely to be due to lymphogranuloma. The vulval ulcer might

represent the secondary genital ulceration described by Greenblatt and Wermer (1945). The very high dilution of this woman's serum at which fixation of complement occurred suggests that the disease had been present for a considerable time, while her consort's symptoms were those usually seen within a few weeks of infection; it seems probable, therefore, that the woman was the infecting partner, especially as it is believed that in women the infectious phase is longer than in men. Although the cause of the cough and haemoptysis in Cases 2 and 3 has not been proved, these symptoms are probably unrelated to the venereal infection.

Proctitis, as seen in very mild form in Cases 1, 3, and 4, may, if the patient is not treated by antibiotics, lead after many months or years to stricture formation. This syndrome, which is commoner in women, is exemplified by Case 6. This patient's recurrent arthritis is similar to the arthritis described in other patients with lymphogranuloma venereum; the knees are among the joints most commonly affected (Longmire, 1944). Many sufferers from lymphogranulomatous strictures also have anorectal or rectovaginal fistulae, which characteristically open internally close to the stricture on its anal side. Another late manifestation of lymphogranuloma seen in women is the condition known as esthiomene, in which ulceration and elephantiasis of the external genitalia produce gross deformities.

The diagnosis in our cases is confirmed by the raised titres of the complement-fixation tests and, in all but one case, by the positive Frei intradermal tests. The Frei test becomes positive usually between 7 and 40 days after the appearance of adenitis, and may remain positive for life. It is uncertain as yet whether antibiotic treatment may cause a reversal. The criteria on which a diagnosis can be made, using the complement-fixation test, Bedson *et al.* (1949) concluded that, in a patient with symptoms compatible with a diagnosis of lymphogranuloma venereum, a titre of 1 in 16 or over indicates active infection and a titre of 1 in 32 is suggestive of infection. There is no typical leucocyte response to lymphogranuloma venereum or to any particular manifestation thereof. Eosinophilia has been reported, but the presence of parasites cannot be excluded as a cause of the eosinophilia in Cases 2 and 3. Hyperglobulinaemia without other evidence of liver disorder is a well-recognized accompaniment of lymphogranuloma venereum; the gamma fraction largely accounts for the increase, the degree of which is related to the activity and duration of the disease. The greatly increased sedimentation rates sometimes found in lymphogranuloma are probably dependent on this change in the plasma globulin.

The tetracycline group of antibiotics provides specific therapy. In the earlier manifestations of the disease dosages of 250 mg. four times a day for from 15 to 30 days produce complete control of the infection with disappearance of the buboes and healing of open lesions without subsequent recurrence. In the later stages, with strictures, fistulae, and elephantiasis, prolonged antibiotic therapy should precede any surgical procedure. There were no toxic complications from the use of tetracycline in any of the four cases we treated with this drug. The sulphonamide drugs also have some therapeutic action in lymphogranuloma venereum, and the course of the disease in Case 4 was probably modified by the sulphadimidine given him for the suspected urinary infection.

Summary

To the small group of patients recorded as having acquired lymphogranuloma venereum in Great Britain are added two with the inguinal syndrome seen in the immediate post-primary stage.

The cases of two other male patients who illustrate the rare pseudo-appendicitis syndrome, that of a woman with the late anorectal syndrome, and that of a symptomless but probably infectious female patient are also reported.

The recent influx of West Indian immigrants of both sexes and the greater likelihood, with the rapidity of air transport, of males reaching Great Britain in the infectious state may make lymphogranuloma venereum a commoner clinical problem in this country.

Our thanks are due to Mr. R. H. Boggon and Professor J. B. Kinmonth for permission to publish details of cases under their care.

CAUSE OF ANOMALOUS RESULTS IN THE ERYTHROCYTE SEDIMENTATION RATE USING WINTROBE'S METHOD

BY

F. T. SHANNON, M.B., M.R.C.P.

AND

E. G. L. BYWATERS, M.B., F.R.C.P.

From the Special Unit for Juvenile Rheumatism,
Canadian Red Cross Memorial Hospital, Taplow,
Maidenhead, Berks

In current clinical practice the erythrocyte sedimentation rate (E.S.R.) is usually measured by either the Westergren method (Westergren, 1921), using citrated and diluted blood, or by the Wintrobe method (Wintrobe and Landsberg, 1935), using oxalated undiluted blood. While the latter method has some practical advantages in that haematocrit readings can be made in the same tube and the oxalated blood specimen can be used for other routine haematological investigations, there is evidence that the Westergren method provides a more reliable index of disease activity and progress (Gilmour and Sykes, 1951; Goldberg, Glynn, and Bywaters, 1952; Goldberg and Conway, 1952; Alexander and Andrews, 1957). These authors have pointed out the occasional failure of the Wintrobe method to reflect the clinical state of the patient when the disease process is very active; the anomaly is seen of a high Westergren rate associated with a normal or near normal Wintrobe rate.

The Wintrobe method continues to be widely used, and it was felt that further information on the incidence and causes of such anomalous readings would be of value.

Incidence of Anomalous Wintrobe Readings

For the past five years all in-patients in this unit have had weekly E.S.R.s measured by both the Westergren and the Wintrobe method simultaneously, together with the

haematocrit. The number of duplicate readings thus obtained is estimated to be at least 19,000. For the purpose of this investigation these results have been sampled by taking a random selection of the case histories of 100 patients and analysing all the E.S.R.s recorded at weekly intervals during their hospital stay. The total number of duplicate readings in this sample was 2,540. The patients were mainly children or young adults, the diagnosis being rheumatoid arthritis in 40 and rheumatic fever or chorea in 47. The remaining 13 were a miscellaneous group consisting of cases of lupus erythematosus, polyarteritis nodosa, dermatomyositis, erythema nodosum, and Henoch-Schönlein purpura.

An arbitrary definition of an anomalous result was used for the purposes of analysis: this was the occurrence in simultaneous readings of a Westergren rate of 50 mm. or more in one hour associated with a Wintrobe rate of less than 20 mm. in one hour. Such a result has been termed "discordant." When the Wintrobe rate was 20 mm. or more in one hour in association with a Westergren rate of 50 mm. or more in the hour, the result has been termed concordant.

When a discordant result occurred, the clinical notes showed that without exception the Westergren rate was a more accurate reflection of the activity of the disease either as assessed at the time or as revealed by the subsequent clinical course. Not infrequently serial weekly rates would all show discordancy, and in these cases the Wintrobe readings rarely gave any useful information about deterioration or improvement that could be seen both clinically and in the Westergren readings.

From the Table, where the results of 2,540 simultaneous readings are summarized, it will be seen that such anomalous Wintrobe readings were found on at least one occasion in 26 of the 100 cases and that they occurred in 4.6% of all readings. When Westergren readings of 50 mm. or more an hour are considered, then 23% of the corresponding Wintrobe readings were below 20 mm. an hour, and thus failed to provide an accurate indication of the activity of the disease process. With each set of duplicate readings the

Frequency of Discordant Westergren/Wintrobe Readings in 100 Cases of Rheumatic Fever (R.F.), Rheumatoid Arthritis (R.A.), and Others (Misc.)

	No. of Cases	No. of Duplicate Readings	Westergren Readings > 50	West. > 50 Wint. < 20 (Discordant)	No. of Cases Showing Discordancy
R.A.	40	1,280	383	108	19
R.F.	47	1,014	86	7	6
Misc.	13	246	29	1	1
Total	100	2,540	498	116	26

haematocrit level was recorded, and it was found that the mean P.C.V. of the discordant group was 40.6 ml./100 ml. and that of the concordant group was 36.5 ml./100 ml. (The difference is 4.1 ml., over 10 times its standard error of 0.31 ml.)

Fig. 1 shows in a child with Still's disease that over the course of one year 29 out of 55 Wintrobe readings, each accompanied by a Westergren reading over 50 mm./hour, were below 20 mm./hour, and some loose association with high haematocrit level may be seen as Lewi and Clarke (1954) have noticed. There is rather a wide scatter, however, when the haematocrit level is plotted for the same period against erythrocyte sedimentation rate Wintrobe (Fig. 2). These anomalous results seem more frequent in patients on cortisone therapy, and, as may be seen in Fig. 3, when the dosage is decreased or discontinued tend to disappear in a reverse direction to changes in haematocrit value. It may also be seen from inspection of this chart that haematocrit change is not the only conditioning factor.

Factors in Causation of Anomalous Wintrobe Readings

Experiments were therefore carried out to establish more accurately the conditions under which anomalous Wintrobe readings may occur. The influence of three factors was studied: the haematocrit, the plasma viscosity, and the internal diameter of the sedimentation tube.

FIG. 1.—Girl aged 4 years. Still's disease. Course, over 59 weeks, of E.S.R. (Wintrobe and Westergren) and of haematocrit readings, showing development of anomalous Wintrobe readings on cortisone associated with high haematocrit levels.

Methods

Blood samples were obtained by venepuncture in the antecubital fossa, dry syringes and needles being used. 2 ml. of blood was placed in a bottle containing 0.5 ml. of 3.8% sodium citrate and 6 ml. in a bottle containing 10 mg. of a dried oxalate mixture (ammonium oxalate 6 mg.+ potassium oxalate 4 mg.).

On the citrated specimen a Westergren one-hour E.S.R. was carried out, using standard 200-mm. tubes and techniques.

On the oxalated specimen a Wintrobe one-hour E.S.R. was carried out, using a standard 100-mm. tube and technique. The standard Wintrobe tube has a bore of 2.5 mm. diameter. At the same time and from the same specimen, a second tube having an internal diameter of 4.5 mm. was set up in exactly the same manner and in the same stand, the E.S.R. being read together with that in the standard tube. (On some specimens a third tube having an internal diameter of 3.5 mm. was set up in an identical fashion, and when this was done the upper levels of the red cells were read at 10-minute intervals for two hours on all three tubes.)

Fig. 2.—Same case as Fig. 1. Correlation between E.S.R. and haematocrit readings is poor except at low haematocrit levels. Dotted line represents Hynes and Whitby correction curves. All Westergren readings above 50 mm./hr.

The haematocrit level was measured in the standard Wintrobe tube after centrifuging for 30 minutes at 3,000

r.p.m. The remainder of the oxalated blood was centrifuged for 15 minutes, and the separated plasma used for the estimation of the plasma viscosity.

All viscosity measurements were carried out in the same instrument, a modified Ostwald capillary viscosimeter having a reservoir capacity of 1 ml. This was suspended vertically in a water bath at 37° C. The time of flow of distilled water in this instrument at 37° C. was 41.5 seconds, and all plasma viscosity readings are expressed in relation to this figure—that is, plasma viscosity relative to water at 37° C. = time of flow (plasma)/time of flow (distilled water). (The relative viscosity of pure fibrinogen in normal saline, between 300 and 1,000 mg. per 100 ml., showed thus a linear relation to concentration.)

The viscosimeter was cleaned and dried between each estimation, and after the plasma was placed in the reservoir 15 minutes were allowed for temperature equilibration before readings were taken.

All E.S.R.s were set up within one hour of the blood being taken and plasma viscosity measurements carried out within six hours.

In all, 151 blood samples were tested, and these were obtained mainly from patients with rheumatoid arthritis, rheumatic fever, and chorea, a minority being from patients with other diseases of the collagen group or with pulmonary tuberculosis. Five were from healthy young adults.

Results

It has been shown that the plasma relative viscosity provides a measurement of those plasma protein changes which are responsible for the aggregation and sedimentation of the red cells (Hardwicke and Squire, 1952), and when used as a clinical test provides a more reliable index of disease activity than the E.S.R. (Miller and Whittington, 1942; Lawrence, 1950). Thus the viscosity measurements may be used as a standard by which the effect of the other variable factors in red-cell sedimentation may be assessed.

In this series, the relative viscosity of plasma ranged from 1.65 to 2.39, and was considered to reflect accurately the patients' clinical state. The upper limit of readings found in normal people and those cases showing no evidence of disease activity was 1.8, and figures above this were considered abnormal.

When the mean one-hour E.S.R.s are plotted against plasma viscosity (Fig. 4) the curves given by the Westergren and standard Wintrobe methods show several differences. Beyond a relative viscosity of 1.8, the mean Westergren rate rises more rapidly than the Wintrobe to a maximum at a viscosity of 2.3. The Wintrobe rate shows a maximum rate of increase from a viscosity of 1.8 to 2.0, after which a very small increase occurs to a maximum at a viscosity of 2.1; the rate then decreases until the mean rate attained at a viscosity of 2.3 is only as high as that attained between 1.9 and 2.0.

The effect of the haematocrit on the standard Wintrobe E.S.R.s is shown in Fig. 5. In this graph the readings at each viscosity level have been divided into three groups

FIG. 3.—Boy aged 14 years. Still's disease. Development of anomalous Wintrobe readings on cortisone, partially independent both of haematocrit levels and of Westergren rates.

according to the packed cell volume (39% and below, 40-42%, and 43% plus). An increase of the haematocrit level reduces the overall height of the curve, and each curve reaches a maximum rate, after which a fall takes place. The viscosity level at which this maximum mean rate is reached becomes progressively lower with increasing haematocrit readings, so that in the group with P.C.V. 43% and above the maximum mean rate is reached at a viscosity of 2, the descending limb of the curve is as long as the ascending limb, and the mean reading at the maximum viscosity is in fact the same as that shown in a normal range of viscosity (1.7-1.8). When a similar subdivision of the Westergren readings is made the curves obviously do not show such a regular relationship to the plasma viscosity (Fig. 6); but, while there is a depression of the mean rates in the highest haematocrit group at viscosity levels below 2.1, the maximum mean rates in each group are reached at the maximum

FIG. 4.—Relationship of mean E.S.R. to mean plasma relative viscosity. (Figures on curves indicate number of readings.)

FIG. 5.—Effect of relative viscosity on Wintrobe E.S.R. at three haematocrit levels: there is a significant difference at a viscosity of 2.3 between each of the three haematocrit groups.

FIG. 6.—Effect of relative viscosity on Westergren E.S.R. at three haematocrit levels.

viscosity level. In the series there were 39 Westergren readings of 50 mm./hour or above; in nine of these readings the Wintrobe rate was below 20 mm./hr. The 30 concordant

FIG. 7.—Effect of tube diameter on E.S.R. at varying relative plasma viscosities: all haematocrit levels 40% or more. The differences between the two curves at relative viscosities of 2.2 and 2.3 times are statistically significant.

FIG. 8.—Mode of fall at three tube diameters (Wintrobe) in anaemic blood of high Westergren E.S.R.

FIG. 9.—Mode of fall at three tube diameters (Wintrobe) in blood with more normal haematocrit level and high Westergren E.S.R. (see text).

readings had a mean P.C.V. of 37.2% and mean viscosity of 2.1, while in the nine discordant readings the mean P.C.V. was 42.7% and the mean viscosity 2.2 times.

The readings obtained in the modified tube of 4.5 mm. internal diameter were of the same order as those in the standard Wintrobe tube when the P.C.V. was below 40%. Above this level, however, a difference is seen in those instances where the plasma viscosity exceeds 2.1 (Fig. 7). The mean readings in the standard tube fall off rapidly after this viscosity level, but those in the 4.5-mm. tube show a further rise to 2.2, after which they too are slightly lower. Of the nine readings which were discordant on the basis of the standard Wintrobe rates, only two were discordant in the 4.5-mm. tube. No discordant reading rates found in the 4.5-mm. tube unless it was also given by the standard tube.

Differences in the mode of fall in tubes of 2.5 mm., 3.5 mm., and 4.5 mm. are illustrated in Figs. 8 and 9, where the E.S.R. is plotted at 10-minute intervals for two hours. With the first blood sample (Fig. 8), where the P.C.V. was 35% and Westergren rate 68 mm./hour, all three tubes show the typical sigmoid curve with a flat initial "period of aggregation" followed by a rapid fall until packing of the cells shows the rate of fall. In the second sample (Fig. 9), however, with a P.C.V. of 40% and Westergren rate of 86 mm./hour, the initial period of aggregation is followed in the standard tube by a slow rate of fall over the two-hour period, while the 4.5-mm. tube exhibits the typical sigmoid curve and the 3.5-mm. tube shows an intermediate pattern. The one-hour readings are discordant in the 2.5-mm. tube but not in the 4.5-mm. tube.

Discussion

When a high Westergren rate and a low Wintrobe rate occurred together the clinical evidence suggested that the latter observation was at fault. Correlation with plasma viscosity, while not entirely regular, was more consistent with the Westergren readings. Clinical support for this view is the Westergren readings. Clinical support for this view is the Westergren readings. Clinical support for this view is the Westergren readings.

The frequency with which erroneous Wintrobe results may be encountered obviously depends on the criteria adopted. In the group considered here the large discrepancy between the two readings which we took to define an anomalous result gives a conservative estimate of the frequency with which Wintrobe results are erroneous. Gilmour and Sykes (1951), in a series of over 700 patients, the majority of whom had pulmonary tuberculosis, found that when the Westergren rate was above the accepted normal level the Wintrobe readings were within normal limits in 27% of the female cases and 28% of the male cases. Goldberg *et al.* (1952) reported anomalous results in 10 of 86 patients.

The causation of this discrepancy has been the subject of several reports, in Scandinavian literature (Östner, 1952) and in English. Schuster (1939) found that the tube diameter was inadequate in blood with a high red-cell count. Collins, Gibson, Race, and Salt (1939) also found the tube diameter to be important, and advocated the use of a wide-bore tube. Hardwicke and Squire (1952) and Eastham (1954) demonstrated that the rate was retarded in plasma of high viscosity. Lewi and Clarke (1954) pointed out that the depression of the rate by increasing haematocrit values was disproportionate in plasma of a "high rouleaux formation intensity."

The results of the experiments reported here confirm each of these observations and enable them to be integrated into a reasonable and simple explanation of the anomalous rate.

The fundamental fault appears to be in the narrow internal diameter of the Wintrobe tube. An increase in the tube diameter increased the one-hour E.S.R. of blood showing anomalous rates in the standard narrow tube when

conditions are otherwise identical (Fig. 7). The tube diameter becomes important only when the P.C.V. and plasma viscosity are in the upper half of the range, as the mean readings in the first part of Fig. 7 are almost identical. The effect of these two factors is additive: as the haematocrit value increases, the level of viscosity at which retardation of the rate is seen decreases (Fig. 3).

The combination of these three factors enables a logical hypothesis to be formed in the light of the known mechanism of the E.S.R. As the red-cell aggregates fall they displace upwards the plasma in the lower half of the blood column, the force producing this movement being the difference between the specific gravity of the cell aggregates and that of the plasma. Frictional resistance occurs at the cell/plasma and plasma/tube-wall interfaces. When the haematocrit level is increased a greater volume of plasma must be displaced and a decrease of the "apparent settling velocity" of the cells occurs (Ham and Curtis, 1938).

If at the same time as the haematocrit level increases there is an increase in the plasma viscosity, it is clear that a further diminution in the rate of fall of the red cells must ensue owing to an increase in the frictional forces. In these circumstances the internal diameter of the tube becomes increasingly important, since the total frictional resistance offered by the tube wall to the upward movement of the plasma at any viscosity level is inversely proportional to the fourth power of the radius.

This explanation would account for all the facts observed in the experimental investigation. Such a combination of circumstances does not appear in the Westergren method in the usual range of P.C.V. and plasma viscosity because these are both substantially reduced by the diluting anticoagulant used.

Conclusions

When the sedimentation rate is estimated by the Wintrobe method the incidence of misleading results is high enough to outweigh its advantages, which are mainly of a technical nature.

The erroneous results are due to the additive effects of the inadequate bore of the Wintrobe tube, a high plasma viscosity, and a haematocrit level above 40 ml./100 ml. As the haematocrit level increases above this figure the incidence of erroneous results increases rapidly, and it is clear that no adequate method of correction based on the haematocrit level alone can be applied.

Our thanks are due to Dr. R. Consden for his help and advice.

The Ministry of Health's leaflet "Maternity Care," first brought out in 1949, describing the various services available to expectant and nursing mothers under the National Health Service, has again been brought up to date. Every mother receives a copy when she obtains her welfare food documents from the local offices of the Ministry of Pensions and National Insurance. A small stock of the revised leaflet is being sent to local health authority clinics and hospital maternity clinics to meet occasional demands.

This paper springs from an attempt to assess the clinical significance of idiopathic hirsutism in women. The association between hirsuties and other masculine characteristics, and with disturbances of menstrual periodicity, has been investigated and the familial incidence of the condition studied.

As a necessary preliminary to the inquiry a survey on the variations in the degree of hair growth in women was undertaken. The results are to be reported elsewhere (Thomas and Ferriman, 1957). The lip, chin, and lower abdomen were chosen for study, and observations were made upon a consecutive series of 584 general medical and surgical patients unselected except in so far as patients with diseases, such as myxoedema, known to influence hair growth were excluded. It was found that there was no clear demarcation between hirsute and non-hirsute subjects, hirsuties existing as a graded phenomenon. A system of grading was therefore elaborated, five grades of terminal (coarse) hair growth being recognized at each site. Grade 0 was the absence of hair. There were two minor grades (1 and 2) and two major grades (3 and 4), the latter approximating to the popular conception of hirsuties. In the 15-44 age group a little over one-half showed a grading of 0 at all three sites, whereas an appreciable proportion—in the region of 10-15%—had a major degree of hirsuties at one or more sites. In the post-menopausal period the incidence of facial hirsuties increased greatly, whereas hair on the lower abdomen virtually disappeared.

Hirsuties, Body Build, and 17-Ketosteroid Excretion

It seemed of interest to determine whether any relationship existed between the degree of hair growth and other characteristics which show differences between the sexes. Shoulder and hip width and the 24-hour urinary excretion of 17-ketosteroids were chosen for study. A comparison has been made between results obtained for groups of "hirsute" and "non-hirsute" subjects.

Probably the most useful means of distinguishing between the skeletal measurements of males and females is a comparison between shoulder and hip widths (for example, Tanner, 1951; Lindegård, 1953; Škerlj, 1953), males having a greater shoulder width and females a greater hip width in relation to height.

Measurements of biacromial and bi-iliac width were made on 43 hirsute subjects and 101 non-hirsute subjects, all being within the 18-44 age range. Hirsute subjects were defined as individuals showing a major degree of hirsuties on the lip, chin, or lower abdomen; they were a selected group derived from various sources. A subgroup, comprising those in whom the onset of hirsuties was stated by

the patient to have been during adolescence, was also utilized. The non-hirsute group consisted of a consecutively observed series taken from the survey reported by Thomas and Ferriman (1957) with zero or minor grades of hirsuties. The results obtained are shown in Table I, where the means

TABLE I.—Mean Biacromial and Bi-iliac Widths, in Centimetres, for Non-hirsute and Hirsute Subjects

Group	Biacromial Width	Bi-iliac Width	No. in Group
Non-hirsute	36.63 ± 1.60	29.04 ± 1.74	101
Hirsute:			
All subjects	37.71 ± 1.95	29.19 ± 1.63	43
Onset during adolescence	38.40 ± 1.64	28.98 ± 1.73	24

and standard deviations for the different groups are given. The difference between the non-hirsute and all hirsute subjects is brought out clearly in Fig. 1.

Biacromial width is significantly greater in the hirsute as compared with the non-hirsute group employing the *t* test ($t=6.66$; $P<0.001$), and is particularly so for the hirsute subgroup with onset of hirsuties during adolescence ($t=7.68$). No significant difference between the groups with respect to bi-iliac width is detectable (by analysis of variance). This latter finding indicates that the observed difference in shoulder width does not depend upon differences in general body size.

Estimations of the 24-hour urinary excretion of 17-ketosteroids were obtained for 66 hirsute and 25 non-hirsute subjects. The hirsute group was similar to that just described; the non-hirsute group consisted of individuals with a grading of not greater than 1 at all three areas, the large majority having a grading of 0 at each site. The results obtained are displayed in Fig. 2. The histogram demonstrates a striking difference between the two groups. The mean value for the hirsute group was 13.02 ± 6.6 mg./24 hours, the corresponding value for the non-hirsute subjects being 7.00 ± 2.6 . It is of interest that this latter value is appreciably lower than that ordinarily found for the normal female 17-ketosteroid excretion, but it will be realized that it is derived from a specially selected group. The difference between the two is statistically significant ($t=4.45$; $P<0.001$).

Hirsuties and Menstrual Periodicity

The association generally believed to exist between hirsuties and oligomenorrhoea was investigated during the course of the survey on hair growth in women to which

FIG. 1.—Distribution of biacromial widths for hirsute and non-hirsute subjects.

CONSTITUTIONAL VIRILISM

BRITISH
MEDICAL JOURNAL 1411

reference has already been made. A menstrual history was taken in all 584 patients. For the purpose of this investigation it was decided to accept as oligomenorrhoea only the occurrence of cycles of at least five weeks and when this had been present for at least two years. Many patients were of course more severely affected than this. The change in hair distribution which takes place in later life precludes the consideration of decades above the age of 54. Patients whose lower abdomens had been shaved for abdominal operations before being examined were excluded. There remained 349 patients for analysis.

Table II shows the incidence of oligomenorrhoea in patients with a major degree of hirsuties on the lip, chin, or lower abdomen (hirsute) as compared with the incidence in the remainder (non-hirsute). It will be seen that 10 out of 53 hirsute patients as compared with only 13 out of

TABLE II.—Incidence of Oligomenorrhoea in Hirsute and Non-hirsute Subjects

Age Group	Non-hirsute		Hirsute	
	Oligomenorrhoea	Total	Oligomenorrhoea	Total
15-24	3	68	2	14
25-34	3	64	4	16
35-44	3	67	2	11
45-54	4	97	2	12
Total	13	296	10	53

296 non-hirsute patients suffered from oligomenorrhoea. The difference is highly significant ($\chi^2=28.95$; $P<0.001$).

Recently a small but more elaborate analysis was begun, employing a grading of hair growth over the trunk and limbs in addition to the sites already described and using somewhat less stringent criteria for the occurrence of oligomenorrhoea. The correlation between oligomenorrhoea and menorrhoea. The correlation between oligomenorrhoea and hirsuties is emphasized, this menstrual disturbance occurring in 6 out of 9 of hirsute patients and in only 7 out of 99 of non-hirsute patients.

The incidence of epimenorrhoea in the same group of 349 patients was also studied, but no obvious difference between hirsute and non-hirsute patients in this respect was apparent.

Inheritance

The idiopathic form of hirsuties is generally thought to be familial in nature. It was decided to investigate this point by interviewing all possible relatives of subjects below the age of the menopause with a major degree of hirsuties, the only restriction being that those interviewed should live within a reasonable distance of the hospital. Because of limitations of time it was possible to examine the relatives of only 29 probands, and of the first-degree relatives 16 sisters and 24 mothers were seen.

Table III shows the incidence of a major degree of hirsuties at any of the three sites in the mothers, in the sisters, and in a control group. The increased incidence of

TABLE III.—Incidence of Hirsuties in Relatives of Hirsute Subjects

	Hirsute	Non-hirsute
Sisters	9	7
Mothers	11	13
Control group	32	208

hair on the lip and chin occurring with age introduced a complicating factor; all mothers with a major degree of hirsuties on the lip and chin were therefore asked at what age the excess hair had appeared, and only when this was before the menopause was the hirsuties regarded as significant. The control group consisted of all subjects in the 15-44 age group of the survey reported by Thomas and Ferriman (1957) in whom it had been possible to estimate the degree of hair growth at all three sites.

The incidence of hirsuties is clearly greater in both sisters and mothers than in the control group, and the differences are statistically significant (for the sisters $\chi^2=11.30$, $P<0.001$; for the mothers $\chi^2=9.95$, $0.01>P>0.001$).

Calculation of the degree of correlation between the hirsuties grading as between sisters and between daughters and mothers demonstrates that it is approximately equal for both, the value of the correlation coefficient being in the neighbourhood of 0.5. This, taken in conjunction with the fact that hirsuties exists as a graded phenomenon, suggests that the inheritance is multifactorial.

The incidence of oligomenorrhoea in the sisters and mothers was also compared with that in the same control

TABLE IV.—Incidence of Oligomenorrhoea in Relatives of Hirsute Subjects

	Oligomenorrhoea	Total
Sisters	5	16
Mothers	3	24
Control group	16	240

group. The results are given in Table IV. The incidence in both groups of relatives is higher than in the controls. The difference is definitely significant for the sisters ($\chi^2=8.51$; $0.01>P>0.001$), but does not reach the level of statistical significance for the mothers ($\chi^2=0.92$).

An observation of some interest concerned the variability of the condition within members of the same family. Relatives of patients with major grades of hirsuties on the lip, chin, or lower abdomen were encountered with oligomenorrhoea but without hirsuties of this order. A more extensive assessment of hair growth involving other areas of the body might have revealed a tendency to hirsuties in these relatives. However, oligomenorrhoea probably occurs at times without gross hirsuties in the syndrome under discussion, and gross hirsuties can certainly exist with normal menstrual periodicity.

Discussion

The association of major degrees of hirsuties with increased shoulder width and a raised urinary excretion of 17-ketosteroids reported here is considered to indicate a general tendency towards masculinity in hirsute women. The recognition of a constitutional variant in women in which the deviations from the normal are in the male direction has been made several times before (for example, Kretschmer, 1936; Bayer, 1939), although detailed analyses have not been undertaken. Many of the differences between males and females are a matter of degree, and in this respect individuals can be regarded not so much as male or female but as masculine or feminine. The term androgyny (Draper, 1941) has been employed to refer to the presence of android features in the female and gynaecoid features in the male. This concept has been applied by Tanner (1951) for differences in body build between males and females, and is implicit in the studies on hair growth of Danforth and Trotter (1922) and Dupertuis, Atkinson, and Elftman (1945).

The term "constitutional virilism" is convenient to describe the individuals under discussion. Some 135 such patients have been under study. The condition presents features additional to those described above, and, although these have not been investigated so systematically, some comment is perhaps permissible. Oligomenorrhoea is clearly the characteristic menstrual disturbance, but epimenorrhoea and bouts of menorrhagia have also been encountered. Anovulatory cycles occur with some frequency in some of the patients, but the majority probably ovulate quite regularly. Laparotomies have been performed for various reasons on a number of these patients (only occasionally with a view to wedge resection of the ovaries) and polycystic ovaries have been observed in several. The practice of family limitation and other factors make the assessment of infertility difficult in these days. It can be stated unequivocally, however, that virilism of this character is no

*The material contributed by one of us (P. K. T.) formed part of a thesis submitted for the degree of Doctor of Medicine of the University of London.

absolute bar to conception: indeed, the most hirsute patient in the series had five children. On the other hand, it does appear likely that there is a definite tendency to infertility in a certain proportion of the patients.

Enlargement of the clitoris had not been looked for systematically, but it has been observed on only two occasions, and is regarded as distinctly uncommon. It would also have been of interest to make an assessment of the degree of muscularity and subcutaneous fat development. A further aspect that merits attention is that of the personality structure of these individuals.

Barr and Bertram (1949) reported the discovery of special chromatin bodies in the nerve cells of cats, found only in female animals. These observations were extended to human skin by Moore, Graham, and Barr (1953) and later to other tissues, and it has become customary to think of the relationship as an all-or-none phenomenon. However, it is noteworthy that Davidson and Robertson Smith (1954) noted a considerable variation in the ease with which the characteristic "drumsticks" could be found in polymorphonuclear neutrophil leucocytes from female patients, the incidence ranging from 1:6 to 1:98. Some preliminary observations have been made on the incidence of these chromatin bodies in hirsute women, and, although the numbers as yet are few, a possible difference between hirsute and non-hirsute subjects may exist, a lesser incidence being encountered in the former. This is conceivably a further expression of a general tendency towards masculinity.

Summary

An association has been demonstrated between hirsuties and two other masculine characters in women—namely, increased shoulder width and raised 17-ketosteroid excretion. A significant correlation has also been demonstrated between hirsuties and oligomenorrhoea. The term constitutional virilism is a convenient one to describe the composite syndrome. The condition appears to be genetically determined, and the results obtained suggest that the inheritance is multifactorial.

We wish to thank all those who referred cases, and in particular Dr. Joan Chappell and Mr. K. A. K. Hudson. We thank Professor H. Grünberg, F.R.S., and Dr. J. S. Small for advice. Dr. J. F. Heggie kindly allowed us laboratory facilities. The 17-ketosteroid estimations were performed by Dr. A. B. Anderson, Dr. W. G. Dangerfield, and Mr. C. W. Hall. One of us (P. K. T.) was in receipt of a grant from the North Middlesex Hospital, which is gratefully acknowledged.

"During the last 10 years the majority of men blinded in the second world war have been settled in their homes after the hospitals had healed their wounds and St. Dunstan's had taught them how to be blind." This is stated by Sir IAN FRASER in his introduction to the 42nd annual report of St. Dunstan's, "Blindness Conquered," which covers the year ended March 31, 1957. Throughout the Commonwealth there were about 1,750 such blinded persons; some had stayed in their own countries, where local organizations were looking after them, others had regained some sight, and a substantial number after training had gone back to Commonwealth countries.

RECOVERY AFTER DEPRESSIVE ATTACK OF 30 YEARS' DURATION

BY

G. M. WODDIS, M.R.C.S., L.R.C.P., D.P.M.
Physician-Superintendent and Consultant Psychiatrist.
The Coppice, Nottingham

Most authorities refer to the difficulty of making prognoses in depressive attacks. The statistical surveys of Fuller and Johnston (1931), Lundquist (1945), and Danziger (1946) all refer to the extreme variation in length of attack, but it has not been possible to find any description of a specific case of long duration in any of the literature studied.

The patient who is the subject of this article was studied in one hospital for over 20 years, for 12 years by me personally, and his history shows that he suffered from a single unbroken attack of depressive psychosis lasting at least from 1918 to 1949, when he made a complete recovery at the age of 69. He is still leading an active and successful life.

Case History

The patient, a Church of England clergyman, was admitted to The Coppice in 1929 at the age of 49. He was then extremely depressed, lethargic, retarded in thought, and monosyllabic in speech. He had ideas of personal unworthiness, thought God had deserted him, and his general attitude was one of hopelessness and despair.

He was the youngest child of his father's third marriage, there being 13 children in all. The father, a worrier, irritable, strict, and demanding absolute obedience, was 68 when the patient was born, and lived to the age of 95, working as a parson until he was 90. There was no family history of overt mental illness, and so far as is known no other members of the family have ever needed psychiatric treatment. As a child and at school the patient always felt he was a dud compared with his brothers, who had won open scholarships at Oxford. He was conscientious and drove himself hard, was afraid of failure, and compensated for his feelings of scholastic mediocrity by excelling at games. Apart from this over-conscientiousness there was no evidence of obsessional features in his personality.

He was intended for the study of medicine and was expected to complete his preliminary studies in one term. Hard slogging ended in failure, and he had his first attack of depressive illness then, characterized by suicidal thoughts. The next five years were spent in a mental home, but during the last three years of this period he was employed as games organizer.

His symptoms in this attack were similar to but milder than those which developed in his second major attack. He was depressed, felt that everything was no good, that he was a misery and did not deserve to live. In spite of suicidal thoughts he made no suicidal attempts, and he appears to have made a complete recovery.

At the age of 26 he entered a theological college, was ordained, joined the Indian Army, and went to India at the age of 31. Three years later, on the outbreak of the first world war, he saw service in Mesopotamia, where he was captured by the Turks. Over two years were spent in prison camps, seeing terrible sights and undergoing privation of every sort, some self-inflicted when his sense of duty led him to make sacrifices for those of less favourable rank than himself.

On his return to England he felt that everything was an effort and that he found no pleasure in meeting people. So far as is known he had remained perfectly stable on

DEC. 14, 1957

RECOVERY AFTER DEPRESSIVE ATTACK

his recovery from his first illness for a period of some 14 years, and, although mildly self-depreciatory, did not show depressive phases or mood swings. His marriage and return to India in 1920 brought no improvement. He began to feel a failure and became depressed. Nine months' leave made no difference, but he drove himself on until 1926, when he was invalided home. Treatment in a nursing-home and Maudsley Hospital followed, and by the time he entered the latter in May, 1927, he was acutely depressed, despondent, unable to concentrate, sleeping badly, and had made two attempts at suicide. He was constantly praying for forgiveness for the unpardonable sin.

One month later he was removed from Maudsley Hospital and admitted to Holloway Sanatorium, from which he was transferred to The Coppice in September, 1929.

On his admission to Holloway Sanatorium he was profoundly depressed, said that he had lost God, was unable to concentrate, and could not sleep. At times, especially at night, he was agitated and was praying aloud for forgiveness. As the acute symptoms subsided he remained depressed, quiet, apathetic, self-centred, and monosyllabic. Between then and 1942 his condition altered little. He was unsociable, withdrawn, lacking in initiative, unoccupied, and mute unless directly questioned. The only variation was a gradual diminution in the intensity of his emotions, with monotony of symptoms and affective flattening, until he reached a level of quiet withdrawn depression with self-absorption and self-depreciation as the principal features. This persisted for 13 years.

His mood showed no diurnal variation, and for many years he slept fairly well on 2 dr. (7 ml.) of paraldehyde orally, without early morning waking. He complained constantly of constipation, and his complaints were sometimes justified. He insisted that he had deserted God, had always been no good, and would never be any different. In the garden he paced the same stretch of ground, with bent head, biting his nails.

In 1942, over a period of five months, he received E.C.T. totalling 20 treatments in all. He remained a man without hope, quietly depressed, locked in his own thoughts, and taking little interest in people or things. He insisted he was "dead" but showed a little more physical initiative.

At no time during all these years did his psychiatric condition show any atypical features. There was never any suggestion of a paranoid attitude, and his thinking and behaviour never suggested a schizophrenic component.

In 1948 a sudden change occurred. He began to take an interest in a dog belonging to one of the staff, and started taking it out for walks and training it in obedience. His improvement was now rapid, and he swung into a mildly hypomanic phase, organizing games, looking after the tennis courts and sports equipment, writing his first letter for 20 years, and going to the pictures for the first time in his life. During this phase the minor obsessional traits in his personality were more obvious and his perfectionist demands led to some degree of fault-finding.

After a number of leaves spent working in agricultural camps, he was finally discharged in 1949. He has adjusted himself with complete success to the changed world in which he finds himself, and is working again as a clergyman, enjoying life, and being fit and happy. During most of this time he has worked as a curate in a rural area, sometimes being in charge of three parishes when there was no vicar. He has purchased a small car, which he has learnt to drive, comes to see me regularly on his way to London, and plays a very active part in the life of the parish.

This adjustment was not easy. His wife had shown an interest in him and visited him at intervals throughout the years, but she had had to make a life for herself and the sons of the marriage, and earn a living for them in London. He now travels to London regularly to see his wife, corresponds with her, and at this level their relationship is

harmonious. At one time he was much concerned about the youngest son, who after his demobilization was rather silent, withdrawn, morose, and unhappy. However, the boy overcame his difficulties and both sons are in good jobs.

Discussion

The diagnosis in this case is of interest. The patient's attack of depression started at the age of 49, but, in view of the previous attack at the age of 20, it would be reasonable to suppose that this was a manic-depressive psychosis—the second attack, as is often the case, being the long one. His somewhat hypomanic behaviour on recovery reinforced this view. Perhaps it might simplify matters if one were to follow Lundquist's view and call this a depressive reaction. Lundquist (1945) gives as characteristic of the depressive reaction: (1) marked depression without demonstrable connexion with lesional factors; (2) anxiety; (3) inhibition; (4) suicidal thoughts; and (5) depressive delusions. The patient had all these characteristic symptoms, though not all were present throughout his illness.

Lundquist, in his masterly review of the whole subject, quotes a number of authors whose publications are not available to me. Among these are Lange (1928), who stated categorically that the risk of a "chronic" course is greater when the disease sets in after the age of 40. Lange also cited Kraepelin, Regis, and Petren as describing individual cases "up to 20 years"; and Rehm (1919) is quoted by Halberstadt (1937) as referring to "certain elderly melancholics whose illness may last for more than 20 years." My patient, on indisputable evidence, suffered from an unbroken attack of psychotic depression for at least 23 years. On his own showing he had found the going hard, and had a sense of failure and blunting of emotional reactions for seven years prior to this.

An interesting point raised by Halberstadt (1937) is the failure in many papers to differentiate between "chronicity" and "incurability." He points out with reference to various authorities, including Rehm and Lange, that a long stay in mental hospital produces a condition similar to prison dementia, with poverty of ideation. This my patient certainly had for many years, but the absence of arteriosclerotic changes or senile criteria of any sort made it theoretically possible for him at any point to cease to be a chronic depressive. His blood pressure was never more than 160/80 and he never showed signs of arterial thickening. This seems to have been more important than the fact that after the subsidence of the acute symptoms there was monotony of symptomatology and affective flattening. Henderson and Gillespie (1950) also make this point.

Conclusion

The odds against recovery from manic-depressive illness of over 20 years' duration have been given by Danziger (1946) as less than 100 to 1 based on the U.S. Bureau of Census Study. The subject of this paper happened to be the hundredth one. He himself is convinced that his interest in the dog was the beginning of his recovery, and there was certainly a time relationship. However, it is possible that the true explanation is that the patient was ready to start a remission when the right stimulus appeared.

I would like to pay tribute to the staff of the Coppice Hospital, not only the nursing staff but the gardeners, the engineering staff, the kitchen staff, and others, whose sympathetic, enthusiastic, and patient help during the recovery phase contributed so much to the patient's full adjustment to normal social life.

Medical Memoranda

Spontaneous Pneumothorax and Subcutaneous Emphysema

Spontaneous pneumothorax and subcutaneous emphysema are both rare complications of asthma, and the combined conditions even more rare. So far as I know, no case of subcutaneous emphysema recurring during a subsequent asthmatic attack has previously been reported.

CASE REPORT

A boy aged 1 year 9 months was admitted to hospital on November 13, 1955, with a history that three weeks previously he had had a coryza with "wheezing," which had cleared in a week. Five days before his admission he developed another cold in the head, and later began coughing and wheezing. On admission the child was miserable and frightened. He cried lustily while being examined, and then quite suddenly swellings began to appear on each side of his neck, and these gradually increased in size. The crackling sensation elicited on palpation showed these to be due to subcutaneous emphysema. Clinical examination of the chest was impossible, as the child was very apprehensive, but a chest x-ray examination showed that he had a right pneumothorax and also demonstrated the subcutaneous emphysema of the neck.

During the next two or three days this subcutaneous emphysema spread up into his face and down over the anterior and posterior chest walls, and then gradually disappeared. Treatment consisted in sedation and a course of oxytetracycline.

