The Public Health Act, 1848, had a stormy passage through Parliament. It established a General Board of Health of three members and empowered it to authorize the setting up of local boards of health in districts where the death rate was high or where 10% of the inhabitants petitioned for one. A local board could employ an "officer of health" who had to be "a member of the medical profession." The General Board was charged with the duty of approving the appointment and removal of these officers. Just prior to the passing of this Act two local authorities, Liverpool and London, had appointed medical officers of health under powers obtained in privately promoted local Acts.

The General Board of Health came to an untimely end in 1854, when a proposal to continue it was defeated in the House of Commons by 74 votes to 65. This happened despite the fact that an epidemic of cholera was raging at the time. But the activities of the Board had hurt too many private interests for it to be popular with either Parliament or press. By 1854 local boards of health had been established in 182 districts. How many had appointed officers of health is not known, but this book records the names and some particulars of 39. Their duties are set out in a circular dated February 12, 1851, which is reproduced in full. The first appointment to be approved was that of Dr. Buck, of Leicester. Some were appointed for short periods only and failed to obtain reappointment. Dudley, for example, recorded that the continuance in office of their medical officer of health would be "a totally useless and uncalled for expense." Other areas were more enlightened. In Darlington Dr. Stephen Edward Piper was appointed in 1851 and remained in office until 1882. He was forthright in his annual reports, the first of which is included in the book.

Little is known now about these "officers of health," and students of the history of public health will be greatly indebted to Professor Fraser Brockington for having ferreted out so much information hitherto hidden away in long-forgotten official files, medical journals, and directories and local newspapers.

ALLEN DALEY.

CLINICAL USE OF RADIOISOTOPES

Clinical Use of Radioisotopes. By William H. Beierwaltes, M.D., Philip C. Johnson, M.D., and Arthur J. Solari, B.S., M.S. (Physics). (Pp. 456+ xiii; illustrated. 80s. 6d.) Philadelphia and London: W. B. Saunders Company. 1957.

Good textbooks on the clinical applications of radioactive isotopes have hitherto been surprisingly rare, perhaps because too few people were prepared to write authoritatively on the whole of a very diverse and rapidly widening group of subjects. The present work joins a select group of two or three comprehensive and careful books in this field, in which radioisotope applications are as well described as they were in biochemistry by Sacks, in therapy by Hahn, and in biology by Hevesy. The text is developed from lectures on this subject given regularly to medical students and practitioners at the University Hospital, Ann Arbor. Appropriately, therefore, it deals most fully with established and frequent uses of radioisotopes, and radioiodine receives nearly twice as much of the book as all other isotopes put together. The presentation here is, in general, excellent, giving a practical and informative account of clinical management as well as the theoretical basis of the radioiodine procedures described. Occasionally the amount of detail on alternatives and procedures may obscure the general plan of treatment

or investigation, but these sections are full of practical guidance and experience. The discussion of other isotopes, although much shorter in space, is admirably comprehensive—most applications of significance being mentioned, even if briefly and sometimes perhaps rather uncritically. The chapters on radiophosphorus and on haematological uses are, however, rather scanty, external counting for iron is not described, ¹³¹C receives only half a page and radiosodium is not mentioned. The treatment of bladder carcinoma is somewhat inadequately discussed, and no references since 1942 are given on radiocalcium or radiostrontium metabolism. These, however, are mainly minor omissions, and the general balance of the book is remarkably good in a subject which is no longer one subject but many. A useful discussion is also given of health precautions, of the instruments and management of a radioisotope unit, and of the essentials of radiation physics. For the clinician seeking or possessing some knowledge of this field this is an essential and outstanding book.

E. ERIC POCHIN.

STRUCTURAL PSYCHOLOGY

Structural Psychology: De Humani Mentis Fabrica. By D. and K. Stanley-Jones. (Pp. 179+vi. 21s.) Bristol: John Wright and Sons Ltd. 1957.