A month later the child was readmitted for four days with a mild attack of asthma, which gradually subsided without treatment.

On May 12, 1956, the boy was again admitted, this time with a 24-hour history of breathlessness and wheezing, for which he had been given ephedrine, without improvement. His temperature was 99.6° F. (37.6° C.), his right tonsil was injected, and there were generalized rhonchi in the chest. On sedation he settled down well. The following morning the child, although generally much better, seemed to have a rather puffy face. This was found to be due to subcutaneous emphysema which had developed overnight and involved the neck and chest wall as well as the face.

Over the next 48 hours this increased in extent and then disappeared during the following week. An x-ray examination of the chest on this occasion showed consolidation of the anterior segment of the right lower lobe. There was no pneumothorax. Treatment was again sedation, and he was also given a course of sulphadimidine. At no time was the child particularly distressed by the presence of the subcutaneous emphysema.

Family History.—The patient was an only child. His mother suffered from hay fever. His father gave a rather interesting story: he had been in the R.A.F., and described how, when undergoing an examination in which he had to perform the Valsalva manoeuvre, he had suddenly developed a swelling in the neck. In his case, however, further investigations proved that he had a laryngocele.

COMMENT

Various theories on the mechanism of subcutaneous emphysema complicating asthma have been suggested, but the most generally accepted seems to be that an alveolus ruptures and air escapes into the lung tissues and tracks along perivascular spaces to the hilum and then along the fascial planes into the neck. It is possible for the pressure of this escaping air on the large vessels at the hilum and in the mediastinum to cause cardiac and respiratory embarrassment. Some air may track towards the periphery of the lung and collect under the pleura. If the pressure of this causes

the pleura to rupture a pneumothorax will result. Alternatively, an emphysematous bulla may rupture during an attack and produce this complication.

Air is usually absorbed quickly from the tissues, and it is only if the rate of escape into the tissues is exceptionally great that any distress is likely to occur. In a crying, frightened child conditions exist for this to take place—hence the importance of sedation.

Only two fatal cases have been reported. In one of these (Peterson, 1947) the subcutaneous emphysema was thought by the pathologist at necropsy to be incidental, the outstanding feature being the blocking of respiratory passages by tenacious mucus. The other patient (Wagner and Wagner, 1937) had, in addition, a localized spontaneous pneumothorax, and the final asthmatic attack lasted five months.

Two cases have been reported in which incision of the subcutaneous tissues has been necessary to allow the escape of air. One case occurred in a man of 21 who had suffered from asthma most of his life (Schrire and Schrire, 1952). During an asthmatic attack he developed gross subcutaneous emphysema, which spread down his arms to his hands and over the trunk as far as the groins. His breathing was laboured and his pulse rate rose to 150 a minute and was irregular. Following a transverse incision in his neck with exposure of the trachea, he made a good recovery.

Thirty cases of subcutaneous emphysema complicating asthma have been reported in the literature, but as this condition is usually benign, requiring no specific treatment, it is possible that it may be far more common.

Action of Senna

On February 23, 1957, two reports were published in the *British Medical Journal* (Browne *et al.*, 1957; Duncan, 1957) demonstrating the effectiveness of senna preparations as laxatives in controlled clinical trials. At that time the precise mode of action of senna and similar compounds was attracting our attention. It is traditional in pharmacological teaching to classify a number of purgatives as "irritant." Not only senna, but cascara, rhubarb, aloes, mercury, and sulphur come into this group—a diverse collection. The assumption seems to have been made that these substances directly "irritate" the intestinal mucosa, as a result of which the activity of the gut and, in particular, peristalsis is augmented so as to eject the offending material. The obvious inflammatory changes visible on, say, sigmoidoscopy in any patient with violent bowel activity, from whatever cause, lends support to this theory. However, the question is, which is cause and which the effect?

The manufacturers of the standardized senna preparation ("senokot") used in the two clinical trials quoted go so far as to claim that their product "stimulates bowel peristalsis by the same neuromuscular mechanism that operates in the normal reflex of defaecation. There is no mucosal irritation." Another firm declares of an allied product that it "stimulates peristalsis and the secretions of the colon solely by contact with the mucosa." Search as we may in the literature, we can find no enlightenment on the fundamental mode of action of the so-called irritant purgatives.

The results of a preliminary experiment that we have completed may perhaps be worthy of notice. Ten albino mice each weighing about 20 g. were dosed individually by stomach tube with 180 mg. of standardized senna preparation (senokot) each day, this dose being considerably in excess of that used in medical practice. Fluid intake and diet were regulated. Moderate purgation was obvious within 12 hours. At intervals ranging from 2 to 11 days after the beginning of treatment the mice were sacrificed, post-mortem examinations were made, and sections of the ileum

and colon of each animal were prepared for histological examination. In no case was there seen any macroscopical or microscopical evidence of inflammatory change in the gut.

A similar experiment was next carried out, but five of the mice each received 180 mg. of senna preparation daily and the other five were given 360 mg. each day. Treatment was continued daily for four weeks in all, but the diet otherwise was not controlled. At the end of the experimental period all the mice were sacrificed and examinations made as previously. Again, no evidence whatever of inflammatory reaction, despite the mild purging that was observed while the animals were under treatment.

There is a *prima facie* case, therefore, for believing that senna at least, and probably other "irritant" purgatives as well, act not so much by direct damage to the mucosa as by some mechanism of the gut. Pharmacological experiments to elucidate this are in progress. The findings so far are suggestive, but remain to be repeated and confirmed. Details will be published when the experiments are concluded.

Spontaneous Ulnar Nerve Paresis

When a peripheral nerve lesion in the arm is first noticed after an operation there is a tendency to attribute it to mismanagement in the theatre. The thing speaks for itself—*res ipsa loquitur*—as may be said later. The following three cases of ulnar nerve paresis which developed during inpatient treatment are interesting in that two of the patients did not visit the operating theatre. In these two cases the paresis was noted during recovery from a serious illness; in the third case it was noticed after an operation. Almost completely recovery has taken place in about six months in each case. There was no apparent cause for the ulnar nerve paresis in any of these cases.

CASE REPORTS

Case 1.—A housewife aged 56 was admitted to hospital in April, 1955, suffering from acute cholecystitis which resolved slowly under expectant treatment, including rest in bed and opiates. During the third week in hospital she complained of weakness and paraesthesia in the right hand. Examination revealed a partial ulnar nerve lesion, there being hypoaesthesia and muscular weakness in the hand. The sensory changes affected both ventral and dorsal areas of ulnar distribution, but the flexor carpi ulnaris was not affected. No cause for the paresis could be found, and recovery took place slowly over the next three months. The patient volunteered the information that for many years she has, at intervals, been awakened at night with numbness and tingling in the right ulnar area which passes off on moving the arm into a more comfortable position. Right lateral recumbency is the position which provokes these attacks.

Case 2.—This patient, a married woman aged 45, was a civil servant. She was treated in hospital for extensive second-degree burns of the back by the exposure method. For this she lay prone for a total period of three weeks, frequently putting her arms above her head on the pillow. A fairly large amount of sedation was required. About a week after admission she noticed a weakness in the right hand which examination showed to be an ulnar nerve paresis. Almost complete recovery was noted six months after her discharge from hospital.

Case 3.—A fitter aged 54 was admitted to hospital for a left ureterolithotomy. Two days later he complained of weakness in the left hand which proved to be an ulnar nerve paresis. Careful review of his theatre management failed to

reveal any cause for his paresis. Almost complete recovery was noted six months after his discharge from hospital.

COMMENT

The first patient's experience of waking in the night with the whole or part of an arm paralysed or anaesthetic is a common one. The arm has been uncomfortably placed and a slight move in bed allows it to recover, perhaps with some tingling, and sleep to be resumed. I have questioned about 30 presumably normal people—mostly colleagues and nursing staff—about this, and the comments which follow are based on their answers. The first feature of note is the difficulty in getting accurate information. It is often sound sleep which is disturbed by the phenomenon, it is rapidly resumed, and memory is blurred. Subjects have denied the experience only to come forward a few days later to tell of it. These features make statistical analysis worthless, and none is offered.

Nocturnal episodes of paralysis occur at all ages, and in a very high proportion of people. Only one person questioned had never experienced such episodes; amongst the others the frequency of occurrence varied from once only to as many as five times a night. Few people are troubled more than once a month. Two postures are particularly apt to produce attacks; one is lateral or semiprone recumbency in which it is the under arm that is affected, and the other is supine recumbency with the arm above the head on the pillow. There is considerable variation in the severity of the attacks. In the grossest form encountered there is complete paralysis and anaesthesia of the hand, forearm, and elbow. The victim has to draw the arm from its uncomfortable position with the other hand; recovery then occurs, the last noted abnormality often being paraesthesia in the ulnar side of the hand. Less severe attacks are similar in nature. Over half the people questioned had noticed differential involvement of the ulnar side of the hand; a fair number could definitely draw the line of abnormality down the middle of the ring finger. No one had noticed a differential involvement of the radial side of the hand.

Very few of those questioned were able to offer any explanation of why they woke during the episode—it is not uncomfortable until recovery starts—but there was a general agreement that they woke because of the attack. Some had experienced bad dreams. Occasionally people are woken by the alarm clock, to find their arm affected. This observation suggests that while the attack usually wakes the patient it does not do so with urgency.

The most probable explanation of the attacks is that they are ischaemic, that the posture adopted occludes some vessel, and that the paresis results from the ischaemia. Where there is a definite peripheral nerve distribution, the ischaemia must be presumed to act, at least in part, by causing ischaemia of the nerve itself. In any case there can be little doubt, firstly, that the termination of the attack depends on altering the position in bed, and, secondly, that if an episode remained uninterminated in this way, then in due course damage would result to the nerve, which would be noticed as a paresis for some time subsequently. While the sequence of events leading to waking is undetermined it is very probable that it is in the nature of a defence mechanism involving higher centres, which would be interfered with by narcotics or analgesics.

As already indicated, the frequency of the episodes is not great, but if one considers the possible sequel to a narcotic or sedative having been given on the occasion when the attack occurs, then a temporary paresis is a distinct possibility, and is offered here as the probable explanation of the three cases of ulnar nerve paresis described. Most sedated patients lie supine, but there is a growing tendency for the semiprone (or "tensil") position to be used because of its advantages to the airway.

Permission to publish the above case reports has kindly been given by members of the surgical staff of the Manchester Royal Infirmary.

Surgical First Assistant, Manchester Royal Infirmary.

Reviews

LIFE AND WORK OF FREUD

Sigmund Freud: Life and Work. Volume 3: The Last Phase, 1919-1939. By Ernest Jones. (Pp. 536; illustrated. 35s.) London: Hogarth Press. 1957.

In this third volume of his trilogy, Dr. Ernest Jones brings the story of Freud to an end. Although not so exciting as the first volume, nor so informative as the second, it nevertheless contains much of fascinating interest to the student of psycho-analysis: for the author combines an account of the last 20 years of Freud's personal life with a survey of the amazing "second period" of his contributions to mental science, a history of the psycho-analytical movement (which includes, incidentally, a good deal of Jones's autobiography), and a general appraisal of Freud's contributions to biology, anthropology, sociology, religion, occultism, art, literature, psychiatry, psychology, philosophy, and criminology.

Throughout the whole of his trilogy Jones evidently found himself on the horns of a literary dilemma. It was clearly his duty to put on record the immense amount of information he possessed at first hand, or otherwise gleaned, regarding Freud's life and the growth of psycho-analysis; but the more he overloaded his account with detail, either personal or scientific, the more risk he ran of sacrificing the literary canons of biography to the utilities of a psycho-analytical Domesday Book. Fortunately for students of psycho-analysis he chose the former alternative, leaving the story of Freud to tell itself. And that, greatly helped by a judicious selection from Freud's voluminous correspondence, is exactly what it does do. Readers who are interested less in the development of Freud's systems of thought than in discovering what manner of man he was, will find much to interest and even to delight them. They will no doubt also enjoy Jones's account of the various dissensions and defections that punctuated the history of the psycho-analytical movement, and which he retails with obvious relish. All this may not be the best of biography, but it provides reading that is essential to the full understanding of psycho-analysis and of the architect of its fortunes.

EDWARD GLOVER.

GROWTH OF NAVAL MEDICINE

Medicine and the Navy 1200-1900. By J. J. Keevil. Introduction by Sir Henry Dale. Volume I—1200-1649. (Pp. 255 +viii; illustrated. 40s.) Edinburgh and London: E. and S. Livingstone, Ltd. 1957.

Commander Keevil, who is no stranger to the art of letters, has in this first volume of *Medicine and the Navy* demonstrated a most enviable capacity for delving into the mysteries of the long-gone past. Using an enormous mass of information from which he has been able to glean his facts, he has woven a most interesting and vivid story of the trials and tribulations of the seamen who made this country of ours the leading maritime nation in the world. In navigating his ship through the troublous waters of prejudice, superstition, folk-lore, and, at times, just sheer pigheadedness, he has outlined the story of the growth of naval medicine. At the same time he has painted a fine picture of the jealousies that existed between the College of Physicians and the Company of Barber Surgeons; indeed, much of his story is a demonstration of the dichotomy of the profession rather than naval medicine as such. But that very "schizophrenia" from which "medicine" suffered right up to the beginning of the nineteenth century is used to show how the pressure exercised by the not always so silent Service drove the profession to realize that the complete doctor, not necessarily merely the naval variety, must have the dual qualification of physician and surgeon.

The story does not make it quite clear whether, to-day, we have to thank the Navy for the combination of gin and lime, but Volume I proves that the Navy at least put "lime" on the gastronomic map as an essential addition to

the diet of a seaman. Perhaps Volume II will trace the origin of the addition of the Plymouth product. One looks forward to the publication of the second volume, which doubtless will demonstrate the same careful attention to the detail of the growth of a medical service which justifiably has won the admiration of all the navies of the world.

J. DOWSE.

THE LUNG AND SYSTEMIC DISEASE

The Lung as a Mirror of Systemic Disease. By Eli H. Rubin, M.D. (Pp. 288+xx; illustrated. 95s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

The ever-widening use of radiography in chest disease has had profound effects upon clinical practice. It has provided the means for earlier diagnosis of some pulmonary diseases than would be possible by other means, and thus it has become, in the form of mass and routine radiography, an essential tool in the control of pulmonary tuberculosis. It has permitted an anatomical precision in diagnosis unattainable by other methods. But its very success has carried with it certain dangers. One of these is that chest physicians, and especially those concerned principally with tuberculosis, might become mere experts in the reading of chest radiographs, to the detriment of the ideal of the study of the patient as a whole. Fortunately this danger is largely counteracted by the fascinating glimpses of a variety of general systemic disorders which the chest radiograph sometimes gives. The interpretation of a radiographic abnormality may thus call for wide knowledge and experience of general medicine, and for specialized investigation far outside the confines of the respiratory system.

The object of Dr. Rubin's book is to discuss the problems presented by patients in whom an abnormality in the lungs, usually manifest chiefly in the radiograph, is a leading feature of a general systemic disorder. The subject is discussed under the headings of diseases of metabolism, diseases of the blood, allergic diseases (including the collagen diseases), diseases of the skin and mucous membrane, abdominal diseases and cardiovascular diseases. Some rather arbitrary placing is inevitable in fitting all the conditions discussed into these categories. For instance, hypertrophic pulmonary osteoarthropathy and cystic fibrosis of the pancreas are listed as diseases of metabolism; diffuse interstitial fibrosis of the lungs of the Hamman-Rich type is included with the collagen diseases under allergic diseases; and sarcoidosis is listed under diseases of the skin. Since the problem is, of course, a practical one, it is perhaps impossible to present it in a strictly logical way. The task of dealing informatively and clearly with such a wide cross-section of medicine is formidable, and Dr. Rubin is to be congratulated on his courage in attempting it. The illustration of the text by case-histories derived from his own extensive clinical experience, and the bibliographies which follow each section, add greatly to the value of the book. It constitutes a useful source of reference both for chest physicians puzzled about the systemic implications of lung shadows and for general physicians seeking information about the lung changes in diseases usually presenting with extrapulmonary manifestations.

J. G. SCADDING.

B.C.G. VACCINATION IN THE U.S.A.

B.C.G. Vaccination Against Tuberculosis. By Sol Roy Rosenthal, M.D., Ph.D. With sections by Dr. Camille Guérin, Dr. Bernard Weill-Hallé, and Dr. Arvid Wallgren. (Pp. 385+ix; illustrated. 55s.) London: J. and A. Churchill, Ltd. 1957.

A number of books and symposia on B.C.G. vaccination have appeared recently, but this is apparently the first of its kind from the United States, probably the only country that lacks any widely based official scheme for this form of prevention of tuberculosis. It is appropriate that the author should be Dr. S. R. Rosenthal, of Chicago, who for many years has made and studied the vaccine and advocated its wider application.

The prime purpose of the book is to examine the current doubts and questions of professional groups in the U.S.A., but it is likely to be of general value in assembling much of the knowledge on this subject, a great deal derived from the author's personal experiences. About half the book is devoted to the bacteriology of B.C.G. and to methods of preparation and administration, including a chapter on host response. Then, after consideration of the production of tuberculin sensitivity in animals and man and of experimental immunity, the principal trials in man are summarized and discussed. A point here is that while the U.S. Public Health Service's Puerto Rico study is referred to and criticized—though the author's emphasis on the non-isolation of the vaccinated subjects as a factor in its unimpressive results is unlikely to be widely accepted—no mention is made of the equally discouraging results of the concurrent trial in schoolchildren in Georgia. After an interesting discussion on the results of vaccination in persons already infected by the tubercle bacillus, the final chapter aims to place B.C.G. correctly in the setting of a tuberculosis control programme, particularly in the U.S.A. Short sections of the book are contributed by Guérin, by Weill-Hallé, and by Wallgren.

P. D'ARCY HART.

CONTRIBUTIONS TO PSYCHO-ANALYSIS

Selected Contributions to Psycho-Analysis. By John Rickman, M.D. Compiled by W. Clifford M. Scott, M.D. With an Introductory Memoir by Sylvia M. Payne, C.B.E., M.B. (Pp. 411. 30s.) London: Hogarth Press and Institute of Psycho-Analysis. 1957.

Dr. Scott may be congratulated on the difficult task of choosing and arranging a selection of the late Dr. John Rickman's papers. A further volume will appear later. For many years Rickman held a distinctive place in British psychiatry. The *British Journal of Medical Psychology*, under his editorship, became the accepted medium for contributions from psychiatrists of every "school" and from research workers in mental hospitals. He was one of the founders of the Institute of Psycho-Analysis, and from 1948 until his death editor of the *International Journal of Psycho-Analysis*.

The papers are arranged chronologically, and most of them appeared in psycho-analytical and psychiatric journals; but several are of more general interest. "Psychology in Medical Education" and "The Development of Psycho-logical Medicine" are reprinted from the *British Medical Journal*, and an excellent paper, "The Study of Hysteria in Two World Wars," appeared in the *Lancet*. These add considerably to the appeal of the volume. "The Development of the Psycho-Analytical Theory of the Psychoses" occupies almost one-third of the book. This unique survey of developments in psycho-analytical theory between 1894 and 1926 might well have been a separate volume. It traces the early development of psychopathology in the Freudian system, and so will be of special value to postgraduate students in psychiatry. Unfortunately but scanty reference is made to the work of non-Freudian writers of this period, some of whom were valued by Freud himself. Psycho-analysis has altered substantially since 1926, and Rickman was well qualified to assess the importance of changed emphasis. Dr. Payne in her introductory memoir tells us that he planned to bring his papers—and presumably this paper—up to date. But his early and unexpected death made the revision impossible. This volume will certainly take an honoured place as a source book in psycho-analytical literature.

E. A. BENNET.

TABLE TALK

Tea with Walter de la Mare. By Russell Brain. (Pp. 127. 12s. 6d.) London: Faber and Faber. 1957.

This little book of 127 pages is the record of 28 tea-time conversations with Walter de la Mare, made between August 11, 1951, and May 20, 1956, during which time Sir

Russell Brain was President of the Royal College of Physicians. The talks ranged widely, for de la Mare—"W. J.," as the author came to call him—rapidly introduced new topics by what the psychologists call free association: as, for example, "We discussed William Harvey and the circulation of the blood. What, asked W. J., did he really discover? Surely people must have known that the blood went round the body before Harvey. Didn't he spend a long time in a cave? He said he once wrote a poem about him ending up in the circulation of ideas." As this passage shows, de la Mare built his conversation around questions. Naturally enough, literature figured largely in his talk, but there is much in this book about dreams and death, childhood and memory, mind and the unseen.

The book is brilliantly successful, and, though Russell Brain does not obtrude himself, his stimulating contribution to the conversations and his part in the admirable construction of the book are everywhere apparent. In the introductory chapter he writes: "A tea-talk is by its nature limited in time: after dinner you can talk all through the night, if you like; but not after tea. A tea-talk has something of the restrictions of an art-form and the transience of mortality." And in the final paragraph, "This was to be the last of our talks, for when I next saw him his own cage-door stood open. . . . He greeted me with a smile and a joke about his lack of party manners. We spoke a little and I took his hand. Then, after a pause, he said: 'All these onlookers! There are so many of them. I wonder where they come from.' He died a few hours later, in the night following the longest day."

This book proves that, while letter-writing may have died in the twentieth century, conversation remains. It joins on our shelves the pre-eminent Boswell and, juxtaposed but how far removed, Erckmann's *Conversations with Goethe*. The recording of conversation is once again shown in this book to be an essential element in good biography.

D. V. HUBBLE.

STRESS SIMPLIFIED

The Stress of Life. By Hans Selye. Introduction by Sir Heneage Ogilvie. (Pp. 324+xx; illustrated. 18s.) London, New York, Toronto: Longmans, Green and Co. 1957.

The first sentence of the preface states that the main purpose of this book is to tell, in generally understandable language, what medicine has learned about stress. The book contains five parts: (1) the history and discovery of stress; (2) the physiological mechanism underlying the stress response of an organism; (3) diseases of adaptation; (4) a sketch of a unified system of medicine; and (5) psychosomatic and philosophical implications of the stress concept. The paper cover explains that Selye's studies on stress have often been compared with "the contributions of Pasteur, Ehrlich and Freud," and Sir Heneage Ogilvie, in the introduction, comments that Dr. Selye's work is "perhaps the greatest contribution to scientific medicine in the present century." Few workers would at the moment wholeheartedly endorse these sentiments. There can be no doubt that Selye's physiological findings are of basic importance. It is possible that his hypotheses in the field of clinical medicine are of equal importance; it remains to be seen. The physiological section of the book (Parts I and II) is clearly and lucidly written and presents a complex subject in a way simple enough to be valuable for the intelligent layman or the elementary student. The medical applications of the stress concept (Parts III and IV) are equally well and convincingly written, and for this reason may misrepresent the subject to the uncritical reader. The publication offers interesting and fairly easy reading; it is persuasive and misleading in parts for the unwary; and it forms an object lesson on the way in which a lifetime of specialized research may be integrated into a single picture and presented in a simple, understandable way. This book is well printed and produced; it contains some plates, a glossary of scientific terms, and an index.

SATURDAY DECEMBER 14 1957

ANTIBIOTIC COMBINATIONS

The advisability of using pairs of antibiotics instead of single ones is the most debated subject at present in the whole confused field of chemotherapy. It is not a new subject: the indications for combined treatment were stated in this journal four years ago by L. P. Garrod,¹ and these are the indications around which discussion centres now. They are—to achieve a synergic effect, when this is possible; to cover all the elements in a mixed infection; to delay the development of bacterial resistance; to permit the use of smaller doses of each antibiotic, thus diminishing the risk of toxic effects; and to treat urgent cases before a bacteriological diagnosis has been made. The issue now is not whether these are indications for combined treatment, but how often they are, whether such treatment should be resorted to exceptionally, or become a regular practice.

The present controversy dates from the Fourth Antibiotics Symposium in Washington in October of last year, when the chairman, Dr. Henry Welch, heralded the use of antibiotic combinations as marking a new era in therapeutics. Meanwhile antibiotic manufacturers had been devising new combinations, and the grandiloquent claims made for them provoked some briskly critical reactions²⁻⁴ on both sides of the Atlantic. Last May there followed a report⁵ by H. F. Dowling to the Council on Drugs of the American Medical Association entitled "Mixtures of Antibiotics," again examining the alleged advantages of such mixtures and granting their existence only in special circumstances. Thus synergism has been demonstrated between penicillin and streptomycin in the treatment of enterococcal endocarditis and between streptomycin and a tetracycline in brucellosis, but apart from these and a few instances in individual patients it has not been proved. For the treatment of mixed infections of the air passages or in relation to the alimentary tract (e.g., peritonitis) a single broad-

spectrum antibiotic may be preferable to a mixture. That the acquisition of bacterial resistance is delayed by combined treatment is undoubted in tuberculosis; in other infections this has yet to be demonstrated. The advantage of reduced toxicity from a smaller dose of each of two components has been claimed for a mixture of streptomycin and dihydrostreptomycin. The observations of J. A. Wier and his colleagues⁶ show that the claim may be mistaken. In any case the argument would not apply to most mixtures, because Dowling and others insist that for adequate effect a mixture should contain full doses of both components. Another condition which has been repeatedly emphasized is that the organism must be normally sensitive to both antibiotics if any advantage is to be gained from combined treatment, though in fact there is one exception to this—namely, the action of penicillin plus streptomycin on an at least partially streptomycin-resistant strain of *Str. faecalis*.⁷

These arguments were put forward as a corrective to propaganda in favour of the large-scale administration of mixtures for a wide variety of clinical purposes before their value for many of these has been properly ascertained. It is admitted that they may have some unascertained value in particular circumstances. Synergy is one possibility, but it is often unpredictable, and can be verified for the individual case only by complicated laboratory tests; that the effect will be the exact opposite of the one desired is also a possibility. The prevention or delay of acquired bacterial resistance is the other possible advantage about which much more information is desirable. One clinical trial designed for this purpose suggested that for the particular combination used the delay was short.⁸ Further studies on these lines would be helpful; to plan and carry them to a clear conclusion will not be easy. Against these mainly hypothetical advantages in the use of commercial mixtures have to be set several undoubted drawbacks—expense, fixity of relative dosage, and the likelihood that a drug with toxic potentialities such as streptomycin is being used unnecessarily. Another consequence which would follow the general use of commercial mixtures has perhaps not been sufficiently emphasized. It is difficult enough to appraise the relative merits of individual antibiotics now that there are so many; if various mixtures are to be used before their actions when given separately have been fully explored, this task will become hopeless.

Some of this controversy has centred round the 2:1 mixture of tetracycline and oleandomycin marketed as "sigmamycin." That this combination has a synergic action on some strains of staphylococci was reported by A. R. English and his colleagues,⁹ whose findings are the main foundation of the claims

made for this product. In a recent paper in this *Journal* Garrod¹⁰ reported that he had failed to confirm the results of these authors' *in vitro* tests: for over 70 strains of staphylococci the minimum inhibitory concentration of this combination was in no instance significantly lower than that of the more active of its components. His paper includes observations on the relationship between oleandomycin, erythromycin, and spiramycin and a discussion of their relative merits leading to the conclusion that erythromycin is preferable to the other two. These *in vitro* findings are confirmed by E. Wiesmann,¹¹ who tested 10 strains of staphylococci and 10 of streptococci and other bacteria with tetracycline, oleandomycin, and the 2:1 combination, obtaining no evidence that the latter exerts any synergic action. More recently R. W. Fairbrother and J. E. Southall¹² have observed more varied effects from the 2:1 combination in tests with larger numbers of several species of bacteria: both synergism and antagonism were seen, the former almost exclusively when the strain was sensitive to both antibiotics. The difference was only twofold in 38 out of 44 of these instances: a significant degree of synergism was thus very exceptional.

A much more extensive study, employing several methods of test, is now reported by M. Finland and W. F. Jones.¹³ They first compared the *in vitro* activity of erythromycin, oleandomycin, and spiramycin against large numbers of strains of staphylococci and of several varieties of streptococcus, much to the advantage of the former. They then compared the activity of 2:1 mixtures of tetracycline with each of these three antibiotics with that of each of the four acting alone, using 34 strains of staphylococci with different sensitivity patterns. Although in general activity of these mixtures was no more and sometimes less than would be expected as an additive effect, some of the strains used reacted differently. The tetracycline-erythromycin mixture showed synergy against one strain but what appears to be distinct antagonism against several others. Tetracycline + oleandomycin was more active than either of its components against 7 of 8 strains but with only a twofold difference in 7 of them: here there were two instances of antagonism. Tetracycline + spiramycin afforded 3 examples of marked synergy. These erratic results make it easier to understand why the findings of other workers using this form of test have been discordant. Although there must be reasons for these differences, and it would be interesting to know them, it is probably true to say that the effects of combined action cannot be determined satisfactorily in so simple a fashion.

Another form of test used by Finland and Jones must be granted much more practical significance.

Each antibiotic and each combination in two different proportions were administered to normal subjects, and the inhibiting activity of the plasma for three different organisms was determined after 1, 3, 6, 10, and 16 hours. With equal total doses (in some tests the combination doses were higher) the antibacterial activity conferred on the plasma by any combination never significantly exceeded that produced by the more active of its components. Of the three combinations tested, tetracycline + erythromycin was the most active, as would be expected. These findings must carry more weight than any purely *in vitro* study, and they fail to confirm that this type of combination has the virtue claimed for it. There remains a question about the individual status of antibiotics in the erythromycin group. Discussing the apparent inferiority of oleandomycin and spiramycin, Finland writes, "It is, of course, possible that one or another of these erythromycin-like agents will be found to possess special virtues, not yet revealed, but the burden of proof must rest with those who advocate their use to demonstrate such an advantage clearly and unequivocally before any of these agents could be considered as acceptable so long as erythromycin and other available and more effective agents retain their usefulness."

USE AND ABUSE OF BLOOD

Since the war there has been a great rise in the amount of blood used in hospitals, whose demands could not have been met without the rapid organizational and technical advances that have been made in the transfusion service. Although as a whole the service appears to be satisfactory at the moment, many workers in this field, as correspondence in this *Journal* has shown, are apprehensive about the future. What are the facts? In 1951 approximately 500,000 bottles of blood were issued to hospitals: this year the figure will be over 700,000. If, as Drs. C. Bowley and J. Darnborough¹ imply in an informative and thought-provoking letter, the rise continues at this rate, the present service may prove to be inadequate.

There are several reasons for the increased use of blood transfusion in treatment. First, the rapid strides in surgical techniques, anaesthesia, and the use of antibiotics has allowed the surgeon to perform operations previously impossible. Operations on the heart and lungs, pelvic evisceration, porto-caval anastomosis, and so on are becoming commonplace in many hospitals. Requests for from 5 to 10 bottles of blood are commonly made for these cases, and often all are used. There has also been a great increase in the amount of blood used for the treatment of civilian injuries and of obstetric and intestinal haemorrhage. The indica-

tions for exchange transfusion have been extended from haemolytic disease of the newborn to include any jaundiced infant in danger of kernicterus, whatever the cause of the jaundice. Large volumes of blood, plasma, and plasma products are being increasingly used in the management of haemophilia. The demand for blood for patients in all these categories will certainly not decrease in the future; in fact, it will probably increase. Then again blood is now often required for patients suffering from diseases which can be treated by other means. It is not uncommon for patients with iron-deficiency or pernicious anaemia and post-operative or post-natal anaemia to be given blood so that they can be discharged from hospital more quickly: Bowley and Darnborough quote instances of this in their letter published this week (page 1432). There is usually little justification for such transfusions. Apart from the chance of the patient being sensitized to blood group antigens or of developing a post-transfusion virus hepatitis (the incidence of this is approximately 0.2%), there is still the possibility of giving incompatible blood: the factor of human fallibility can never be entirely removed, however excellent the laboratory and clinical facilities.

A third group of patients to whom blood is now often given are those suffering from incurable diseases. Although not affecting the outcome, a blood transfusion may allow the patient a measure of comfort in the terminal stages. This is, of course, a matter entirely for the clinician in charge of the case, but a difficult decision may have to be made by the pathologist in charge of the hospital blood bank when he or she, having only a limited quantity of blood available, is faced with two requests, one for a dying patient and the other for a patient undergoing, say, a gastrectomy. Difficulties of this sort should be the concern of a senior member of the hospital's pathological staff—a point made by Dr. C. B. V. Walker.² So often the blood bank is administered by the resident pathologist, who is not always willing or able to question requests from clinicians. A further important reason for the increased demand for blood is the practice of surgeons to request blood to be crossmatched and available for immediate use at routine operations.³ At the present time, over the country as a whole, approximately 14% of all blood issued to hospital laboratories is returned unused, and usually out of date, to the transfusion centres. In some areas it is as high as 25%. Probably most of the blood returned in this way has been crossmatched with a view to use

during surgery. In practice it should be possible to cut down this wastage of blood. Pilot tubes, as mentioned by Dr. M. S. Beare⁴ and Dr. George Discombe,⁵ are now in use in the majority of regional centres. Clinicians should keep a close watch on the bottles crossmatched in this way, and make sure that unused bottles are returned to the bank as soon as possible: it is rare for blood not used within 24 hours of an operation to be used at all. Again, it would be advantageous if surgeons were more specific about their needs: often blood is requested solely because the houseman is not clear about his chief's requirements and so crossmatches an excess "to make sure." But in many cases the surgeon would be satisfied if the patient's blood was grouped and the assurance was given that compatible blood could be obtained within 20 minutes to a half-hour.

The shortage of blood is not spread uniformly throughout the blood groups: the supply of rhesus-negative blood is invariably restricted. One method of overcoming this is to take blood from these donors more often, but this has its limits. In some areas women who have been found to be Rh-negative at antenatal testing are sent a letter in which the special value of their blood, particularly for haemolytic disease of the newborn, is explained to them, and they are encouraged, as an entirely voluntary service, to enrol as regular donors as soon as they are fit. A response of up to 23% has been achieved by this simple measure. A factor which may increase the shortage of blood in the future is the loss of National Servicemen, who in the past have made a substantial contribution to the blood banks. One possible way of obtaining additional donors would be to ask the relatives of patients to give their blood. This has obvious advantages, but some, not so obvious, disadvantages. If each hospital took blood from patients' relatives it would greatly increase the number of "one time only" donors. Each hospital laboratory would require special, often very scarce, sera, because donor blood requires more detailed tests than is necessary for recipients. It is more time-consuming to take blood from 5 to 10 relatives a day than to bleed 50 donors at one session lasting 2-3 hours. Perhaps more use could be made of the American system whereby relatives are asked to donate blood to replace that given to the patient. Hospitals could hold donor sessions for relatives at, say, fortnightly intervals and put experienced staff in charge; or they could refer relatives to convenient donor sessions near by. Many who responded might be encouraged to become regular donors. The paying of donors, which has been tried and found wanting in some countries, has little to recommend it, and would be repugnant to the

majority of them: most donors refuse even the offer of a small sum of money to cover the cost of their journey to the session.

The solution of the problem of providing hospitals with all the blood they want is not just a matter of recruiting more donors and of replacing the existing inadequate buildings where much of the work of the transfusion service goes on. The urgent need is for everyone, whether regional transfusion officer, hospital pathologist, or clinician, to think how present facilities can best be used. W. A. Ramsay,⁶ speaking recently at a symposium on "Compatibility Tests for Hospital Use," said, "I don't know what we are going to do about it (the increasing use of blood). It is a very thorny problem as to whether blood should be available every time it is demanded by a clinician, and it is indeed a problem which will have to be settled." But by whom is it to be settled? At the moment the burden is borne by the hospital pathologist in charge of the blood bank, and it is no light one. Placed as he is between the staff of the transfusion centres and the clinicians in the wards, he attempts to acquaint both sides with the difficulties, receiving complaints from both and thanks from neither.

LOCAL PROPHYLAXIS OF INFLUENZA

Can one prevent influenza by gargling or by local applications to the nose or throat? Many must have asked this question in the past few weeks, and I. G. K. Menon¹ thinks that he has answered it in the affirmative in work done at the Pasteur Institute, Conoor. After confirming the inactivating action of various iodine preparations on influenza virus when mixed and held for 15 minutes before inoculation into eggs, Menon and C. W. Shaw² used iodine in a school at Lovedale shortly after an outbreak of influenza developed in May, 1957. One section of the schoolchildren among whom cases of influenza had already occurred received colloidal iodine spray to the throat and nose twice daily and a daily painting of the throat with Mandl's paint. The other section received only saline gargles and a placebo containing quinine. When numbers of cases had occurred in the latter section Mandl's paint was applied twice daily to the throat, and later colloidal iodine was used as well. The authors observed a sharp drop in the numbers of fresh cases each time within 24 hours of using Mandl's paint, and they infer that the treatment had a prophylactic effect on the infection. Unfortunately their

deductions lack statistical validity. However, the destructive action of iodine on influenza virus is worth recalling. J. D. Stone and Sir Macfarlane Burnet³ demonstrated in 1945 that iodine vapour in a concentration of one in ten million would inactivate influenza virus almost instantaneously provided the virus was present in the form of a wet mist. So Menon's claim has some theoretical backing and further exploration of the idea is justified.

Meanwhile Russian workers⁴ have long advocated the local prophylaxis of influenza with specific antiviral preparations such as immune horse serum and more recently with live virus vaccine.⁵ Details of both methods were given recently by A. A. Smorodinzew⁶ and by Czech workers⁷ at the Third International Meeting of Biological Standardization held in Prague. The prophylactic action of an antiviral horse serum given intraperitoneally to mice on the development of influenzal pneumonia was reported by P. P. Laidlaw and others⁸ at the National Institute for Medical Research so long ago as 1935. American workers^{9,10} thought that, dose for dose, immune horse serum was more efficient when given intranasally to mice than when given intraperitoneally, but they also thought that there was some risk of sensitization if the same material was used in man. J. Zellat and W. Henle¹¹ showed that it was not possible, by means of intranasal serum, to protect ferrets, in which influenza virus infection is closely similar to that in man.

Smorodinzew⁶ recommends that the hyperimmune horse serum should be given by local insufflation of a dried powder, but the Czech workers sprayed into the nose an atomized liquid preparation,⁷ giving 0.5 ml. via each nostril. No adverse reactions were observed among 8,000 workers from among a group of 30,000 under observation at several industrial centres. Allergic patients were excluded. Among patients given the serum, morbidity fell in some groups to a half or one-third that found in untreated controls, particularly during the first week after the application. This trial of serum in the face of an outbreak of influenza demands the most scrupulous assembly of the two groups of immunized and control persons. Provided no bias entered into the selection, the results described may be contrasted with those following administration during the same period of inactivated vaccine, because this requires at least a week before antibodies develop. As for live influenza virus vaccine, this is a subject fraught with difficulty, as experiments at Salisbury^{5,12} have shown.

CARE OF THE CHRONIC SICK

In the debate on the report of the Guillebaud Committee in the House of Commons last year¹ there was much emphasis on the need for developing services designed to help old people. Official guidance on how to overcome the administrative difficulties in the way of such development has been meagre, and the Ministry of Health's recently published report² on the services available for the chronic sick and elderly is therefore welcome. The findings in the report, which was prepared by Dr. C. A. Boucher, are based on a national survey carried out in 1954 and 1955 of the services provided

for old people, and the principal general conclusions and recommendations have been issued by the Minister in the form of memoranda to hospital authorities and welfare authorities. One of the report's most important recommendations is that "hospital authorities should give high priority in the allocation of their resources to the establishment in every hospital centre of a geriatric department under the charge of a specialist physician, whether a general physician with a special interest in the subject or a physician working only in this field, and with full supporting services." At the time of the survey geriatric physicians of consultant or S.H.M.O. status had been appointed in only one-third of the hospital groups which had beds for the chronic sick. It was therefore possible to compare the quality of the services provided by hospitals with and without geriatric units. Much of the work done for the elderly and chronic sick by general physicians is highly successful, but unless a physician has been specifically appointed to be responsible for the planning of the geriatric services the best use is not always made of hospital beds. The surveying teams found that where there was a consultant whose primary interest was in geriatrics "the service benefits incomparably." The report also shows that the standards of hospital staffing vary greatly throughout the country and that sometimes they are totally inadequate. In one hospital group a paediatrician provided medical supervision of the chronic sick, in another a consultant in obstetrics and gynaecology, while in a third area a consultant anaesthetist decided on priority of admission and supervised the medical care of the patients.

While few would contend that geriatrics is a clinical specialty, it is generally accepted that the care of the aged sick presents problems not encountered in the treatment of other patients. The practice of geriatric medicine has as its object the physical and social rehabilitation of patients suffering from the effects of degenerative changes and from long-continued illness. The report states that "the Minister recognizes that there are not at present enough candidates with appropriate experience in general medicine applied to the care of old people to fill consultant appointments on a large scale." Some of the desired increase in the number of consultant appointments might be attained if senior medical registrars were allowed to spend one or two years of their tenure of office in established geriatric units. Such training would be valuable even for those who remain in "general" medicine, since all physicians must practise some geriatrics. Indeed, even in general hospitals containing well-developed geriatric departments the proportion of patients over 60 in the acute medical wards may already be over 50% and is likely to increase.

While the report deals at greatest length with the hospital care of the elderly, since there has previously been no "official" policy on this, it also makes recommendations for improving the services provided by local authorities. A comprehensive service can be achieved only if the welfare and hospital authorities fully accept their respective responsibilities, which the Minister has

now defined. The welfare authority is expected to provide care for the infirm (including the senile) who may need help with dressing, toilet, meals, and so on, and also to care for those elderly persons already in welfare homes who have to take to bed and are not expected to live more than a few weeks. Many welfare authorities are not at present providing these services; nor can they provide them without incurring heavy additional expenditure on premises and staff. Both hospitals and local authorities should find the present report of great value in their planning of geriatric services and in making of improvements in the existing organization. There are suggestions for the provision of laundry services, health visiting, chiropody, and advisory health clinics, the outstanding example of which is the consultative health centre at Rutherglen.³ All these ancillary services are aimed at the maintenance of the health of the elderly in their own homes. Indeed, the success of the geriatric services can be measured only by the extent to which the needs of the elderly at home are met and by the efficiency with which a hospital serves the local community.

ANDROGENS AND ERYTHROPOIESIS

Administration of androgens causes flushing of the face, but it is less well recognized that androgens stimulate haemopoiesis, with a rise in the haemoglobin percentage. Both these effects have been frequently observed in patients regularly receiving androgens for the treatment of metastatic breast cancer. In a recent series of 68 cases⁴ clear evidence of increased erythroid activity was found in 35%. In this group the average rise in haemoglobin was from 12.9 g. to 17.2 g. per 100 ml. There was a similar rise in the red-cell count. That this rise in haemoglobin was due to haemopoiesis and not to haemoconcentration was shown in 11 of these cases, in which the red-cell mass was measured by isotope tagging. There was a significant rise in red-cell mass in 6 of these, the peak response occurring two to four months after the start of testosterone therapy. These increases occurred in persons who were receiving no medicinal iron or other haematinics. They were accompanied by no significant change in the concentration of serum iron, but occasionally this tended to fall slightly. This slow, steady rise in haemoglobin in response to androgenic hormones suggests that they provide a specific stimulus to erythropoiesis. The ability of the androgens to stimulate production of red cells beyond the normal range is especially interesting, since this property is shared by very few other agents, anoxia and cobaltous chloride being the main ones.

It would seem that testosterone may prove to be beneficial in some other anaemic conditions. B. J. Kennedy and A. S. Gilbertsen⁴ have already found it to be so in some anaemic patients. In a man with chronic glomerulonephritis, uraemia, and primary hypogonadism the haemoglobin was raised from 8.2 to 14 g. per 100 ml. after five months' therapy. In another man with an atypical myelofibrosis and chronic myelogenous leukaemia the haemoglobin was raised from 6.1 to 14 g. per

100 ml. after six months' treatment. Such cases of anaemia are usually resistant to traditional haematinics, and androgens may well prove therefore to have a place in their treatment. But little is yet known about the best use of androgens in such disorders. It might be expected that they would be most effective in patients whose production of androgens is inadequate. It is especially so in hypopituitarism and eunuchoidism, and scattered reports of the value of androgens in the anaemia associated with these conditions have appeared.^{5,6} Many wasting disorders are associated with deficient production of androgen, and testosterone may prove of value in other secondary or "toxic" anaemias besides those of metastatic carcinoma. Cortisone does not have the same erythropoietic effect as androgens: its action is irregular and may be absent in many cases for reasons which are quite unknown.

HAEMATITE PNEUMOCONIOSIS IN CUMBERLAND MINERS

The deposition of iron oxide in the lung, known as siderosis, and found among knife grinders, silver polishers, electric arc welders, and, especially, iron ore miners, was long believed to be a harmless retention of dust, unaccompanied by any consequent fibrosis. Now more recent investigations have shown that the radiographic shadows indicate a certain amount of fibrosis, reticulation, and focal emphysema. These lesions are associated with dyspnoea on exertion or chronic bronchitis. A study of the iron-ore mining industry in Cumberland,¹ where, in the north-west area, the haematite deposited at depths approaching 1,500 ft. (450 m.) is dry, crystalline, and with an index of hardness similar to that of pure quartz, has revealed that a progressive massive fibrosis does occur among the miners, and that it is a modified form of infective pneumoconiosis, with a high incidence of associated tuberculosis. Furthermore, a surprisingly large number of cases of primary lung carcinoma have been observed.

Analysis of the causes of death among 58 iron-ore miners on whom post-mortem examinations have been performed during the past two and a half years shows that 30% have died of pulmonary tuberculosis, suggesting that the dust predisposes to infection and the development of progressive tubercular disease. With regard to carcinoma of the lung, even when the rising incidence during the past 50 years among the general male population is taken into consideration, the number of deaths from primary lung carcinoma among the relatively small number (about 1,000) of haematite miners now employed is disturbingly high. Among 58 necropsies of iron-ore miners between 1954 and 1956 there was an incidence of 12% as compared with 5% in 661 males, not haematite miners, of more than 30 years of age. The striking feature of the tumours is their location in sites where dense fibrosis is commonly seen—that is to say, at the periphery, immediately under the pleura, and only later involving the hilum. The only similar increase in lung cancer in other siliceous industries has been noted in moulders, foundrymen, and asbestos and chromate workers. Moulders and foundrymen, like the haematite

miners, are exposed to the physical combination of silica and iron, acting as an irritant and leading slowly to fibrosis, while both asbestos and chromate contain a varying amount of iron in their chemical composition. It is suggested, therefore, that silica alone is not the causal agent of the tumours of iron-ore miners, and that they arise from the epithelial cells, damaged by the chronic irritation of ferric oxide and silica, at the edge of a fibrous mass.

Another lesion occasionally seen in haematite miners is a lymphadenitis of the hilar glands, with an associated sclerosing bronchitis and ulceration into a bronchus. The development of pulmonary tuberculosis and carcinoma is a slow process—the average age of those dying of the former was 57 and of the latter 61—and can be correlated with the great increase in mechanization at the beginning of this century, with a consequently great increase in production of dust. During the last 20 years measures undertaken to suppress dust have improved the general health and the radiographic appearances of the lungs of iron-ore miners, but it is only by keeping accurate records in the industry, in hospitals, and in post-mortem rooms that a true picture of the factors responsible for the disease can be established.

SUCCESS STORY

As the clinical physiologist of the operating team, the anaesthetist has been well to the fore in the spectacular advances made by surgery in the past twenty or thirty years. In the words of a great contemporary surgeon, his "understanding and expert partnership have won him a new respect and importance."¹ The meetings held in London last week to mark the silver jubilee of the Association of Anaesthetists fittingly celebrated the maturity of what is now an essential specialty. Twenty-five years ago, as Dr. T. Cecil Gray said at the jubilee dinner (see page 1445), there were only fifty specialist anaesthetists in the whole country. There were no chairs of anaesthesia, no diplomas in anaesthetics, and no Faculty of Anaesthetists. Cyclopropane had just been introduced, but intravenous anaesthesia with barbiturates had barely been heard of, and the use of trichlorethylene, curare, and hypothermia in anaesthesia was still a good many years ahead. In nearly all these advances British anaesthetists led the world, and they were admirably supported by the British pharmaceutical industry. No wonder the Minister of Health, speaking at the jubilee dinner, said that the growth of anaesthesia was a part of the success story of science.

ROYAL COMMISSION DELAYED

The chairman of the Royal Commission on Doctors' and Dentists' Remuneration has written to the Minister of Health and the Secretary of State for Scotland to say that the Commission's task is proving more complicated and therefore taking longer than he had first expected. His letter is published in this week's *Supplement* at page 193. Its implications will be considered by the Council of the Association at its meeting on December 18.

FOOD AND HEALTH*

BY

H. M. SINCLAIR, D.M., M.R.C.P.
Vice-President, Magdalen College, Oxford

The theme selected this year for World Health Day is "Food and Health," but I think it would be better slightly to alter this to "Food for Health." It is not always remembered that the purpose of food is to promote health, and nutrition stands here pre-eminent, as it is now the most important single environmental factor affecting health. Since *salus populi suprema lex*, the Ministry of Health should be the key Government Department, but it tends to be a rather junior Ministry of Disease.

A century and a half ago my great-grandfather, Sir John Sinclair, created and became first President of the Board of Agriculture. Later Fisheries were added, and recently Food was included as an addendum. The purpose of agriculture and of fisheries is to produce food, and the purpose of food is to promote health. To ensure that the maximum amount of the right type of food is produced these activities might best be concentrated in the Ministry of Health, and I should like to propose the abolition of the Ministry my great-grandfather created. Indeed, during the second world war the Cabinet sensibly decided that nutritional policy should be dictated by the Ministry of Health and that the implementation of that policy was the province of the Ministry of Food and only secondarily of the Ministry of Agriculture and Fisheries. Under the wise scientific guidance of Sir Wilson Jameson at the Ministry of Health and of Sir Jack Drummond at the Ministry of Food, that policy was highly successful, particularly as in this war, unlike at certain disastrous periods in the first world war, we had brilliant Ministers, outstandingly Earl Woolton, who sought and took scientific advice.

Nutrition of Children

We all know the remarkable effect that the diet of the expectant mother has upon the complications of pregnancy and upon the health of the infant. The infant mortality in this country is only one-seventh of what it was a century ago and half what it was twenty years ago, and it continues to fall in a most encouraging way. But the stillbirth rate is not falling and the death rate from toxæmia of pregnancy remains high. The Welfare Foods Service, which costs over £15 million yearly and was recently transferred from the Ministry of Food to the Ministry of Health, is no doubt responsible for a very significant part of the improvement, but I suspect that we have been a little too complacent about its merits and have not striven through research to reach perfection in it. There are, we know by experiment, defects in cow's milk as a food for infants, since it is demonstrably inferior to human milk in the type of fat it contains, and National dried milk has more serious defects; orange juice may not be the ideal vehicle for vitamin C because of the citral it contains (though almost no research has as yet been done on this); and cod-liver oil is far from being the best vehicle for vitamins A and D because of its negligible content of vitamin E and essential fatty acids and high content of foreign unsaturated fatty acids.

*Address (here slightly abridged) delivered in the Beveridge Hall of London University on April 6, 1957, to celebrate World Health Day, in the presence of Mr. Dennis Vosper, the then Minister of Health, and of H.E. Mrs. Pandit, with Sir Allen Daley in the chair.

An annual expenditure on research of one-hundredth of that cost of over £15 million might well have saved millions of pounds: for instance, the Government has accepted a recommendation of a committee under the chairmanship of Lord Cohen of Birkenhead that welfare orange juice is not required by children over 2 years of age, to whom it has unnecessarily been administered for 15 years at a cost of about £½ million yearly. A little research costing a few thousand pounds could have established that and so saved £7½ million. Therefore, though the Welfare Food Service has been and is a great contribution to the health of the nation, we might do well to examine it critically and make it even more significant.

A remarkable improvement has occurred in the heights and weights—and indeed in the health—of schoolchildren. The present admirable school meals service may be traced to the Destitute Children's Dinner Society of a century ago, but as recently as 1934 an administrative rule was made that a child must be both poor and suffering from malnutrition in order to qualify. We passed through the period of "feeding centres" for necessitous and undernourished children to the present excellent school meals and milk services, which in their present form date from 1945 and 1946 respectively. I hope these have come to stay, because they not only contribute importantly to the nutrition of the child, but also educate the child—and through the child the family—in the right choice and preparation of foods.

Having handed this well-deserved bouquet to the Ministry of Education, whose Chief Medical Officer is the Chief Medical Officer of the Ministry of Health, I must add a word of caution. I have for years carried on a lonely campaign against the overfeeding of children. In every animal in which the experiment has been made it has been shown that overfeeding during the period of growth and development shortens this period, so that adult size is reached earlier, and also shortens life. I believe this is a real danger in the U.S.A., and I believe we also must be careful lest by overfeeding children we hasten chronic degenerative diseases. Cow's milk is not a perfect food for man, mainly because of the composition of its fat, and I think we most seriously need research into the optimum diet for producing the optimum rate of growth of children.

Degenerative Diseases in Adults

I have mentioned chronic degenerative diseases, and we think of these in particular in turning as I now do to adults. A former Surgeon-General of the U.S.A., Dr. Thomas Parran, once said that like an iceberg nine-tenths of our malnutrition—and the most dangerous part—lies under the surface. One-tenth is obvious and easily detected; not many years ago we had gross cases of rickets, scurvy, and nutritional anaemia in this country. Still in different parts of the world pellagra and beriberi are endemic, and in certain countries goitre and imbecility from cretinism are widespread; indeed, though we know the cause and method of prevention of beriberi, it is increasing. No research is needed to detect these tragedies, because they are so obvious: food and education are required for their prevention. Only 22 years ago, Dr. Cicely Williams first described kwashiorkor, a disease of protein malnutrition that kills half the infants born in certain underdeveloped countries. Can it be that other nutritional disorders remain unrecognized?

When Dr. Williams made that discovery I was a medical student, and I started to work on human nutrition because I had become convinced that what was and is perhaps the most serious problem in medicine arose from alterations in our diet from the processing and sophistication of foods. My clinical teachers could not answer why the expectation of life in this country of the middle-aged man is hardly different from what it was at the beginning of this century or even a century ago. That means that despite the great advances in medicine—pneumonia almost abolished, tuberculosis comparatively rare, the magnificent advances in surgery, endocrinology, and public health—a middle-aged

man cannot expect to live more than four years longer than he could a century ago—and indeed in Scotland the expectation of life is now actually decreasing. This is because of the dramatic increase in this country, and in the more privileged countries of the world, of certain chronic degenerative diseases. Degenerative diseases found predominantly in the more highly civilized countries include coronary thrombosis, pulmonary infarction, cancer of the lung, peptic ulcer, gall-bladder disease, appendicitis, and the so-called collagen or mesenchymal diseases (which include such widely diverse conditions as certain allergies—for instance, asthma, nephrosis, disseminated lupus erythematosus, ulcerative colitis, and rheumatoid arthritis).

From work on lower animals combined with a study of the distribution of these diseases of civilization there is a reason to suspect that they may have their origin in a relative deficiency of essential fatty acids. These highly unstable vitamins are found mainly in vegetable oils, and they are stabilized in nature by the presence of vitamin E. In the body, conversion into the even more unstable vitamin arachidonic acid is achieved by vitamin B₆, and again vitamin E is required for protection. We therefore have this trinity of vitamins required: essential fatty acids, vitamin E, and vitamin B₆. Absence of one or other or all can produce deficiency. The balance of the diet is far more important than is often supposed.

In deficiency in lower animals three main structural defects occur. First, cholesterol and phospholipids, which with protein comprise the building-stones of cells, are not transported properly and become deposited for instance in arteries. Secondly, because the building-stones are absent, cell membranes, including the myelin of nerves, are not formed properly and the mitochondrial membranes inside cells are probably defective, with consequent faulty metabolism in the cells. Thirdly, the connective tissue that binds cells together is defective. The cholesterol is deposited in the intima as atheroma, in the skin as xanthoma, in the cornea as arcus senilis, and in the lens of the eye as senile cataract; as arcus senilis, and in the lens of the eye as senile cataract; it is perhaps of interest that when early in the war I examined Canadian Indians living on a primitive diet in Northern Canada I found arcus senilis almost absent even from elderly ones, whereas in young English and New Zealand pilots being trained there—carefully selected for full health and carefully fed according to accepted rules—therefore not surprised at the very high incidence of atheroma found in young United States soldiers killed in the Korean War.

The faulty structure of cells and of connective tissue gives rise in lower animals to a precarious state in which a slight insult or stress to the body produces a violent reaction which the normal tissue would avoid. Several years ago Professor Ramalingaswami, now of the All India Institute of Medical Sciences, showed with me that follicular hyperkeratosis, a common skin condition in India, was probably caused by this deficiency; and more recently I have suggested it also causes the alarmingly frequent bladder stone of malnourished children in the Far East.

We believe this deficiency of this trinity of vitamins is a basis of certain diseases of connective tissue, of certain nervous diseases, of duodenal ulcer, of certain diseases of bone and teeth, of degenerative diseases of the circulation such as coronary thrombosis and dissecting aneurysm of the aorta, and that it even plays a part in carcinoma of the lung, since the defective structure of the cell makes it more susceptible to a chemical carcinogen. In this connexion it is worth recalling, as Sir Ernest Kennaway has recently done, that cholesterol is carcinogenic. It appears that the damaged epithelial lining of the nose and gut allows foreign proteins to enter more easily, with consequent allergic disorders, and perhaps allows viruses to enter more easily; poliomyelitis is now a disease of adults in civilized countries and is no longer "infantile paralysis"; and there is published evidence indicating that essential fatty acids in the diet protect man against the virus that causes the common cold.

I must add a special word about teeth, for they are connective tissue, and caries—the most prevalent disease of man—is a disease of civilized countries. Yet, as in all these other conditions, almost no research is done into its cause. The annual cost of the National Dental Service is of the order of £40 million, and since the prevention of caries would enormously decrease that expenditure research into the cause might seem desirable on financial considerations alone. Research has indeed proved that deficiency of vitamin B₆ in lower animals can produce caries, but instead of seeking the cause in man we embark upon a policy of adding fluoride to drinking-water without, in my opinion, fully adequate investigation by research into the chronic effects of that, particularly in old people. I am not alone in that view. Two days ago I received a letter from one of the leading nutritional experts in the U.S.A. in which he mentions his recent experimental results that cause him to question the value of fluoridation and to deplore "the regimentation of the American physicians and dentists [who] know nothing about fluoridation and say what they are ordered to say." I believe this is one of many examples where a little learning is a dangerous thing, and where health may be injured and science brought to disrepute by the incautious and premature application to public health of insufficiently investigated procedures. Enthusiasm to apply the fruits of research is laudable, but eagerness must be tempered with wisdom, which includes having all the relevant facts available.

Processing of Foods

Some may wonder what has happened to the diets of more highly civilized countries so that these chronic degenerative diseases are increasing so rapidly. Almost every alteration we make tends to decrease the trinity of vitamins I have mentioned, and in some instances adds antagonistic fatty acids that increase the dietary need of the essential ones. It has been known for twenty years that the fat of cows and sheep contains very little of the essential fatty acids and a large amount of an isomer that may be antagonistic; milk, butter, dripping, and the fat of the meat of these animals are seriously deficient, therefore, and the time may well come when we shall have to abolish the cow unless we undertake research to overcome this defect by alteration of the fat of milk or of the balance of the diet. The advice given in Leviticus vii, 22-23 may be sound if divorced from its context: "And the Lord spake unto Moses, saying, 'Speak unto the children of Israel, saying, Ye shall eat no manner of fat, of ox, or of sheep, or of goat.'"

Further, our present practice of producing prime beef and mutton by feeding stable concentrates decreases the unsaturated fatty acid content further. We do the same with pigs, and we stabilize lard to make it keep better. Then we fry it, which not only tends to destroy essential fatty acids but can produce substances that will cause cancer in rats and mice. We feed hens on concentrates that are deficient in the unstable fatty acids, and the eggs in consequence are deficient. We hydrogenate fats to make margarine, though some margarine contains important amounts of essential fatty acids. We now remove from bread and flour much of the vitamin B₆ they contain, and they were our most important source of this vitamin; and we add the flour "improvers"—agene (now forbidden) and chlorine dioxide—which oxidize most of the vitamin E and destroy at least some of the essential fatty acids as well and even chlorinate part of these, with production of what may be a powerful antagonist. We do not know as yet whether this is significant, because the requisite research has not been done. To show the extent of our ignorance of what we are doing, let me mention that recent work at the British Baking Industries Research Association has shown that bran contains a powerful antioxidant which will permit cakes baked from wholemeal flour or from white flour to which bran has been added to keep at the temperature of the body for a whole year, whereas without bran they keep only a few days before going rancid—and rancidity indicates loss of essential fatty acids.

Need for Nutritional Research

The problem is not only one of Western countries. Coronary thrombosis, described recently by Dr. J. N. Morris, of the Medical Research Council, as "a modern epidemic" here, is becoming prevalent in India as foods are altered to make them more stable and more easily stored and distributed. Despite this we admit the necessity of altering natural food by processing and by the addition of chemicals. This is done to alter and improve taste and to preserve foods, and it is hallowed by tradition: spices were added primarily to conceal off-flavours, but it is interesting that we have lately learnt that they contain powerful anti-oxidants that protect essential fatty acids and vitamin E. I pay tribute to the high standard of the food manufacturers, who have a laudable sense of responsibility; and even if they did not, they, being astute business men, would hardly produce products intentionally that would eventually harm their customers. The difficulty, as Sir Charles Dodds has pointed out, is that it seems to be no one's business to do the relevant human nutritional research and to watch what is being done and keep abreast of advancing science.

The Food and Drug Administration in the U.S.A. carries out extensive toxicity tests on lower animals, and, as Sir Edward Mellanby pointed out six years ago, "we are in the undignified position of having often to rely on the decisions arrived at in the U.S.A. before policy or action can be determined." This Food and Drug Administration in the U.S.A. has stated that of 704 chemicals used in foods no fewer than 428 are known to be innocuous. Perhaps that is comforting, perhaps not. And those believed to be innocuous are so classified because they do not kill rats or mice. Man is a different animal, as is sometimes forgotten. When, after some ration trials I attended in Canada during the war, it was found that a soup prepared by a U.S.A. scientist made ill those troops who managed to drink it, he plaintively remarked: "That's odd! Rats grew all right on it." We know a great deal about animal nutrition, and millions of pounds are spent in its study, yet only a negligible sum is spent upon research into human nutrition.

Surely it is to the advantage of the Government, of the people, of the food manufacturers, and of the life assurance companies that more research should be done: obviously to the Government because the National Health Service costs £630 million annually, and untold millions are lost through minor illnesses and absenteeism, and even through the lassitude and vague ill-health that malnutrition early causes. Poor health impairs productive capacity, low production brings undernutrition and ill-health and less productive power, and so the vicious cycle goes on.

We need what exists in certain other countries—an Institute for Human Nutrition, where all information will be gathered together and collated, to which people will come who seek such integrated knowledge, be they medical practitioners or educators or food manufacturers, and in which the frontiers of knowledge will be advanced by experimental research and by the epidemiological correlation of diet with disease, and where ideas can be interchanged between different countries. Such work is international. Much knowledge is still to be gained by studying food practices that are hallowed by tradition and established in folk-lore. Much ignorance is still to be dispelled because of the fads and prejudices and nonsense that surround the subject of food. As the population of the world increases, doubling itself in the next fifty years, we must seek new sources of foods and new methods of preserving and transporting foods. New problems thereby arise. The aim of all is the same: to produce not dehydrated canned fodder but appetizing wholesome food. "Good digestion wait on appetite, and health on both"; but appetite is largely a matter of custom and experience; "one man's meat is another man's poison," and we must study and respect local preferences.

Physical science has provided most of the comforts that man needs, and medical science has conquered most of his ills

except the degenerative diseases. These lie, at least in part, in the province of nutritional science. We know that the right food is the basis of health, but we are still ignorant of what constitutes the right food and how to provide it for mankind. The objective of human nutritional science is long-range, but with an immediate dividend in health and happiness. We need more knowledge upon which we can base an intelligent and effective provision, use, and management of food. The new science of nutrition will shed much-needed light on one of the most fundamental, widespread, urgent, and inadequately managed problems in the whole domain of human welfare. For nutrition has now become the most important single environmental factor affecting health in every country of the world. All men seek freedom from want, and the two fundamental wants of man are food and health.

PROMOTION PROSPECTS OF SENIOR REGISTRARS IN SCOTLAND

BY

HAMISH WATSON, M.B., M.R.C.P.E.

Chairman, Scottish Registrars' Group Council

This paper is an attempt to analyse, on the basis of detailed information, the extent and nature of what has come to be known as the senior registrar problem as it applies to Scotland. It has been prepared from tables supplied to the British Medical Association by the Department of Health for Scotland, giving the year of birth of all consultants and senior registrars in Scotland as on December 31, 1956. The figures for consultant vacancies are based on the assumption that they will retire on reaching the age of 65 years, and no account has been taken of any "wastage" factor. No names have been given and the figures have been broken down to cover all specialties in each region and also in Scotland as a whole; total numbers and average ages have been used for the conclusions reached.

Present Establishment

From Table I it will be seen that there are 250 senior registrars in Scotland; 41 of them have already held their present posts for more than four years, and many others have held previous appointments in this grade. Their average age at 35 is already three years more than the few who do gain promotion will find their total life earnings considerably less than they should have been, because the salary scales were based on the Spens assumption that 32 would be the average age of consultants when first appointed. For the same reason the remuneration of those in all the junior hospital grades is correspondingly very much too low. The present salary scales were designed to ensure a steady rise with age and experience for those considered worthy by appointment boards. They are not only too low for the reasons just given, but the plateau at which have become established for those marking time at the second-year registrar and fourth-year senior registrar salaries were not envisaged and are quite contrary to the understanding and interpretation of the hospital staffing structure which was accepted by the profession in 1948.

Much has been said about the ratio of consultants to those in the training grade, and it is often suggested that if only some satisfactory mathematical formula could be found the problem would be resolved. Closer examination of the situation, not only as it exists to-day but as it will be in future years, shows that this is far from being true, and that such a "solution" would give rise to future

Prospects of Promotion

A study of Tables II, III, and IV will show that the promotion prospects for those already trained and in training are so very bad that, with the escape routes to the Services, the Colonies, and the Dominions almost closed, immediate action is required to rectify the grave position in which they find themselves. Having applied in good faith for advertised appointments in the training grade of the hospital service, they expected to have a reasonable chance of becoming consultants, and it is now quite obvious that they do not have this—nor can they in the foreseeable future. Their difficulties are increased because compulsory full-time contracts have made alternative training impossible. There is no reason to believe that they are any less able than those who became consultants during the build-up of the hospital service in and after 1948, or, for that matter, those who will so easily find vacancies in 1977-81. It would therefore seem unreasonable to expect them to accept a rank junior to that of consultant even if the structure of hospital staffing were changed to include a new career grade.

The solution most frequently advocated by the profession is a review of all consultant posts, which, it is claimed, would reveal the need for the creation of many new ones. The figures presented in this report show that to solve the present problem the number required would be impossibly large, and that, even if they could be created, finding enough consultants in 20 years' time would become well-nigh

TABLE I.—Numbers and Average Ages of all Consultants and Senior Registrars in all Specialties in each Region and in Scotland as a Whole

impossible. The short- and long-term problems which have been revealed are so difficult to solve and the possible solutions so incompatible that it seems obvious that the time has come when an independent commission should be set up to review, not junior hospital staffing, but the whole structure of hospital staffing, which in its present form is quite unsatisfactory.

It has been suggested that Tables II and IV refer to a time in the future when it is not known what the nature of hospital staffing will be, and that therefore no valid argument or conclusions can be based upon them. There is no doubt, however, that these consultants will be 65 in the years indicated, and it is unlikely that, irrespective of what may happen in individual specialties, the overall number of responsible posts, whatever name is given to them, will be reduced. In fact, all the discussions which have so far taken place indicate that, if anything, it will be increased. It seems reasonable, therefore, to draw what conclusions we can from the information that is available.

Another criticism has been that these figures, applying only to Scotland, do not present a true picture of the problem, as Scotland traditionally exports doctors. An attempt has been made to test the validity of this argument, and, though figures are not yet available for the whole of

Scotland, Table V shows the position in the Western Region, which contains more than 50% of the total establishment of consultants and senior registrars in Scotland and which therefore must be highly significant. The figures were supplied by the Western Regional Hospital Board and refer to the three-year period 1953-5. It will be seen that during this time 110 consultant posts were filled. Of these, only 17 were filled by local senior registrars and 14 were filled by senior registrars imported from outside the Western Region—that is, only 31 of the 110 consultant vacancies, or 28%, were filled from the senior registrar grade. During this period only six senior registrars were exported to fill consultant posts outside the Western Region—that is, 23 of the 130 senior registrars in the region became consultants during these three years. There is therefore no evidence that we are exporting consultants; the trend, if anything, would appear to be in the reverse direction.

In calculating the prospects of promotion and in attempting to evolve suitable ratios between the various grades, it has usually been assumed that the majority of vacant consultant posts would be filled by senior registrars. Table VI, however, shows that only 37% have been so filled. This demonstrates clearly that the "senior registrar problem" is even more serious, and the chances of promotion are in

fact very much less than the preceding tables suggest. If all the consultant vacancies in Scotland during the next five years are filled by senior registrars working in Scotland there will be on average only 14 jobs for 250 men each year. If consultants, S.H.M.O.s, university staff, etc., are as successful in competition for these posts as they have been during the last three years, then only four of them will be filled by senior registrars; surely a grave situation which deserves

As a result 26 S.H.M.O.s were regraded consultant. This necessitated the creation of 26 new consultant posts. These are not included in the figures given above.

more vigorous action than it has received in the past, when years of discussions have concerned mainly matters of principle.

It is now four years since the Strachan Committee was constituted by the Central Consultants and Specialist Committee to examine the structure of junior hospital staffing. During this time all matters relating to hospital staffing structure have been persistently shelved pending, firstly, its report.

TABLE VI.—*Previous Grades of All Consultants Appointed in Scotland During the Last Three Years (1953-5 for Western Region)*

and, latterly, the rather leisurely and protracted discussions which have been taking place between the Ministry of Health and the Joint Committee. They have been long years for the senior registrars, who are four years older, whose families are four years older, and whose prospects are no brighter. Yet, from what I hear, a settlement now seems further off than ever. Cold comfort this for those who have waited so long and who cannot go forward and cannot go back.

As the profession is unable to agree, and the profession and the Ministry are unable to agree, surely the time has come for an independent commission to review the whole structure of hospital staffing and to stop juggling with the junior staff in abortive attempts to make them fit in with a sacrosanct senior staffing structure. With good will on all sides, and in the light of the experience gained since 1948, it should not be impossible to work out a suitable plan for the future which will prevent a recurrence of the present intolerable situation in which so many senior and highly skilled young men find themselves through no fault of their own.

DIAGNOSTIC RADIOLOGY IN ENDOCRINE DISORDERS

At its annual congress last month the British Institute of Radiology spent an afternoon discussing the diagnosis of endocrine disorders. The congress was held in London, under the presidency of Dr. L. F. LAMERTON, from November 27 to 29. After an opening address by Lord COHEN OF BIRKENHEAD on "The Physician's Debt to Radiology," the congress settled down to a three-day scientific programme on problems of diagnosis, therapy, and radiobiology. Dr. F. G. SPEAR (Cambridge) gave the Mackenzie Davidson memorial lecture.

With Dr. J. E. BLEWETT (King's College Hospital, London) in the chair, Dr. A. W. SPENCE (St. Bartholomew's Hospital, London) opened the session on radiological diagnosis in endocrine disorders. After expressing the physician's gratitude to the radiologist for his ever-increasing help, especially in the diagnosis of adrenocortical syndromes, where the patient was now often spared from unnecessary surgery, Dr. Spence went on to describe the commoner endocrine disorders individually. Pituitary tumours might be hormone-secreting, like the eosinophil adenoma, he said, or they might exert their effects by destroying the anterior lobe and causing hypopituitarism, as did the chromophobe adenoma and suprasellar tumours. Radiology might be the

Adrenal Lesions

only way of distinguishing the two latter conditions, as their clinical effects could be exactly similar. In the diagnosis of hyperparathyroidism and adrenal cortical hyperactivity, skeletal radiographs helped considerably, and also in assessing bone age in cretinism, hypogonadism, and sexual precocity. Calcification in the adrenals might help confirm the tuberculous nature of Addison's disease, while renal calcification was a sign of the increased renal excretion of calcium in hyperparathyroidism. Hypoparathyroidism was associated with increased density of the bones and calcification of the basal ganglia. Serial radiographs of the hands in acromegaly and of the heart in myxoedema confirmed the effectiveness of therapy.

Tumours Around the Sella Turcica

Tumours Around the Sella Turcica

Dr. G. F. SWANN (National Hospital, Queen Square) then described the radiological appearances of intrasellar and parasellar tumours. He had investigated this subject because of a case with unusual features. Tracings of the radiographs of 50 cases of intrasellar tumour showed that their main features were deepening of the sella with thinning of the floor and dorsum sellae, backward tilting of the posterior clinoid processes, and elevation and undermining of the anterior clinoid processes. Suprasellar extension caused displacement of the third or lateral ventricles. There was no correlation, however, between the appearances of the sella and the development of endocrine changes—the latter occurring in only 20 cases. A parallel series of 50 cases of craniopharyngioma showed less enlargement of the pituitary fossa, but destruction of the posterior clinoid processes and hollowing of the anterior clinoids with adjacent calcification. Intrasellar calcification tended to be commoner among the younger patients, but bore no relationship to the size of the sella. All cases showed deformities of the ventricular system, and in 30 there were endocrine changes, in the majority of instances hypopituitarism.

In 15 cases of suprasellar meningioma visual failure was the predominant symptom and there were no endocrine changes. Radiology showed destruction of the posterior clinoid processes and hollowing of the anterior clinoids with calcification above. The floor of the sella was not affected. Carotid angiography confirmed the nature of the tumour by demonstrating the typical vascular pattern.

Raised intracranial pressure caused flattening of the sella, due to enlargement of the third ventricle, hollowing of the anterior clinoid processes, and destruction of the posterior clinoids. Secondary endocrine changes were rare.

Hypothyroid Children

Hypothyroid Children

Dr. R. ASTLEY (Children's Hospital, Birmingham) discussed hypothyroidism in children. The main radiological change was the delay in appearance of the centres of ossification, which were also abnormal, being dense, honey-combed, or fragmented. The metaphyses were widened, with a line of increased density, and there was also a general decrease in the length of bones although their width was normal or increased. Other features included delay in closure of cranial sutures and fontanelles, presence of Wormian bones, hypoplasia of vertebral bodies, and occasionally calcinosis of soft tissues.

Epiphyseal dysgenesis was best revealed in the femoral heads, and serial radiographs would show gradual improvement after the institution of thyroid therapy. Until 6 years the bone age was best estimated from a radiograph of the carpal bones, but after this the elbow was more useful. An important differential diagnosis was dysplasia epiphysealis multiplex. In this condition dwarfism, stubby digits, and mottling of the epiphyses occurred, but pain was a prominent symptom in contrast to the painlessness of hypothyroidism. Characteristic radiological features of dysplasia epiphysealis multiplex were the irregularly shaped mottled epiphyses and marked sloping of the lower epiphyses of the tibiae and talus. There was, of course, no response to thyroid therapy.

Dr. J. W. LAWS (Hammersmith Hospital, London) brought the session to a close with a paper on the radiology of the adrenals. In the diagnosis of adrenal hyperplasia or tumours he found that perirenal insufflation with either oxygen or carbon dioxide combined with an intravenous pyelogram and tomograms gave the most useful information. The outline of the normal adrenal gland was triangular, with an area of 1.8 sq. cm.: in adrenal hyperplasia both glands were increased in size, whereas if an adenoma was present the contralateral gland was reduced; convexity of the borders of the gland was pathognomonic of a tumour. False negative results might be obtained if the tumour was small, or if it was malignant and thus impaired the spread of oxygen throughout the surrounding tissue planes. Dr. Laws then briefly discussed the hormones produced by the adrenals and their clinical effects. With the advent of cortisone cases of adrenal haemorrhage might now recover and later show areas of calcification.

In Addison's disease a chest film was essential to exclude pulmonary tuberculosis, while serial films might show decrease in heart size once effective therapy was begun. Cushing's syndrome produced striking effects on protein metabolism, and these manifested themselves radiologically as osteoporosis and by spontaneous fractures. Primary aldosteronism always had to be differentiated from potassium-losing nephritis, and an intravenous pyelogram might help by showing in the latter condition evidence of poor renal function due to previous pyelonephritis.

Preparations and Appliances

SUBSTITUTE FOR THE SOUTTAR TUBE

Mr. J. K. B. WADDINGTON, consultant thoracic surgeon, Aintree Hospital, Liverpool, writes: The treatment of oesophageal stricture by a spiral-wire Souttar tube is often unsatisfactory. The irregular inner surface becomes clogged by curds of food particles and may be invaded by tumour cells growing between rings of wire. Moreover, its metallic construction encourages ulceration of the tumour, with the result that the tube sloughs through the stricture and finishes up in the stomach.

To avoid these inconveniences, a "polythene" tube 4 in. (10 cm.) long by $\frac{1}{4}$ in. (9.5 mm.) in diameter was devised. Its flared end provides a better "lead-in" for food into the tube, it rests lightly on the stricture, and does not ulcerate. The smooth surface remains clean, and it is impenetrable by tumour cells. The tube is easily introduced by orthodox methods, and where the stricture is tortuous the tube can be softened in hot water to make introduction easier. The flared upper end can be trimmed with scissors if it is too large to pass through a female oesophagoscope. Having used this type of tube for twelve months, I now prefer it to the regular Souttar tube, and it has on occasion been *in situ* for as long as four months without requiring any attention. The initial models were procured for me by Messrs. Alexander and Fowler, of Liverpool, and are manufactured by Portland Plastics Ltd., Hythe, Kent.

Lesions of the sacro-iliac joint which are radiographically similar to those seen in ankylosing spondylitis may be found

in Reiter's disease (associated with urethritis), in paraplegics (with bladder and prostatic infection), ulcerative colitis, and Crohn's disease. The sacro-iliac joint is very rarely involved in destructive arthritis of generalized distribution—e.g., rheumatoid arthritis. The almost universal, early, and very frequently symmetrical bilateral involvement of the sacro-iliac joints as the cardinal feature of ankylosing spondylitis strongly suggests that this very unusual distribution of arthritis is in some way influenced by a local lesion in the pelvis. It may well be that a chronic inflammatory focus in the lower uro-genital or alimentary tract is responsible, in susceptible patients, for this very frequent bilateral involvement of the sacro-iliac joint in ankylosing spondylitis.—I am, etc.,

London, S.E. 1.

Influenza Epidemic

SIR,—Eyestrain would appear to be a very common manifestation of post-influenzal debility. After influenza epidemics in the past few years there has always been an increase in the number of cases requiring refraction as compared with the same period of the previous year when there has been no influenza epidemic. I have noticed, however, that this has not happened following the recent epidemic of Asian influenza, and in fact the local executive council's figures for refractions in this town in October and November show very little change from the same period last year. I wonder whether other manifestations of post-influenzal debility have been absent, and I also wonder whether doctors in other parts of the country have experienced the same freedom from debility following Asian influenza.—I am, etc.,

Dudley, Worcs.

Effect of Rubber on Haemoglobin

SIR,—The addition of as little as 1 part in 1,000 of formaldehyde to a solution of normal adult haemoglobin increases its resistance to alkali denaturation. This effect is not produced by acetaldehyde, acetone, ethyl, and methyl alcohol, or phenol. As a practical measure, it seemed necessary to discover whether storage of haemoglobin in contact with commercial rubber could alter its alkali-resistant properties.

A preparation of adult haemoglobin was made in the usual way. It contained 9.6 g./100 ml., and gave a reading of less than 1% for the alkali-resistant residue by Singer's technique. It was divided into three parts. One part was stored in contact with glass only. The second part was added to some snippings from an ordinary clean laboratory rubber bung which had been boiled in distilled water and drained. The third part was added to parts of a flexible indiarubber, similarly treated. Snippings from the rubber bung were also kept beneath distilled water, and developed no colour throughout the experiment. All preparations were stored at about 5° C. Aliquots of haemoglobin were tested at intervals for alkali-resistance by Singer's 1-minute method. The glass-stored part gave readings below 1% throughout. The parts stored in contact with ordinary indiarubber gave readings as follows: 3rd day, 2.7%; 14th day, 2.3%; 40th day, 2.5%. The part stored in contact with the rubber bung gave the following readings: 3rd day, 2.9%; 14th day, 3.8%; 21st day, 5.2%; 48th day, 6.0%; 52nd day, 6.65%.

No explanation is offered of these findings, which may be summarized by saying that on prolonged storage of haemoglobin solutions in contact with vulcanized rubber there occurs a small but perceptible rise in the residue that is measured in the Singer 1-minute denaturation test. One may conclude that caution is necessary in interpreting minor changes in alkali-resistant haemoglobin in samples that may have been long in contact with rubber.—I am, etc.,

ALAN B. RAPER.

Femoral Hernia

SIR,—I am in substantial agreement with Mr. Robin Burkitt's advocacy (*Journal*, November 16, p. 1176) for Professor A. K. Henry's midline extraperitoneal approach¹ in femoral hernia operations when the femoral ring is closed by a flap of pectineal fascia. My criticism of operations at the femoral ring level was directed against closure of the ring by bringing together the anterior and posterior boudaries, which lie far apart and tend to tear away after suture.

My preference is for the low operation. The accepted teaching is that the curved edge of Gimbernat's (lacunar) ligament forms the inner boundary of the femoral ring and lies at the upper end of the femoral canal. The purpose of my article² was to show that the curved edge of Gimbernat's ligament lies at the lower end of the femoral canal, where it forms the anterior and medial boundaries of the femoral hernial orifice. This name, the femoral hernial orifice, I gave to the circular opening of new formation which surrounds the neck of the hernial sac and is the hole where the hernia has broken through the fascial layers at the lower end of the femoral canal. It is the femoral hernial orifice, which is an opening with strong walls reinforced by Gimbernat's ligament, which I affirm should be repaired. The operation is quick and easy, and can be done, if necessary, with a local anaesthetic.—I am, etc.,

Sheffield, 10.

Acute Respiratory Diseases in Young Children

SIR,—Your invitation to the College of General Practitioners and their hospital colleagues (*Journal*, November 23, p. 1228) to concerted study of the problem of acute respiratory disease in young children is to be applauded. Research on family infections, dietary habits, social and economic conditions will not suffice. In all such analyses the study of the whole person, the psyche as well as the soma, must be carried out.

When a patient attends the surgery he presents himself not because of anatomical or physiological disturbance but for alleviation of his suffering. When an adult patient is brought by somebody else we already suspect an abnormal emotional attitude to the illness, by either person, or both. This is not so interpreted in paediatric cases. In our assessment of diseases of children care must be taken to differentiate between the suffering of the child and the suffering of the mother. The child may well be "the presenting symptom" of the mother. The acceptance of the mother's overt anxiety as a direct result of the child's condition and the neglect of her emotional problems result in reattendances.

Research in my own practice on the problem of the catarrhal child has led me to these tenets. Firstly, the primary reason for the admission of children to hospital with varying phases of sino-laryngo-tracheo-bronchitis is my own anxiety about prognosis. The amount of anxiety is related more to the agitation, anxiety, and despair of the parents, with their increasing demands, than to the course of the illness. The necessity for further advice and treatment in hospital, "the dilution of responsibility," is resorted to, so relieving the child, the parents, and the practitioner from an accumulated tension. Secondly, the largest group of children admitted to hospital belong to the over-protected type. Subdivisions of this type are the overindulged child, the result of the mother attempting to make up for what she missed in her own unhappy childhood. Or the child towards whom the mother is basically hostile but proves otherwise to the outside world by spoiling overlove. Another type is the child whom the mother uses as her love object, concealing her unconscious estrangement from her husband and producing, if she can, the timid, dependent, clinging child. The mother in attempting to mould the child according to her own complexes must inevitably meet resistance as the

BRITISH
MEDICAL JOURNAL

1435

child reaches out for independence. If she succeeds the child may even enjoy his dependency and sickness. Perhaps in these spheres more information could be obtained from research into the reasons why the number of boys admitted to hospital is greater than that of girls.

Treatment in my own practice of the catarrhal child has resolved itself into symptomatic treatment of the child and, inevitably, psychotherapy for the parent. As I hope to show in a paper later, the resultant lessening of tension in the mother and the relief of pressure on the child have led not only to amelioration of the child's symptoms but also to a positive, healthier attitude to life on the part of the whole family. It is to be hoped, therefore, that all such research will not neglect the fields of psychological medicine.—I am, etc.,

Unheralded Pulmonary Embolism

SIR,—I read the article by Drs. H. Cohen and J. J. Daly (*Journal*, November 23, p. 1209) with considerable interest. It should focus attention still more on the problem of pulmonary embolism and will help to emphasize that pulmonary emboli do occur in those who are apparently normal in health and activity. My own experiences support this.