This book, much of whose content has already appeared in the *Journal of Nervous and Mental Disease*, presents the offspring of marriage between two unorthodox parents whom one might, on *a priori* grounds, have considered somewhat incompatible. The authors have revived the Eppinger-Hess theory of autonomic antagonism and imbalance (without, however, acknowledging paternity) and have joined it with a species of psychoanalysis which appears to bear the brand of Melanie Klein. The nature of the typology which results may be indicated by the following quotation: "Passing in final review the marshalled ranks, we find on one side oral sucking lust, eupepsia, vasodilatation, slowing of the heart, and the defences against heat, all associated with the anterior hypothalamus, the parasympathetic and with sleep; on the other side oral-biting rage, dyspepsia, vasoconstriction, quickening of the heart, and the defences against cold, all associated with the posterior hypothalamus, the orthosympathetic and with wakefulness."

In spite of some interesting sidelights, including the reason why the cow jumped over the moon, it is difficult to take this book seriously. The evidence on the physiological side is highly selected and the authors appear to be quite uncritical; on the psycho-analytic side the evidence appears to be largely non-existent. The authors claim not add to the scientific value of either. The authors claim that "this is believed to be the first printed book in which a distinction has been made between Author's and Printer's hyphens." To me it appears that this will be the only claim this book has for serious consideration by physicians and psychologists.

H. J. EYSENCK.

DEVELOPMENTAL ANOMALIES OF THE EYE

Developmental Abnormalities of the Eye. By Ida Mann, C.B.E., M.A., D.Sc., M.B., B.S., F.R.C.S., F.R.A.C.S. Foreword by Sir John Herbert Parsons, C.B.E., D.Sc., LL.D., F.R.C.S., F.R.S. Second edition. (Pp. 419+xi; illustrated. 90s.) London: British Medical Association. 1957.

When it was published initially in 1937 Ida Mann's monograph on the developmental anomalies of the eye was unique, and it rapidly established itself as the standard reference in the English language on this subject. The book has been out of print for some time, and it is good to see that a second edition has appeared. The first edition was written at the end of a period of considerable activity in experimental embryology and at a time when the interpretation of many of the clinical pictures presented by ocular deformities

offered an exciting exercise, activity in which Professor Mann participated with enthusiasm and success. In the intervening period this interest has lapsed to some extent and no outstanding or revolutionary work has appeared. The writing of the present edition of this monograph has thus not required much alteration in its presentation of the subject; but, although unchanged in essentials, new knowledge of syndromes and their interpretation has been added. The book, beautifully produced and illustrated, is clearly and interestingly written; to read it is a pleasure, for the author combines a wealth of knowledge and experience with an imagination which is unusually constructive and a critical faculty equally keen. It still remains the best and most authoritative source of information on this subject in our literature.

STEWART DUKE-ELDER.

HEART DISEASES IN CHILDREN

Pediatric Cardiology. By Alexander S. Nadas, M.D., F.A.A.P. (Pp. 587+xxii; illustrated. 84s.) London and Philadelphia: W. B. Saunders Company. 1957.

It has become increasingly evident in the last few years, as methods of diagnosis and treatment have improved, that the manifestations and management of heart diseases in children differ in many important respects from those in adults. On almost every page of his book Dr. Alexander Nadas illustrates these differences. While some may question the wisdom of dividing cardiologists by the age group of their patients, this book shows that paediatric cardiology has become a subject of its own.

The book is divided into four parts of unequal length. There is an excellent presentation on "the tools of diagnosis" (history, physical examination, routine tests, radiology, electrocardiography, phonocardiography, cardiac catheterization, angiocardiology). The second and third parts deal fully and systematically with acquired and congenital heart disease, the latter receiving pride of space, almost half of the book. The final section, some ten pages, discusses anaesthesia for children with heart disease (written by Dr. Robert M. Smith). Despite the full coverage of the field, this is not meant to be a textbook or an encyclopaedia. It is in many ways a very personal book, but it manages to present a skilful and judicious blend of the author's own experiences at the Children's Medical Center in Boston and the findings of others. A certain lack of balance between sections probably reflects the author's own interests. Thus, ten pages on theoretical aspects of electrocardiography contrast strangely with only four pages of text on hypertensive heart disease, an important and difficult subject where expert guidance would have been welcome. Angiocardiology is also rather skimpily treated, although reference to specific findings is interspersed throughout.

This book is a mine of helpful practical information presented in a lively and clear style with many touches of humour. But there are a few strange expressions—for example, "digitoxicity" for "digitalis intoxication." The illustrations are good, but the reproduction of electrocardiograms is often only just adequate, most of them having been recorded with a direct-writing electrocardiograph. There is a good selective bibliography. The evident enjoyment with which Dr. Nadas must have written this book will be matched by the reader's, among whom one would hope to find many paediatricians and cardiologists.