During the past year pulmonary embolism was the immediate cause of death in 41 (9.45%) of 433 consecutive necropsies. In four cases the patients were normally ambulant at the time of their first embolic episode—of these, one died immediately, two died of right-sided heart failure due to further emboli, and in the fourth the pulmonary infarct became infected, empyema followed by infectious pericarditis causing the patient's death. In only 5 of the 41 cases was the diagnosis of pulmonary embolism made prior to necropsy.

In emphasizing the frequency of pulmonary embolism and the apparent lack of awareness of the problem, I feel that I should qualify the statement made by these authors that one week's bed rest "is not generally associated with venous thrombosis." Pulmonary embolism between the fourth and seventh days following operation is by no means rare—there were four cases in my series. Only by a greater awareness of the problem can the correct diagnosis be made with increasing frequency and the appropriate therapy instituted. Drs. Cohen and Daly have shown us how rewarding correct diagnosis can be.—I am, etc.,

JOHN BURSTON.

Cosham, Hants.

Blood-sugar Estimation

SIR,—In his letter (*Journal*, November 30, p. 1305) Dr. J. Kleeberg mentions my method of approximate estimations of blood-sugar ranges. I am, however, afraid that a few inaccuracies have crept in, probably because, judging from the reference, Dr. Kleeberg has only had the opportunity to see my short letter¹ and not the full paper.²

First of all, may I point out that the method was specifically devised for the use of a drop of whole blood and not of serum, and this is one of its main merits? Furthermore, the colour does not fade after 15 seconds, but, on the contrary, continues to increase in intensity for quite a while, and this is the reason why it should be read within about half-a-minute from the time the blood has been washed off. I do not think that the reading of results within less than one minute can be regarded as a disadvantage; this makes the test really rapid and should not present any difficulties. The only possible difficulty, if any, is the correct colour appreciation. May I also point out that this is not a "tes-tape" method, as Dr. Kleeberg assumes? "Clinistix" only has been used because of some of its properties which makes it suitable for this particular purpose.—I am, etc.,

Dislocation of the Jaw

SIR,—Like your correspondent Dr. M. S. Sanders (*Journal*, November 23, p. 1240), I had a case of unilateral forward dislocation of the jaw while yawning in a lad of 18. Fortunately this occurred while he was getting up, so he was able to come to morning surgery.

I find it easier, when reducing dislocations of the jaw, to have the patient sitting in a low chair and to stand before the patient, so that my elbows are almost fully extended while exerting pressure downwards with the thumbs and upwards with the fingers. I was able to reduce the dislocation quite easily, but as he left the surgery he said, "Thank you," which caused a recurrence of the dislocation. This time, presumably owing to increased muscle spasm, it was much more difficult to reduce, and so he left without any expression of gratitude, and the condition has not recurred.—I am, etc.,

D. A. G. WILLIAMS.

Northampton.

Epistaxis

SIR,—Mr. J. P. Stewart's valuable contribution on epistaxis (*Journal*, November 23, p. 1231) has drawn attention to one of the problems which beset ear, nose, and throat departments all over the country. With experience of 20 years (including a period in general practice) I share his cynicism about the increasing admissions to hospital since 1948, and I have noted too that the admissions for epistaxis are more frequent at week-ends. The E.N.T. departments have so few beds. The single-handed surgeon often has no junior help and must therefore remain continually on call for such cases, many of which are sent to hospital without warning. Although I am well supplied with help, work here has been seriously interrupted on many occasions by the blocking of the narrow corridors of our clinic and wards by ambulance drivers with exsanguinated patients supine on blood-stained stretchers waiting for a non-existent bed. May I make a plea to general practitioners to treat all but the worst cases at home? May I suggest that the following methods be given a trial before the ambulance is sent for? After all, the bleeding episode has ceased by the time the case can be seen at hospital and the bleeding vessel is often invisible, making cautery impossible.

The first-aid books are at fault. The proper first-aid treatment is pressure applied to the bleeding point by pressing hard on the soft part of the side of the nose, or more simply by pinching the nose tight between the finger and thumb. The patient should then retire to the nearest sink, sit down before it on a chair and, leaning forward, bathe the face with the coldest water obtainable. Even if the pressure on the nose fails to stop the bleeding after five minutes, continued pressure is indicated to give the blood every chance to clot in the nose and seal off the bleeding vessel. If the head is leaned forward the blood will overflow at the back of the nose and escape from the mouth. If the head is held back the blood will flow into the throat and cause spluttering and choking, which will increase the haemorrhage and anxiety. Deep breathing in and out of the mouth will tend to empty the veins and the neck, and a cork held between the teeth will help too. Such treatment will stop most nose bleeds. If it fails, the patient must be put to bed and the nose plugged.

Nasal plugging has two functions—first, to apply pressure directly or indirectly to the bleeding vessel, and, secondly, to give the vessel time to heal or become obliterated by organized blood clot. For the second reason, the plug should obviously be left in place as long as possible. It is no use soaking the plug with adrenaline, whose physiological action is vasodilatation after preliminary vasoconstriction. If adrenaline is absorbed it will raise the blood pressure and increase anxiety, and if a plug soaked in adrenaline is left in for more than 24 hours it will stink and infect and congest the nasal mucosa. The early removal of such a plug may be rewarded with further serious haemorrhage. A plug which can be left in sufficiently long to allow the bleeding point to heal is one containing antibiotic (I prefer penicillin and sulphathiazole). A sufficient length of 1 in. (2.5 cm.) gauze (or, in emergency, bandage) is wetted under the tap, and wrung as dry as possible, so as to be sufficiently damp for the powder to adhere. A teaspoonful of the antibiotic powder is placed in the palm of the hand, the gauze is bunched up and the powder rubbed well into it between the two palms. With or without

preliminary cocaineization, the nose is packed tight from the floor upwards in such a way that no loose end can fall into the nasopharynx. The plug can be left in for up to a week, but four days is usually long enough. Of course, the nose may bleed through the plug—an indication perhaps for more packing or consultant help; but I would say that nearly every case of serious haemorrhage admitted to institutions under my care in the last ten years has responded to the use of such a plug left in for four days. The importance of reassurance and rest in bed cannot be overestimated.

Nasal cautery in its various forms is very valuable for recurrent cases if the bleeding site is obvious. I would disagree with Mr. Stewart about trichloroacetic acid. This is the easiest of all to use, but sufficient water must be added to the bottle containing the crystals. A very small quantity of the resulting syrupy fluid can easily be applied on a plain or cotton-tipped probe, after the application of cocaine.—I am, etc.,

York.

R. THOMAS.

Control of Cholera

SIR,—The article by Sir Leonard Rogers (*Journal*, November 23, p. 1193) is one of the most remarkable examples of concise exposition I have ever read in your *Journal*. This article within five pages summarizes a vast amount of personally conducted research on cholera over a period of 86 years, including his own medical career of 65 years, and should be studied by every member of the profession as a lesson in lucid description and in the value of deductive research in furthering advance in medicine.

Probably no other man has conducted such prolonged research on one disease for so long a period of time. By his work in cholera prevention, apart from his original work, which forms the basis of treatment, he must have prevented more deaths than any other living member of the profession or indeed than any living person; and cholera is only one of the props of the pedestal on which his fame rests. Surely, therefore, his name should be added to the list of the greatest doctors—Harvey, Pasteur, Lister, Pavlov, Ross, and Fleming?—I am, etc.,

Windsor.

PHILIP H. WILLCOX.

SIR,—I must protest most emphatically against Sir Leonard Rogers's reference to India as "the Hindu Republic of India" (*Journal*, November 23, p. 1193). We are a secular democracy and the freedom of culture and religion is a fundamental right, ensured by our constitution. Of the 357 million Indians, 117 million are non-Hindus, of whom the bulk are Mohammedans, apart from the 8.2 million Christians.

It is far from my thought to suggest any similarity between Sir Leonard's reference and the performance of the hysterical anti-Indian section of the press. Yet even such unconscious inaccuracies as Sir Leonard's will do much harm, which is easily done but very difficult to undo in the present political climate, especially as people are generally uninterested and therefore ready to swallow anything printed on paper. While it is interesting to investigate subliminal advertising, it is urgent to avoid inaccuracies like this, not only in the interest of truth but of better relationship also.—I am, etc.,

London, W.1.

K. V. SHAH.

Aldosterone Excretion in Pregnancy

SIR,—Dr. R. Schuurmans rightly points out in his letter (*Journal*, November 23, p. 1239) that the urinary excretion of adrenal cortical hormones may not always reflect the rate of secretion by the adrenal glands, and, indeed, studies with radioactive cortisol and aldosterone have suggested that the turnover of adrenal cortical hormones is greater than would be expected from the amounts of these hormones and their metabolites found in the urine.^{1,2} Nevertheless, the estimation of urinary corticosteroids is frequently of value in the clinical assessment of the activity of the adrenal glands despite individual variation and the technical difficulties of complete recovery.³

Dr. Schuurmans suggests that the reduced excretion of aldosterone in the urine of patients with toxæmia of pregnancy may be due to dilution in an increased volume of extracellular fluid. This possibility assumes that the output of aldosterone from the adrenal glands is at a constant rate and implies that the urinary excretion of other adrenal cortical hormones and their metabolites would be similarly affected. We have observed little difference between the rates of excretion of hydrocortisone and cortisone and their tetrahydro derivatives by pre-eclamptic and normal pregnant patients, a finding consistent with those of Appleby and Norymberski.⁴—We are, etc.,

SIR,—Dr. R. Schuurmans in his letter (*Journal*, November 23, p. 1239) appears to pose a paradox. In the last paragraph he states, "In this way the primary role of aldosterone in sodium and water retention has been firmly established," while in the first he affirms that the fall in aldosterone excretion is the result of the rise in the extracellular fluid volume, that presumably it had helped to effect and of whose increase it was the primary cause. He concludes that there is no reason to look outside the mechanism of aldosterone effects of retaining salt and water to explain their retention in pregnancy and, presumably, in toxæmia, when such retention is still more marked.

He attempts a far-fetched reconciliation by enunciating an unlikely hypothesis that the urinary aldosterone is a very poor measure of adrenal activity, contending that this hormone can on occasion be poured into the circulation and exert its activities in the tissues before it is excreted by the kidneys. But he makes no attempt to elucidate the analogy and to establish it in the context of the matters under consideration; although he does cite in support certain features of primary aldosteronism to which toxæmia bears slight resemblance.

Even were his hypothesis correct, how can he explain the findings of Venning,¹ who demonstrated that the aldosterone secretion was no higher in normal pregnancy than in toxæmia, when salt and water retention is so marked, if his explanation of the retention depends on the primary role of aldosterone? And those of Venning² and Rinsler,³ who found that in the later stages of toxæmia, when there was an increasing oedema, the aldosterone excretion actually fell? It is impossible to reconcile the heightening salt and water retention on the one hand with the diminishing excretion of a substance advanced as responsible for their retention.

Then again, haemoconcentration is held now to be a characteristic accompaniment of the increasing severity of toxæmia. The newer evidence indicates that a reduction of blood volume increases the secretion of aldosterone.⁴ Emphasis is thus shifted away from the extracellular fluid, and that Dr. Schuurmans invokes for aldosterone secretion, and is directed to the circulating blood volume. An increase of aldosterone secretion—and not a diminution met with—should therefore accompany the toxæmic state as it mounts. A fresh paradox is imposed if we continue to subscribe to the view that an aldosterone mechanism dominates the scene where salt and water retention is concerned in toxæmia. If its secretion depends on blood volume it should be increased as toxæmia worsens. This it does not do. If salt and water retention depends primarily on aldosterone we could never explain how their retention increases while its secretion diminishes.

From the known behaviour of this hormone, its primary intervention in the mechanism of pre-eclamptic oedema cannot be sustained. I would rather commend to the attention of obstetricians interested in the aetiology of

toxæmia the recent study by Berliner,⁵ who has demonstrated that water retention can be made consequent on the clamping of the renal artery; and to the utero-renal reflex that can impose such an effect. There is no reason to search for another mechanism, if I may borrow Dr. Schuurmans' diction.—I am, etc.,

J. SOPHIAN.

Hospital Confinement

SIR,—Recent correspondents discussing whether it is better for babies to be born at home or in hospital seem to have overlooked one point of some importance to the parents. A patient of mine has recently applied for a home help while she is confined at home. She has been told a home help will be provided at a cost of £7 12s. per week, unless her means are deemed inadequate, in which case some reduction will be made. If, on the other hand, she goes into hospital she will get not only treatment but board, lodging, and service for nothing. I do not wish to argue whether or not this state of affairs is right, but it obviously encourages the parents to lean towards hospital confinements.—I am, etc.,

Newick, Sussex.

J. R. CALDWELL.

Knock-knee in Children

SIR,—Mr. H. J. Seddon's second proposition (*Journal*, November 30, p. 1303) is that "the responsibility for assessing the efficacy of any particular treatment rests on those who use it rather than on those who do not" (my italics). I am glad he agrees with me, therefore, that it is fundamentally wrong for an individual to declare as ineffective a treatment of which he or she has no measure of experience. That was my point (*Journal*, November 9, p. 1110). I did not seek to prove that splints are effective. I am no authority on this, but Mr. Seddon carefully avoids giving us the voting figures from his Institute poll. He simply declares a majority. There might be 3 to 4 or 1 to 6 in favour of splints. At least it shows that there is a division of opinion and that some of his colleagues would seem to stand condemned.

Dr. A. J. M. Morley's paper (*Journal*, October 26, p. 976) indicates that about 3 out of every 100 children still had 3 in. (7.5 cm.) of knock-knee at the age of 11. What a pity they had not been treated before the ordeal of secondary school. Portia set Shylock a task which was hopeless before the days of hypotensive anaesthesia. Mr. Seddon asks me to prove that I have an effective method of treating a condition which he knows gets better by itself. Most of us will continue to treat—perhaps to splint—gross knock-knee, but will do as we have always done, and refuse to give placebos to mild cases as a treatment for aunty's or grandmother's anxiety.—I am, etc.,

London, S.E.19.

D. F. ELLISON NASH.

SIR,—At the Robert Jones and Agnes Hunt Orthopaedic Hospital we have, for the past five years, been keeping careful photographic records of a large number of foot who have been investigated for abnormalities of foot posture, and as these photographs have included, of course, the knees, these records, together with our clinical experience, strongly support the views put forward by Dr. A. J. M. Morley (*Journal*, October 26, p. 976), and defended so skilfully by Mr. H. J. Seddon (*Journal*, November 30, p. 1303). I do not think it too fanciful to say that the child unfolds like a flower, and that almost every child is bow-legged at the age of 18 months and knock-kneed at the age of 2½ years.

I am, however, most disturbed that Mr. Seddon should give support to Mr. T. T. Stamm's contention (*Journal*,

November 9, p. 1110) that children should be given appliances, however harmless these may be, in order to treat the mother. Where abnormal apprehension exists in the parent over such things as knock-knees, it is always worth while spending a short time trying to discover the cause for this, and, if this is done, an assurance related specifically to the anxiety will often suffice, particularly if this is combined with the offer to review the child's condition in six to twelve months' time. Where this happy result is not then achieved, the mother requires psychological help, and in practice this is in my experience most smoothly achieved through the child guidance service. If, however, this appears too fanciful, and more "common sense" therapy is preferred, which will, I admit, have the advantage of treating the anxiety of the doctor as well as that of the parent, then it is plainly the duty of the surgeon who prescribes knock-knee splints to see that these remain completely efficient during the whole period they are used. If this is done, I think it will soon be apparent that such splints are never efficient in the parents' hands for longer than a few hours or days, if the children and the parents are to have normal sleep and to retain their general health.—I am, etc.,

Wellington, Shropshire.

G. K. ROSE.

Stimulating the Elderly

SIR,—I notice an increasing tendency on the part of some consultants to stimulate elderly patients who are in the terminal stages of an illness to make efforts which are sometimes beyond their powers and certainly beyond their inclinations. I am quite prepared to believe that bedsores may be avoided and life possibly a little prolonged by these efforts to get out of bed, take a few steps, breathe more deeply, and generally "buck up," and yet it seems to me that this stimulation sometimes amounts almost to bullying and is not so much being kind as being cruel to no very good purpose. I know that if I were in the terminal stages of some disease I should feel like an animal that wanted to slink into the bushes and, as far as possible, be left alone to die in peace.—I am, etc.,

London, S.W.7.

J. N. LORING.

Tabulating Data

SIR,—We regret that there were two errors in our paper (*Journal*, September 14, p. 619) which we failed to notice in the typescript. In our first formula (page 622) the expression $\frac{Na}{N}$ should, of course, be $\frac{Nd}{N}$. In the last formula

on this page the expression $\sqrt{1-Pd}$ should read $\sqrt{100-Pd}$.

We are grateful to our friends in Kuala Lumpur, Drs. Thomas Wilson and A. T. H. Marsden, for drawing attention to the first of these (*Journal*, November 23, p. 1242). Neither affects the accuracy of the numerical tables or the scope of the method.—We are, etc.,

London, W.C.1.

C. N. SMYTH.
M. N. BAINBRIDGE.

Three-year Driving Licences

SIR,—As a consequence of the Road Traffic Act, 1956, all drivers with surnames beginning A-F must now take out their driving licences for a period of three years. From a financial point of view this has several advantages, for, apart from a considerable cutting in staff and effort, the net gain from holders of licences who die in the period and whose reliefs find it indecent to reclaim a few shillings must be considerable.

From a medical angle it is surely a most dangerous situation. During a period of three years a man may well begin to suffer from "sudden attacks of disabling giddiness or fainting"; his vision may deteriorate so that not only can he not read a number plate "containing six letters and figures," but he may become quite blind; "either hand or foot," or both, may be lost; and "any other disease, mental or

physical," may appear and render the driving of a motor vehicle "to be a source of danger to the public."

There are penalties for making false statements on the application form, but if a man signs to say that he is quite well in 1957 he cannot be held to have made a fraudulent statement should his mind or body become deranged in 1960. When, through the courtesy of my M.P., I took this matter up with the Ministry of Transport, I was told that the licensing authorities are empowered to revoke a driving licence if they have reason to believe that the holder is suffering from a disease or physical disability likely to cause him to be a source of danger to other road users—small comfort, I feel, to the relatives of those slain by such a disability. The number of accidents due to physical defects on the part of drivers may be small, but surely it is folly to invite this unwarranted addition to the already appalling toll on the roads.—I am, etc.,

Kelvedon, Essex.

D. J. E. L. CARRICK.

Senna as a Laxative

SIR.—As a follow-up to two articles, by Professor J. C. McClure Browne *et al.* (*Journal*, February 23, p. 436) and by Mr. A. S. Duncan (p. 439), I inquired of my patients, obstetrical and gynaecological, what laxatives, if any, were used. I found that 45% did not take any particular preparation. I would like to believe, but doubt, that this was due to advice given on diet. The disturbing finding was that of the remainder 39% took liquid paraffin, either on advice from the doctor or on their own initiative. In the future perhaps more attention will be given to the criticism of liquid paraffin in the *British National Formulary* (1957): "Leakage from the anus is not only embarrassing but may also lead to pruritus ani. Liquid paraffin, when highly emulsified, is to a small extent absorbed from the alimentary tract; it may then be deposited in the mesenteric lymph nodes and in the liver and spleen, and, after prolonged usage, may provoke a chronic inflammatory paraffinoma. Liquid paraffin interferes with absorption from the gut of carotene and vitamins A and D."

The pregnant woman is filled full of vitamin tablets yet so often is prescribed liquid paraffin. For three years, apart from advice on diet, I have found it unnecessary to prescribe any other laxative than standardized senna ("senokot"), about which the articles already referred to were enthusiastic. The pregnant woman, so difficult to please because of nausea, has a choice with regard to this preparation of chocolate granules or tablets. And she can go on taking it nightly without ill effect. When visiting a professor in Bagdad recently I was pleased to find "senokot" available there, an arrangement which was unaccountably deficient as far as many other British drug preparations were concerned.

While on this subject may I point out that often the only criticism many obstetric patients make about confinement is the discomfort caused by castor oil, oft repeated, in medical induction of labour. Although castor oil was cultivated and used in Egypt seventeen hundred years before Christ, this is no reason to perpetuate its use. It is unnecessary in obstetric practice.—I am, etc.,

Bristol.

G. GORDON LENNON.

Infants' Feeding-bottles

SIR.—I was interested in Dr. D. J. Thomas's somewhat amusing and typically male letter (*Journal*, November 23, p. 1240), as I have recently been looking after my brother's 2-months-old baby and was presented with an upright non-valve type of bottle and a teat with the minutest hole. On one occasion, when fed by my brother, the baby spent over an hour in good, strong sucking, and only managed to get one ounce (28 ml.) of milk, so I can sympathize with Dr. Thomas and his baby. However, the solution to the problem is simple—make the hole bigger, and the milk can be made to flow at whatever rate is desired. The reason why manufacturers sell teats with such tiny holes

is merely because it is easy to make a hole bigger, but impossible to make a big hole smaller. Dr. Thomas, being a man, has probably never tried to clean the boat-shaped type of bottle or he would at once realize why this ridiculous shape is fast becoming extinct.—I am, etc.,

Ardara, Co. Donegal.

P. M. FLEURY.

Dangers of Nitrous Oxide

SIR.—I was very interested to read your annotation (*Journal*, November 30, p. 1293) on the dangers of nitrous oxide. I feel I should like to comment on a few of the points raised. As far as I can gather from the literature, the only danger with regard to the use of nitrous oxide is the concomitant hypoxia previously considered necessary. Nowadays the standard practice in major surgery, since the advent of relaxants and following work by Brennan, Gray, etc., is the use of nitrous oxide with high oxygen percentages, in conjunction with the necessary adjuvants. Unfortunately, in dental and casualty type ambulant patients, the association of hypoxia with nitrous oxide is still considered *de rigueur*. Lip service has been paid by many to using higher oxygen concentrations than formerly was the case, but the basis of the methods, and of the teaching of the methods, is still reliance on asphyxia as the means of making nitrous oxide work. From this follow all the evils you mention, even and including the cause of the "fainting," owing to the effects of asphyxia on the myocardium.

In your annotation you mention that I have re-emphasized what was previously known by a generation of dental anaesthetists. If that is the case it was unfortunately allowed to be forgotten. I do not think that, until Klock¹ published his article, it was seriously considered that patients could have been satisfactorily induced and maintained on nitrous oxide, using oxygen at or near atmospheric concentrations. I have used this technique now on some 4,000 cases; on all types of patients ranging from children of 2½ years to an arteriosclerotic man of over 80 years. The results are as satisfactory as those of any nasal nitrous oxide can be. Minor difficulties, such as possibly undue movements of the limbs or excessive crying, are due to faults by the administrator and not to a fault in the type of administration. These faults can be suitably corrected by intelligent manipulation of the mixture to maintain a level nitrous-oxide concentration while still dealing with a pink, quietly breathing, relaxed, analgesic, and amnesic patient. Hypoxia, of whatever degree or duration, is undesirable; with the technique I now use, it is also unnecessary. Why should it still be used? Probably because of a misconception as to the mode of action of nitrous oxide. This substance has all the advantages enumerated in your annotation, and in addition carries no metabolic toxicity or ill effects on the myocardium. To change from such a useful, convenient, satisfactory, and safe agent to any more poisonous substance reputedly more potent would surely be a retrograde step. Proper use of nitrous oxide is what is required; I suggest the introduction of an asphyxial element into nitrous-oxide administration is making an improper use of the substance.—I am, etc.,

Cheltenham.

POINTS FROM LETTERS

Expression of Placenta

Dr. CONN MCCLUSKEY (Dungannon) writes: When the placenta is in the vagina in the third stage of labour it often requires firm pressure on the fundus to express it. Even this amount of trauma distresses the patient, as observation of her face shows, and it may even predispose to obstetric shock. For some time I have instructed the mother to lay her own hand flat across the fundus; I place mine over hers and apply pressure. I find that she can contract and relax various fingers to protect the tenderest points. My patients are emphatic that this manoeuvre almost entirely eliminates a pain which obviously strikes very deeply into their consciousness.

Obituary

G. C. BERG, M.D., D.P.M.

Dr. Charles Berg, consulting psychiatrist to the British Hospital for Functional and Nervous Disorders and to the Institute for the Scientific Treatment of Delinquency, died at his home in Harley Street on December 5. He was 65 years of age.

George Charles Berg was born in India on July 5, 1892, and was educated at Birkbeck School and at Lausanne in Switzerland. He became a medical student at St. Thomas's Hospital, qualifying in 1915 and graduating M.B., B.S. in 1921. After holding the posts of casualty officer and resident anaesthetist at St. Thomas's, Dr. Berg joined the R.A.M.C. On and served as a captain during the first world war. On demobilization he went into general practice in north London for a time, but before long he was on the way to achieving a reputation as a specialist in medical psychology. Having held clinical assistantships in the mental department at St. Thomas's and at the Bethlem Royal Hospital, he proceeded to the M.D. in psychological medicine in 1927, taking the D.P.M. in the same year. His main interest was in psycho-analysis, and for many years he was on the staff in psycho-analysis, and for many years he was on the staff of the Tavistock Clinic. During part of the second world war he was medical officer and acting medical superintendent of Peckham House Mental Hospital. He wrote a number of books, including *War in the Mind* (1941), *Deep Analysis* (1946), *Clinical Psychology* (1948), and quite recently a book entitled *Being Lived by my Life*, which he described as "A Sort of Autobiography."

Dr. Berg was twice married. By his first wife he had a son and a daughter, and by his second wife, Ruth Santo, he had two daughters.

We are indebted to Dr. EDWARD GLOVER for the following appreciation: The death of Dr. Charles Berg removes one who played a distinguished part in maintaining and advancing the traditions of medical psychology, a faculty which in recent years has been overshadowed by the development of modern psychiatry. Although by training an experienced psychiatrist and closely conversant with the principles and practice of psycho-analysis, he was *par excellence* a medical psychologist whose sympathies and intuitions were caught and held by those forms of mental conflict which warp or inhibit the character of man, bringing in their train inadequacy and suffering. The warmth of his sympathies was reflected in his own personality, and it is not surprising that his professional services were in constant demand and that he ranked among the most successful of psycho-therapists.

In addition to his therapeutic interests, Dr. Berg turned his abundant energies in a number of other directions. Endowed with an unusual flair for exposition, an effortless ability to write in a persuasive style, a good deal of his time was devoted to medico-psychological journalism and to the production of books which, without sidestepping the complexities of his subject, could be read with easy understanding by Everyman. Throughout his professional life, however, he was governed by the desire to produce a synthesis of his wide experience in the form of a systematic textbook; and his earlier essays in this direction were unusually successful. It is to be hoped that this projected outline will ultimately be published.

Needless to add, Dr. Berg was held in high esteem by colleagues as well as by his patients. Those who knew him more intimately could not but be impressed by the vitality and diversity of his character, his almost exuberant spirits, his humour, tolerance, and capacity to establish sympathetic contact. He enjoyed a certain richness of individuality which made him outstanding in any company. His death represents a considerable loss to the faculty to which he devoted his life.

F. JASPER ANDERSON, C.I.E., M.C., F.R.C.S.

Lieutenant-Colonel F. J. Anderson, formerly professor of surgery at the Medical College, Calcutta, died in Calcutta on November 28 at the age of 71.

Frederick Jasper Anderson was born on March 10, 1886. He was educated at Epsom College and studied medicine at St. Bartholomew's Hospital, qualifying in 1911 and graduating M.B., B.S. in 1912. The same year he passed high into the Indian Medical Service. In the first world war he saw active service in France, Belgium, Mesopotamia, and Egypt, was mentioned twice in dispatches, and was awarded the Military Cross for conspicuous gallantry in action. He remained on semi-active service until 1921, when he returned to England and obtained the F.R.C.S. in 1922. In 1923 he was selected for civil employ in the Madras Presidency and held various appointments in the districts and in Madras itself until 1928, when he was appointed officiating principal and professor of surgery at the Andhra Medical College, Vizagapatam, being confirmed in that post a year later. In 1934 he was transferred to Calcutta as professor of surgery, a post he held until his retirement in 1941, when he was immediately re-employed in the same capacity for the duration of the emergency, finally retiring in 1945. He was awarded the C.I.E. in 1939.

Anderson combined boldness and dexterity as an operator with great surgical wisdom and judgment—a combination that brought him a reputation that was far from local and patients from all over India. He was a good teacher who preferred the bedside and the operating theatre to the lecture-room for this purpose, and many of the leading Bengal surgeons received their first impetus and encouragement from him.

A bachelor, he had two ruling passions in life—surgery and racing. For years he owned and raced a string of horses in Calcutta with considerable success. When his re-employment ceased in 1945 he remained in Calcutta in private consulting practice, largely because it gave him the chance to indulge his hobby, which he did up to the end of his life. Anderson was a downright man. His brusque, abrupt manner concealed, from those who knew him slightly or whom he considered bogus, an essential kindness which his patients and his students soon discovered. He did not suffer fools gladly, and he hated any form of pose. His friends will miss him sadly, and his death leaves a gap in both British and Indian circles in Bengal, which alike regarded him with reverence for his skill and with affection for his sportsmanship.—J. B. H.

MANFRED SAKEL, M.D.

Dr. Manfred Sakel died from a heart attack at the age of 57 at New York on December 3. He became famous through the introduction of the insulin-coma treatment of schizophrenia.

Manfred Sakel was born in a small town of the Bukovina, a north-eastern province of the Austro-Hungarian empire. After graduating in medicine at the University of Vienna in 1925, he went to Berlin to work at a well-known private psychiatric hospital. Sakel was a therapeutic activist, having been deeply impressed by Wagner-Jauregg's malaria treatment, which was the first breach in the wall of therapeutic nihilism separating the psychotic patients from doctors as well as the outside world. During his Berlin period Sakel first produced insulin coma in catatonic patients for therapeutic purposes. After Hitler's rise to power he returned to Vienna, where he was given the opportunity of continuing his work at the university clinic, which again became a centre of therapeutic enthusiasm, having been the birthplace of the malaria treatment of general paralysis. Psychiatrists from all over the world went there to learn from Sakel and his team the lengthy and arduous but often highly successful insulin-coma treatment.

Sakel emigrated to America in 1937. His treatment became established as the standard therapy in early schizo-

Exeter; St. Lawrence's Mental Hospital, Bodmin; and Hope Hospital, Salford. The Minister said he was also asking for plans to be prepared for the first phase of some hospital development in Hull, and for additional beds at Ilford or Barking, but details of these two schemes had yet to be worked out with the boards concerned.

Risks from Aircraft Carrying Nuclear Bombs

The PRIME MINISTER expanded on December 3 the explanation he had given the previous week that if an aircraft carrying nuclear bombs were to crash there would be no danger of an explosion. Mr. GEORGE BROWN (Belper, Lab.) asked if the Prime Minister could give an assurance that a crash could not cause a fall-out of radioactive material as a consequence of the breaking of the container in which the bomb was carried. The PRIME MINISTER stated that if a machine crashed when carrying atomic or hydrogen bombs, or indeed when it was in transit carrying nuclear material in any form, whether by air or on the land, it was possible that there might be an oxidization of any plutonium concerned. Plutonium oxidized fairly easily. The danger would be of a very limited kind, and would be dealt with at once under the established precautionary procedures. The hazards of uranium 235 were far less than from plutonium, because it neither burned nor oxidized easily. He did not therefore think that the risks referred to—there was none from an explosion—were sufficient to justify any action which would seriously reduce the state of readiness or the training of bomber aircraft, whether British or American.

Parking in Harley Street

The Government were asked by LORD COLWYN on December 4 what they intended to do about the parking facilities in Harley Street, Wimpole Street, Devonshire Street, Weymouth Street, etc. LORD MANCROFT, Minister without Portfolio, pointed out that the immediate responsibility for dealing with the parking problem in the Harley Street area was not that of the Government but of St. Marylebone Borough Council. The Road Traffic Act, 1956, gave the council, in common with others in the London area, power to propose to the Minister of Transport schemes for the regulation of parking on the public highway, by means of parking meters or otherwise. One such scheme submitted by the St. Marylebone Council was at present the subject of a public inquiry (see *Supplement*, p. 202). LORD COLWYN asked if it would be possible for the doctors to have some form of badge, certificate, or disk on their cars, in order to get out in an emergency. Cars were being parked in double rows, and when a hospital rang up a doctor for an emergency operation he could not get out because of this double parking. LORD MANCROFT could not comment on a subject still before a public inquiry; but having served for some years on this local authority, and having been chairman of the public health committee, he could assure Lord Colwyn that the point he had made and the problems of doctors were borne fully in mind.

Pre-natal Care

Sir KEITH JOSEPH (Leeds, North-East, Lab.) asked the Minister of Health whether, while recognizing that the 1,094 maternal deaths due to pregnancy and childbirth during the years 1952-4 were only a minute fraction of the two million pregnancies in the same period, he was satisfied that the avoidable factors—set out in the Ministry of Health Report No. 97 on Public Health and Medical Subjects—which caused the deaths in about 50% of these fatalities and which must have adversely affected the welfare of many non-fatal cases, had been adequately brought to the minds of all concerned, including those few mothers who neglected available pre-natal care or, despite strong medical advice, refused hospital delivery. Mr. WALKER-SMITH stated on December 4 that copies of the published report, to the number of 1,200, had been issued to a wide range of interested bodies and persons, including hospital authorities having maternity beds, local medical committees,

¹ See leading article, *Brit. med. J.*, 1957, 2, 280.

and medical officers of health. Some time ago, on the advice of the Standing Maternity and Midwifery Advisory Committee, arrangements were made for the holding of local professional conferences throughout the country to discuss measures for the improvement of antenatal care. Also notes had been issued for the guidance of the editors of women's journals, emphasizing the need for all expectant mothers to seek and follow medical advice during pregnancy.

Psychiatric Research

Dr. DONALD JOHNSON (Carlisle, Con.) asked if the Minister of Health was aware that several distinguished workers in psychiatric research had recently left this country to work overseas; and what proportion of the total sum spent on medical research in this country was spent on research into the causes of mental illness. Mr. WALKER-SMITH replied that he was not aware that any appreciable number of psychiatric research workers had left this country to work overseas. The total sum spent on medical research and the proportion of this total spent on research into the causes of mental illness could not be accurately calculated, since they combined expenditure by hospital authorities, universities and medical schools, and private research funds, as well as by the Medical Research Council. Of the Medical Research Council's budget of approximately £2,300,000 for 1956-7, £58,000 was spent on work directly connected with the causes of mental illness. The latter figure did not include expenditure of a similar order in neurology and psychology, which were closely allied to psychiatry.

Disclosure to Insurance Companies

Sir ARTHUR HARVEY (Macclesfield, Con.) on December 4 asked the Secretary of State for Air what medical information regarding members of the Service was disclosed to insurance companies. Mr. CHARLES ORR-EWING, Under-Secretary, told him "None." This question had been reviewed many times in the past, and it had been decided that it would not be in the public interest to disclose this information.

Doctors' Pay

The MINISTER OF HEALTH on December 9, replying to questions about the doctors' pay, said it was too soon to specify any precise period for the Royal Commission's inquiry. The chairman had informed him that the report would not be ready until some considerable time after Easter.

Medico-Legal

ALLEGED INJURY TO OPTIC NERVE

On December 3 at Manchester Mr. Justice Lynskey gave judgment for the Manchester Regional Hospital Board and Mr. John Evans in an action for damages brought against them by Mrs. I. Sullivan.

Evidence was given that on September 8, 1955, Mrs. Sullivan submitted to an operation by Mr. Evans at Accrington Victoria Hospital for the removal of nasal polypi. On recovering from the anaesthetic her right eye was swollen and remained so for several days. She asked the ward sister several times "if her eye would be all right," and two days after the operation herself noticed that the eyeball had the appearance of red jelly and that she could not see. However, she accepted the reassurance that her sight would ultimately be all right. Four days after the operation the ward sister asked the resident surgical officer to examine her because the swelling still persisted. As soon as he had looked into the eye with an ophthalmoscope he telephoned Mr. Evans, who visited her and arranged her transfer to the care of an eye specialist.

It was claimed on behalf of the plaintiff that the nursing staff did not heed her complaint of blindness and failed to appreciate the possibly serious consequences of the operation and therefore did not draw the attention of any medical officer to her condition. Against the surgeon it was alleged

that he had caused injury to the right optic nerve or bleeding into the orbital tissues of the eye, resulting in damage to the optic nerve and blindness, and that he should have been aware of the possibility of the dangerous bleeding and the immediate remedial steps required. It was also claimed that he should have warned the nursing staff of the necessity for special vigilance and explained to the patient the inherent danger of the operation.

Professor V. F. Lambert was the expert called on behalf of the plaintiff. In his evidence he said that he himself had had no personal experience of such a complication after this operation and at the time in question knew only of two cases reported in the literature. He did not think that the occurrence of such bleeding behind the eye necessarily indicated lack of skill on the part of the operator, but in a lecture he had given at the Royal Society of Medicine in February, 1955, he had drawn attention to the possibility that where this type of haemorrhage was recognized early immediate decompression might prevent irreversible damage to the sight.

Mr. Evans himself testified that he had performed hundreds of similar operations, had never experienced such a complication before, and was not at that time aware of the content of Professor Lambert's lecture. His operating technique was no different on this occasion from what it had been on others, and he gave no special instructions to the nursing staff because there was no occasion for him to do so.

On behalf of Mr. Evans two experts were called, Mr. E. J. Mitchell, the ophthalmologist to whose care Mrs. Sullivan was subsequently transferred, and Mr. McKie Reid. The latter, with the help of a skull, explained how retro-orbital haemorrhage could occur as a result of operations in the ethmoid region. He gave his opinion that such a rare accident could not be reasonably anticipated in any particular case and could not be prevented by any known means. He was quite definite that he himself would not advise or undertake decompression in this kind of case, since he firmly believed such intervention would almost inevitably do more harm than good.

The judge found that there was no lack of reasonable skill and care on the part of the surgeon and that the nursing staff were not negligent because they failed to recognize the significance of the appearance presented by the patient and her complaint that she could not see. He found himself bound to find in favour of the two defendants.

The Medical Protection Society instructed Messrs. Le Brasseur and Oakley, solicitors, to act for Mr. Evans.

WRONG INJECTION

The accidental injection of adrenaline instead of procaine was reported at an inquest held on December 3 at Eastbourne.¹ A verdict of death by misadventure was recorded on Mrs. E. E. Hunnisett, aged 29, of Lower Willington, near Eastbourne, who died on November 19. She had been admitted to hospital for delivery of a baby, and a local analgesic was required. A nurse held out a bottle from which the doctor filled his syringe. He injected 6 to 7 ml. into the patient, and then noticed that her condition deteriorated. He asked to see the bottle, and then saw the label "Adrenaline." The bottle had been put on a trolley by another nurse, and it was said in evidence that neither of the nurses nor the doctor examined the bottle to make sure that it contained procaine. The coroner said there was no evidence of criminal negligence, but it was a well-known fact, or should be appreciated by qualified doctors, that when they gave an injection they should check the injections themselves. The jury added the following rider to their verdict of death by misadventure: "This matter should be brought to the attention of the appropriate medical and hospital authorities with the recommendation that the supervision and checking of drugs should be overhauled to ensure the prevention of a similar occurrence in future."

¹ *Daily Telegraph*, December 4, 1957.

Vital Statistics

Influenza

Deaths from influenza in the great towns reported during the week ending November 30 were as follows, with the figures for the previous week in parentheses: England and Wales 84 (70), Scotland 6 (11), Northern Ireland 1 (3), and Eire 13 (16). From the week ending August 24 to November 30 deaths from influenza in the 160 great towns of England and Wales numbered 3,163.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1948-56 (influenza, 1952-6) are shown thus - - - - -, the figures for 1957 thus ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The incidence of most infectious diseases increased during the week ending November 23 in England and Wales. The largest rises in the numbers of notifications were 265 for measles, from 1,695 to 1,960, 155 for dysentery, from 278 to 433, 143 for whooping-cough, from 472 to 615, 107 for food-poisoning, from 136 to 243, and 60 for scarlet fever, from 550 to 610; the only large fall was 124 for acute pneumonia, from 623 to 499.

The largest rises in the incidence of measles were Yorkshire North Riding 54, from 59 to 113 (Middlesbrough C.B. 96); Nottinghamshire 46, from 32 to 78 (Hacknall U.D. 52); Suffolk 41, from 25 to 66 (Beccles M.B. 43). A small rise in the incidence of whooping-cough occurred in every region, but no large changes were recorded in the local trends. The largest rise in the number of notifications of scarlet fever was 23 in Staffordshire, from 22 to 45; within this county the largest rise was 14 in Stoke on Trent C.B., from 10 to 24. 4 cases of diphtheria were notified, being 1 fewer than in the preceding week; 2 of the cases were notified in Middlesex, Edmonton M.B. The fall in the incidence of acute pneumonia was greatest in the southern section of the country, and in Yorkshire and the northern counties a small rise occurred, from 99 to 114.

The notifications of acute poliomyelitis numbered 67 and were 11 fewer for paralytic and 10 more for non-paralytic cases than in the preceding week. The largest returns were Berkshire 12 (Reading C.B. 11), Yorkshire West Riding 7 (Bradford C.B. 2), Durham 6 (Sunderland C.B. 2, Blaydon U.D. 2), Kent 6 (Broadstairs and St. Peter's U.D. 2, Folkestone M.B. 2).

The largest rises in the number of notifications of dysentery were 31 in London and Lancashire. The chief centres of infection during the week were Yorkshire West Riding 112 (Huddersfield C.B. 27, Hemsworth U.D. 25, Sheffield C.B. 15, Leeds C.B. 11), Lancashire 81 (Eccles M.B. 27, Liverpool C.B. 16), London 60 (Islington 32), Derbyshire 28 (Glossop M.B. 24), Durham 24, Warwickshire 24 (Warwick R.D. 19).

The largest returns of food-poisoning were 56 in Wiltshire, Devizes R.D., and 54 in Surrey, Epsom and Ewell M.B.

16 of the 17 cases of post-infectious acute encephalitis were notified in the Metropolitan borough of Finsbury.