GERALD R. GRAHAM.

Many an amusing turn of phrase keeps Richard Gordon's latest novel, *Doctor in Love*, up to the high standards set by the earlier volumes of this saga. The doctor applies himself to the art of general practice, and learns among other things that "living professionally with a woman is an unusual relationship." The hazards of partners, locums, assistants, and patients are apt to divert him from wooing his girl, but not for too long. If the end seems to owe more to the film-cutter's shears than to the evolution of the story's plot, that is in keeping with this genre—and perhaps with life too. The book is published by Michael Joseph for 12s. 6d.

TESTOSTERONE THERAPY IN DWARFISM

Man's growth hormone, which is presumed to exist in the anterior pituitary, still hangs back shyly in the wings of the theatre, allowing its better-known brethren to occupy the centre of the stage. Unlike them, it stimulates no other endocrine gland to produce a hormone, so we have only indirect evidence of its presence, whether in excess or deficiency; and, again in lonely distinction, there is no animal extract of it which is effective in man. The hormones available for treatment in dwarfism are androgens, such as testosterone, and thyroid, which acts as a growth stimulating hormone only in hypothyroidism. The limitations of the androgens as stimulants of growth are well recognized; they produce virilism and they advance the bone age. The bone age, or skeletal age, is a useful term indicating the stage of skeletal maturation—that is, epiphyseal formation and fusion. In conditions in which androgens are produced in excess, such as congenital virilizing adrenal hyperplasia, the patient grows rapidly but his bones mature even faster, so that his final stature is short, for when total epiphyseal closure is achieved growth ceases. These unwanted side-effects of testosterone therapy—virilism and advanced skeletal maturation—have caused clinicians to be cautious in using it to stimulate growth in children. E. H. Sobel and colleagues^{1,2} have studied in twenty-seven dwarfed healthy children the effect of testosterone in varying dosage in order to assess the relative effect on height and skeletal maturation. They reported three interesting conclusions. First, a dose of 5 mg. of testosterone daily was as effective as larger doses in promoting linear growth. Secondly, in about half the children the skeletal age (calculated in months and assessed by radiographs of the hand and wrist) advanced more rapidly than the height-age (also calculated in months and related to the standard heights of Boston children). Thirdly, while the stimulating effect of testosterone on growth

did not continue in the year after therapy was stopped, the apparent effect on skeletal maturation continued. There is therefore a delay in the epiphyseal development to a degree which is recognizable by radiography.

If their first conclusion is confirmed, that methyl testosterone in a daily dose of 5 mg. provides a maximal stimulant to growth, and if the clinician decides to use testosterone for this purpose, this smaller dose (for methyl testosterone is usually given in a daily dose of 10 mg.) should diminish the risk of virilism developing. Their second conclusion is worthy of consideration. It is a reminder that the increase in linear growth and the advance in epiphyseal development are two separate aspects of growth whose balance, although it runs to a predetermined pattern in the healthy individual, may be disturbed in diseases affecting growth, such as coeliac disease. It is a reminder, too, that hormonal therapy will produce different results in different individuals. In a few of these children skeletal maturation lagged behind height; in some, skeletal maturation advanced more rapidly than height, while in others they ran coincidentally. These diverse responses presumably depend on constitutional differences in metabolism, which cannot yet be exactly determined.

The evidence that in almost half the children testosterone quickened skeletal maturation in advance of height indicates that in this group the hormone is likely to reduce ultimate height. Both the second and third conclusions emphasize the need to check regularly epiphyseal development and fusion by radiographs if treatment by testosterone is embarked upon, and to interrupt therapy from time to time to allow the skeletal changes to become apparent by radiography.

In the remaining one-half of all dwarfed healthy children it would be possible then, if the conclusions of Sobel and colleagues are accepted, to increase their annual height increments by giving testosterone without reducing their ultimate height. But there is no evidence, even in this group of children, that their ultimate height would be increased. Many of them are of constitutionally short stature and their height has already been genetically determined—a secret hidden from the enthusiastic therapist. In some of them testosterone therapy can only anticipate a satisfactory growth spurt which would occur at puberty. In what varieties of dwarfism, then, is it rational to use testosterone therapy?

Dwarfism may be dogmatically defined as a height at least 10% below the fiftieth percentile. The causes of dwarfism are complex, and Lawson Wilkins³ lists twenty aetiological groups, of which only four are

of endocrine origin. In many cases, perhaps in the majority of children attending out-patient clinics, careful investigation fails to elucidate the aetiology. Special attention must always be given to cases in which there is evidence of an arrest of growth, whether partial or complete, over a long period. The dwarfs to whom it may be decided to give testosterone are comparatively few in number. They will include the rare patients with organic hypopituitarism, which is the result of some destructive process such as a craniopharyngioma. These children may also need treatment by cortisone, and for the best results of therapy it is necessary to balance the cortisone (which will retard growth) with an effective protein-anabolizer. A little more frequent are the children with "functional" hypopituitarism, who are presumed to have a deficiency of the growth hormone.⁴ These children, if correctly diagnosed, will have no sexual development at the age of puberty, and for them too testosterone is correct therapy. They can be easily distinguished from the primordial dwarfs who have an average skeletal age despite extreme dwarfism and in whom testosterone does not accelerate growth. The third group of dwarfed patients in whom testosterone therapy should be considered are boys in whom there is a prolonged delay in growth and sexual development. These patients suffer socially and psychologically to such an extent that treatment after a long period of observation is justifiable. It should begin with chorionic gonadotrophin, and if this fails testosterone should be given. The improved confidence and muscular strength well justify carefully planned therapy. Here again care is needed, for testosterone can itself suppress the formation of the anterior pituitary sex hormones. Testosterone is, then, not a complete replacement either for the growth hormone or for the male sex hormones. We may console ourselves for the continuing lack of a therapeutic growth hormone by considering how it may be misused when it arrives.

NUTRITION IN AFRICA

Malnutrition often gives rise to noticeable, and sometimes dramatic, clinical signs, and in the course of observing, treating, and investigating such conditions physicians will inevitably come face to face with many basic problems of biochemistry, physiology, and pathology. The clinical nutritionist may thus become absorbed in the study of such diverse and fundamental issues as the physiology and biochemistry of lactation, the mechanism of intestinal absorption, the interrelationship between amino-acids and vitamins, and many others. It might be thought that such problems lay only within the province of the biochemist and of

the physiologist; but there is evident need for another specialist, the nutritionist, who, while being familiar with these matters, must also span the range between the chemistry of the living cell at one extreme and the production of food at the other. Whereas the biochemist may confine himself to the investigation and description of the metabolic pathway of some essential constituent of the body, and the physiologist may do likewise for an isolated body function, the nutritionist, especially in economically under-developed areas of the world, must go much further. Thus his interests touch on agricultural practice, economics, politics, education, eugenics, and sociology. It is little use knowing, for example, that a particular tissue requires a given mixture of amino-acids for its normal functions without also knowing how to produce such nutrients in a given locality, how to distribute them and make them accessible and acceptable to the people whose health requires them. Within a narrower sphere the effects of food processing, cooking, the presence of added chemicals, the effect of one food material on the nutritional value of another, the nutritional demands of disease, and so on, must be considered by the nutritionist, and may be overlooked by other medical scientists.

These points are well illustrated by the information contained in two recent publications^{1,2}—the report of the third nutrition conference of the C.C.T.A. (Commission de Coopération Technique en Afrique au Sud du Sahara) and *Nutrition Research in Africa South of the Sahara*. Of the two, the latter publication is in many ways the more useful and gives information about the work in progress and already completed in the past ten years in member countries of C.C.T.A. The report gives the titles of communications given at the conference, the official speeches, and also the recommendations and conclusions. The first C.C.T.A. conference was held in 1949 in the French Cameroons and took the form of a general discussion of nutritional problems in Africa. The second conference was in Gambia in 1953, when the theme was malnutrition in African mothers, infants, and young children.³ The third conference met to discuss practical means of improving nutrition in Africa. Although the discussions were confined to African territories, many of the topics were of universal

interest—such as the energy requirements of breast-fed infants, the composition of breast milk in African mothers, protein malnutrition and infection, the lingual buccal mucosa in health and in malnutrition, protein-rich foods, agriculture and nutrition, the role of public health services in nutritional education, dental fluorosis, the effects of malnutrition on the eye, the relationship between intellectual function and nutrition, and many others.