Week Ending November 30

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 772, whooping-cough 635, diphtheria 5, measles 1,843, acute pneumonia 486, acute poliomyelitis 56, dysentery 461, paratyphoid fever 5, typhoid fever 2.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending November 23 (No. 47) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Medical News

Galton Medal.—Dr. C. P. BLACKER received the Galton Medal of the Eugenics Society from its president, Sir CHARLES DARWIN, F.R.S., at the Jubilee Dinner of the society on December 4. Dr. Blacker was secretary of the society from 1931 to 1952. The only previous recipient of the Galton Medal, the society's highest award, was Sir ALEXANDER CARR-SAUNDERS in 1944.

Association of Anaesthetists: Silver Jubilee.—The Association of Anaesthetists of Great Britain and Ireland was founded on July 1, 1932, 25 years ago. It celebrated its silver jubilee by a four-day scientific meeting last week at the Royal College of Surgeons, from December 4 to 7, for which nearly 500 anaesthetists registered—including a number from the Continent and United States—and a 25th anniversary dinner in the Great Hall of the College on December 5. Dr. T. CECIL GRAY, of Liverpool, the president of the association, presided at the dinner, and the chief guest was the Minister of Health, Mr. DEREK WALKER-SMITH, Q.C. Proposing "The Association," Mr. WALKER-SMITH congratulated them on their silver jubilee. Twenty-five was a good age—old enough for maturity, yet young enough for vitality. The growth of anaesthesia was a part of the success story of science, and many would define the ideal age as one that combined eighteenth-century culture with twentieth-century anaesthesia. The association had kept pace with the great developments in anaesthesia: already there had been a 60% increase in the number of consultant anaesthetists since 1949. Nowhere in the world was the practice of anaesthesia finer than in Britain. Dr. GRAY, replying, took his audience back to the morning of July 1, 1932. At breakfast, being the Top People, they would open their *Times*, and there they would find the headings much the same as now: the Bank Rate (a cut from 2½% to 2%), animal lovers protesting to Parliament, and a notice that the Ministry of Health had sent to all practitioners a book called *Nomenclature of Diseases*—perhaps the first step in a courtship which, according to one's views, had ended in seduction, rape, or a "happy though irregular union." In those days, however, there were only fifty specialist anaesthetists in the whole country; Liverpool had only two, Edinburgh and Birmingham five each. Then had come a burst of great discoveries: "evipan" in 1932, "pentothal" in 1934, pethidine in 1939, then curare, and later still controlled respiration and heart machines. At this moment, continued Dr. GRAY, they looked back with gratitude to those who had made their association what it was—to Dr. Ivan Magill, "that uniquely great man," and Dr. Harry Featherstone, who had pressed so far-sightedly for a diploma in anaesthetics, both happily at the dinner, and others such as Boyle, Clausen, and Howard Jones. One presidency of their association had been outstanding, that of Mr. A. D. Marston, when with Lord Webb-Johnson the first steps had been taken to set up a faculty of anaesthetists at the Royal College of Surgeons. The Faculty, the B.M.A. Group, and the Association of Anaesthetists were a trinity. Finally, the Association of Anaesthetists were a trinity. Finally, the Health Service would inevitably suffer unless the status of every doctor working in it was respected, whether he be of general practitioner, surgeon, anaesthetist, or any other kind of doctor. Dr. VERNON HALL, treasurer of the association, proposed the toast of "The Guests." Beginning with the Minister—"seventh in succession since the Conquest of 1488"—and the presidents of the Royal Colleges, Dr. Hall disposed of his lengthy roll of honour with wit and commendable brevity. In the regretted absence of Lord Cohen of Birkenhead, gracious replies were made by Professor HENRY K. BEECHER, of Boston, and Dr. C. R. VAN ECK, vice-president of the World Federation of Societies of Anesthesiologists.

Poliomyelitis Vaccine Production.—Two extensions to Glaxo Laboratories' poliomyelitis vaccine production unit at Sefton Park, Stoke Poges, were opened by the Parliamentary Secretary to the Ministry of Health, Mr. RICHARD THOMPSON, on November 27. With the extra capacity, completed last month at a cost of £150,000, the company hopes to raise its production of poliomyelitis vaccine by 50% by the early summer. The extensions consist of a 10,000 sq. ft. (920 sq. m.) safety-testing suite and a second animal house. The larger of the two buildings is being used for "non-virus" procedures—preparation of the synthetic medium on which the tissue cultures are propagated, preparation and maintenance of the monkey-kidney tissue cultures themselves, and safety-testing of both the single-strain vaccine pools and the final trivalent vaccine. The photograph shows the apparatus used for rolling the tissue-culture tubes during their incubation in the later stages of the safety tests. A technician is replacing cultures which have just been examined for evidence of virus damage. The new animal house is designed for safety-testing the vaccine *in vivo* under sterile conditions. The space in the main production laboratories thus gained will be used for increasing the output of the vaccine pools.

"Current Medical Research."—For some years past short statements on research policy and reviews of progress in selected fields of medical and biological research have been a feature of the Medical Research Council's annual reports. These reviews are not limited to the Council's own contributions but are authoritative records of new advances, of how they were made, and of their general significance. To meet the needs of those who would not ordinarily read the Council's annual reports, the review articles from the last report (1955-6)—which in most cases embody information available up to May, 1957—have been reprinted as a separate booklet (*Current Medical Research*, H.M.S.O., price 2s. 6d. net). There are two "policy" articles, the first on clinical research, and the other on research in genetics, and then 13 review articles which cover such subjects as cancer of the lung, poliomyelitis vaccination, protein deficiency, radiation and leukaemia, and chemical aspects of antibiotics.

Royal College of Surgeons.—Under its president, Sir JAMES PATERSON ROSS, the Royal College of Surgeons held its annual meeting of fellows and members on December 11. The business meeting was preceded by two postgraduate lectures, an exhibition of the research being carried out by the College, scientific films, and a Bradshaw lecture by Sir RUSSELL BROCK, one of the two vice-presidents. The council's annual report (for the year ended July 31, 1957) records that last year out of 757 candidates for the final fellowship examination 209 were admitted fellows; in addition 6 practitioners "of more than 20 years' standing" were elected to the fellowship. In the ballot for the council, which took place on July 4, no fewer than 2,379 fellows voted. Among the notable events of the year were the continued rebuilding of the College, the opening of the Nuffield College of Surgical Sciences, the opening of the department of anaesthetics, and the establishment of a Court of Patrons. Gifts to the College included £40,000 from Cerebos Ltd., a further gift

of £35,000 from the Wellcome Trustees to complete the Wellcome museum, £20,000 from the Coulthurst Trust for the new library, and £15,000 from Sir ARTHUR SIMS to found the Sims research fund. The income and expenditure account, however, showed a loss of £3,945. The council has decided to inaugurate next year a ceremony at which diplomas will be presented, analogous to a university degree congregation. The first of these ceremonies will be on June 11. Next year also another provincial meeting is to be held, this time in Cardiff on September 27. The use of the library continues at a high level and many thousands of volumes of periodicals have been catalogued. It is hoped to find means of publishing a new catalogue of the College's paintings, as it is now 27 years since the last catalogue appeared and more than 50 new paintings have been acquired. Postgraduate education, and the activities of the scientific departments and the Buckston Browne Farm, which are described fully in the annual scientific report, are mentioned only briefly. It is recorded that the College has taken a leading part in the establishment of an International Federation of Surgical Colleges, whose inaugural meeting will be in Stockholm next July. Lastly, an official College Grace has been adopted: "God grant Grace to the Queen, wisdom and prosperity to this Royal College, and to every one of us a thankful heart for His good gifts to-day."

British Association of Plastic Surgeons.—At a meeting on November 29, with the president, Mr. R. P. OSBORNE, in the chair, the following officers were elected: *president*—Mr. J. S. TOUGH; *hon. treasurer*—Mr. R. P. OSBORNE; *new members of council*—Air Commodore G. H. MORLEY and Mr. MORTIMER SHAW.

Birmingham University.—Besides the new post of senior tutor and assistant dean (*Journal*, November 23, p. 1253), the Medical Faculty has another new office, that of admissions tutor, to which Dr. J. M. MALINS, university clinical lecturer on medicine, has been appointed. An M. C. Smith lectureship in pathology (cancer research) has been established, for three years in the first instance, from income from the M. C. Smith bequest and a contribution from the Birmingham Branch of the British Empire Cancer Campaign. The first M. C. Smith lecturer is to be Dr. J. S. HOWELL. An offer from Messrs. Smith, Kline, and French, of Philadelphia, to establish three research scholarships in the department of medical biochemistry and pharmacology has been accepted.

Parkin Prize.—The Court of Session has approved a request from the Royal College of Physicians of Edinburgh to change the subject of their triennial Parkin prize. The prize (£100) was established by a bequest from Dr. John Parkin (1801–86), a fellow of the College, and under the terms of the deed was awarded for the best essay "on the curative effects of carbonic acid gas or other forms of carbon in cholera, the different forms of fever, and other diseases." The prize will now be offered for essays on the results of treatment in protozoal, bacterial, or viral diseases, or on the influence of climate or environmental conditions on epidemic disease.

Presse Médicale's Awards for Medical Films.—The annual prize of 100,000 francs offered by the French medical journal *La Presse Médicale* for 16-mm. medical films will be awarded in Paris next March. Both teaching and cinematographic quality will be considered in judging the films. Entries should be submitted before February 15 to the Secretariat, *La Presse Médicale*, 120, Boulevard Saint Germain, Paris, 6.

COMING EVENTS

Airborne Medical Society.—Winter clinical meeting at St. Mary's Hospital, Paddington, 5.30 p.m. on January 31, 1958. Professor C. G. ROB will preside. Refreshments afterwards.

N.A.P.T. Commonwealth Chest Conference.—July 1–4, 1958, at the Royal Festival Hall, London. Details from the

secretary-general, National Association for the Prevention of Tuberculosis, Tavistock House North, Tavistock Square, London, W.C.1.

Modern Educational Treatment of Deafness.—International Congress, July 15–23, 1958, at Manchester University. Details from Professor A. W. G. EWING, Department of Education of the Deaf, the University, Manchester, 13.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Sunday, December 14

SOUTH-EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY.—At Physiology Theatre, Guy's Hospital Medical School, 10.30 a.m., Sir Russell Brock: Present Position of Cardiac Surgery.

Monday, December 16

HARVEIAN SOCIETY OF LONDON.—At 11, Chandos Street, W., 8.15 p.m., film by Mr. R. Clarke, M.A.: Whales, and Open Boat Whaling in the Azores.

● **HUNTERIAN SOCIETY.**—At Talbot Restaurant, London Wall, E.C., 7 for 7.30 p.m., second dinner meeting. 8.30 p.m., discussion by Dr. P. M. F. Bishop and Dr. F. Dudley Hart: Use and Abuse of Cortisone.

MANCHESTER MEDICAL SOCIETY.—(1) SECTION OF ODONTOLOGY: At Lecture Room, Dental Hospital, 5 p.m., presidential address by Mr. F. Taylor-Monks: Conservative Surgery in the Treatment of Adamantinoma. (2) SECTION OF GENERAL PRACTICE: At Large Anatomy Theatre, 9 p.m., Dr. D. Longson: Corticosteroids.

MIDDLESEX COUNTY MEDICAL SOCIETY.—At Middlesex Guildhall, Westminster, S.W., 6.30 for 7 p.m., presidential address by Dr. C. A. Birch.

Wednesday, December 18

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. H. K. Vernon: Indications for Treatment of Enlargement of the Prostate.

Thursday, December 19

HILL END HOSPITAL MEDICAL SOCIETY.—8.45 p.m., Dr. E. R. Cullinan: Medicine in the Tropics.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of London, 8.30 p.m., Dr. Robert Forbes: Medical Litigation, Past and Present.

NORTH-EAST LONDON CLINICAL SOCIETY.—At Prince of Wales's General Hospital, Tottenham, N., 2.30 p.m., meeting.

ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: Vision at Varying Distances. Accommodation.

Friday, December 20

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., Mr. K. G. Rotter: clinical demonstration.

ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—At Royal Faculty of Physicians and Surgeons of Glasgow, 8.30 p.m., Professor W. M. Smart: Sun and the Hydrogen Bomb.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Higgle.—On November 29, 1957, at Baddesley Ensor, Warwickshire, to Jean (formerly Lowick), M.B., Ch.B., wife of Clement B. Higgle, M.R.C.S., L.R.C.P., D.P.H., a brother for John-Charles.

Thorne.—On December 4, 1957, to Pamela (Dr. Houchin), wife of Napier Thorne, M.D., M.R.C.P., of 2, Wheatley Street, London, W., a sister for Susan.

Uytman.—To Camilla Marion Uytman (formerly Walton), M.B., Ch.B., and John Douglas Uytman, M.B., Ch.B., D.P.M., of 10, Windsor Street, Dundee, by adoption, a son, Donald John, born May 13, 1957.

DEATHS

Anderson.—On November 28, 1957, in Calcutta, India, Fredrick Jasper Anderson, C.I.E., M.C., M.B., F.R.C.S., Lieutenant-Colonel, I.M.S. (retired), aged 71.

Brook.—On November 25, 1957, at his home, Bellfield House, Bellfield Park Avenue, Weymouth, Dorset, Alexander Barnett Brook, M.B., Ch.B., late of Puddletown, Dorset, and Invergordon, Ross-shire.

Clegg.—On November 24, 1957, at Thornton House, Thornton-in-Craven, Yorks, Frederick Clegg, M.B., Ch.B., aged 65.

Cooper.—On November 29, 1957, at 23, Bramley Road, Bramhall, Cheshire, Emor Reuben Cooper, M.B., Ch.B., D.P.H., also of 3, St. James's Square, Manchester.

Cox.—On November 25, 1957, Ralph Cox, M.B., B.Ch.

Evers.—On November 25, 1957, at Faversham, Kent, Charles John Evers, M.D., aged 94.

George.—On November 28, 1957, William Hubert George, M.B., F.R.C.S., of 90, Reddings Road, Moseley, Birmingham.

Glover.—On November 22, 1957, John Lee Glover, B.M., B.Ch., of Curry Rivel, Somerset.

Holland.—On November 16, 1957, at 134, Stoke Lane, Westbury-on-Trym, Bristol, William Algernon Louis Holland, M.R.C.S., L.R.C.P.

Livesey.—On November 19, 1957, in Bulawayo, Stanley Martin Livesey, M.B., Ch.B., F.R.C.S. Ed., aged 78.

McWhirter.—On November 21, 1957, at 112, Newhaven Road, Edinburgh, 6, Elizabeth Patricia McWhirter, M.B., Ch.B., D.P.H.

Magee.—On November 24, 1957, Andrew Victor Magee, M.B., Ch.B.

Napier.—On November 13, 1957, at Breakwater Flat, Elie, Fife, Alexander Harper Napier, M.B., Ch.B., Lieutenant-Colonel, I.M.S., retired.

Reford.—On November 13, 1957, at Newry, Co. Down, John Hope Reford, C.M.G., M.D., D.T.M., D.P.H., formerly of Uganda.

Tangay.—On November 16, 1957, Thomas Victor Tangay, M.D.

Thompson.—On November 20, 1957, Edward Roland Thompson, M.B., Ch.B., of Oak Hayes, Crewkerne, Somerset, aged 75.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Contraceptives and Cervical Erosions

Q.—Is there any evidence that the use of vaginal diaphragms for contraception causes erosion of the cervix or is in any way related to the apparently increased incidence of cervical erosion nowadays?

A.—I do not know of any evidence to show that vaginal diaphragms and similar contraceptive appliances cause erosion of the cervix. Nor are there any controlled observations which indicate that erosion of the cervix is more common now than it was in the past.

Oxygen for Suffocation by Smoke

Q.—Is there any point—or danger—in administering oxygen to someone showing respiratory distress due to inhalation of smoke in a fire? Or should oxygen be given only if the victim is unconscious?

A.—In most instances the respiratory distress is due to irritation of the upper respiratory passages, bronchospasm, and perhaps mucosal oedema. The distress usually passes off when the person leaves the offending atmosphere and sits down. However, all such cases should be watched with great care, as fires may liberate substances which cause delayed pulmonary oedema. If respiratory distress continues, or worsens for more than a few minutes, and cyanosis is present, then oxygen should be given at once and continued. The chest should be auscultated for rales, oxygen being particularly useful in these cases, as it not only compensates for the poor pulmonary ventilation due to respiratory obstruction but also creates a high gradient across the lung alveoli which helps counteract diffusion difficulties due to pulmonary oedema. If available the new types of positive-pressure respirators are of value, as they may improve total ventilation and distribution of oxygen. Distress is also relieved as respiratory effort is diminished.

Milroy's Disease

Q.—What is the aetiology and treatment of Milroy's disease? A patient who has suffered from it in one leg since her early twenties and who is now over 60 has rapidly become much worse, and her other leg is now affected. She gets acute pain as well as a generalized aching, and cannot walk or even stand for more than a few minutes.

A.—The diagnosis of Milroy's disease is best reserved for cases of lymphoedema of the legs which are both congenital and familial, as that is the condition which Milroy himself described. It would seem that the inquirer's patient had therefore been suffering from lymphoedema praecox rather than Milroy's disease.

Milroy's disease is rare. It is probably genetically inherited, and is due to an error in development of the lymphatics: these can be shown to be abnormal by lymphangiography. It is now known that there is no venous or lymphatic obstruction. Treatment is aimed at the local lymphatic obstruction. Treatment is aimed at the oedema and at the complicating attacks of cellulitis and lymphangitis. Mild cases with reversible oedema and little fibrosis are best treated conservatively: oedema is reduced by bed rest and elevation and massage of the limbs, and a well-fitting elastic stocking from toes to groin is then applied to control further formation of oedema. Attacks of inflammation are dealt with early and energetically by bed rest, elevation, and antibiotics. Sources of infection (e.g., trichophytosis, cuts, etc.) must also be treated. Severe cases with an unsightly and grossly deformed limb from irreversible oedema

and fibrosis, particularly those subject to recurrent attacks of inflammation, are best treated surgically. Surgical treatment aims at removing the oedematous subcutaneous tissues and covering the area with free partial-thickness skin grafts.

A sudden increase in extent and severity of the disease with spread to the other leg after forty years is unusual, and one would want to exclude an obstructive lymphatic or venous cause for the oedema (e.g., secondary malignant lymph nodes, pelvic or abdominal tumour, etc.) before attributing the recent changes to the same disease. If, however, the diagnosis of primary lymphoedema can be confirmed, in view of the patient's age and the extent of the condition conservative treatment as outlined above would be the treatment of choice.

Screening Tests for Cancer

Q.—(1) Are there any promising biochemical screening tests for the presence of malignant disease, and if so what is their reliability? (2) Is there any correlation between the finding of a direct or indirect Coombs test and the presence of malignant disease? If so, what is the explanation?

A.—(1) At present no reliable biochemical diagnostic test for cancer is known. Tests depending on the increase in circulating mucoprotein, determined either polarographically or chemically, are used, but have more value in prognosis and as an objective indication of the course of the disease than for diagnosis. The problem of diagnosis by biochemical tests is being approached from different fields, but as yet no reliable test is available.

(2) A positive direct antiglobulin (Coombs) test occurs only rarely in malignant disease. It may be found in a small proportion of cases of leukaemia, lymphadenoma, and reticulosarcoma, and is then often associated with haemolytic anaemia. Serum antibodies may also be demonstrable by the indirect antiglobulin test, but such evidence of autoimmunity is by no means an essential component of the haemolytic state in these diseases. These auto-antibodies are thought to be derived from the malignant cells themselves—lymphocytes, reticulum cells, etc.—which in the course of neoplastic transformation have acquired the capacity to react against some normal body antigens. Explanations of this phenomenon are still speculative, but, for example, it might be that a tumour cell which has lost the gene determining a particular antigen would come to treat that antigen, still present in the normal body cells, as a foreign one and manufacture antibodies accordingly. In carcinomatosis the antiglobulin test is scarcely ever positive despite the frequency of haemolytic states. The mechanism of haemolysis in these cases is obscure.

Physical Basis of Depression

Q.—What anatomical and physiological changes characterize depressive illnesses? What is known of their pathogenesis?

A.—There are no anatomical or structural changes in the large majority of cases. Occasionally, however, depression appears as an early and prominent symptom of organic disease of the brain, such as general paralysis of the insane, degenerative vascular disease, or less often intracranial tumour.

Some authorities insist that physiological factors play a part in the aetiology of depression, but, if they do, their nature is obscure. Certainly many bodily functions show disturbance in some degree in depressive illnesses, but the disturbance is probably not causal in any way. Its pattern is so variable that it can hardly be said that there are characteristic physiological changes. In some cases the systolic blood pressure is raised, the pulse slow; gastric and intestinal movements tend to be slowed, and there is then loss of appetite and constipation; the face tends to be pale and cold, the peripheral circulation sluggish; muscular tone and tendon reflexes tend to be reduced; usually there is

impotence, and often amenorrhoea. This picture, which may occasionally resemble myxoedema, but which is little altered by administering thyroid extract, is especially common when there is also retardation in mental processes. When agitation and anxiety are more in evidence than retardation, the picture may be very different, with rapid pulse, flushed face, raised muscular tone, and brisk reflexes.

Depressive illness tends to occur when the patient has met psychological stresses which are intense, prolonged, or, especially, multiple. It then represents the reaction of a more or less predisposed person to the stresses, when he has failed to adapt to them more effectively. The disturbance in bodily functions is one aspect of this reaction and is akin to the physiological changes associated with emotions such as fear.

Degree of Pituitary Insufficiency in Simmonds's Disease

Q.—A Bantu woman, aged about 30, has not menstruated since a severe post-partum haemorrhage three years ago. Her appearance does not suggest Simmonds's disease, vaginal examination discloses no abnormality, and in all other respects she seems healthy. What is the likely cause of her amenorrhoea, what further investigations are indicated, and what treatment is recommended?

A.—If the standard causes of secondary amenorrhoea have been excluded, the most likely explanation of her condition is that an ischaemic necrosis occurred in the anterior lobe of the pituitary at the time of the post-partum haemorrhage. If in fact she is in all other respects healthy, and if on vaginal examination the uterus was found to be of normal size and the lower genital tract showed evidence of continuing oestrogenic effects, the pituitary necrosis was presumably not a large one. In this case there may possibly be a spontaneous resumption of menstruation within the next year or two. Sometimes regular menstruation can be restarted by producing two or three artificial cycles by either of the usual methods; (a) a course of oestrogen followed by progesterone, or (b) a course of mare serum gonadotrophin followed by chorionic gonadotrophin.

It is, however, very important to make sure that there is not a more severe degree of pituitary insufficiency. The absence of any appearances of classical Simmonds's disease is of no importance in this regard; in fact, emaciation and premature senility usually indicate that the pituitary is functioning normally. The most significant clinical findings suggesting a serious pituitary insufficiency are that the patient is lethargic and weary, the uterus is atrophied, the thyroid too small to palpate, the pubic hair is lost from the mons, and the axillae are hairless and devoid of sweat or sebaceous secretion. If these signs are present, the patient should be sent to hospital for a full endocrine investigation.

Treatment of Spasmodic Dysmenorrhoea

Q.—What is the best treatment for dysmenorrhoea? What place has hormone therapy in its management, and how should it be conducted?

A.—Dysmenorrhoea is a symptom and not a disease; moreover, according to its cause, it assumes many forms and requires a different treatment. For example, the patient in question might be suffering from haematometra in a rudimentary horn of a bicornuate uterus, from pelvic endometriosis, or from premenstrual colonic spasm.

Assuming that the questioner has in mind the so-called spasmodic dysmenorrhoea occurring at the age of 18 to 25 years and without any apparent organic abnormality in the uterus, it still remains impossible to state a "best" treatment. The appropriate treatment might then vary from attention to general health, change of environment and psychotherapy, up to presacral neurectomy. Each case has to be assessed separately, and in many nothing more than analgesics, combined possibly with amphetamine, is necessary to tide the patient over the few years which elapse

before spontaneous cure takes place. Either pregnancy or advancing years can bring permanent relief. Dilatation of the cervix still, of course, has its place in treatment. There is not much to be said in favour of hormone therapy in such a case. Progesterone makes matters worse. Androgens act (according to the technique used) by suppressing ovulation or uterine contractions, but the possibility of side effects is so real that they are best avoided in young girls. If an oestrogen—say, stilboestrol 1 mg. three times a day—is given during the first half of the cycle, it suppresses ovulation, and the subsequent period should then be painless. This can be useful on isolated occasions, often as a diagnostic procedure, but is not a treatment to be advised over an indefinite period of time. Some authorities give oestrogen in a smaller dose during the second half of the cycle with a view to preventing uterine ischaemia; the results are not convincing.

In assessing the results of treating this type of dysmenorrhoea it has to be remembered that any measure, even the administration of a placebo, will give a measure of relief in 60% of cases.

NOTES AND COMMENTS

Genetic Hazard of Chest Radiography.—Dr. R. SAFFLEY (Brixburn, West Lothian) writes: I wish to express complete disagreement with the answers given by your contributor on the genetic hazard of chest radiography ("Any Questions?" November 23, p. 1255). In recent articles both Ardran¹ and Stanford² have shown that chest radiography may be one of the greatest single contributors to gonad radiation, and, since mass radiography apparatus gives from 5–16 times the dosage emitted by normal chest radiographic apparatus, this is also in direct contradiction to the second part of the answer.

REFERENCES

- ¹ Ardran, G. M., *Brit. J. Radiol.*, 1957, 30, 436.
- ² Stanford, R. W., *ibid.*, 1957, 30, 497.

OUR EXPERT replies: On p. 117, Table 3K, of the Medical Research Council report *The Hazards to Man of Nuclear and Allied Radiations*,¹ the genetically significant radiation from chest radiography and mass radiography is given as negligible. The papers quoted by Dr. Saffley assume that there is direct radiation to the gonads from mass radiography and chest radiography. This is extremely unlikely, and particularly so in the case of mass radiography, where the tube and screen are fixed and the field size is restricted.

REFERENCE

- ¹ *The Hazards to Man of Nuclear and Allied Radiations*, 1956, Cmd. 9780. H.M.S.O.

Corrections.—In the article by Dr. J. E. Davies entitled "Chronic Brucellosis in General Practice" (November 9, p. 1082), the dose of streptomycin (p. 1086) should have been given as 0.5 g. by injection night and morning.

Dr. G. Hurst writes to say that in his letter on chlorpromazine jaundice (*Journal*, November 30, p. 1307) he should have stated that the dose of chlorpromazine given in his case history was 75 mg. daily and not 25 mg.

MARK AKENSIDE*

BY

Sir JOHN CHARLES, K.C.B., M.D., F.R.C.P., D.P.H.

Chief Medical Officer, Ministry of Health, Ministry of Education, and Home Office

For the readers of *The Gentleman's Magazine* its editor, "Sylvanus Urban, Gent," had prepared a varied bill of fare in the April number of 1737. Among the literary attractions were a tale from the Arabian Nights, an article recording "Observations upon the effects of Tea," a scheme for the benefit of the Counties, "by keeping the gentry there for 14 years and no parliament during that time," and a short note on "Why handsome women often marry ordinary men." There were also discussions on legislative projects—one, cautionary, against the placing of a new duty on sweets; another, speculative, suggesting that there should be an Act of Parliament to prohibit the drinking of any liquor made by fermentation or infusion.

In the closely printed poetical section of the magazine (p. 244) the reader would have found an ingenious preface to some verses entitled "The Virtuoso; in imitation of Spenser's style and stanza." It read as follows:

"Newcastle upon Tyne. April 23rd. I hope, Sir, you'll excuse the following poem (being the performance of one in his sixteenth year) and insert it in your next magazine, which will oblige, Yours, etc., Marcus."

Of the verses themselves two stanzas perhaps will serve to show the mastery of the Spenserian metre and the pert imagination of the youthful poet:

"Whilom by silver Thames's gentle stream,
In London town there dwelt a subtle wight;
A wight of mickle wealth, and mickle fame,
Book-learn'd and quaint; a Virtuoso hight.
Uncommon things, and rare, were his delight:
From musings deep his brain ne'er gotten ease,
Nor ceasen he from study, day or night;
Until (advancing outward by degrees)
He knew whatever breeds on earth, or air, or seas."

"He many a creature did anatomize,
Almost unpeopling water, air, and land;
Beasts, fishes, birds, snails, caterpillars, flies,
Were laid full low by his relentless hand,
That oft with gory crimson was stain'd:
He many a dog destroy'd, and many a cat;
Of fleas his bed, of frogs the marshes drain'd,
Could tellen if a mite were lean or fat,
And read a lecture o'er the entrails of a gnat."

Within three months there appeared in *The Gentleman's Magazine* two other pieces, "Ambition and Con-

*Read to the Section of History of Medicine at the Annual Meeting of the British Medical Association, Newcastle upon Tyne, 1957.

tent; a fable" in heroic couplets (p. 309), and "The Poet. A rhapsody" in blank verse (p. 441). Both appeared under the *nom de plume* of "Marcus." Thereafter for a period of twelve months there was a silence, noisily broken in the August number of 1738 (p. 428) by "A British Philippic: occasioned by the insults of the Spaniards, and the present preparations for war." It was signed not "Marcus" but "Britannicus." This change of *nom de plume* prompted an editorial note:

"It often turning to our inconvenience, to sell a greater number of one magazine than of another, and believing the above noble-spirited Poem will be acceptable to many, not our constant readers, we have printed it in folio, price six pence. . . . And if the ingenious author will inform us how we may direct a packet to his hands, we will send him our acknowledgements for so great a favour, with a parcel of the folio edition."

Akenside's Early Days

The ingenious and versatile author of all these pieces was in fact Mark Akenside, second son of a Newcastle butcher of the same name and his wife, born Mary Lumsden. Both parents were Northumbrian Presbyterians of the lower middle class, and the father was the owner of a prosperous butchering establishment on Butcher Bank overlooking the Side and the River Tyne. Here Mark Akenside was born on November 9, 1721, and thence taken to be baptized by the Reverend Benjamin Bennet at the Close Gate Mission House on November 30. Tradition relates that when Marcus was 7 one of his father's cleavers fell on his foot, and "halted him for life." That the injury was severe and the orthopaedic result unsatisfactory can be gathered from Lettsom's statement many years later: "One leg of Dr. Akenside was considerable shorter than the other, which was in some measure remedied by the aid of a false heel." (Abraham, 1933.)

It is strange that for a writer who within three months of his twenty-second birthday had become almost a national figure in the world of poetry so little can be set down to give a consecutive account of his early education. It is known that he was a pupil at the Newcastle Grammar School, but that subsequently he attended the private academy of a dissenting minister, Mr. William Wilson. It is also surmised that he returned later to the Newcastle Grammar School, where he would have benefited from the educational direction of one of the school's great headmasters, Mr. Dawes, but there is no precise record to this effect. What is clear from the

internal evidence of *The Gentleman's Magazine* is that in his early teens Mark Akenside was already possessed of much more than the Shakespearian measure of "small latin and less greek," and was widely read in the mythologies and in the English poets.

With such gifts it is not surprising that his parents and friends destined him for the Ministry, and, the requisite money being provided by the Dissenters' Society, dispatched him to Edinburgh in the autumn of 1739, shortly before his eighteenth birthday. One winter at divinity and theology seems to have satisfied the young Akenside that his call lay in other directions.

Some time in 1740 he published privately a little sheaf of poems, including "An Ode on the Winter-Solstice," and "Love, an Elegy." The latter, written before his nineteenth birthday, laments:

"Too much my heart of Beauty's power hath known,
Too long to Love hath reason left her throne;
Too long my genius mourn'd his myrtle chain,
And three rich years of youth consum'd in vain."

It ends on a more sanguine note:

"I break triumphant through thy flimsy toils;
I see thy dying lamp's last languid glow,

Resume the paths my earliest choice began,
And lose, with pride, the lover in the man."

Student in Medicine

Having renounced both theology and love, Akenside became a medical student, and on December 30, 1740, was elected a member of the recently formed student society, the now famous and historical Royal Medical Society of Edinburgh. The debates of the Society, which were catholic in their range, gave Akenside an opportunity to display his gifts of eloquence and his knowledge of literature. He seems also to have developed some political ideas, and the impression made upon his contemporaries, one of whom, Dr. Robertson, became an eminent divine, was that Parliament was the goal of his ambitions. Among those contemporaries was Jeremiah Dyson, with whom Akenside struck up a friendship which lasted throughout his life. Dyson has been described as "by birth a tailor, by education a dissenter, and from interest or vanity in his earlier years a republican." He became ultimately a crusted Tory, and the *éminence grise* of the North Ministry. His inherited wealth enabled him in due time to be Akenside's Maecenas.

Despite all these distractions Akenside appears in about eighteen months to have picked up a sufficient knowledge of medicine to make him a competent practitioner, although he left Edinburgh without taking any degree. His mind at that time has been described as showing "equal readiness in science as in literature."

Returning to Newcastle at the end of 1741 or early in 1742, he began to call himself a surgeon and to seek for practice. Whether he did so from the somewhat inappropriate address on Butcher Bank or with what success we do not know. But the money borrowed from the Dissenters' Society towards his education for the Ministry was repaid then or later.

There is a tradition that he spent much time with a relative at Morpeth; and, seeking the inspiration "of solitary Wensbeck's limpid stream," composed "The Pleasures of Imagination," that meditative essay in three books upon which his reputation as a poet mainly rests.

"The Pleasures of Imagination" duly completed would appear to have been sent to Dodsley, the London publisher, towards the end of 1743—about the time of Akenside's twenty-second birthday. Dodsley referred it to Alexander Pope, for the price asked by Akenside—namely, £120—seemed a substantial one. Pope's reply has become classical. "Make no niggardly offer since this is no every day writer."

Dodsley accepted the advice, and "The Pleasures" duly appeared anonymously in a large quarto edition on January 17, 1744. There exists in manuscript a dedication of this volume to Jeremiah Dyson—"Dat, Dicat, consecratque. Marcus Akenside."

The poem had an immediate success, and a cheap edition appeared four months later making known the author's name.

At Leyden University

Armed now with sufficient cash for his immediate purposes, Akenside left the "dales of Tyne" and the "Northumbrian shades" for London. His stay there, however, was only preparatory to his descent upon Holland and the University of Leyden early in April, 1744. There he joined Jeremiah Dyson and other friends of his Edinburgh days, and, having been enrolled a member of the University, set about the business of acquiring a Doctorate of Medicine. That he should have been able to do this in approximately six weeks—for his degree was awarded on May 16, 1744—hardly accords with our modern ideas about these matters. But the pattern of performance would appear to have been standardized. Lettsom, who took such a Leyden M.D. nearly 20 years later, spent even less time about it. A thesis had to be submitted in Latin, and sustained before the examiners in the same language. Akenside, the acclaimed poet of "The Pleasures of Imagination," wrote a dissertation on "The origin and growth of the human foetus," which roused some interest because it challenged some of the views of the great Antony van Leeuwenhoek. But, the task accomplished and the doctorate acquired, Akenside and Dyson embarked at Rotterdam on the relatively slow voyage to London. The occasion prompted the composition of an ode, "On Leaving Holland":

"Farewell to Leyden's lonely bound,
The Belgian Muse's sober seat;
Where dealing frugal gifts around
To all the favourites at her feet,
She trains the body's bulky frame
For passive, persevering toils;
And lest from any prouder aim,
The daring mind should scorn her homely spoils,
She breathes maternal fogs to damp its restless flame."

Entry into Practice

Within a few weeks of his return to England, Akenside began to practise in Northampton. It was not a successful venture, as Dr. Stonehouse, being then in the full flood of his activities, left little scope for his 23-year-old competitor. whatever the latter's reputation as a poet. And in fact Akenside had sufficient time on his hands to write not only one of his most powerful satiric efforts, "An Epistle to Curio," but to prepare for publication in March, 1745, his first book of "Odes on Several Subjects." There are records, too, of amiable debates with medical and literary colleagues on such subjects as "The opinions of the ancient philosophers with regard to a future state of rewards and punishments."

From these erudite musings in somewhat bucolic surroundings Akenside was rescued by Jeremiah Dyson. The latter transported him about Christmas, 1745, to a house at North End, whence he could practise amongst the opulent inhabitants of Hampstead and frequent the celebrated "Long Room" at the Spa, and all the clubs and assemblies. In addition Akenside found for himself in January, 1746, a post as editor of Dodsley's magazine, *The Museum*, and contributed extensively to its pages. After two years at North End it became clear that for one reason or another professional success was eluding Akenside, and Dyson again came to the rescue. On this occasion he placed his friend in possession of a small but convenient house in Bloomsbury and made him an allowance of £300 per annum. From that moment Akenside was established. His sources of poetical inspirations may have become less productive, but he set himself assiduously to enhance his professional standing and

at the same time to engage in the social life of the literary and scientific groups which clustered around the Royal Society.

Admission to Royal College of Physicians and Royal Society

It is easy to follow the progress of Akenside in the hierarchical structure of the Royal College of Physicians. He was successively licentiate, candidate, and Fellow, being admitted to the first degree in June, 1751, and to the Fellowship in 1753. In between he had applied to be admitted by mandamus to the degree of Doctor of Physic in the University of Cambridge and had been accepted. He was twice a censor at the College, in 1755 and 1760, and carried out with his three colleagues their assigned tasks, of examining candidates for the licentiate and of inspecting the shops and drugs of the apothecaries. Furthermore, he was called upon to deliver two of the series of lectures in the College gift, the Goulstonian and the Croonian, and on October 18, 1759, "made," as the annals record it, the Harveian Oration. He was diligent in his attendance at the quarterly comitia, and discharged his various duties with satisfaction and those requiring the literary graces with every possible distinction. Of these various addresses and of his contributions to the *Medical Transactions* of the College I shall have more to say. For his association with the College of Physicians Akenside relied almost entirely on his own activities, but for his introduction to the circles of the Royal Society he was again indebted to Jeremiah Dyson.

Samuel Johnson has said that "there is nothing which has yet been contrived by man, by which so much happiness is produced as by a good tavern or inn." Dinner at "The Mitre," summer and winter alike, was the custom of that curious adjunct to the Royal Society "The Royal Society Club," commonly known as "The Royal Philosophers," or more briefly "The Royals." Membership, though small and select, was not limited to Fellows of the Society. Akenside first appeared there, probably introduced by Dyson, on July 20, 1749. Though a guest he would have had the privilege of paying for his own dinner. But a guest had to be invited, and his acceptability was determined by some of the brightest minds of the epoch. It is very evident that Akenside had all the gifts that suited best this genial and familiar form of intercourse. Hardinge (1814) has commented on his "eloquent reasoning, historical knowledge, and philosophical taste, enlivened by the happiest and most brilliant illusions"—all of which would commend him in that circle. At any rate, he was so popular as a companion that at these weekly dinners that between April, 1751, and July, 1752, a period of 16 months, he was an invited guest on no fewer than 33 occasions. On July 30, 1752, he became a full member of the club. On February 8, 1754, at the age of 32, he was elected into the Fellowship of the Royal Society itself.

Society and Court Physician

In the field of medical practice and hospital appointments Akenside's success was not quite so rapid. He resided at the house in Bloomsbury Square, and no doubt practised amongst the elegant society of that neighbourhood, having behind him the comfortable competence of £300 per annum provided by Jeremiah Dyson's munificence. Not till January, 1759, did he obtain any hospital appointment, and then about the same time he became assistant physician to both Christ's Hospital and St. Thomas's Hospital. Within three months of his joining the latter hospital he became, in March, 1759, a full physician, and so remained until his death in 1770 (Parsons, 1934).

Early in 1759 he moved from Bloomsbury to a house in Craven Street, just off the Strand, where on the evening of January 22, 1761, he had the privilege of entertaining Joshua Reynolds. Craven Street was also near to the Charing Cross Coffee Houses—and in particular "Toms," which Akenside is known to have frequented.

In 1760 Akenside, together with Dyson, had transferred his political allegiance from the Whigs to the Tories. Dyson

in due time became a Privy Councillor, the friend and confidant of Lord North, and Cofferer to the Royal Household.

Akenside in 1761 became one of the three physicians to the Queen. It was in this year also that he received from Thomas Hollis, a republican, the gift of Milton's bed. Here is the dedicatory letter:

"An English Gentleman is desirous of having the honour to present a bed which once belonged to John Milton, and on which he died, and if Dr. Akenside believing himself obliged, and having slept on that bed, should prompt him to write an ode to the memory of John Milton and the asserter of British liberty, that gentleman would think himself abundantly recompensed."

There is no record that Akenside ever wrote the ode so commissioned, but references to Milton are scattered throughout his writings.

In 1762 Akenside moved again to Old Burlington Street—which was tending to become the Harley Street of the period and was already the centre from which some of his colleagues of the Royal College of Physicians were conducting their practices. From 1762 onwards Akenside's life seems to have followed a set and orderly pattern—a modicum of private practice, attendance at his hospitals, periodical duties as Court Physician, appearances at the comitia of the College of Physicians and the meetings of the Royal Society, the round of the coffee houses, dinners with "The Royal Philosophers," and a revision of some of his poetry. These made up his day, his week, his year. There is no record of foreign travel, or even of any return to his birthplace and his youthful haunts, though from time to time he spent a few days in the country near London with the Dysons or other landed friends. It can be assumed from the fact that he continued in his hospital appointments that his private practice, though agreeable, was not extensive. He never married.

In December, 1767, he made his will, leaving his "whole estate and effects of whatever kind" to Jeremiah Dyson. All too early the terms of that will came to be implemented. The even course of life was interrupted and terminated. In June, 1770, Akenside fell ill of a "putrid sore throat," or, according to others, of a "putrid fever." He died on Saturday, June 23, in the bed of Milton, and was buried five days later in his parish church of St. James's, Piccadilly.

Such are the simple facts of the life of Mark Akenside, so far as they can be gathered from the exiguous material available. It remains to attempt an assessment of his achievements as a poet, of his accomplishments as a physician and medical writer, and of his merits as a man.

The Poet

His poetical works comprise the two versions of "The Pleasures of Imagination"—altogether some 4,000 lines of blank verse, 33 odes in two books, the "Hymn to the Naiads," and a sheaf of shorter poems and inscriptions, including the *Juvenilia* of *The Gentleman's Magazine*. With the exception of the two or three magnificently satiric pieces they make austere and Augustan reading.

Samuel Johnson, who regarded the heroic couplet as the ultimate perfection of prosody, had little respect for Akenside either as the writer of blank verse or as the composer of odes. Of "The Pleasures of Imagination" he said, "I found it mighty dull, and as for the style—it was fit for the second table." As to the odes, he concluded, "One bad ode may be suffered, but a number of them makes one sick." But he really touched the heart of the matter when he said that Akenside's thoughts were cold. And that seems to be the general opinion—a recognition of the icy elegance, coupled with the feeling that here was a poet very near to genius but lacking the essential fire and warmth.