Dietary fat and its possible relation to atherosclerosis is being much discussed at present, even at the level of the World Health Organization.⁴ Some work is being done in Africa on this problem, but there is a noticeable absence of work on the basic nutritional importance of fat. Pre-occupation with the possibility of obesity and over-nutrition in some countries should not distract attention from the fact that many African diets are poor in fats, and that there is now good evidence that some fatty acids are essential in animal nutrition.⁵ A difficult and complex problem which is receiving some attention in Africa is the interrelationship between malnutrition and disease and parasitism. Interest in this is by no means confined to the tropics, as evidenced by much current research elsewhere on susceptibility to tuberculous infection,⁶ body reaction to injury,⁷ and the nutritional requirements of leucocytes and bacteria,⁸ but much useful information may well be gained from more detailed and extensive studies in African countries where malnutrition, infection, and parasitism commonly exist together.

Several workers in Africa are concerning themselves with child growth and development and the effects on these of nutrition. Up to the present, the results of study of the growth of children in America, England, and other advanced countries have been used as "normal" standards. The possibility of overnutrition, however, lends a new emphasis to the importance of these African studies. A progressive series of growth patterns is being drawn up in relation to different nutritional levels. Further comparative studies may thus provide a much clearer understanding of desirable levels of nutrition than investigations confined to a single population. Much of our knowledge about the physiology and biochemistry of lactation has been derived from animal experiments. The presence of widespread protein malnutrition has stimulated research on lactation and breast-feeding in humans in Africa. Again, the results of these studies may provide information of use to paediatricians in Britain, where there has been a marked decline of breast-feeding in later infancy.

These publications of the C.C.T.A. emphasize the growing importance of nutrition as a separate medical

science. Through the work of the Medical Research Council's nutrition research team, under the directorship of Professor B. S. Platt, and of a few others Britain is making important contributions in this field, but if we are to keep pace with other countries much more work ought to be sponsored by academic and other institutions. The immediate object of such research is the prevention of malnutrition. But there is a further end which may be attained as an outcome of all this investigatory work—that is, an understanding of the optimum level of nutrition, which is a matter that concerns us all.

PULMONARY COMPLICATIONS OF INFLUENZA

Experience has shown that influenza epidemics are unpredictable in their courses, and that many factors affect them. In general terms, epidemics in the British Isles start at some time in the autumn or early winter, reach a peak in about February, and then disappear with the advent of warmer weather in the spring. This pattern focuses attention upon the powers of natural and acquired resistance to such an infection. No proof satisfactory to statisticians exists that natural resistance to infection is progressively depressed during the winter months, but clinical impressions strongly suggest that this is so. The virus of Asian influenza has arrived in early autumn and is likely to remain with us for another six months; the weather during the coming winter may determine to some extent the course of the epidemic. The recent discovery of many new respiratory viruses has demonstrated the complexity of acquired resistance to this group of organisms. We are all constantly bombarded by various types and strains, and, with the passage of years, build up a series of antibodies. Consequently when a new strain arrives the older members of the community are likely to have met it, or something resembling it, before, and this may modify the degree of systemic response to fresh infection. The influenza virus A, in common with other viruses, is apt to change the pattern of its dominant antigens from time to time, or even to develop new antigens. This in turn may alter its virulence. Fortunately the virulence of the Asian strain appears to be fairly low, and has not apparently been enhanced during its journey from the East. We must hope that it will remain mild during the next few months, although the possibility of a change for the worse cannot be ruled out.

The virus of Asian influenza is unlikely to cause many deaths on its own account, but this by no means holds for bacteria which may become associated with

it. Secondary infection, particularly by staphylococci, streptococci, or pneumococci, might easily occur in local epidemics and lead to a sudden rise in mortality rates. For this reason a constant watch will have to be kept upon the nature of the secondary infecting organisms during the next few months. Post-mortem examinations should be carried out whenever possible; and it is important that regular information about the progress and nature of the epidemic should be given as quickly as possible to the medical profession.

The clinical recognition of Asian influenza—that is, infection by an antigenically distinct strain of influenza virus A—in individual patients may be difficult, and serological confirmation is necessarily retrospective. The problem facing general practitioners at present is the assessment and management of acute viral respiratory infections in general. This is the season of colds in the head, and by all accounts the clinical course of Asian influenza is mild in the majority. Therefore most sufferers will pass uneventfully through the stages of a benign illness, being fortified by such remedies as aspirin, whisky-and-lemon, and soothing inhalations, the differentiation between coryza and influenza being determined by whether the symptoms are predominantly in the upper respiratory tract or take the form of general aches and weakness. Next in severity are patients whose initial symptoms are more distressing or who show no signs of recovering at the end of forty-eight hours. The possibility of pulmonary complications is the most pressing problem for the physician to clarify. A general assessment of the degree of constitutional upset, in conjunction with the temperature and the pulse and respiratory rates, is likely to be more rewarding than physical examination of the chest in the early stages. Auscultation may soon reveal scattered moist sounds, but localized crepitations and the signs of consolidation often do not appear for several days. Radiographs of the chest—taken, if necessary, by portable machines—are very useful in cases of doubt: they put the pulmonary component of the infection in its proper perspective and determine to a large extent the form that treatment shall take. Specific antibiotic therapy, to forestall or combat pulmonary complications, is by no means standardized, but should take into account the most likely bacterial invaders—namely, staphylococci, pneumococci, and streptococci. Probably the most fashionable drugs for this purpose at the moment are the tetracyclines; they have the disadvantage that an effective blood concentration cannot be achieved in under twenty-four hours, and with the common occurrence of gastro-intestinal symptoms in the present

epidemic their uncertain action upon the bowels may cause confusion. For these reasons the quicker-acting penicillin is preferable for routine use.

In most sharp epidemics of influenza cases of overwhelming and rapidly fatal infection occur sporadically. The total duration of symptoms from onset to death varies from a few hours to three or four days. Necropsy may show no more than a blood-stained serous exudate in the lungs, but more commonly discloses a very extensive bacterial invasion, usually by *Staphylococcus aureus*. The clinical features are those of profound circulatory failure with increasing cyanosis. Treatment should consist of penicillin in large doses, 1 g. of erythromycin four-hourly (the first doses being given intravenously), 25 mg. of hydrocortisone six-hourly (either by intravenous drip or intramuscularly), and continuous oxygen. Staphylococcal antitoxin or gamma globulin should also be given, if available. The benefits of such heroic treatment may be questionable, but the attempt to reverse the progress of the infection in these cases is justified by the high mortality rates with any less comprehensive therapy.

Chronic bronchitic patients constitute a serious problem in an influenza epidemic. They should be among those given priority in any scheme of vaccine prophylaxis, and specific remedies should be administered earlier and in larger doses than for the rest of the population.

DUCKS AND D.N.A.

Many biologists regard the artificial transformation of species as the most profound and exciting problem in the whole of modern science. It is known to be possible in principle. In 1928 F. Griffith¹ discovered that by mixing dead encapsulated ("smooth") pneumococci of one type with living non-encapsulated ("rough") pneumococci of a second type, and then injecting the mixture into mice, it was possible to induce the formation of living encapsulated pneumococci of the former type. Later research showed that there was no need to inject the mixture into mice, for the transformation can occur *in vitro*,² and that the transforming agent can be extracted from bacterial cells.³ In 1944 a group of scientists led by O. T. Avery at the Rockefeller Institute showed⁴ almost conclusively that the transforming agent was a desoxyribonucleic acid, and this hypothesis has resisted every subsequent effort to unseat it. The work of Avery and his colleagues is the keystone of our modern belief that D.N.A. is the chemical determinant of heredity—that is, that the difference between one D.N.A. and another causes the difference between one genotype and another. In the process of bacterial transformation the D.N.A. extracted

from bacteria of one type acts as if it were a soluble and infective gene; it somehow enters into the genetic machinery of bacteria of another type and causes them to acquire a genetic trait characteristic of the organisms from which the D.N.A. is extracted.