Edmund Gosse describes Akenside as "a sort of frozen Keats"—a somewhat inept comparison, for, despite the fact that they both followed the medical way, they had little in common. The academic perfection of Akenside is a pale thing beside the sensuous, evocative magic of Keats. Yet

the Akenside who could commence an "Ode to the Evening Star" with the lines:

"To-night retir'd the queen of heaven
With young Endymion stays."

was in Pope's phrase "no every day writer."

George Saintsbury (1908) has written about him more sympathetically than most. Akenside had always been to him a greater puzzle than almost any other English poet. "There is so much to admire in him and so little to enjoy." And he hints that the last years of Akenside's life—while he was chiselling and re-chiselling "The Pleasures of the Imagination"—showed promise of a second spring. "The second version," says Saintsbury, "is far better verse—less stiff . . . than the first—and perhaps his very best work in the metre is to be found in the opening fragment of a fourth book which is dated as late as 1770. Here . . . we are very nearly in presence of Wordsworth."

The Doctor

Akenside the doctor lived under the shadow of Akenside the poet. And yet he was no amateur apothecary, but an active, competent, and experienced physician. That experience came to him not so much from private practice as from his assiduous attendance at St. Thomas's Hospital—every Tuesday morning to see his medical patients, every third Thursday to receive the new admissions, every Saturday to join with his fellow physicians and surgeons in the grand consultations enjoined by the hospital statutes.

Even Lettson, who had no great respect for him as a man, was constrained to say after walking the wards at St. Thomas's: "Akenside, however, would sometimes condescend to explain a case of disease to the pupils which always appeared sagacious; and in spite of his irritable temper he was more followed than Russell" (Abraham, 1933).

From his medical writings, not too numerous but adequate for the purpose, it is possible to make a fair and reasonable assessment of his ability and condition. They comprise in temporal order, the Leyden M.D. dissertation "De ortu et incremento foetus humani" (1744); the Goulstonian Lectures entitled "Opinions on the Lymphatic Vessels" (1755), which were again expounded to the Royal Society two years later (1757); the Harveian Oration of 1759; "An account of a blow upon the heart and its effects," which was reported to the Royal Society on December 22, 1763; the massive "De Dysenteria Commentarius" (1764); and finally the three papers, "Observations on cancers," "Of the use of ipecacuanha in asthmas," and "A method of treating white-swellings of the joints," which appeared in the first volume of the *Medical Transactions* of the College of Physicians, published in 1768. Another paper, "On the putrid Erysipelas," though read before the College shortly before his death, was never completed for publication.

A few general observations will suffice. All the writings before 1759, when he became Physician to St. Thomas's, are, broadly speaking, academic in origin and approach. But both his thesis on "The origin and growth of the human foetus" and the Goulstonian Lectures on "The Lymphatics," as given in synopsis form before the Royal Society, contain original and imaginative speculation and argument. Akenside has in fact a considerable claim to be regarded as the first man to describe clearly and correctly the functions of the lymphatics.

The writings after 1759 are all clinical, and with the exception of the "De Dysenteria Commentarius" are written in clear, lucid English prose. As to content, they present the findings of a keen observer and the logical conclusions of a physician able to call to his aid a good memory and extensive experience, albeit restricted by the limited pathology of the period. They are written in terms of the admirable prescription which serves as introduction to that memorable first volume of the *Medical Transactions*:

"The experience of many ages hath more than sufficiently shewn, that mere abstract reasonings have tended very little to

the promoting of natural knowledge. By laying these aside, and attending carefully to what nature hath either by chance or upon experiment offered to our observation, a greater progress hath been made in this part of Philosophy, since the beginning of the last Century, than had been till that time from the days of Aristotle."

As an example of Akenside's narrative style, his observation, and his quick diagnosis and treatment one cannot do better than present the introductory paragraphs of the contribution on cancers.

"In the summer of the year 1761, a man of about threescore years of age came to St. Thomas's hospital from a village at some distance; not with any intention of being admitted as a patient, but in order to obtain present assistance for an uncommon disorder. He was in general healthy, and apparently of a good habit of body; but had been accustomed, during the greater part of his life, to a constant succession of wens, that shot out in several places; on his head, trunk, arms, and legs; which in disposition he inherited from his father. As often as these wens became inconvenient from their size, his method was to cut them off with a razor; at which times he constantly found that they grew upon the part by five or six suckers, as he called them. He had not much trouble in extirpating them, except when the razor passed through those suckers; at each of which, he felt on the instant a most acute pain; but in this manner he fairly got quit of them. When I saw him, he had three such wens: one on the forehead near the edge of the hair, about the size of a horse-bean; another on the short ribs of the right side, as big as a hen's egg; and the third on the greater extremity of the os ulna of the right arm, somewhat less than a common nutmeg. This last was the occasion of his applying to me: for, as it advanced in size, a numbness was produced in the fore arm and hand; so that the use of them had of late been much impaired, as with a palsy; while, from the proximity of the wen to the joint of the elbow, he was afraid of employing his razor, as he had been used to do in other parts of his body.

"Upon examination, I found these wens to be hard, indolent tumours, sitting loose and moveable upon the cellular membrane. . . . I directed it to be cut off."

But of his cases none perhaps has stirred more interest than that described in "An Account of a Blow upon the Heart, and of its Effects."

"On the 11th of September, 1762, Richard Bennet, a lad about fourteen years of age, was brought to a consultation of the physicians and surgeons of St. Thomas's Hospital. His disorder was a palpitation of the heart; so very violent to the touch, that we all concluded it to be an aneurysm, and without remedy. . . . He was taken into the hospital that same day, being Saturday. . . . But on the Tuesday morning following, he died, without any previous alarm or alteration.

"The origin of his complaint was a blow, which he had received six months before, from the master whom he served, as waiter in a public house. The master had owned that he had pushed him slightly on the left side with his hand. The boy informed us that he himself was then carrying a plate under his arm; and that the blow or push, from his master, drove the edge of the plate forcibly between two of his ribs. He was immediately very ill from the hurt; sick, and in great pain. His mother also informed us, that she thought the palpitation was more violent about a fortnight after the accident, than when we examined him. . . .

"On the day of his death, Mr. Cowell opened him; when to our great surprise, we found no aneurysm, nor the least extravasation of blood either from the cavities of the heart or the large vessels. But on the left ventricle of the heart, near its apex, there was a livid spot, almost as large as a half-crown piece, bruised and jelly-like; the part underneath being mortified quite to the cavity of the ventricle. From thence upward, toward the auricle, there went several livid specks and tracts of inflammation, tending in like manner to gangrene. The heart did also, throughout its whole surface, adhere very closely to the pericardium; and the whole outer surface of the pericardium, as closely, to the lungs. The other viscera were quite sound.

"So that the mischief here was properly a contusion of the heart; the edge of the plate having struck it, probably at the instant of its greatest diastole."

The Man

Of Akenside the man it is not easy to write in approving terms. He was ambitious, arrogant, petulant, conceited, and wanting from time to time in that humanity which should characterize the physician.

FIVE YEARS OF GENERAL PRACTICE

A STUDY IN SIMPLE EPIDEMIOLOGY

BY

JOHN FRY, M.D., F.R.C.S.

General Practitioner, Beckenham, Kent

Until recently epidemiology was regarded as a relatively dull branch of medicine dealing largely with analysis of mortality rates and notifiable infections. Now, thanks to the teachings and writings of a more enlightened generation of epidemiologists, it has acquired a new and dynamic conception applicable to many common diseases in all branches of medicine, and it has developed a live philosophy whose principles are necessary in resolving many of the present-day medical problems.

In a like fashion "general practice" has also been neglected and untried as a field of medical research, and it is only in the past half decade that there has been some reawakening of interest. The scope of research in general practice has become apparent with the advantages of close doctor-patient relationships, of the knowledge of patients' personal, family, and social backgrounds, and of a close and intimate follow-up that may extend for the lifetime of patient and/or doctor.

A marriage of these two branches—general practice and epidemiology—would be expected to result in some interesting and profitable observations. This paper is presented to show some of the potentialities of epidemiological and clinical research in general practice. The subjects studied were chiefly the "trivial" and "minor" diseases of the community; but then these are also the common disorders that affect the majority and which entail overall a very significant amount of personal suffering, with natural economic costs. They were studied over a period of five years (1952-6) inclusive in one London suburban practice by means of simple methods that were eminently compatible with the daily routine and which did not interfere in any way with the normal happy doctor-patient relationships that exist in general practice.

Methods

Research, clinical and epidemiological, depends essentially on proper planning and record-keeping and on a discriminative analysis of the results. The methods and techniques have to be developed to fit the investigation being undertaken and the individual or group using them. In this practice the methods of recording have been evolved over the past 10 years and have been so adapted to the normal

Lettson, who walked Akenside's wards as a pupil, has left the most unprepossessing account of him, and from it much of the unkind opinion derives:

"Great was my disappointment in finding Akenside the most supercilious and unfeeling physician that I had then, or have since known. If the poor affrighted patients did not return a direct answer to his queries, he would often instantly discharge them from the Hospital. He evinced a particular disgust to females, and generally treated them with harshness. I was informed that this moroseness was occasioned by disappointment in love; but hapless must have been that female that should have been placed under his tyranny.

"I was inexpressibly shocked at an instance of his inhumanity exercised towards a patient in Abraham's Ward, to whom he had ordered bark in boluses; who in consequence of not being able to swallow them, so irritated Akenside, as to order the sister of the ward to discharge him from the hospital, adding 'He shall not die under my care.' As the sister was removing him, in obedience to the doctor, the patient expired.

"I never knew him to spit, nor would he suffer any pupil to spit in his presence. One of them once accidentally did so, who stood at some distance behind him. I was present. The doctor instantly span round on his artificial heel, and hastily, to demand 'Who was the person that spat in his face?'

"Sometimes he would order some of the patients on his visiting days to precede him with brooms to clear the way, and prevent the patients from too nearly approaching him. On one of these occasions Richard Chester, one of the Governors upbraided him for his cruel behaviour. 'Know,' said he, 'thou art a servant of this Charity.'" (Abraham, 1933.)

But all opinion was not quite so censorious. Mr. Meyrick, a surgeon and apothecary, frequently called in Akenside in consultation. To use his own words—"I knew him as a friend and recommended him as a physician. We were not much alike, for he was stiff and set, and I all life and spirits. He often frowned upon me in a sick room. He lost a good deal of business by the solemn sententiousness of his air and manner."

There is a long, balanced, and on the whole favourable study of Akenside by the lawyer-litérateur George Hardinge in Nichols's *Literary Anecdotes of the Eighteenth Century*, with which I would conclude these quotations:

"My father admired him as a gifted poet, as a man of genius, of learning, and of taste. . . . As I grew up into man, Akenside honoured me with a most affectionate regard. . . . When I came from College to the Inns of Court . . . I was often his dinner-guest, and generally with him alone. In addition to all his powers, arising from his genius and his eloquence, I had the enjoyment of his portfolio enriched by capital prints. . . . He had in general society a pomp and stiffness of manner, not in expression. . . . But the misfortune of this manner was in some degree connected with his figure and appearance. He looked as if he never could be undressed; and the hitch in his gait . . . compared with a solemn cast in his features, was, at the best, of a kind that was not companionable and rather kept strangers at a distance from him. Though his features were good, manly and expressive, a pale complexion of rather a sickly hue, and the laboured primness of a powdered wig in stiff curl, made his appearance altogether unpromising, if not grotesque. But, where he was intimate, was admired, and was pleased with his party, he conversed most eloquently and gracefully. He had the misfortune, however, to have little or no taste for *humour*, and he took a jest very ill. . . . His religious opinions were, I believe, a little whimsical and peculiar, but in general he kept them very much to himself. . . . He lived incomparably well."

These three commentaries, representative of a number of others, are all agreed on the complex character of the man. They underline the mixture of genius and—to use their contemporary idiom—of melancholy which are to be found in him. It was a melancholy at times corrosive, but more often, and especially in the company of his peers, mellow and kindly. But it would be a mistake to regard him as profoundly unhappy or dissatisfied with his achievements. After all, he had made his way from the northern city of his birth to the great metropolis, endowed only with his natural gifts and mother wits to become, in the words of his admirer, Cooper, "the twofold disciple of Apollo."

My thanks are due to Sir Harold Boldero, the Registrar, for permission to quote from *The Annals of the Royal College of Physicians*, and from the College lists.

daily routine that they add only about 30 minutes a day to the doctors' working-time.

Full details of the methods used have been reported (Fry and Blake, 1956), but in brief they are as follows.

1. A *day-book* records all daily consultations and visits with details of each patient's name, age, sex, reason for consultation, etc., in terms of disease groups (see below) and in addition notes are kept of referrals to hospitals for consultations, admission, or for direct radiological or pathological investigations. This day-book will give information of the volume of work performed in terms of time and seasons, of age and sex, and of disease groups, but such records will not give details of specific diseases or of individual patients in the practice.

2. A summary of each patient's diseases year by year is obtained easily by the use of specially prepared individual punch cards that are used each year for each patient. These cards will give a record of all attendances by the patient in terms of specific diseases as well as disease groups, age, sex, etc. The information is punched out on the card and analysed at the end of each year.

3. Information on specific diseases is recorded simply by means of a card-index system. A specific disease, such as hypertension or peptic ulcer, is allocated a box, and into this box are placed cards, each with the patient's name, date of birth, and short clinical details. As each new case of the appropriate disease is diagnosed so a new card is added to the box.

The population at risk has varied to some extent over the period under review with patients moving in and out of the practice; the numbers at risk for each year are shown in Table I, the figures being taken at the end of each year.

TABLE I.—Practice Population (1952-6)

	1952	1953	1954	1955	1956
Males	2,319	2,391	2,432	2,550	2,580
Females	2,354	2,501	2,615	2,705	2,871
Totals	4,673	4,892	5,047	5,255	5,451

Volume of Work

The most useful basic unit of work in assessing the amount of work done is the "consultation," taking this to mean all types of doctor-patient contact at the consulting-room and at the patient's home or in hospital. The attendance rate per patient per year obtained by dividing the total number of consultations by the numbers at risk gives a figure which can be compared year by year in the same practice and with other practices. The average attendance rates for this practice are shown in Table II and are remarkably constant within certain limits in spite of the changing incidence of epidemics and climatic conditions. These figures bear a relationship to the type of practice, geographically and socially, and also to the character and outlook of the doctor, and they vary to a considerable extent, as can be seen from Logan's (1954) studies, where the average attendance rates for eight practices varied from 2.9 to 4.7.

TABLE II.—Yearly Attendance Rates Per Patient (1952-6)

	1952	1953	1954	1955	1956	Average
Males	2.9	2.5	2.9	2.9	3.2	2.9
Females	3.5	3.6	3.2	3.9	3.8	3.6
Average	3.3	3.2	3.1	3.4	3.5	3.3

In each year the attendance rates for females were appreciably higher than for males, confirming once again the fact that women are more frequent attenders at doctors' surgeries.

As would be expected, these attendance rates vary considerably with age, and it is the very young and the elderly who require relatively more attention than other age groups.

Table III presents the attendance rates for the five years in age groups, and it is seen that the greatest rates are for infants in the first year, when frequent supervision is necessary, including at least five attendances for vaccinations and immunizations. In adolescence there is again a fall in rates, and this continues until the sixth decade, when the attendance rates rise.

TABLE III.—Attendance Rates Per Patient in Age and Sex (1952-6)

Age:	0-	1-	5-	10-	20-	30-	40-	50-	60-	70+	Average
M.	7.8	3.5	3.2	2.1	2.6	2.4	2.3	3.6	4.2	5.7	2.9
F.	7.0	3.3	3.4	2.2	4.0	3.2	3.7	4.5	4.7	6.5	3.6
Average	7.5	3.4	3.3	2.2	3.3	2.9	3.0	4.2	4.5	6.1	3.3

Individuals

The family doctor should get to know his patients reasonably well, since in any one year he will see almost three out of every four of the patients in his practice. The proportions of individual patients seen in each of the five years is shown in Table IV.

TABLE IV.—Percentage of Patients Attending in Any One Year

	1952	1953	1954	1955	1956
Patients attending	77%	71%	68%	72%	70%

A most striking fact is that over the total period of five years 91% of all those at risk were seen on one or more occasions. It is interesting to speculate why the 9% never attended. Is it because they are "healthy" or because they are "inflated"—that is, are they on the list of patients in error?

The fact that pathological and radiological facilities are not universally available to all family doctors in all areas is a national disgrace and a scandal. It is quite impossible to practise a high standard of medical care without these facilities being available directly to the doctor. It is also quite unreasonable to expect a young doctor to step from hospital practice, where investigations are possibly overdone, to that of general practice, where in many areas these facilities are still not freely available to the family doctor. The new hospital-trained entrant to general practice will feel completely lost and utterly frustrated. Full facilities should be available in all areas to all family doctors.

Amongst the arguments used against allowing these full facilities it is stated that the hospital departments would be swamped with work. What are the facts? In my own area full facilities are available, and the local hospital laboratory finds that only about 20-25% of its work is directly for family doctors.

In my practice, records over the five years show that a fairly constant proportion of patients were referred for investigations each year, as were the proportion of those sent for consultations and direct admission to hospital. Table V shows that approximately 13% of patients in the practice were sent for radiological and/or pathological investigations. The vast majority of this 13% did not require further referral to consultant, and those that did were sent with some of the necessary investigations already carried out. In this way consultants' time was saved and the interest of the family doctor maintained. Almost 8% of patients required the assistance of a consultant at hospital, and only 0.7% needed admission as emergencies. It is obvious, then, that the family doctor is able to manage over 90% of his patients without reference to the hospital consultant.

TABLE V.—Proportion of Patients Referred for Radiological and Pathological Investigations and to Consultants in Hospital

	Radiological	Pathological	O.P.	I.P. (Emergency)
Patients referred	7.1%	6.4%	7.8%	0.7%

Disease Groups

Major difficulties in recording information and data on the incidence of disease in general practice are the large number of possible diagnostic labels and the difficulty in arriving at an accurate diagnosis. In an attempt to overcome these problems a number of broad "disease groups" were defined. By this means an accurate diagnosis was not imperative and the possible diagnostic labels were restricted to a manageable number. In all, 18 disease groups were used: rheumatic, digestive, cardiovascular, central nervous system, upper and lower respiratory infections, specific fevers, eye disorders, ear, nose, and throat disorders, skin conditions, neuroses, pregnancy and gynaecological disorders, vaccinations and immunizations, accidents, urinary disorders, dental, endocrine, varicose veins, and miscellaneous groups.

The incidence of the disease groups shows that the situation is quite different from that found in hospital practice. Over the five years the most frequent groups were: (1) Infections of respiratory tract 30% of total; (2) digestive disorders, 12%; (3) skin disorders, 10%; (4) psychoneuroses, 8.5%; (5) "rheumatism," 6.5%; (6) cardiovascular disorders, 6%.

Certain sex differences were observed in these groups. Rheumatic disorders were more frequent in females in a ratio of 7:5. Respiratory infections predominated in males by 5:4. Psychoneuroses were more frequent in females by as much as 3:1. Accidents predominated in males by 5:4. Varicose-vein disturbances were five times more frequent in women. In the other groups there were no significant differences in the two sexes.

Studies of the age distribution of these broad disease groups (Table VI) brought out certain striking patterns that have some practical applications.

TABLE VI.—Average Yearly Attendance Rates Per 1,000 at Risk in Age Groups for Some Disease Groups

	0-	5-	10-	20-	30-	40-	50-	60-	70+
Upper respiratory infections	750	1,050	550	475	400	350	375	250	200
Lower respiratory infections	250	550	175	200	225	250	450	750	925
Digestive disorders	150	175	240	250	375	440	525	500	500
Skin disorders	375	275	410	375	325	350	325	225	275
Psychoneuroses	50	125	275	250	230	275	225	200	200
Male	50	200	475	525	750	700	550	200	200
Female	50	125	275	250	230	275	225	200	200
Rheumatic conditions	10	110	215	250	350	500	425	430	430
Cardiovascular disorders	1	10	33	50	125	355	500	1,250	1,250

* The rate for the first year of life was 550 per 1,000 at risk and for ages 1-4 it was 350.

Upper respiratory infections, including such common conditions as colds, sore throats, coughs, and "flu," were conditions as colds, sore throats, coughs, and "flu," were much more frequent in young children under 10, with a peak at the seventh and eighth years, followed by a dramatic fall and a more or less constant level in adult life. This fall and a more or less constant level in adult life. This natural pattern is of importance when considering any radical forms of treatment. The rates for infections of the lower respiratory tract, including both acute and chronic conditions of the lungs and bronchi, show quite a different pattern of age distribution, for apart from a peak in the 5-9 period the tendency is towards a rising level with age. Digestive disorders had peak levels of attendance in the very young and the elderly.

Skin conditions seemed to be as common in all age groups.

The psychoneuroses had a pattern all their own with a peak in middle age, the peak being accounted for entirely by the females, the rate for males being constant.

Cardiovascular disorders showed the expected patterns of a predominantly degenerative disorder with a low rate in youth rising sharply with age.

Rheumatic conditions followed a pattern similar to that of the previous group, but there seemed to be a fairly constant rate after 50 and no rise with old age.

Specific Diseases

Whilst "disease groups" are useful in presenting patterns in a broad fashion, especially when accurate aetiological diagnosis is difficult, and when the large number of separate entities renders the keeping of records difficult, far more interesting and valuable information will be obtained if "specific" diseases can be defined, recorded, and followed up. This is quite possible in general practice if one restricts the conditions to be studied to a manageable number.

The value of studying common diseases such as hypertension, peptic ulcer, asthma, etc., in general practice is that, by taking into account all the grades of the condition, minor as well as major, a better natural picture of the disease will be obtained. The impressions derived from hospital reports tend to be somewhat false in some instances, as only the major grades might be presented, the minor ones not being referred to hospital by the family doctor. This will apply especially to conditions such as hypertension and peptic ulcer, and if one applies the hospital conclusions universally, then many cases might be managed on wrong lines.

The method used to study specific diseases was by means of the card index, and each new case of specific disease was recorded and filed with its fellows in a separate box. By these simple means the conditions were observed and recorded, and Table VII shows their incidence over the

TABLE VII.—Incidence of Certain Specific Conditions in the Practice (1952-6)

Disease	M.	F.	Total	% Over 5 Years
Acute chest infections (new cases)	307	281	588	115
Acute tonsillitis	302	315	617	125
Acute otitis media	377	380	757	150
Chronic bronchitis	142	98	240	48
Asthma	23	27	50	10
Pulmonary tuberculosis (new cases)	8	15	23	5
Peptic ulcer	112	38	150	30
Neoplasms (all types)	41	45	86	17
Acute abdomen (all types)	30	28	58	11
Epilepsy	25	21	46	9
Diabetes	18	10	28	5
Coronary artery disease	51	26	77	15
Hypertension	110	216	326	65
Anaemia	15	74	89	18
Organic C.N.S. disease	27	47	74	17
Migraine	50	117	167	33

five years. The figures quoted for the acute infections of the respiratory tract, anaemias, acute abdomen, and pulmonary tuberculosis refer to new cases occurring in the practice during the five years under review, but in the instances of less acute and more prolonged conditions some of the cases were first diagnosed over longer periods and the figures represent a total incidence rather than a five-year record.

Acute and chronic conditions of the respiratory tract are far and away the most common specific conditions that the average British family doctor will meet, but at the same time the high levels of peptic ulcer, hypertension, and migraine should be recognized.

An examination of the distributions of these conditions according to age and sex reveals some interesting facts.

Acute chest infections by definition included all cases of acute bronchitis, pneumonia, and pleurisy. The incidence shows a maximal level in the young and old (Table VIII).

TABLE VIII.—Incidence of Acute Chest Infections Per 1,000 at Risk, in Age Groups

0-	1-	5-	10-	20-	30-	40-	50-	60-	70+
180	115	115	25	20	22	45	55	130	150

TABLE IX.—Incidence of Acute Otitis Media Per 1,000 at Risk in Age Groups

0-	1-	2-	3-	4-	5-	6-	7-	8-	9-	10-	20-	30-	40+
300	175	200	475	700	750	550	625	200	250	55	6	50	5

Acute otitis media follows a different pattern of age incidence. It is largely a condition of children, with a maximal peak at 5-7 followed by a falling rate and a very low one in adults (Table IX).

Acute tonsillitis is also predominantly a disease of childhood, but here there is an appreciable incidence in young adults. In my practice it is very rare in infants and in the elderly (Table X)—in fact, I do not recall ever having had a case over 60.

TABLE X.—Incidence of Acute Tonsillitis Per 1,000 at Risk, in Age Groups

0-	1-	2-	3-	4-	5-	6-	7-	8-	9-	10-	20-	30-	40-	50+
—	10	—	160	150	240	250	130	160	180	100	90	80	35	10

Chronic bronchitis is a difficult condition to define. Here the diagnosis has been restricted to patients with cough and sputum persisting for longer than three months in any two consecutive years. There was a male preponderance of 3:2, and the pattern of an incidence rising with age (Table XI) suggests either a cumulative response to some irritating factors or a degenerative condition.

Peptic ulcer is a common condition in our community and is more frequent in men by as much as 4:1 in this practice. The 150 patients mentioned have all had the diagnosis confirmed by positive radiological examinations. The patterns of incidence encountered over the past five years (Table XI) show maximal peaks of activity in adults

TABLE XI.—Incidence of Chronic Bronchitis, Peptic Ulcer, and Migraine Per 1,000 at Risk, in Age Groups

	10-	20-	30-	40-	50-	60-	70+
Chronic bronchitis			10	25	80	160	225
Gastric ulcer { Male		2	8	10	30	11	10
Female			4	8	3	11	8
Duodenal ulcer { Male		40	85	85	60	11	5
Female		6	25	18	12	8	
Migraine { Male	10	17	25	22	23	25	20
Female	18	27	85	80	55	25	20

from 20 to 59. There is a relatively low incidence of duodenal ulcer at 60 and after, and it is tempting to inquire whether the natural history of duodenal ulcer is towards a natural and spontaneous "cure" with advancing age. This is further suggested by the fact that of the 150 patients, only 32 (21%) have had to undergo surgical treatment; all the others seem to manage quite well following their normal occupations with alkalis and diet for their acute episodes.

Migraine is truly a psychosomatic disorder, and, as in other similar conditions such as hypertension and peptic ulcer and in the psychoneuroses themselves, there are marked sex differences and the age distribution shows certain peaks and trends. The rate for males (Table XI) shows a more or less constant level from age 20 onwards, but in the females, who account for over two-thirds of the cases, there is a definite peak between 30 and 59 years. Here again this natural pattern is suggestive of a tendency towards a spontaneous cessation of activity with age, which, if confirmed, will help in understanding suitable management and prognosis.

Hypertension has tended to be rather a mechanistic diagnosis based on the readings of the sphygmomanometer. Fortunately it is becoming more widely appreciated that these readings of themselves are of little help in the clinical management of the patient. A diagnosis of "hypertension" by present-day criteria must never be the indication for prescribing drastic, potentially dangerous, and unpleasant remedies. With the criterion that a persistent (found on two or more separate occasions) diastolic blood pressure of over 100 mm. Hg constituted "hypertension," the condition was present in at least 326 patients in this practice, with a rate of 13% for all those over the age of 40. This

very high level of incidence makes one wonder yet again whether "hypertension" based on the readings of a machine is a "disease" in the true sense of the term. From Table XII it will be seen that over the age of 70 at least half of

TABLE XII.—Incidence of Hypertension Per 1,000 at Risk in Age Groups

	40-	50-	60-	70-	80+
Males	18	74	125	360	420
Females	32	100	260	500	450

those alive will have hypertension. In view of this high frequency it is essential that we clarify our views on the need for treating such large numbers of cases that are in the majority of instances quite symptomless. Table XII shows the incidence of known hypertension in the practice, and the rise with age is apparent in both sexes. In patients under 80 the rate in females was almost twice as high as in males.

Discussion

It may well be asked, "What is the use of all these epidemiological facts and figures?" and, quite rightly, the question demands a definite answer in favour of their collection if family doctors and others are to be encouraged to go on carrying out like and similar investigations.

These studies over the past five years have gone a long way in helping me to acquire some knowledge of the patterns and natural histories of the common conditions of general practice—conditions on which there is very little information in the standard textbooks.

Apart from the old wives' tales that one heard, there was no suggestion in medical literature that children tended to "grow out of" their coughs, colds, sore throats, and ear-aches around the ages of 7 and 8. Records collected over this and longer periods definitely suggest that this is a scientific fact. The high level of symptomless "hypertension," twice as common in women as in men, and which requires no specific therapy, was never stressed in my teaching hospital. The epidemiological suggestions that there might be a natural tendency for cases of migraine and duodenal ulcer to undergo a spontaneous remission and "cure" have never been suggested to my knowledge.

Facts such as these have very definite application to the proper management of our patients. If there is this tendency for children to grow out of their respiratory infections, then surely the present high rate of tonsillectomy is unjustified logically as well as medically? If there is this natural tendency towards spontaneous remission in duodenal ulcer, then are our strict dietetic restrictions, bed rest, and other unpleasant measures really justified? If the natural course of migraine is towards a spontaneous remission in the majority of cases, then it would be of great comfort to patients to know this. Obviously these few figures quoted from just one general practice require confirmation. This in itself is more than a justification for further such studies in general practice research.

Even the apparently dull figures relating to the volume of work done at the various ages have been of real value as a piece of operational research. Because of the facts that the young and old require such a disproportionately large amount of extra work, special clinics have been organized for these two groups, with good effects for both doctor and patients.

Another reason why it is necessary to obtain further information on the incidence and nature of morbidity in general practice is to help teaching hospitals plan a more realistic system of medical education that will take into account the common conditions of general practice that are encountered only in general practice. Such information would also be of value to our public health colleagues and even to the top-level administrators who control and govern our destinies.

For all these reasons, and because it is stimulating and educational for the doctor undertaking this work, it is felt that there is a real and continuing need for developing methods of collecting such epidemiological and clinical data from general practice.

If such records are to be developed then it is vital that some unified system of recording and nomenclature be devised, and it would be most appropriate that a conference, or some other steps, be organized at which the various interested bodies could inquire into future possibilities.

Summary

A report is presented of five years' work in a London suburban general practice. The importance of studying epidemiological and clinical data from this field lies in the information that can be obtained on the true patterns of disease as they occur in the community.

The basis of research in general practice and elsewhere is a sound system of record-keeping. In general practice any system has to be adapted to the peculiar features of the work. The methods used are described.

Over the period of five years (1952-6) there was a constant rate of attendance, with an average of 3.3 attendances per patient per year. Females were more frequent than males (7.5 in infants) and the attenders by 6:5. The young (7.5 in infants) and the aged (6.1 in those over 70) required most attention. Almost three out of every four patients are seen each year and over the five years 91% of the practice were attended.

The great value of having full radiological and pathological facilities available is stressed. In any year an average of 13.5% of patients are sent directly for investigations, and a further 7.8% are referred for out-patient consultations and 0.7% for emergency admissions.

Respiratory infections of various types were by far the most common group of diseases seen in this practice, with a rate of 30% of the total. The next most frequent groups were digestive disorders (12%), skin disorders (10%), psychoneuroses (8.5%), "rheumatism" (6.5%), and cardiovascular disorders (6%). The age distributions of these groups are noted and their bearing on aetiology and management is discussed.

Of more importance is a study of the natural patterns of certain specific disorders. In frequency, respiratory infections are most important, but the very appreciable incidence of hypertension, peptic ulcers, and migraine is noted, all with an incidence of over 3%. Examination of epidemiological data on age incidence suggests features that might be of some help in elucidating aetiology and rational management of these common conditions. Thus it is probable that there is a peak level of incidence of the acute respiratory infections in childhood at 5-7 followed by a dramatic decline: this question the usefulness of some of the more drastic remedies is so frequent and so symptomatic that its abnormality is doubtful in many elderly patients. The natural history of the two psychosomatic conditions, migraine and peptic ulcer, suggests that there might be a tendency towards a spontaneous remission with age.

The need for developing the use of general practice records in the country as a whole is apparent, and steps to encourage these in a uniform manner are suggested.

GONADAL DYSGENESIS: MODERN CONCEPTS

BY

R. HOFFENBERG, M.D., M.R.C.P.

AND

W. P. U. JACKSON, M.D., M.R.C.P., D.C.H.

From the Endocrine Clinic, Groote Schuur Hospital, and
Department of Medicine, University of Cape Town

The syndrome of gonadal dysgenesis ("ovarian agenesis") has stimulated great interest in recent years. Knowledge accruing from the study of this subject has led to far-reaching developments in the understanding of the general field of sexual differentiation.

In the course of the past three years we have studied a number of patients with this condition. Arising from our investigations we wish to report certain observations.

The Concept of Gonadal Dysgenesis

Three main components make up the full syndrome.

1. *Sexual Infantilism*.—Fundamentally this is due to a failure of gonadal development. The gonads are represented by mere white streaks of primitive tissue lying on the posterior aspects of the broad ligaments. Primary amenorrhoea with failure of secondary sex characters is all but invariable. A raised level of follicle-stimulating hormone (F.S.H.) provides an important diagnostic criterion.

2. *Shortness of Stature*.—The majority of patients are between 4 ft. 6 in. and 4 ft. 10 in. (137 and 147 cm.) in height. This conflicts with the tall, eunuchoid stature generally found in cases of prepubertal gonadal failure. This shortness of stature is generally attributed to a distinct genetic anomaly (Albright *et al.*, 1942b).

3. *Associated Congenital Anomalies*.—A multiplicity of anomalies, affecting almost every organ or tissue of the body, have been described. Webbing of the neck, cubitus valgus, and coarctation of the aorta are the most widely known. These malformational anomalies do not all occur together. Individual patients show varying combinations; in fact, cases of proved gonadal dysgenesis have been noted without obvious congenital abnormalities (del Castillo *et al.*, 1947; Grumbach *et al.*, 1955; Greenblatt *et al.*, 1956).

Nuclear Sexing.—The recent recognition of male nuclear patterns in many anatomically female cases of "Turner's syndrome" (Polani *et al.*, 1954) has been explained in the light of Jost and other workers' experiments on animals (Jost, 1953). They have shown the female form to be basic or neuter, and male differentiation to occur only in the presence of functioning testes during embryonic development. This observation led to the adoption of the term "gonadal dysgenesis" in preference to "ovarian agenesis" and suggested that the syndrome was, in fact, a variety of intersexual development. Grumbach *et al.* (1955) have postulated a relationship between gonadal dysgenesis and male pseudohermaphroditism.

Investigations and Reflections

Twenty-seven cases of gonadal dysgenesis have been seen in the course of the past three years at the Endocrine Clinic, Groote Schuur Hospital. Many patients with primary amenorrhoea are seen and treated at other clinics. The number of cases in this series testifies to the frequency of occurrence of gonadal dysgenesis. The salient clinical features of each case are presented in the Table (see next page).

after a time in any event, but the oestrogen dosage may be halved or temporarily abandoned if desired. The further addition of progesterone does not appear to have any value in the treatment of gonadal dysgenesis.

Conclusions and Summary

A series of 27 patients with gonadal dysgenesis is presented. The absence of raised levels of urinary gonadotrophin excretion in this syndrome is shown to be a not uncommon finding. Cortisone was found not to reduce high excretions of gonadotrophin when these were present.

Attention is drawn to the comparatively infrequent occurrence of the classical congenital anomalies of "Turner's syndrome." Scepticism is expressed about the existence of cubitus valgus. Several patients in this series had good breast development when they were first seen. Biopsy in one untreated patient showed the breasts to consist of fat only. Tests of adrenocortical function displayed no impairment—even where sex hair was deficient. This tends to refute the view that the adrenal cortex alone governs axillary hair growth. Three cases are described in which moderate-to-severe osteoporosis occurred. This finding is discussed.

The presence of "ovarian stroma" and developing follicles on histological examination of the gonadal streaks is considered in relation to nuclear sexing of these patients. The anomalous finding of clitoral enlargement in "genetic" females is mentioned. Reference is made to patients who claim to have menstruated and to "normal-looking females" with gonadal dysgenesis.

The diagnosis of gonadal dysgenesis is discussed with particular reference to nuclear sexing. It is pointed out that this syndrome is probably the most common cause of primary amenorrhoea—whatever the appearance of the patient.

The treatment of gonadal dysgenesis is outlined.

MORBIDITY FROM T.A.B.T. INOCULATION IN R.A.F. RECRUITS

BY

J. D. E. KNOX, M.B., Ch.B.
Late Squadron Leader, R.A.F.

AND

W. P. STAMM, F.R.C.P.
Air Commodore, Consultant in Pathology and Tropical
Medicine to the Royal Air Force

Several clinicians at Royal Air Force schools of recruit training have gained the impression that a variety of morbid conditions, apart from immediate local and general reactions, may follow inoculation with T.A.B.T. (a phenolized vaccine containing *Salmonella typhi*, *Salmonella paratyphi A* and *B*, and tetanus toxoid).

Robertson and Leonard (1956) stated that the conditions usually affected the joints and reticulo-endothelial system, and very occasionally seemed to initiate a cycle of events leading to a syndrome resembling the "collagen disorders." They suggested that infective conditions of all kinds, including upper respiratory infections, were more common during the seven to ten days following inoculation. They postulated that "all the immunological processes are disturbed at this time, giving rise to a general lowering of resistance to infection." These claims clearly called for a full investigation, for if they were substantiated the justification for routine inoculation of Service personnel would need careful reconsideration. This paper reports the results of such an investigation, carried out at five R.A.F. schools of recruit training over a period of one year. The opportunity was also taken to record the incidence of local and general reactions following inoculation.

Materials and Methods

At each of the five centres arrangements were made for recruits with even Service numbers to receive the usual doses of T.A.B.T. (0.5 ml. subcutaneously followed by 1 ml. four to six weeks later), and for those with odd numbers to be left uninoculated until arrival at their next unit. Both groups continued to be vaccinated against smallpox. Special records of sickness were kept on all recruits during their eight weeks of training, and a pathologist (J. D. E. K.) was

appointed in overall charge of the arrangements at unit level. No special advice was given to the unit medical officers on matters of sterilization of syringes and needles, route and site of inoculation, etc., since the primary purpose of the trial was to establish whether there was any morbidity from T.A.B.T. inoculation as currently practised in the R.A.F. At the end of the experimental period the records were collected and analysed by the Medical Statistical Branch of the Air Ministry.

The numbers of recruits with even and odd numbers were 27,733 and 27,726 respectively, taking Royal Air Force and Women's Royal Air Force together. The actual number of recruits in the test group was 27,512, and 27,947 were in the control group. The difference in the size of the two groups from the "ideal" is accounted for as follows: 940 recruits who should have been in the test group were not given T.A.B.T. and 719 who should have been in the control group were given T.A.B.T. This results in a decrease in the number in the test group by 221, with a corresponding increase in the control group. It is thought that these errors were purely administrative and are unlikely to have biased the results.

Results

The overall incidence of sickness and the separate incidence of "diseases caused by infection," "accidents, poisoning, and violence," and "other diseases," are given in Table I. The total R.A.F. sickness rate of the test group

TABLE I.—Incidence of Sickness in Control and Test Groups, R.A.F. and W.R.A.F.

	R.A.F.				W.R.A.F.			
	Control		Test		Control		Test	
	No.	%	No.	%	No.	%	No.	%
Total No. at risk	27,063	—	26,680	—	884	—	832	—
Diseases caused by infection	7,876	29.1.0	7,471	28.0.0	252	28.5.1	189	22.7.2
Accidents, poisoning, and violence	2,768	102.3	2,622	98.3	105	118.8	85	102.2
Other diseases	5,352	197.8	5,331	199.8	332	375.5	225	270.4
Total	15,996	591.1	15,424	578.1	689	779.4	499	599.8

is significantly lower than that of the controls and this difference is most pronounced in the group "diseases caused by infection." Analysis of this latter group shows that it consists mainly of diseases of the upper respiratory tract, and in these the difference in incidence still persists (Table II).

TABLE II.—Incidence of Upper Respiratory Infection in Control and Test Groups, R.A.F.

Disease	Control		Test	
	No.	%	No.	%
Total No. at risk	27,063	—	26,680	—
Acute nasopharyngitis	1,915	7.0.5	1,845	6.9.5
Acute tonsillitis	778	28.7	647	24.2
Other acute upper respiratory infection	2,245	82.8	2,181	81.8
Influenza	237	8.8	223	8.4
Lobar pneumonia	40	1.5	36	1.3
Bronchopneumonia	37	1.4	36	1.3
Primary atypical, other, and unspecified pneumonia	118	4.4	117	4.4
Acute bronchitis	130	4.8	144	5.4
Bronchitis, chronic and unqualified	145	5.3	137	5.1
Total	5,645	209.0	5,366	201.0

In view of Robertson and Leonard's statement that reactions chiefly affected joints and the reticulo-endothelial system, a detailed analysis was made of diseases of bones and joints (Table III). It showed that there was no significant difference between the test and control groups. Diseases affecting the reticulo-endothelial system were too few for any valid statistical comparison, but the cases seen were equally distributed between the test and control groups.

TABLE III.—Incidence of Diseases of Bone and Joints in Control and Test Groups, R.A.F.

TABLE IV.—Immediate Local and General Reactions to T.A.B.T. at Each Centre, R.A.F.

Centre	No. at Risk	Percentages Affected					
		Local Reaction			Local and General Reaction		
		Negligible	Considerable	Admitted or Detained	Slight	Considerable	Admitted or Detained
1	6,305	97.06	1.38	0.03	0.24	0.10	1.19
2	4,453	97.62	1.10	0.04	0.52	0.20	0.52
3	2,479	96.37	1.49	0.08	0.65	0.24	1.17
4	8,600	96.69	2.34	0.03	0.38	0.14	0.42
5	4,843	97.03	1.32	0.10	0.27	0.06	1.22
Total	26,680	96.96	1.64	0.05	0.38	0.14	0.83

The immediate reactions, both local and general, to the inoculations were recorded, and are summarized in Table IV; the incidence of recruits rendered temporarily unfit for duty and requiring admission to sick quarters was approximately 1%.

A number of medical officers gave the majority of their inoculations intramuscularly, but no difference could be detected between the immediate local and general reactions to these injections and those following subcutaneous inoculation.

Because of the possibility that T.A.B.T. might contain "A" substance (Crawford *et al.*, 1952) an analysis of reactions to T.A.B.T. by blood groups was carried out at one of the centres on those subjects whose blood group was known. The results (Table V) show no significant difference between persons of different blood groups.

TABLE V.—Immediate Local and General Reactions to T.A.B.T. by Blood Groups

Blood Group	No. at Risk	Percentages Affected					
		Local Reaction to T.A.B.T.			Local and General Reaction to T.A.B.T.		
		Negligible	Considerable	Admitted or Detained	Slight	Considerable	Admitted or Detained
AB	82	98.78	0.00	0.00	0.00	0.00	1.22
A	913	98.02	0.88	0.00	0.22	0.00	0.88

O	976	98.05	1.03	0.10	0.10	0.00	0.72
Rhesus +	1,826	98.03	0.88	0.05	0.22	0.05	0.77
Rhesus -	334	97.60	1.20	0.00	0.00	0.00	1.20
Total	2,160	97.96	0.93	0.05	0.18	0.05	0.83

During the investigation the opportunity was taken to inquire into the relationship between T.A.B.T. inoculation, smallpox vaccination, and false-positive serological tests for syphilis. The results, details of which have already been reported by Mason and Headland (1955), showed that smallpox vaccination may give rise to 2% false-positive Kahn reactions but that T.A.B.T. had no such effect.

No cases of peripheral neuritis were seen, such as were described by Miller and Stanton (1954). There were two cases of acute encephalitis, both in the control group; two cases of poliomyelitis, one in each group; and four cases of meningitis, two in each group.

Discussion

The results of this investigation do not support some of the impressions recorded by Robertson and Leonard. The present results do not exclude the possibility of individual rare syndromes, such as the single cases of "collagen disease" reported by these authors, being caused by T.A.B.T. inoculation.

That unit medical officers were all too ready to ascribe miscellaneous morbid conditions to inoculation was exemplified by occasional cases of traumatic synovitis belonging to the control group being labelled "T.A.B.T. arthropathy." It appeared that many junior medical officers had been warned by their professional seniors of the important aetiological role of T.A.B.T. in what Ogilvie (1954) terms "ephebiatrics."

It should be remembered that T.A.B.T. is usually given at a time when the recruit is adapting himself to a new environment, and that the immediate post-inoculation period is the time when his reaction to "herd life" may be expected to become apparent.

Although the admission of 1% to sick quarters following T.A.B.T. inoculation seems reasonably small at first sight, it can cause considerable administrative embarrassment when large numbers are involved. This admission rate, however, was less than that due to vaccination (1.5%).

Summary

A survey was carried out on 55,459 R.A.F. and W.R.A.F. recruits to determine the morbidity following T.A.B.T. inoculation. The incidence of disease in the test group was significantly lower than that in the controls; nearly all this difference was accounted for by "diseases caused by infection" and persisted in "diseases of the upper respiratory tract."

The admission rate to sick quarters following T.A.B.T. inoculation was 1%, and following smallpox vaccination 1.5%.

No difference in immediate local and general reactions could be detected between subcutaneous and intramuscular T.A.B.T. inoculation.

There was no significant difference between the reactions to T.A.B.T. inoculation classified according to the blood groups of the patients.

T.A.B.T. does not appear to give rise to false-positive Kahn reactions, but vaccination may cause up to 2% false-positive results.

No cases of peripheral neuritis were seen.

We thank the Medical Statistical Branch of the Air Ministry for their willing assistance, and particularly Mr. E. W. N. Ratcliff, who carried out most of the statistical analyses. We also thank the Principal Medical Officer of Technical Training Command and the numerous medical officers, administrative officers, and airmen, without whose co-operation this investigation could not have been completed. We are indebted to the Director-General of Medical Services for permission to publish this paper.

Since the second world war 976 new homes for the aged had been opened in England and Wales, said the Minister of Health, Mr. DEREK WALKER-SMITH, Q.C., when opening an L.C.C. home for the elderly this month. Referring to the size of the problem in Britain, he said that to-day one person in nine was over 65, compared with one in 21 at the beginning of the century. By 1975 this proportion would have risen to one in seven.

MEGALOBlastic ANAEMIA OF
INFANCY TREATED WITH FOLIC
ACID

BY

FRANK WALT, M.R.C.S., D.C.H.

Consultant Visiting Paediatrician, Paediatric Department,
McCord Zulu Hospital, Durban

S. HOLMAN, M.D., B.Sc., D.C.P.

Late Senior Lecturer in Pathology, Durban Medical School;
Late Clinical Pathologist, King Edward VIII Hospital,
Durban

AND

P. NAIDOO, M.B., B.Ch.

Late Registrar, Paediatric Department, McCord Zulu
Hospital, Durban

Megaloblastic anaemia in infants was thought to be rare at the McCord Zulu Hospital, Durban, until an incidence of 5.4% was found in 1954 (Walt *et al.*, 1956). Diagnosis was made by bone-marrow examination alone, patients for aspiration being chosen on clinical grounds or when the haemoglobin was below 6.7 g./100 ml. Because that investigation left many questions unanswered a controlled project was initiated. The objectives were to find the true incidence of megaloblastosis; the significance of reticulocytosis; the rapidity with which the bone marrows returned to normal; the part played by antibiotics, particularly penicillin; the cause of the sudden drop in haemoglobin or "crisis" in some patients; and the reasons for the development of megaloblastosis. Answers to some of these questions can now be given.

Although it has been known for a long time that folic acid will cure the megaloblastosis and therefore a deficiency of folic acid is presupposed, we still do not know whether the deficiency is due to lack of intake, absorption, or utilization, nor why it is commonest amongst our cases of kwashiorkor.

Material and Methods

These were similar to those described previously (Walt *et al.*, 1956). To determine the incidence of megaloblastic anaemia in this hospital the bone marrow of every case admitted to the children's wards was aspirated within 24 hours of admission. The series ran from February 14, 1955, to June 5, 1955 (excluding 23 days between March 22 and April 13 because of the Easter vacation), during which time 217 cases were admitted. The bone marrows of 201 cases were examined; of the 16 cases not aspirated, 6 were omitted in error and 10 patients died within a few hours of admission, post-mortem specimens not being obtained.

A further objective was to determine whether the reticulocyte response was a satisfactory measure of effective therapy with folic acid and whether a particular pattern of reticulocyte response could be observed. Two groups of patients were therefore chosen, the first comprising all cases with megaloblastic anaemia and the second consisting of non-megaloblastic cases taken entirely at random; this was done arbitrarily by using every fifth patient admitted as a control case. If the fifth patient suffered from megaloblastic anaemia the next non-megaloblastic case was placed in the control group. This series yielded 18 cases of megaloblastic anaemia and 31 control cases (non-megaloblastic).

The two groups were treated in exactly the same manner, each being given 5 mg. of folic acid three times a day, followed by re-aspiration of the bone marrow within 96 hours. Reticulocyte estimations by the method of Dacie

(1950) were performed three times a week, and haemoglobin levels determined with a Sahli haemoglobinometer twice a week; bone-marrow films were stained with May-Grünwald-Giemsa stain, and all were examined by one of us (S. H.).

The bone marrows were graded into severe, moderately severe, and mild megaloblastic marrow entirely upon the

cytological picture and not on the severity of the primary illness or the degree of anaemia. On the whole we found the sicker child to be more anaemic with a more severely affected marrow, but a fair number of exceptions to this were observed. The bone-marrow grading was as follows:

Severe Megaloblastic Marrow.—Erythropoiesis is very largely or entirely megaloblastic. The predominant cells

are primitive very basophilic megaloblasts. Diagnosis is easily made.

Moderately Severe Megaloblastic Marrow.—Erythropoiesis is largely if not entirely megaloblastic; the predominant cell is only a moderately primitive basophilic or polychromatophilic megaloblast. Classical megaloblasts of Ehrlich abound. The diagnosis is extremely easy.

Mildly Megaloblastic Marrow.—Erythropoiesis is only partially megaloblastic, and is frequently predominantly normoblastic. The cells show partial megaloblastic changes and in general are rather mature cells of the polychromatophilic or even the orthochromatic type. Frank megaloblasts may be very scarce or even entirely absent. Diagnosis may be extremely difficult or even impossible.

All cases were given the appropriate treatment for their primary disease (Table I), and for complications where necessary, such as high-protein diets, antibiotics, and parenteral fluids.

Incidence

Of the 201 patients studied, 18 (9%) had a megaloblastic marrow. Of these, 11 cases were mildly affected, 6 moderately, and 1 severely.

Kwashiorkor was of common occurrence in the megaloblastic series and was present in 16 (89%) of the 18 cases, but in the control group of 31 cases it occurred only 10 times (32%). On the other hand, infection was the predominant feature in only 2 (11%) of the 18 megaloblastic cases, but it occurred in 18 (58%) of the 31 control cases (see Graph). The infections commonly seen

Graph showing number of cases with uncomplicated kwashiorkor, kwashiorkor with infection, and infection alone in both groups.

were bronchopneumonia, gastro-enteritis, otitis media, and bacillary dysentery. An antibiotic or chemotherapy was used in all the control cases and in 13 (72%) of those with megaloblastosis.

Reticulocyte Response

Reticulocyte counts were adequately repeated in 13 cases of megaloblastic anaemia and in 28 controls. All the megaloblastic cases but only six (21%) control cases developed a reticulocyte peak of more than 11% (Table II) after treatment with folic acid. If one accepts the normal reticulocyte count to be less than 5%, then some of the control cases and some of the megaloblastic cases already had a reticulocytosis when admitted (Table III). Three control cases (Nos. 147, 184, and 248) had counts of 5.6%.

TABLE II.—Difference in Reticulocyte Response in the Two Groups

Highest Reticulocyte Count	Megaloblastics		Non-megaloblastics	
	No.	%	No.	%
0-5.5%	0	—	8	28
5.5-11.0%	0	—	14	50

Results

Of those with megaloblastosis five died (Cases 105, 122, 175, 179, and 284), two deaths occurring less than 72 hours after admission and the others on the fifth, eighth, and thirteenth hospital day. Their admission haemoglobins were respectively 6.7, 9.7, 7.4, 4.8, and 7.6 g./100 ml. One case (No. 154) had a normoblastic bone marrow on admission, but when re-aspirated nine days later megaloblasts were present. In four other cases (Nos. 152, 169, 234, and 260) the bone marrows did not show true megaloblasts on admission, but the presence of many bizarre myelocytes caused us to repeat the examinations five, seven, three, and five days later respectively, when megaloblasts were found. Three of the control patients died—one in less than 48 hours after admission, one on the fifth day, and one on the fifteenth day. The mortality rate for the controls was 10% and for the megaloblastic anaemia cases 28%.

Discussion

The incidence of megaloblastosis of 9% in this series is appreciably higher than the incidence of 5.4% previously reported (Walt *et al.*, 1956). We feel that this increase can be explained by the use of routine bone-marrow examinations rather than marrow aspirations on clinically suspicious cases only, together with a possible seasonal summer increase, as was suggested in our first investigation (Walt *et al.*, 1956). Some of the additional cases that were detected were probably mild megaloblastic anaemias most of which would have improved spontaneously without folic acid therapy. The relatively high incidence emphasizes once more the value of "a high index of suspicion" for this disease.

Reticulocyte Response

A high reticulocytosis has been accepted as an indication of response to therapy, but the figures have varied with different workers. Their range seemed to be between 4% and 7% (Zuelzer and Rutzky, 1953; Altmann and Murray, 1948), but we had previously found this too low a figure, and in this investigation set out to find an average for our cases. It is well known that a reticulocytosis will result not only from folic acid therapy but secondarily to haemorrhage, a good diet, control of infection, etc., and for this reason the control cases were also given folic acid. Some cases may have had some treatment elsewhere which could have caused a reticulocytosis before being admitted to our wards, but it is very unlikely that this included folic acid; however, we cannot be certain, because the histories are unreliable and parents are not told what treatment is administered. Although this could be the explanation, in other cases counts were not performed until four to five days after admission, when specific treatment (excepting folic acid) had already been started, and in the majority the basic reticulocyte counts were normal (Table III). One control case (No. 297) had a basic reticulocyte count of 9% on the sixth hospital day, while in three cases with megaloblastic changes (Nos. 105, 152, and 154) the reticulocyte counts were 6.8%,

8.6%, and 8.0% on the fourth, fourth, and ninth days respectively. These responses could have been due to the antibiotics administered on admission.

Six control cases developed reticulocyte peaks of over 11%, one occurring on the sixth day after commencing folic acid while others occurred much later—the seventeenth day as in Case 153 (Table I). This patient was suffering from kwashiorkor, had a basic reticulocyte count of 1.8% on the first day, and a normoblastic bone marrow. A high-protein diet, penicillin, and folic acid were begun and the reticulocyte count was followed; it was 5.2% on the third day, 7.4% on the fifth, 1.6% on the seventh, 0.6% on the tenth, 2.4% on the twelfth, 0.6% on the fourteenth, suddenly 13.6% on the seventeenth day, and 11.4% on the nineteenth day. Her illness improved rapidly and she was much better when discharged on the twenty-eighth day.

Similar responses occurred among the cases with megaloblastosis, although on the whole they tended to occur earlier and, of course, had much higher peaks. In three cases (Nos. 119, 154, and 274) "double peaks" occurred, all being more than 11% within the first week after beginning folic acid, returning to normal in the second week, and rising again to over 15% in the third week. These can be explained in Cases 119 and 274, both of which responded to folic acid with a reticulocytosis and a rapid return to normoblastic bone marrows followed by complications in the other; toxæmia, an abscess in one, and pneumonia in the other; both became very ill and needed blood transfusions, and on recovery the reticulocytes rose rapidly again. Case 154, admitted with a normoblastic bone marrow, developed megaloblastosis while on treatment with penicillin and high-protein feeding for kwashiorkor. He responded to folic acid with a 19.6% reticulocytosis, improving clinically, and by the third week had 0.6% reticulocytes; he then relapsed with acute bronchitis and high fever, responded to treatment, and produced 18.4% reticulocytes.

It is obvious that in these cases the assessment of therapy cannot be measured by the reticulocyte response, which is irregular and unreliable and not at all as clear-cut and uniform as in pernicious anaemia. This is in direct contrast to the findings of Gerbasi (1953), who states that the reticulocyte crisis begins 48 hours after the commencement of treatment and is maximal on the fourth day.

Bone-marrow Response

Because our diagnosis was usually made by bone-marrow estimation we felt that the best test of cure of the megaloblastosis would be a rapid return to a normoblastic pattern, and in 15 cases the bone marrows were re-examined within 96 hours of starting therapy with folic acid, and all were found to be normoblastic; in 11 cases the bone marrow was normoblastic within 79 hours of therapy.

Haemoglobin Levels

Megaloblastosis was usually associated with an anaemia, but this was not invariable, and when present the anaemia was not necessarily severe. We feel, however, that, as the presence of megaloblasts in the bone marrow is likely to lead to a serious and alarming anaemia at any time, megaloblastic anaemia should be seriously considered in any child with a haemoglobin below 6.7 g./100 ml. as reported earlier (Walt *et al.*, 1956), and a bone-marrow aspiration performed immediately.

Aetiology

Megaloblastic anaemia of infancy (Adams, 1954) and of pregnancy (Adams and Wilmot, 1953) is apparently much more common in Durban than elsewhere in South Africa. Very few cases have been discovered in Johannesburg (Altmann and Murray, 1948) and Capetown (J. F. Brock, personal communication). We cannot account for this, because the diets of the lowest-income groups in these three large centres are probably very similar.

In Italy both Amato (1946) and Gerbasi (1950) have described many cases of megaloblastic anaemia in infants, and

more recently Gerbasi and Burgio (1955) have described it in children with a disease apparently very similar to our cases of kwashiorkor. In our patients infections with tropical diseases such as hookworm, roundworm, and *Entamoeba histolytica* are not heavy and cannot be the sole cause of megaloblastosis, but many of our cases have a large number of leucocytes in the stools, and bacillary dysentery may possibly play an important part. In most cases cultures of stools did not reveal any specific pathogenic organism, but, unfortunately, repeated cultures could not be made.

Many of our cases of kwashiorkor are associated with megaloblastosis, and protein deficiency is obviously an important aetiological factor. The diarrhoea so often associated with it may prevent the absorption of folic acid. The cause cannot be protein lack alone, because some of our cases of kwashiorkor showed only suspicious bone marrows on admission, and despite a high-protein diet of lactified skimmed milk, which we know cures kwashiorkor, they went on to develop typical megaloblasts in the bone marrow. Some other factors must also play a part, because routine bone-marrow examinations revealed more mild cases than were suspected clinically. We believe that some patients develop a mild megaloblastosis which disappears spontaneously when the kwashiorkor improves or as soon as the infection disappears, or when the diarrhoea stops, and that these cases are never diagnosed clinically.

It is possible that vitamin B₁₂ is also necessary in conjunction with high-protein feeding. May *et al.* (1952), on the other hand, have shown that in monkeys the toxæmia from an abscess produced by the injection of turpentine will cause a megaloblastosis of the bone marrow. We feel, too, that infection plays an important part in some cases, but we have not been impressed by the bone-marrow response to penicillin or chemotherapy. Foy *et al.* (1950) thought that the megaloblastosis might be related to protein deficiency, but later they reported, in separate articles (Foy *et al.*, 1951a, 1951b), two cases which responded to penicillin alone. Many of our cases were given antibiotics because of some superimposed infection, and, despite this, they developed megaloblastosis. Others again did not improve until folic acid therapy had been instituted.

Summary

During a controlled study of megaloblastic anaemia in infancy an incidence of 9% was found in 201 cases admitted over a period of three months, during which time routine bone-marrow examinations were made on all admissions.

Of the cases with megaloblastic anaemia 89% had kwashiorkor.

All cases showed reticulocyte peaks of over 11%, but reticulocytosis occurred at variable times and in no set pattern, and could not be used as a test of cure.

The bone marrows became normoblastic within 96 hours of beginning folic acid therapy. Despite this the haemoglobin levels did not rise rapidly.

The aetiology is not known, but protein deficiency, dysentery, and other infections probably play the major part.

Because megaloblastosis is so commonly associated with kwashiorkor it is recommended that all cases of kwashiorkor should be given folic acid for three weeks.

Our thanks are due to Dr. A. B. Taylor, medical superintendent, McCord Zulu Hospital, for his help; to Dr. J. C. Thomas, late provincial pathologist, Natal Provincial Administration, for laboratory facilities; to Dr. S. G. Joubert, provincial pathologist, Natal Provincial Administration, for the serum protein estimations; to Professor J. F. Brock, professor of medicine, University of Capetown, for continued interest, encouragement, and helpful criticism; to Mrs. M. Habermann, who voluntarily gave up much time to carry out the reticulocyte counts; and to Mrs. A. H.

seemed to justify it, or when the leucocyte count was thought to be falling too steeply." In general they have aimed to maintain the leucocyte count between 10,000 and 20,000 per c.mm., and no further cases showing signs of toxicity were encountered.

Greig (1956) used a similar initial dosage of 4 mg. daily, but continued treatment at this level until "the blood count showed no further evidence of improvement." The leucocyte count was brought to "normal levels," and maintenance therapy continued at a dose between 1 and 2 mg. daily. Marrow aplasia occurred in only 1 of 34 cases in his series, and that in a patient who had inadvertently received a double dosage rate for 45 days (8 mg. daily). Recovery took place when busulphan therapy was stopped. Greig noted that in two patients who were thrombocytopenic at the start of treatment the effect of busulphan was to aggravate this feature, and the drug had to be stopped.

A more precise plan of therapy which appears equally safe and allows more rapid remission to be produced has been used by Hyman and Gellhorn (1956). They gave initial doses of 10 mg. daily and followed the peripheral leucocyte count every two to three days until it reached 25% of the original level. Therapy was then discontinued until the leucocyte fall stopped. Further treatment was given if necessary to bring the white-cell level to within the normal range of 6,000-10,000 per c.mm. If initial response was unsatisfactory, doses of as much as 20 mg. daily were given until a suitable rate of fall was achieved. An even more aggressive routine plan of therapy has been used by Dameshek (1957), who gave initial doses of 8-16 mg. daily until the leucocyte count reached 5,000-6,000 per c.mm. The drug was then stopped, and while the white-cell count sometimes continued to fall to 2,000-3,000 cells per c.mm. Dameshek has encountered no deleterious effects from this procedure in a series of 34 cases, apart from two temporary cases of thrombocytopenia. Maintenance with doses of the order of 2-4 mg. daily may be well tolerated and lead to prolonged remission, but unexpected bone-marrow failure has developed suddenly in a few patients so treated (Haut *et al.*, 1955; Storti and Pederzini, 1955, Case VIII).

Clearly, the administration of large doses of busulphan is frequently associated with the development of aplastic states (Wilkinson, 1953; Galton and Till, 1955; and Storti and Pederzini, 1955). In the majority of cases high dosage rates are now used only in patients who have proved resistant to more conservative schemes of treatment, and then only with very close haematological supervision. The dosage employed by Dameshek appears to be too close to the toxicity level to be safely used without very frequent blood counts, and, although in his experience undue marrow depression has not occurred, the advantages of such intensive therapy for routine use would seem to be outweighed by the risks.

It is theoretically desirable to maintain the white-cell count between 5,000 and 10,000 cells per c.mm., and Hyman and Gellhorn emphasize that in their experience the best results of treatment with busulphan are obtained when the leucocyte level has been reduced to below 10,000 cells per c.mm. In practice, however, this ideal is difficult to achieve. Although the response to busulphan may remain uniform for long periods, a change in sensitivity to the drug may occur in either direction. If treatment is stopped the white-cell count may continue to fall to an unpredictable and varying extent.

The two cases reported here did not receive intensive courses of treatment. After the leucocyte count had been reduced to the 5,000-10,000 cells per c.mm. range, by doses of 8 mg. daily in Case 1 and 4 mg. a day in Case 2, maintenance therapy of 4 and 2 mg. per day respectively was given. Both patients developed progressive marrow aplasia during the next four weeks.

Recommendations for Routine Use

The initial conservative dosage of 4 mg. daily used by Galton and Till seems the most advisable regimen for the

treatment of chronic myeloid leukaemia on an out-patient basis when blood counts and physical examination can be carried out at fortnightly to monthly intervals. Treatment should be stopped temporarily when the leucocyte count has fallen to between 10,000 and 20,000 per c.mm., and recommenced at a lower level when the white cells have begun to increase. By this means a very gradual reduction to between 5,000 and 15,000 cells per c.mm. may be effected with little risk of too severe a fall. Higher dosage busulphan therapy in the occasional resistant patient is probably best carried out in hospital unless very frequent visits for blood counts can be made, since a sudden rapid fall may occur even in an initially resistant patient.

The average sensitive patient presenting a high peripheral leucocyte count may be given an initial dose of 10 mg. a day when blood examinations at intervals of two to three days can be undertaken. This may be done, for example, in cases where treatment is begun in hospital. The busulphan should be stopped when the white count has fallen to about 25% of the initial level, as recommended by Hyman and Gellhorn, unless the fall is very precipitous, in which case the drug should be stopped when the count has been roughly halved. When the leucocyte level has stopped falling, treatment may be started again with smaller doses, and an attempt made to reduce the level cautiously to about 10,000 cells per c.mm.

When the early stages of therapy have brought about a satisfactory fall in leucocyte count, improvement in haemoglobin level and in physical condition usually follows rapidly, and a decision must then be made about maintenance treatment. In our view it would be unwise to continue giving busulphan, even in doses as low as 0.5 to 2 mg. daily, to any patient whose leucocyte count is below 8,000 per c.mm. When the white-cell level is between 10,000 and 20,000 per c.mm., and even more so if it is higher, benefit is likely to result from continued therapy. In general the aim should be to adjust dosage so that the count is kept between 10,000 and 20,000 cells per c.mm. Because of the change in sensitivity which has already been mentioned, it is unsafe to leave a patient on treatment without blood examination for more than four weeks.

The onset of purpura or a sharp fall in platelet level at any stage of treatment should lead to prompt cessation of therapy.

Summary

Details are given of two patients with chronic myeloid leukaemia who developed bone-marrow failure while on busulphan therapy. In one case the aplastic state proved irreversible, but in the other recovery occurred.

The literature on toxic reactions to busulphan is reviewed. Initial doses of 4-10 mg. a day are recommended, since more intensive treatment carries a high risk of marrow failure. Careful control of dosage in accordance with the rate of fall of the peripheral leucocyte count is essential. Opinions vary concerning the most satisfactory indications for stopping treatment and the relative advantages of maintenance therapy and intermittent courses in long-term management. The best remissions have generally been achieved when the white-cell count has been reduced to 5,000-10,000 cells per c.mm. by the initial course of busulphan, but the two cases here reported illustrate the risk of continuing treatment, even in very low doses, when the count is at these levels.

Dosage schemes and methods of management which should minimize the risk of marrow failure are suggested for use in patients treated initially in hospital or able to attend frequently for blood counts and also for those who can attend less often as out-patients. We think it unwise to continue giving busulphan in any circum-

stances to a patient whose leucocyte count is below 8,000 per c.mm. or to one who manifests purpura or a sharp fall in platelet level.

RUBELLA ENCEPHALITIS

BY

RONALD J. CANTWELL, M.B., M.R.C.P.Ed.
D.C.H.

Paediatric Registrar, Royal Alexandria Hospital for Sick
Children, Brighton; formerly of Post-Graduate
Medical School, Hammersmith Hospital

Since the classical description by Bénard (1921) of 13 cases of encephalitis occurring amongst 291 hospital patients with rubella, there has been considerable interest in this and other not uncommon complications of the latter. Steen and Torp (1956) reported 88 definite cases of rubella encephalitis from the literature, and added a further three cases of their own. Most of the reported cases have occurred during epidemics of rubella.

The neurological symptoms most often occur one to six days after the onset of the exanthem. They are characteristically brief in duration, with complete recovery in most cases. Usually encephalitic, myelitic, or meningeal signs are elicited either singly or in combination. Death can occur (it occurred in 20% of the cases reviewed by Schleisner *et al.*, 1955). More rarely, permanent sequelae are encountered.

Cases of rubella complicated by neurological involvement do not seem to differ in any way from cases not so affected. Further, there is no relationship between the severity of the initial illness and the occurrence of neurological complications (Barraclough, 1937).

Case 1

A girl aged 6 years was admitted to hospital during a mild epidemic of rubella with a history of onset of headache and drowsiness seven days previously. Next day she developed a generalized maculopapular rash diagnosed by the family physician as rubella. A younger sister aged 3 had developed rubella one week previously, and, although drowsy at the time of the rash, rapidly recovered as the rash faded.

As the exanthem subsided, the patient's drowsiness increased, and the persistence of this together with the severe headache resulted in her being confined to bed. Three days before admission she noticed the gradual onset of "giddiness," which became worse whenever she attempted to sit up in bed. This in turn became progressively worse, until on the day of admission vomiting occurred whenever the "giddiness" was severe. There had been no convulsions or loss

of consciousness, and no diplopia, speech disturbance, or dysphagia. The child had previously suffered from measles, mumps, chicken-pox, and infantile eczema.

Neurological examination revealed an afebrile, intelligent, co-operative girl who continually lapsed into a drowsy state when not engaged in conversation. There was no evidence of cranial nerve involvement and ophthalmoscopic examination was normal. Abnormal findings included mild bilateral horizontal nystagmus and intention tremor. The tendon reflexes were all brisk, but the plantar responses were flexor. Kernig's sign was negative. She had gross ataxia with vertigo when erect, the ataxia being most pronounced when the eyes were closed. There was a tendency to walk on a wide base. The only other positive finding on examination was pharyngitis with fetor. A provisional diagnosis of rubella encephalitis was made and symptomatic treatment given.

Investigations.—Mantoux reaction 1:1,000 negative. Throat swab—no pathogens. X-ray examination of skull and chest normal. E.S.R., 32 mm. in one hour. Lumbar puncture on admission: clear colourless fluid; pressure 70 mm. water; cells, less than one leucocyte/c.mm.; chloride, 125 mEq/litre; protein, 20 mg./100 ml.; Pandy reaction negative; W.R. negative; glucose, 29 mg./100 ml. (probably unreliable, as the specimen was left in the refrigerator overnight without preservative); Hb, 12.7 g./100 ml.; W.B.C., 10,000/c.mm. (55% neutrophils, 40% lymphocytes, 5% monocytes).

Four days after admission the E.S.R. was 16 mm. in one hour; W.B.C., 6,000/c.mm. (30% neutrophils, 60% lymphocytes, 5% monocytes, 5% eosinophils). Lumbar puncture 11 days after admission: cells, 3 leucocytes/c.mm.; chlorides, 117 mEq/l.; glucose, 60 mg./100 ml.; protein, 60 mg./100 ml.; Pandy reaction negative.

The drowsiness and vomiting continued for a further three days, but the vertigo and ataxia lasted another day. From this time onward, recovery was rapid and the patient was discharged 15 days after admission with no residual disability. Two weeks later she started at school again, having made an apparently full recovery.

Case 2

A girl aged 8½ years, the youngest of three children, was admitted to hospital with a history that seven days previously she had had fever and rash. The rash, which faded in two days, was diagnosed by the family physician as rubella. She was well in herself at the time and remained so until the morning of the day of admission, when she awoke with headache and anorexia, and was "off colour" all day. That evening she vomited and had a generalized convulsion which lasted 1½ hours and left her stuporous. She had previously had measles and whooping-cough, but no convulsions.

The mother and two other children were well. The father had had a temporary "influenza"-like illness with fever, headache, sweating, and generalized muscular pains one week before.

On neurological examination the temperature was 99.6° F. (37.6° C.) and pulse 36. The patient was semiconscious, very restless and uncooperative, and showed no recognition of her surroundings. The pupils were equal and reacted to light. Cranial nerve palsies were not present. There was moderate nuchal rigidity, with a positive Kernig's sign. Tendon reflexes were all present but brisk, the plantar responses uncertain. The only other positive finding was an inflamed throat. Her weight was 70% of normal for her age. A diagnosis of rubella meningo-encephalitis was made and she was kept sedated with intramuscular phenobarbitone.

By next morning she was fully conscious but still rather drowsy. She was not confused but had some retrograde amnesia. She was now afebrile and had had no further convulsions. She remained well subsequently and was discharged one week after admission, having phenobarbitone ½ gr. (32 mg.) b.d. When seen three weeks later she was very well and the phenobarbitone was discontinued.

She attended the out-patient department 2½ years later for another complaint, and showed no sequelae of the meningo-encephalitis. Her weight at this time, however, was normal for her age. There was no thirst, polyuria, or somnolence, and the moderate obesity present was thought to be nutritional in origin.

Discussion

As with the encephalitides occasionally associated with other exanthemata, the mode of production of rubella encephalitis is obscure. Three possibilities can be considered: (1) that the encephalitis is due to the rubella virus itself; (2) that the encephalitis is due to the activation of a previously latent encephalotropic virus; and (3) that the encephalitis is the result of an antigen-antibody reaction. All these possibilities are discussed at length by Davison and Friedfeld (1938) and Hurst (1952), and are not considered further here.

The incidence is not known with certainty, as rubella is not notifiable, and many of the milder cases are not reported. However, rubella encephalitis is probably more frequent than the literature suggests, as most neurologists and paediatricians have seen at least one such case. Shaw (1952) showed that the incidence of encephalitis complicating morbilli was 1 in 616, whilst Greenberg *et al.* (1955) reported an incidence of 1 in 702 in New York City. Comparable figures for rubella encephalitis have been obtained during epidemics in closed communities (see Table). Humphrey

Comparative Incidence of Rubella Encephalitis

	Incidence	Mortality Rate	Permanent Sequelae
Morbilli encephalitis	1:1,000 (Litvak, <i>et al.</i> , 1943) 1:616 (Shaw, 1952) 1:702 (Greenberg <i>et al.</i> , 1955)	20% (Hamilton and Hanna, 1941) 23.8% (Steen, 1954) 10% (McMath, 1954) 2.7% (Knouf and Bower, 1954)	40% (Hamilton and Hanna, 1941) 45% (30% serious) (Steen, 1954)
Rubella encephalitis	1:305 (Humphrey and Ekermeier, 1937) 1:640 (Margolis <i>et al.</i> , 1943)	20% (Schleisner <i>et al.</i> , 1955)	Very rare. (No figures available)
Vaccinia encephalitis	1:170,000 (Weinstein, 1947) 1:10,000 (Greenberg and Appelbaum, 1948) 1:100,000 (Conybeare, 1948)	9% (Greenberg and Appelbaum, 1948) 51% (Herrlich, <i>et al.</i> , 1956)	28% (Herrlich <i>et al.</i> , 1956)
Varicella encephalitis		11% (Underwood, 1935) 11% (Conybeare, 1956)	15% (Underwood, 1935) 10% (Ford, 1952)
Mumps encephalitis	1:4-1:5 (Bowers and Weatherhead, 1953) (varies from epidemic to epidemic)	Only 15 in literature (Steiner, 1942) 3.6% (Conybeare, 1956)	20% (Oldfeldt, 1949) 2.5% (Bowers and Weatherhead, 1953)

and Ekermeier (1937) described one case of encephalitis occurring amongst 305 cases of rubella during an epidemic in a children's home in 1935. In the Detroit epidemic reported by Margolis *et al.* (1943) 14 of the 9,000 cases of rubella were complicated by encephalitis—an incidence of 1 in 640.

These figures differ little from those found by Shaw in morbilli encephalitis. Thus earlier views that rubella is complicated by encephalitis less frequently than is morbilli are not justified.

The majority of cases occur during childhood, but this is probably due to the fact that rubella is more frequent in childhood. Margolis *et al.* (1943) reviewed 40 cases from the literature in which the ages were known—25 were under the age of 13. The sex incidence is equal.

Clinical Patterns

Owing to the variability and widespread nature of the neurological lesions, a multiplicity of signs and symptoms

may be encountered. Generally speaking, as in all encephalopathies occurring with the exanthemata, there are three main clinical patterns:

1. *Meningo-encephalitis*.—In this group the main features are headache, drowsiness, and vomiting, with a positive Kernig sign and brisk tendon-jerks. Some cases have a moderate fever.

2. *Encephalitis*.—In this group the main features are confusion, drowsiness which may go on to coma, delirium, convulsions, and cranial nerve palsies. If the cerebellum is involved, vertigo, ataxia, and nystagmus may be prominent (Case 1). When cerebellar signs predominate the prognosis is very good. Occasionally the extrapyramidal system is involved, with tremor and involuntary movements (Goldbloom and Keith, 1937).

3. *Encephalomyelitis*.—In this group, in addition to the above manifestations, evidence of cord involvement with sphincter disturbances (usually urinary retention), and dorsal column and pyramidal tract signs as well, will be encountered.

In the U.K. rubella epidemic which occurred in 1940, polyneuritis was also described as a neurological complication of rubella (Harrison, 1940; Hodges, 1940; Sprott, 1940). Owen and Greenaway (1940) also described a case of rubella which was complicated by retrobulbar neuritis.

Neurological symptoms usually occur after the appearance of the exanthem. This interval varies between one and six days. C.N.S. complications, however, may on rare occasions precede the rash by two to nine days (Zadik, 1927; de Gennes *et al.*, 1934; Rodriguez *et al.*, 1947; Holliday, 1950; Mitchell and Pampiglione, 1954; Steen and Torp, 1956). Bradford (1943) reported a case of rubella encephalomyelitis in which the rash recurred 12 days after the onset of neurological symptoms. Recurrence of the rash, however, is not a rare phenomenon. Humphrey and Ekermeier (1937), studying an outbreak of rubella in a children's home, found that 6% of the children had second attacks of rubella at periods varying from 12 to 43 days after the onset of the initial attack.

The cerebrospinal fluid is usually clear and under normal pressure. There may be a lymphocytic pleocytosis, and the protein, although often normal at the onset, may be raised later. The glucose content is normal.

An initial leucopenia occurs during the exanthematous stage, but a leucocytosis in which neutrophils predominate occurs during the encephalitic phase.

Diagnosis, Prognosis, and Treatment

As Borch Jørgensen (1955) has pointed out, in all cases there is a disordered state of consciousness varying from mild drowsiness to deep coma. This, together with the recent history of rubella and the neutrophil leucocytosis, gives the clue to the diagnosis. The C.S.F. should be examined in all suspected cases to exclude purulent meningitis.

There are no outstanding differences between the pathological changes encountered in rubella encephalitis and the encephalitides which may complicate the other acute exanthemata. Microscopically there is oedema of the brain, and congestion of the meninges when they are affected. Microscopically, the white matter bears the brunt of the damage (McNair Scott, 1952). Generalized hyperaemia with ganglion-cell degeneration and perivascular infiltration with lymphocytes, plasma cells, and microglia, have been described. In contrast to morbilli encephalitis, no pronounced demyelination has been recorded (Ford, 1952).

Neurological complications of rubella are usually acute and self-limiting, often within a few days. Death does occur, however (see Table). Of the cases of rubella encephalitis described in the literature, Schleisner *et al.* (1955) noted a mortality rate of 20%. In these cases death usually occurred within a few days of the onset of the encephalitis, and in many cases was preceded by hyperpyrexia (Schleisner *et al.*, 1955). Bulbar palsy was not infrequently a terminal event.

There are few recorded cases of permanent sequelae following rubella encephalitis. These have included ataxia, cranial nerve palsies, and personality changes (Davison and Friedfeld, 1938; Vestergaard, 1949). In the case described by Mitchell and Pampiglione (1954), despite severe neurological signs and gross mental changes at the height of the encephalitis, follow-up at six months revealed no sequelae and the intelligence was unaffected. The Table compares the incidence, mortality rate, and sequelae of the encephalitis that may follow morbilli, rubella, varicella, mumps, and vaccination with vaccinia virus.

No specific therapy is available, and the patient should receive symptomatic treatment: convulsions should be controlled by barbiturates, feeding given by an indwelling polyethylene tube in the comatose patient, and antibiotics given to control secondary bacterial infection.

Kabat *et al.* (1952) studied the effect of cortisone on acute disseminated encephalomyelitis produced experimentally in rhesus monkeys. They found that the steroids had a capacity to inhibit granuloma formation, a condition which is essential for the production of the encephalomyelitis. The modification of the granulomatous response in turn leads to antibody suppression. From these results, and from the fact that rubella encephalitis may well be a consequence of an antigen-antibody reaction, it would seem reasonable to use the steroids in the treatment of rubella encephalitis. Schleisner *et al.* (1955) treated two cases that developed hyperpyrexia (usually a terminal phenomenon) with cortisone and chlorpromazine. There was a dramatic subsidence of the fever, with complete recovery in both cases.

Summary

A case of rubella encephalitis with predominant cerebellar signs is described, the onset of which preceded the eruption by one day. Another case of rubella meningo-encephalitis is described, the onset of which followed the eruption by one week.

In each instance full recovery ensued and there have been no sequelae. The aetiology, incidence, clinical patterns, pathology, prognosis, sequelae, and treatment of the neurological lesions complicating rubella are discussed. Contrary to general opinion, there is evidence to suggest that the incidence of rubella encephalitis (unlike its sequelae) differs little from that of morbilli encephalitis.

My thanks are due to Dr. J. P. M. Tizard and Dr. Trevor P. Mann for permission to publish details of their cases, and for helpful criticism during the preparation of this paper.

FURTHER OBSERVATIONS ON LONDON FOG

BY

ROBERT E. WALLER, B.Sc.

AND

PATRICK J. LAWTHOR, M.B., B.S., M.R.C.P.

Medical Research Council Group for Research on Atmospheric Pollution, St. Bartholomew's Hospital, London

In an earlier paper (Waller and Lawther, 1955) we reported some observations on fog in London during the winter of 1954-5. In particular, it was noted that a brief period of smoke "fog" in January appeared to affect adversely some patients with chronic bronchitis and emphysema. No water droplets were present at that time, and sulphuric acid was not detected by the methods used. It was, however, pointed out that traces of acid might have been present in the form of minute droplets. During the following winter the Department of Scientific and Industrial Research organized more detailed "smog" measurements in London and some other large towns, using Civil Defence volunteers as observers, and the opportunity was taken to extend the clinical study of patients with chronic bronchitis and emphysema to areas likely to be covered by the measurements.

The D.S.I.R. scheme was used during a dense and persistent fog which occurred early in January, 1956, and the measurements showed that "the distribution of the pollutants was very uneven, wide differences being noted in the concentrations observed from hour to hour at any place and from street to street at any time" (D.S.I.R., 1957). The tests were instantaneous and showed concentrations of smoke and sulphur dioxide 20 or more times the normal. Even greater increases were observed in the sulphate content of the air, and this could have been due to the presence of sulphuric acid. Though these data provided useful information about pollution on one or two notable occasions during the winter, it has proved more convenient to use for the clinical studies the results obtained with routine daily instruments. The present paper deals only with the Greater London group of patients; results from provincial centres will be included in a later paper.

Clinical Observations

As in the work reported earlier, patients with an established diagnosis of chronic bronchitis and emphysema attending a special clinic at this hospital were given diaries in which to record daily their own assessment of their health by means of a simple code.

The five centres taking part were St. Bartholomew's Hospital, Hammersmith Hospital, and the Chest Clinics at East Ham, Croydon, and Edgware. As the areas of residence

covered by these centres overlap and many patients travel to other parts of London in the course of their work, all the results have been combined. Regular diary entries were made by approximately 180 patients, most of whom lived in Greater London.

Patients entered a single letter in their diary each day to indicate their condition, and this was transcribed to a numerical scale as follows:

- A, condition better than usual = -1
B, condition the same as usual = 0
C, condition worse than usual = 1
D, condition much worse than usual = 2.

To assess the average condition of the group each day, the "score" obtained by adding up all the entries on this scale was divided by the actual number of entries. This gave a "mean score" which reflected any general change in the condition of the group. The degree of illness of the Greater London group as measured by this mean score is plotted in Fig. 1. All values lie between 0 and 1, and there are several sharp peaks, each of which represents a sudden worsening in the condition of the group. It is also interesting to note that there is a steady overall worsening throughout the four months covered.

Atmospheric Conditions

Daily measurements of smoke and sulphur dioxide were continued at St. Bartholomew's Hospital, using the standard D.S.I.R. instrument. More detailed observations were made at times when pollution was high. The sampling site is in a smokeless zone and there are therefore no important local sources of smoke; the smoke concentrations measured are similar to those existing in other parts of London except during very calm weather. Similar measurements are made at many other sites in London, but it was felt that these central observations could be applied approximately to the air breathed by the Greater London group of patients. Measurements of sulphur dioxide at this site have to be regarded with some reservation, since there are major sources near by.

In Fig. 1 the daily concentration of smoke has been plotted with the degree of illness. Smoke is intended to serve only as an index of atmospheric pollution in general, since the concentrations of sulphur dioxide and most other pollutants follow a similar pattern. There are a number of

FIG. 1—Degree of illness of a group of 180 chronic bronchitic patients and concentration of smoke in London, November, 1955, to February, 1956.

sharp peaks in the smoke concentration which represent sudden increases in pollution, and nearly all of them are followed closely by marked peaks in the degree of illness. On most occasions when pollution was high the visibility was low, this being due either to the smoke itself or to

accompanying fog. The accompanying Table lists the occasions on which the Air Ministry reported visibility below 440 yards (402 metres) from their roof in Kingsway.

There is a fairly close correspondence between these periods of low visibility and peaks in the degree of illness. The association is not, however, as close as with the concentration of smoke itself. On two occasions when smoke

FIG. 2.—Concentration of smoke in London during a "smog" period in January, 1956.

was high and the patients became worse (November 1 and February 3), the relative humidity was low and the reduction in visibility must have been due mainly to smoke. On another occasion when the patients became worse (November 30) there was some wet fog at first in the morning, but the relative humidity fell later in the day and the visibility was again reduced mainly by smoke. On December 19 fog persisted into the afternoon, followed by a gradual fall in relative humidity and an increase in smoke. Few patients were affected at this time. Wet fog occurred again on January 17 and 28. Smoke remained within normal limits and the patients were not much affected.

During the first week of January there was a clearly defined "smog episode." The concentration of smoke at this time is shown in greater detail in Fig. 2. Between 9 p.m. and midnight on January 4 it reached the very high figure of 10 mg. per cubic metre. At that time the relative humidity was just over 80%, but it increased as the temperature fell in the early hours of the 5th. Wet fog began to form around 4 a.m. and persisted for several hours until

the temperature increased again. The concentration of smoke was minimum when the wet fog was present, but it rose again during the day. Wet fog formed during the early hours of the 6th, when the concentration of smoke was falling, and thereafter the low visibility was due mainly to a mist of large water droplets, whilst the smoke remained within normal limits. A sample taken at 4.5 a.m. on January 6, with a cascade impactor using naphthol-green droplets (Wooten, 1955), showing the presence of water droplets of greatly varied size. The concentration of water at this time was 30 mg. per cubic metre and the mass median diameter of the droplets was 25 microns. Most of the water droplets were seen to be separate from the smoke particles. A few samples were also taken on thymol-blue slides for the detection of sulphuric acid. In a sample taken at 4.40 a.m. on January 6 many acid droplets of widely varying size could be seen; most of the larger ones contained smoke particles.

Discussion

The results shown in Fig. 1 suggest that there is a close correlation between the concentration of pollutants in the air and the clinical condition of the chronic bronchitic patients. In general their condition began to deteriorate as soon as the concentration of smoke rose, and they took several days to recover. The changes do not merely reflect the psychological reaction of the patients on seeing fog, for on several occasions when visibility was low there was little change in the condition of the group. The results presented here support our earlier conclusion (Waller and Lawther, 1955) that smoke "fog" is deleterious to patients with chronic bronchitis and emphysema. The presence of water droplets does not appear to enhance these effects. During the smog episode at the beginning of January (Fig. 2) periods of high smoke concentration alternated with periods when there was wet fog. Many patients were affected during the first evening before wet fog formed. There were several other occasions during the winter—for example, February 3—when their condition deteriorated in the absence of wet fog.

All measurements of pollution and water droplets were made in the City, but the findings are applicable to other heavily built-up areas of London. Although the City is a smokeless zone, pollution from surrounding areas is carried by the wind except in calm conditions, when large differences in smoke concentration occur. This was noticeable on January 4, 1956, when the "smog episode" was developing. At 4 p.m., although the air was quite clear around the hospital, the visibility was only 100 yards (91 metres) in the densely populated area 1 mile (1.6 km.) to the north. The borderline between good and bad visibility coincided closely with the northern boundary of the smokeless zone. The smoke gradually drifted into the City, and by 7 p.m. the visibility was as low as in the surrounding areas. In outlying parts of Greater London, where there is more open space, wet fogs occurred more often during the winter, but the concentration of smoke was not as high as in the densely populated areas.

Wet fog is in fact rare in Central London, and our observations are in accordance with those made by Owens many years ago. During a fog lasting from December 9 to 12, 1924, he found water droplets in samples taken at Cheam, but none in those taken shortly afterwards in London (Committee for the Investigation of Atmospheric Pollution, 1925). He concluded: "It appears justifiable to infer from the above that the 'London Particular' is formed rather by a replacement of water particles by smoke than by the dirtying of the condensed water by smoke, and this appears to be a reasonable result to expect from the higher temperature of the air over London. It further appears improbable that water vapour would condense round oily soot particles when there are ample numbers of hygroscopic nuclei present." No regular measurements of sulphuric acid were made during the winter of 1955-6, but some was detected at times of high pollution. Although most of the sulphur in coal,

coke, and oil is converted to sulphur dioxide on combustion, a small proportion is oxidized to sulphur trioxide. This rapidly combines with water vapour and is emitted from chimneys as a bluish haze of very small sulphuric acid droplets. In very still conditions these accumulate in the same way as smoke and may be responsible for some of the reduction in visibility. If the relative humidity increases the acid droplets take up further water from the air and become larger and more dilute. The presence of wet fog may, however, facilitate the production of more sulphuric acid; sulphur dioxide does not oxidize appreciably in the gas phase, but in solution it more readily forms sulphuric acid. Insufficient measurements were made during the winter of 1955-6 to study the effect of this process, but it seems likely that the formation of wet fog leads to an increase in the total concentration of acid together with an increase in the median droplet diameter and a decrease in the strength of acid.

The concentration of sulphuric acid rises with that of smoke and it may be partly responsible for the effects observed on chronic bronchitic patients. If sulphuric acid does play an important part, the fact that many patients become worse even at times of low relative humidity suggests that small droplets of strong acid might have more effect than large weaker ones; there may be a critical set of conditions in which a given concentration of acid exerts a maximum effect. Pattle and Cullumbine (1956) reported experiments in which they exposed normal subjects to sulphuric acid mists of 39.4 mg. per cubic metre and 1 μ mass median diameter and 20.8 mg. per cubic metre and 1.5 μ mass median diameter. They found that the coarser mist was more irritant than the finer one despite the lower concentration. They did not, however, do any experiments in conditions similar to those in a dense wet fog where the mass median diameter of the droplets might be of the order of 20 μ . Such droplets would be expected to consist of much weaker acid which might exert little physiological effect.

The use of diaries for the assessment of the variation in clinical condition of chronic bronchitic patients appears from this study to be a useful epidemiological technique.

Summary

A close association has been found between the clinical condition of a group of 180 patients with chronic bronchitis and emphysema living in the Greater London area and the concentration of atmospheric pollution measured in the City. Although visibility was generally low at times when the patients were affected, the reduction was mainly due to smoke rather than water droplets. Dense wet fog was observed only rarely in Central London, and it did not appear to enhance the effects of high pollution. The concentration of smoke has been used as an index of pollution, but the actual pollutant responsible for the harmful effects on patients has not been identified. Sulphuric acid has been detected at times of high pollution, and its possible role is discussed.

We are indebted to Dr. C. M. Fletcher and his staff at the Postgraduate Medical School for organizing the extension of the diary scheme to the Hammersmith Hospital and the three suburban clinics; also to Dr. H. J. Trenchard (Edgware Chest Clinic), Dr. R. H. J. Fanthorpe (Croydon Chest Clinic), and Dr. P. Ellman (East Ham Chest Clinic) for their willing co-operation. The meteorological data quoted in the Table were kindly supplied by the Meteorological Office, London.

Medical Memorandum

Serious Haemorrhage After Partial Gastrectomy in Unsuspected Chronic Myeloid Leukaemia

Conditions which predispose to dangerous bleeding following surgery are usually recognized by ordinary clinical examination before operation. Precautionary measures can then be taken. In the following case the patient developed severe haemorrhage associated with unsuspected chronic myeloid leukaemia which produced no recognizable symptoms or signs before operation.

CASE HISTORY

In November, 1955, a 59-year-old man was referred to hospital with vague abdominal symptoms of many years' duration, and anorexia and loss of weight for one year. Repeated investigation elsewhere had yielded negative results. His main complaint was severe pain in both loins and across the middle of the abdomen, made worse by standing, relieved by rest, and not related to meals. There had been no other significant symptom.

Examination revealed considerable wasting but no other abnormality. The haemoglobin was 11.8 g./100 ml. and the stools contained occult blood. A blood film was not examined.

Within a few days he was admitted in emergency with severe epigastric pain and almost board-like upper abdominal rigidity. Immediate laparotomy revealed an active gastric ulcer crater on the upper part of the lesser curve. The spleen was uniformly enlarged to twice the normal size and the liver showed slight uniform enlargement. Partial gastrectomy was performed with Billroth I reconstruction on November 9. Histological examination confirmed the features of a simple chronic peptic ulcer. During the resection and anastomosis, which took little over an hour, there was no abnormal bleeding. Then suddenly, at the time of inspection before closure, profuse oozing started from all the cut surfaces. The wound was closed tightly and the peritoneal cavity drained by a rubber tube. One bottle of blood was transfused during the operation and two bottles afterwards.

Severe blood loss continued from the wound, but gastric aspirations were free of blood and there was no melaena. Twenty-four hours after gastrectomy the abdomen was reopened under general anaesthesia. The peritoneal cavity contained two to three pints (1.1 to 1.7 litres) of fresh blood, and there was profuse oozing from every raw surface. The wound was again sutured tightly, and a further four bottles of blood were transfused on November 10.

Investigation on the day of the second operation showed that the bleeding-time, whole-blood clotting-time, one-stage prothrombin time, plasma fibrinogen, and total serum proteins were normal. These results tended to allay anxiety.

On the third and fourth days after gastrectomy there was further substantial oozing of blood from the wound, and another bottle of blood was transfused. Haematological advice was then sought.

Tests on November 15 showed: Hb, 13.8 g./100 ml.; R.B.C., 4,500,000/c.mm.; W.B.C., 80,000/c.mm. (promyelocytes 14%, neutrophil myelocytes 14%, neutrophil band cells 12%, neutrophil polymorphs 54%, lymphocytes 2%, monocytes 4%); platelets (Lempert) 720,000/c.mm.; red cells, moderate anisocytosis, slight poikilocytosis, mainly normocytic and normochromic. Polychromasia +. Examination of bone-marrow smears from the sternum confirmed the diagnosis of chronic myeloid leukaemia. The bleeding-time, whole-blood clotting-time, and one-stage prothrombin time were again found to be normal, and the capillary fragility and thromboplastin generation test (Biggs and Douglas, 1953) showed no significant abnormality. Fibrinolysis was not detected (Biggs and Macfarlane, 1953).

There was only occasional oozing from the abdominal wound after November 15 for a few days, and it was henceforth never necessary to give a further blood transfusion.

Specific antileukaemic therapy consisted of busulphan ("myleran"), 4 mg. daily by mouth beginning on November 16. Splenic irradiation was impracticable as the patient was too ill to travel to the radiotherapy centre.

On November 22 the abdomen burst and the wound was resutured. No abnormal haemorrhage was encountered and the wound healed satisfactorily. Vitamin B supplement was begun on November 26, as the patient had developed a sore mouth and a swollen, sore, magenta-coloured tongue, along with peripheral paraesthesiae.

He responded admirably to the busulphan therapy. On December 6, after a total of 84 mg. of busulphan had been given, the total leucocyte count had fallen to 8,000/c.mm. At this time the haemoglobin level was 11.2 g./100 ml.

By December 14 he was well enough to return home. Without further specific antileukaemic therapy the haemoglobin level had risen to 14.8 g./100 ml., the red-cell count to 5,000,000/c.mm., and the total leucocyte count was 10,000/c.mm. on January 13, 1956. He remained well for five months, at the end of which time recurrence of leukaemic symptoms necessitated a further course of busulphan, to which he responded once more.

DISCUSSION

It is rare to observe bleeding in the leukaemias in the absence of thrombocytopenia. Rarely, in acute leukaemia, the presence of fibrinolysis (Cooperberg and Neiman, 1955), a circulating anticoagulant (Freeman, 1952), and factor V and prothrombin deficiency (Stefanini and Dameshek, 1955a) have been described. None of these abnormalities was found in the present case.

Occasionally patients with chronic granulocytic leukaemia present a haemorrhagic tendency with a normal or increased platelet count. In such cases surgical procedures are often complicated by severe bleeding which may or may not be associated with qualitatively abnormal platelets (thrombocytoasthenia), poor clot retraction, deficient prothrombin utilization during clotting, a prolonged bleeding-time, and a low serum level of serotonin in various combinations (Bigelow, 1954; Stefanini and Dameshek, 1955b).

Borgeson and Wagner (1929) thought that, in these cases of chronic myeloid leukaemia, the primitive leukaemic cells may infiltrate the vascular walls and proliferate there, causing injury and increased permeability.

The second point of importance is the excellent response to oral busulphan in a patient who was too ill to attend for radiotherapy. This drug is probably the chemotherapeutic agent of choice at present, with the possible exception of demecolcine ("colcemid"), whose place in therapy of this leukaemia has yet to be determined (Blackburn, King, and Swan, 1956).

Finally, the perusal of a blood film pre-operatively would probably have suggested the haematological diagnosis. From the present and past experience we believe that a haemoglobin estimation and examination of a stained peripheral blood film should be done, if facilities are available, before a major surgical procedure.

We are indebted to Professor R. P. Jepson for permission to report this case and to Miss P. A. Hall and Mr. J. Monaghan for laboratory assistance. We are grateful to the Board of Governors of the United Sheffield Hospitals for a grant through the Haematology Research Fund and for support from the Yorkshire Council of the British Empire Cancer Campaign.

Reviews

EPIDEMIOLOGY AND CONTROL OF MALARIA

The Epidemiology and Control of Malaria. By George Macdonald, C.M.G., M.D., F.R.C.P. (Pp. 201+xiv; Appendices pp. xi; index pp. 11. 30s.) London, New York, Toronto: Oxford University Press. 1957.

The wide discrepancies apparent in the epidemiological pictures of malaria emanating from different parts of the world, seemingly unrelated by any matter of principle, have never been adequately explained. In an attempt to inculcate a sense of proportion into the problems involved, Professor Macdonald has adopted a mathematical line of approach, designed to integrate the data provided by circumstantial and biological studies into one coherent whole, and thus provide a rational understanding of disease. It is emphasized that mathematical epidemiology does not attempt to usurp the place of either of the other branches, since it is dependent on both of them. The assumptions put forward are not claimed as precise reflections of invariable truths, but as good working generalizations sufficiently accurate when compared with natural happenings to be used to build up an acceptable model. The average health officer in the tropics, who is not always mathematically inclined, is apt to regard mathematical formulae with a certain degree of apprehension. Recognizing this, the author has, wherever possible, relegated algebraical statements to an appendix.

The first eight chapters of the book are devoted to epidemiological problems and include a description of the malaria survey and its interpretation. The next four deal respectively with the theory of control, the use of insecticides, the place of drugs in malaria control, and the general conduct of an antimalarial campaign. There follows a chapter on malaria eradication, which is of especial interest in view of the programme recently initiated in many parts of the world with that end in view. The final chapter deals with anopheline susceptibility and resistance to insecticides, and is based on the original researches now in progress at the Ross Institute. Techniques for staining blood smears and other procedures used in the conduct of malaria surveys are described in an appendix. A map depicting the epidemiological zones of the world, with a histogram indicating the number of persons at risk and protected from malaria in each of them, is included as an end-paper. The book is lucidly written and should prove of great interest, not only to malariologists, but to all those concerned with the problems of insect-borne disease.

GORDON COVELL.

NEUROLOGY TO-DAY

Modern Trends in Neurology. Second series, edited by Denis Williams, C.B.E., M.D., D.Sc., F.R.C.P. (Pp. 350+xi+24 pp. index; illustrated. 72s. 6d.) London: Butterworth and Co. Ltd. 1957.

This book, edited by Dr. Denis Williams, is a successor to the volume under Dr. Feiling's editorship which was published in 1951. There is, however, no overlap of the subjects dealt with in the two books, with the exception of thrombosis of the internal carotid artery, which is considered in a brilliant essay by Sir Charles Symonds in the present volume. There are 24 articles dealing with many of the growing points of neurology in its widest sense. Fundamentals of physiology and chemistry are dealt with by Dr. Sweet in a most interesting account of the formation and flow of the cerebrospinal fluid with special reference to isotope studies, and by Professor Lumsden in two chapters on the chemistry of myelin and on cell structures and physiology in relation to myelin. Recently recognized clinical entities are described by Dr. Dimsdale in her account of the Royal Free disease, and by Dr. Garland in his article on diabetic amyotrophy. The editor says in his preface that contributors were in-

structed to assume a high level of knowledge in the readers, and possibly this advice has been followed rather too closely in a few of the contributions, but good bibliographies to most of the essays help to remedy this. The production of the book is excellent, and the pathological and radiological illustrations are of an unusually high standard. There are very few misprints, but it is curious to find one of the contributors given a wrong Christian name on two occasions. Dr. Denis Williams should be congratulated on his editorship of a book which will be a necessity to anyone interested in modern developments in neurology, and which is a worthy successor to the 1951 volume.

J. W. ALDREN TURNER.

PAEDIATRIC ENDOCRINOLOGY

The Diagnosis and Treatment of Endocrine Disorders in Childhood and Adolescence. By Lawson Wilkins, M.D. Second edition. (Pp. 526+xxvi; illustrated. £6 12s. 6d.) Oxford: Blackwell Scientific Publications. 1957.

Endocrinology occupies but a small corner of paediatric territory. Progress in this field has been as swift as in any branch of medicine, and the new advances, dependent mainly on the work of biochemists, have given the eager clinician a great deal of homework.

The second edition of this splendid textbook is well timed; for although continuing research allows the book-makers no respite, yet in several branches of paediatric endocrinology the new facts and the most recent methods have now stabilized clinical practice. In these researches the author and those who have worked with him have been pre-eminent, so that this edition is not two years out of date, as are some textbooks on publication, but is 1957 in both theory and practice. It contains, for example, authoritative accounts of goitrous cretinism, of the relationship of mental deficiency to hypothyroidism, of the pathogenesis and treatment of congenital adrenocortical hyperplasia, of the personality problems in children with sexual abnormalities, and of the importance of Barr's technique of chromosomal sexing for the understanding of disorders of sexual development.

The author states his purpose in the preface: "to help the clinician understand, diagnose and treat the endocrine disorders of childhood and adolescence." This purpose is finely achieved. One of the merits of the book is in the author's refusal to trifle with speculation and quackery: the whole work is firmly based on fact and on measurement. Another merit is that, though rooted in science, this work is imbued with the Oslerian clinical traditions of the Johns Hopkins Hospital. For me the book has but one fault. It is here and there repetitive, so that one may find the same statement repeated twice and even three times.

The book is expensive, large, well printed, and beautifully illustrated. It provides inescapable reading for paediatricians; while others who make but occasional reference to it will find their questions answered.

D. V. HUBBLE.

SEX AND MARRIAGE

Love and Marriage. By F. Alexander Magoun, with the collaboration of Richard M. Magoun. Ninth edition. (Pp. 475+xviii. 35s.) London: William Heinemann Medical Books Ltd. 1957.

The Sexual Responsibility of Woman. By Maxine Davis. (Pp. 211+vi. 15s.) London, Melbourne, Toronto: William Heinemann Ltd. 1957.

According to Dr. Magoun there are, in the U.S.A., 1,968 professors giving 657 course of lectures on marriage and parenthood in 550 colleges. This can be taken as a measure of the demand by young people to learn more of these matters and to have books of this type. Alternatively, it could be construed as suggesting that more than enough has already been said about sex and marriage.

The book first named above deals with courtship, love, and marriage in all their respects, the author not hesitating

to enter even the fields of philosophy and religion. An attempt is made to define and analyse love, romance, and hate; statistics from the Kinsey reports are quoted; sexual anatomy and physiology are described. There is also some comment on premarital sex experience, the technique of coitus, coital difficulties, pregnancy and labour, sterility, birth control, and divorce. Parent-child as well as husband-wife relationships are discussed. Not all the facts are correct. For example, it is alleged that "there is more scientific evidence to show that couples are childless because they are unhappy, than there is to show that they are unhappy because they are childless." Nevertheless, judged as a whole, the book gives generally wise information and advice which are couched in such simple terms as to make suitable reading for the young married couple or the couple about to be married. Even older couples who feel they are drifting apart may find the explanation and remedy in these pages.

In recommending the second book to his patients, the doctor may have to be more selective. Dr. Maxine Davis, a woman medical journalist, takes a smaller field, but deals with it in more detail. She argues that the emancipation of woman has not only led to a recognition that woman can enjoy rather than suffer sex, but imposed on woman a responsibility to abrogate her submissive role in the sex act, and to become, at times at least, the more active partner. To this end the author describes at some length marital preparation, the honeymoon, coital techniques, sex desire, frigidity, conception, and contraception—all from the female angle. She also includes comment on menstruation and its management, premenstrual tension, the menopause, and the effects of hysterectomy. While helping some women, this book could deter others because it has the bold and almost sensational style of the journalist. Even anatomy is described in emotional terms, while orgasm "is like the sky rockets and coloured fire that are the spectacular conclusion to an evening's firework display."

T. N. A. JEFFCOATE.

VITAL STATISTICS IN POPULAR FORM

Life, Death and Disease in Sweden. By Erik Ask-Upmark, M.D. (Pp. 56. Sw.kr. 4.75.) Stockholm: Almqvist and Wiksell. 1957.

It is most enterprising of Dr. Erik Ask-Upmark, Professor of Medicine at the Royal University of Uppsala, Sweden, to have produced in English this little book on the vital statistics of his country. The only comparable publication in Britain is *Matters of Life and Death*, produced by the General Register Office, and that, being an official document, does not contain any comment similar to those on "Prosperity and Insecurity" found in the Swedish book.

Sweden is remarkable in many ways. It has the lowest rate of infantile mortality (17) in the world. It has hospitals of world renown, yet its population is only 7.2 millions; they are spread over an area twice that of Great Britain. Sweden has been able to keep out of war for nearly 150 years. The percentage of the population over 65 years of age is 12; this compares with 11% in England and Wales. The illegitimate births are 10% of the total births. There are interesting commentaries on the causes of death: in 1952, 32,644 (50%) of all deaths were due to disorders of the cardiovascular system; malignant disease was responsible for 12,085 deaths; and the third highest cause was violence, with 4,047, of which suicide accounted for 1,192. The tuberculosis death rate is now down to 13 per 100,000 population. There is a section on morbidity, entitled "Panorama of Disease," with subheadings which deal in a sketchy way with tuberculosis, rheumatic disorders, diabetes, obesity, alcoholism, peptic ulcer, diseases of the nervous system, and accidents. Overweight is present in more than 50% of Swedes over 40; some 250,000 individuals have cardiovascular disease; except for France, "the consumption of alcohol in Sweden exceeds that of any other nation," and it is estimated that 2% of men over 25

are alcohol addicts. There are 91,020 hospital beds, of which 30,000 are in mental hospitals. There is one doctor for every 1,394 inhabitants, but the distribution is unsatisfactory—one to 500 in Stockholm, but only one to 5,148 in the rural areas.

The author poses the question, "Are the Swedes happy?" They are prosperous as judged by the motor-cars (60), telephones (264), and radio-receivers (324) per 1,000 inhabitants, but below the surface are anxiety and insecurity. Disturbing factors are the loss in the purchasing power of money; the high income tax; the increase of crime and of alcoholism, and in the use of sedatives: Swedes consume 20 tons of barbiturates every year. "Progressive taxes do not stimulate diligence and . . . inflation does not encourage saving" are maxims not confined to Sweden. The book can be highly recommended as providing in small compass basic medical facts about a country which is close to us in many ways.

ALLEN DALEY.

INTERPERSONAL RELATIONS

Interpersonal Diagnosis of Personality: A Functional Theory and Methodology for Personality Evaluation. By Timothy Leary. (Pp. 518+xix; illustrated. \$12.) New York: The Ronald Press Company. 1957.

This rather lengthy account of psychological and psychiatric research going on at the Kaiser Foundation Hospital in California makes very difficult reading. It attempts at the same time to lay a theoretical foundation for diagnostic testing in psychiatry, to give a description of the techniques actually used at the hospital, to summarize the results achieved, and to integrate all this with a type of psychiatric theory ultimately deriving from Harry Stack Sullivan. The result is confusion only occasionally relieved by gleams of insight. Perhaps the worst failing of the book is the omission of any kind of proof for the validity and reliability of the diagnostic system advocated. It is simply not enough to say, as the author does, that "the validity of this diagnostic continuum can be checked by the reader with clinical experience who can determine if the ordering of categories correlates with his diagnostic experience." If clinical experience is to be the criterion, then why should any reader bother with the excessively complicated contents of a book such as this (the author ends up with 65,536 personality types—at four levels of personality)? Another feature of the book which makes for difficult reading is the adoption on the part of the author of a quite unconventional system of dimensional description in terms of origin and angles rather than the usual factor-analytic one. The author nowhere explains his reasons for this choice of polar co-ordinates, and I fail to see any advantage in rejecting a more orthodox type of descriptive device with its time-honoured use of Cartesian co-ordinates.

Yet, withal, the book stresses many points which are clearly valuable. The emphasis on the objective measurement of interpersonal relations is one of these, and the necessity for the dimensional analysis of such relationships is another. The analysis of behaviour in terms of different levels is not novel, but has probably never been attempted quite as systematically as here. One cannot help feeling that if only the author had analysed his data along orthodox lines, had published the results of such analyses in an attempt to prove or disprove distinct hypotheses, and had been less eager to develop a whole system of personality description *de novo*, this could have been a worthwhile and indeed exciting book. By laying his main emphasis on the clinical rather than the experimental aspect of his work, and by trying to curry favour with psychiatrists by stressing the intuitive appeal to insight rather than the scientific appeal to objective fact, the author has failed to make use of his opportunities and has produced a hybrid which disproves the general law that such mixtures of different heredity tend to be particularly virile, attractive, and healthy.

H. J. EYSENCK.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY DECEMBER 21 1957

ULCERATIVE COLITIS

Few diseases are more distressing than ulcerative colitis and few, until recent years, were less responsive to treatment. During the past few years improvements in both medical and surgical care have brought about a big change in this grim picture. On the medical side there is a full appreciation of the need for vigorous supportive measures, including control of electrolytes, administration of vitamins, and blood transfusion, while the Medical Research Council trial reported by S. C. Truelove and L. J. Witts¹ gave convincing evidence of the value of steroid therapy.

On the surgical side the indications for operation are becoming more clear. The most obvious indication is when the patient's general condition deteriorates despite medical care and especially where there are complications such as arthritis, pyoderma, and anorectal suppuration. The standard operation is an ileostomy, combined, usually at a single stage, with subtotal colectomy. Further justification for radical surgery in such cases is provided by the risk that cancer may develop in the diseased colon. C. E. Dukes and H. E. Lockhart-Mummery² have reported recently that cancer was found in 5.2% of a series of 153 cases studied at St. Mark's Hospital, a figure far higher than the expected incidence in view of the fact that the average age in the whole series was only 42 years.

In the acute, fulminating type of ulcerative colitis the need for operation has been less well established, so the advent of corticosteroid therapy, which is especially useful at this stage, was hailed with relief. In the 50% or 60% of cases which respond its benefit is undoubted, for it relieves the symptoms, improves the general health, and tides the patient over safely into a remission, even though it has little specific effect on the local disease. In the less fortunate, unresponsive minority, however, it may bring an added risk. B. N. Brooke³ has pointed out that in colitis, unlike other diseases of the intestine, there is little natural

tendency for the diseased part to adhere to other viscera, so in unresponsive cases the effect of cortisone on connective-tissue reactions may lead to progressive disintegration of the colon, culminating in peritonitis or frank perforation. Abdominal distension is a particularly ominous sign of incipient perforation and may be an urgent indication for operation. There is also the risk that the steroid therapy may be prolonged uselessly, in the vain hope of a last-minute remission, until the opportunity for operation is past. For these reasons Brooke recommends that if there is no immediate response the steroid therapy should be stopped after one or two weeks.

Whether in acute or chronic cases, most surgeons are convinced that pre-operative steroid therapy adds greatly to the operation risk, presumably by diminishing the resistance to bacterial infections. Therefore, if time permits, it would seem wise to discontinue the steroids and replace by A.C.T.H. for a week or so before operation, though admittedly an ill, emaciated patient finds the bulky A.C.T.H. injections distressing.

Surgical experience has led to many technical improvements in the performance of the ileostomy. By obliterating the gap between the emerging loop and the parietal peritoneum, the risk of an internal strangulation can be minimized. By anchoring the loop, or, better, bringing it out by an extraperitoneal route, the twin dangers of prolapse and retraction can be diminished. By sewing mucous membrane to skin the risk of stenosis (a main cause of excess electrolyte loss) can be avoided. Nevertheless the idea of a permanent ileostomy still appals many people, and indeed even the most perfervid of surgical craftsmen can extract little virtue from this surgical necessity. S. Aylett⁴ has claimed that it may be avoided by anastomosing the ileum to the rectum, either at the time of the primary colectomy or later. He believes that in many cases the rectum is less severely diseased than the rest of the bowel and can be preserved with impunity. He claims that the operation can be performed with little added risk, that it avoids the hazards related to an open ileostomy, and that it can restore the patient to full health without the social disablement that a permanent ileostomy imposes. In his series of 40 cases, 33 were restored to complete health, regained their full weight, and returned to their normal occupation, though admittedly many continued to have several loose stools a day and a few had considerable diarrhoea. Other surgeons, however, believe that to retain the rectum invites the risk of reactivation of the disease, with the possibility of ileal involvement: Brooke⁵ had to restore an open ileostomy in three cases in a series of nine, and J. C. Goligher⁶ similarly in four cases in a series of fifteen.

They argue that, while a permanent ileostomy undoubtedly constitutes a severe disability, the patient soon accepts it and finds ample compensation in the return to full health. The final answer has not yet been given, and there may be room for a compromise solution, in which ileostomy is the first choice for the majority of cases, while ileo-proctostomy is reserved for those, such as children and the feeble-minded, who cannot look after themselves, and for those who after a good trial find it too much of a disability.

The danger to life is shown well in two recent papers. In the M.R.C. trial, 11.9% of the patients died during the six weeks' test or the subsequent nine months' follow-up; among those treated with cortisone the mortality was about 8%. Brooke, whose surgical experience is unrivalled in this country, had a 5% mortality in his series of 126 cases. Admittedly most of these patients came to operation because they were ill, and some dated from pre-cortisone days; but the figures serve to emphasize the severity of the disease. Ulcerative colitis is still a considerable problem.

KURU: A NEW SYNDROME

Sensational accounts in the press of patients in New Guinea "laughing themselves to death" were received with some suspicion by medical readers, and the lucid clinical report given by V. Zigas and D. C. Gajdusek¹ in the *Medical Journal of Australia* justifies their scepticism. The disease in question is called "kuru" by the local inhabitants, a word they also use for trembling from cold or fear. In the 154 patients studied by Zigas and Gajdusek the clinical features have been remarkably constant. The first symptom is locomotor ataxia: the patient places his feet awkwardly and has a swaying, weaving gait. This is followed in about a month by tremor, which is aggravated by excitement or fatigue and affects the trunk, extremities, and head. Some patients make wild athetoid involuntary movements; most manage to walk with the aid of a stick for one or two months and thereafter remain sedentary but mentally active and able to take a part in tribal life. But even this limited activity is impossible after some months, and the patient is left inside the hut. Unable to sit up, he or she develops urinary and faecal incontinence, decubitus ulcers, convergent strabismus, dysarthria, and dies three to six months later. Even at a late stage in the illness intelligence remains unimpaired, but quite early on the patients tend to be over-emotional—excessive laughter alternating with de-

pression or belligerence. Finally the patient becomes withdrawn from his surroundings and develops a mask-like facies resembling that of classical Parkinsonism. It appears that the disease is invariably fatal: only two possible recoveries are known, and it is probable that these patients had been misdiagnosed and had in reality been suffering from hysteria.

The physical signs that have been noted are rombergism, dysarthria, dysphasia, and incoordination. The patients are afebrile and well nourished, until the terminal stages of the illness are reached and self-feeding becomes impossible. There is no nystagmus, extraocular movements are normal, cranial-nerve function remains intact, and no sensory disturbance has been detected. The blood, cerebrospinal fluid, and urine appear to be normal, no evidence of deficiency or excess of metallic elements in the blood has been found, and the limited serological investigations so far carried out have shown nothing abnormal. Complete post-mortem examinations of eight patients have been made and the brains of two others have also been examined. Widespread neuronal degeneration, particularly in the cerebellum and extrapyramidal system, has been found with lesser destruction of nerve cells and neuronophagia in the anterior horn cells, inferior olives, thalamus, and pontine nuclei. The lesions are said to be more diffuse than those found in mercury and manganese poisoning. Histological examination of other internal organs has revealed nothing significant. A wide variety of drugs have been tried in treatment, including antibiotics, hormones, vitamins, and B.A.L. (which was given according to the regimen found effective in hepatolenticular degeneration), but all have been without demonstrable effect.

Kuru has been observed only in a limited region of the eastern highlands of New Guinea, and, although contiguous regions have been under continuous medical supervision for over twenty years, no cases are known to have occurred there. It appears to affect only members of the Fore tribe and those who have intermarried with Fore tribesmen—a population numbering 16,000. A few well-verified cases are known to have occurred 20 to 25 years ago, but old people state that the disease was unknown in the tribe in their youth. At the present time it is estimated that 1% of the Fore people are suffering from it. Of the 154 patients in Zigas and Gajdusek's series, three-quarters were adults and 130 were female. Kuru does not appear to interfere with pregnancy, and infants born of mothers suffering from it are not themselves affected.

Before the Australian administration recently extended its influence to the hitherto isolated and little-

known region where kuru occurs, the Fore people attributed kuru to sorcery, and after each death a sorcerer was accused and made the subject of a gruesome ritual murder in which he was stoned and then had his jugulars severed by biting. The aetiology remains obscure, but genetic predisposition is strongly suggested by the age and sex distribution, the familial incidence in a closely intermarried community, occasionally by several siblings dying from it on reaching approximately the same age, and by the apparent introduction of the disease through marriage to tribes bordering on Fore territory. Some similarity exists between kuru and manganese and mercury poisoning, but the tissues of victims have been thoroughly examined for heavy metals and none has been found in abnormal amounts. However, a few women from communities with a low incidence of kuru have developed it after entry into the region where the disease is common, so that a non-genetic acquired cause cannot be excluded.

VIRUSES IN TREATMENT OF CANCER

In 1912 N. G. de Page¹ noticed that a patient with a massive carcinoma of the uterine cervix improved when vaccinated against rabies. Thirty-eight years later G. K. Higgins and G. T. Pack² treated thirty patients suffering from malignant melanoma by rabies vaccination and reported transient regressive changes in eight. Much experimental work has been done in the last decade to explore the possibilities of using viruses to treat malignant disease. In 1949 Alice Moore,³ of Memorial Center, New York, found the virus of Russian Far East encephalitis to be powerfully oncolytic for the transplantable mouse sarcoma 180 and later for other mouse tumours.⁴ Relatively few of the many viruses tested were able to infect and destroy experimental tumours and most of the effective ones were neurotropic.⁵ R. R. Wagner⁶ showed that transplanted tumours that would support the multiplication of a neurotropic variant of WS influenza virus could not be infected by the non-neurotropic parent strain. Tumour inhibition was always associated with the presence of virus in the tumour and was not observed if the virus failed

to multiply. In the early laboratory studies the virus infection always killed the host, but in immunized animals even highly oncolytic viruses like that of Russian spring-summer encephalitis were ineffective against tumours.⁷ Neurotropic viruses that would infect naturally resistant animals were later found to be capable of inducing regression in transplanted tumours without harming the host.⁸ By serial passage it was also found possible to enhance the oncolytic properties of viruses without changing their effects on the normal host tissues.⁹

In 1951 G. O. Gey grew malignant human epidermoid cells in tissue culture from a carcinoma of the uterine cervix. This strain (HeLa) has grown vigorously through numerous passages. Cultures of HeLa cells could be infected with virulent poliomyelitis virus, which proved to be highly destructive to them. The damaging effect could be prevented if homotypic antibodies were added to the cultures, but heterotypic antibodies were ineffective.¹⁰ For clinical trials the use of highly pathogenic viruses was clearly inadmissible, and it was essential to select from viruses showing oncolytic properties only those of low virulence. To establish infection it was also necessary that the patients should not be immune to the chosen virus. C. M. Southam and A. E. Moore selected six viruses satisfying these requirements and administered them intravenously and intramuscularly to patients suffering from advanced malignant disease for whom other therapeutic possibilities had been exhausted. The early trials with West Nile, Bunyamwara, and Ilhéus viruses¹¹ showed that localization in human tumours did occur, though no regression was observed. Egypt 101 virus,¹² immunologically similar to West Nile virus, induced viraemia and mild encephalitis in twenty-seven out of thirty-four patients, and in fourteen cases the virus was recovered from tumour tissue and often appeared to be selectively localized there inasmuch as its concentration was 10 to 1,000 times higher than in normal tissues. In four of these cases transient regressions of metastatic tumours were recorded, but were clinically significant in one case only. Macroscopic or microscopic changes attributable to virus were not observed in biopsy or necropsy material from the tumours, though pathological changes indicative of virus infection were present in normal tissues. But in thirteen cases virus was recovered from tumours at necropsy.

R. R. Smith and colleagues¹³ chose the adenoidal-pharyngeal-conjunctival group (A.P.C.) of viruses for clinical trial in carcinoma of the cervix. These viruses are of low virulence and many serological types are available, so that strains could be selected according to the antibody pattern of each patient. Furthermore,

A.P.C. viruses were found to be highly pathogenic for HeLa cells *in vitro*. Carcinoma of the cervix was particularly suitable for trial because of its accessibility for repeated clinical and pathological observations, and because virus inocula were grown in HeLa cells, which might have been expected to enhance oncolytic activity. Thirty patients were treated, nine of whom had widely disseminated disease, while the remainder had extensive local growths, in five cases limited to the cervix and parametria. In ten cases A.P.C. virus was administered before pelvic exenteration or radical hysterectomy with lymph-node dissection. Virus was injected directly into the growth by multiple needle puncture per vaginam, or by injection into the aorta through a polythene catheter passed along the femoral artery to the level of the second lumbar vertebra, with tourniquets on both thighs. The virus inoculations caused little harm, but three patients receiving cortisone developed fever, photophobia, malaise, and prostration lasting up to nine days. Virus was recovered from the site of inoculation in twenty patients up to seventeen days later. This, together with the pronounced increase in specific neutralizing and complement-fixing antibodies that occurred five to seven days after inoculation, was interpreted as indicating proliferation as opposed to mere survival of virus. In twenty patients the inoculated tumours showed significant sloughing, which in seven cases extended deeply into the substance of the tumour and was associated with the passage of copious amounts of semi-liquid necrotic malignant tissue. Haemorrhage from fungating tumours was appreciably less after inoculation of virus, and in some cases in which haemorrhage had been a major problem the patients were stated to have been free of bleeding for several months. Necrotizing effects on tumours did not occur when fluid from uninfected cultures was inoculated or when heat-inactivated virus was used, and response was most frequent when low levels of antibody were found before treatment. Damage to normal tissues adjacent to growth was never observed. The virus nevertheless produced only local effects on the tumours, which were always surrounded by a rim of viable tumour tissue, so that progressive growth of the tumour and development of metastases were not affected.

It is difficult to interpret these results. There is little doubt that the tumour tissue became infected with the virus and it is probable that virus proliferated within the tumour cells. The results after intra-arterial inoculation do not appear to have been better than those after direct injection into the tumour, and in both cases only part of the tumour was destroyed. Theoretically, systemic administration with selective

localization would appear to hold more promise, but it is too early to say whether the poor results in these trials reflect the inadequacy of the method or simply indicate that the most effective virus remains to be discovered.

INFLUENZA VACCINES

The present epidemic of Asian influenza was expected as soon as a new antigenic type of virus made its appearance in the Far East, and preparations for its control were immediately considered. Though the use of a vaccine prepared with the new virus strain seemed to be particularly indicated, the difficulties involved in a mass vaccination campaign are considerable, and the effectiveness of such a measure is not fully established. The protective value of influenza vaccines has been clearly demonstrated, but the degree of protection has been variable in different studies. Thus, in an extensive trial carried out in 1943 by American workers¹ the incidence of influenza was reduced by vaccination from 7.1% to 2.2%. On the other hand, similar vaccines tested in 1947 failed to protect against influenza, and this failure was explained by a major antigenic change of the then prevailing virus. The difficulties of testing the efficacy of influenza vaccines are well illustrated in the recent Medical Research Council report.² It includes the results of extensive serological and field trials carried out over a period of two years. Antigenicity of the vaccines was demonstrated by antibody responses observed in the serological trials. A field trial among 14,708 volunteers in 1954-5 gave disappointing results because of the low incidence of influenza during that period. In the winter of 1955-6, however, vaccines including the then current strain of virus conferred some protection, which was shown by significantly smaller absence rates from influenza among industrial workers given these vaccines than in a similar group given an influenza-B vaccine. As in a previous trial in 1952-3³ the degree of protection conferred by influenza-A vaccines in the 1955-6 trial was about 30-40%. This may be an underestimate of the true value of the vaccine, due to sources of error likely to occur in the assessment of the illnesses experienced by the inoculated subjects. On the other hand, it may be the best protection to be expected from this type of vaccine. That this may be so is indicated by some recent results obtained by American workers.⁴ They studied volunteers vaccinated with the Asian strain of influenza virus and subsequently given nasopharyngeal washings containing the same agent. In this study, necessarily carried out on a limited number of volunteers, the nature of the illnesses observed could be determined with reasonable accuracy, and it was shown that 18 out of 23 (78%) unvaccinated and 14 out of 32 (44%) vaccinated volunteers developed

symptoms characteristic of influenza when challenged with the homologous virus strain 19 to 29 days after vaccination. This result reveals a partial protection conferred by the vaccine. However, as the authors point out, the calculated protection observed was 44%, but "within a 95% confidence limit it might be as little as 15% or as great as 70%."

The conclusion seems to be inescapable that vaccination against influenza is still an experimental procedure.⁵ The best that can be expected at the moment is that controlled use of vaccine in the present outbreak may result in partial protection against the disease and may provide useful information for the future.

THE ANXIOUS PATIENT AND THE WORRIED DOCTOR