Artificial genetic transformations have so far been demonstrated only in micro-organisms, and, though all biologists are aware of the extreme importance of trying to make them occur in higher organisms, they are aware also of the very special difficulties which such an enterprise must necessarily meet. (It is possible that the D.N.A. of higher organisms, being neatly packaged with protein in the form of chromosomes, cannot be subverted by exogenous D.N.A.) Great interest has therefore been aroused by certain observations on ducks which a group of French scientists—led by a distinguished endocrinologist and an equally distinguished authority on nucleic acids—are prepared to interpret as evidence of a genetical transformation induced by D.N.A.^{5,6} These workers extracted D.N.A. in an undamaged form from the testicular tissue and (nucleated) red blood corpuscles of Khaki Campbell ducks and injected it at weekly intervals, starting on the eighth day after hatching, into nine ducks and three drakes of the Pekin breed.⁵ Normal Pekins are large table birds with yellow beaks and creamy-yellow plumage. Khaki Campbells, kept for egg-laying, are smaller and have a less dignified bearing; their beaks are greenish black. The treated ducks grew up smaller than normal Pekins and acquired a somewhat different stance and deportment. Their plumage was snow-white, and the beaks of five females developed bold black smudges against a background which was either yellow, as in normal Pekins, or—because of the loss of yellow pigment—rose-pink.

The treated ducks were fertile, and a report on the characteristics of their first generation progeny was eagerly awaited. We now learn⁶ that about three-quarters of the offspring of the treated ducks have beaks of the pale rose colour that is due to the absence of the yellow pigment normal in Pekins; the black smudges seen on the beaks of their treated parents were absent. Similar losses of yellow pigmentation were seen in the legs of rather more than half the progeny of the treated ducks. Their down is at present Pekin-like. Other changes may develop when the ducklings grow up, but at present they differ from the Pekin type only by the apparent loss of yellowish pigmentation in certain areas.

The experiments were avowedly designed to test the hypothesis that genetic transformations can be induced in birds by D.N.A., but they fall somewhat short of doing so. There are no adequate controls. The subjects of the experiment should surely have been divided into two panels, the one to be injected with D.N.A. of Khaki Campbell origin, the other to be left untreated or, better, to be injected with D.N.A. made from Pekin ducks themselves. Such safeguards are particularly important when dealing with animals which, in spite of their outward uniformity of breed characters, are genetically diverse. Breeds of birds are not to be likened to inbred strains of mice. As Dr. Barnet Woolf⁷ points out in a particularly cogent analysis of the evidence, the

Pekin stock is known to have been crossed with Aylesbury ducks in the past, and Aylesbury ducks have white plumage and pinkish beaks. Without adequate controls, we cannot feel certain that the pink-beaked progeny of the treated Pekins were not produced merely by genetic segregation. There is much else to cause misgivings. The transformations produced in micro-organisms by D.N.A. affect only a small minority of the treated cells; here it seems to have affected them all, and at a stage of development at which embryological determination is supposed to be long complete. Again, rightly or wrongly, some misgivings have been expressed at the use of testicular tissue as a source of D.N.A. to be injected into females. These doubts cannot be set at rest until full details of the experiments have been published and adequate control data have been amassed. In short, the idea that these experiments inaugurate a new era in biological science should be treated, for the present, with reserve.

SPORTS AND WORLD CULTURE

Much argument and some research have been devoted to finding the qualities that make a world-beating athlete. But the features that distinguish the social and cultural environment of these unusual people, and why some countries produce disproportionately many of them, have received relatively little attention. A recent study of the Fifteenth Olympiad at Helsinki¹ is pertinent to this theme. Professor E. Jokl, of Kentucky University, and Professor L. Noro and his associates, of the Institute of Occupational Health, Helsinki, provide a method of comparing athletic achievements—for example, the value of a gold medal in boxing with the value of a silver or bronze medal in the 10,000-metre race. The U.S.S.R. and U.S.A., with a combined population of 346 millions, collect a total of 17,706 points, yet four small Scandinavian countries, with a combined population of only 19 millions, collect 12,873 points. The athletic supremacy of these countries is shown by comparison of the points collected per million inhabitants—51 points for the U.S.S.R. plus U.S.A. compared with 678 points for the Scandinavian countries. Is this the result of a higher sports participation rate among Europeans as compared with America and Russia, of better training methods or facilities, or perhaps a reflection of a more advanced cultural pattern in the smaller countries? The remarkable Olympic contributions of those negro and yellow-brown athletes who have been brought up in British or American societies show that the coloured races, at least for certain sporting events, are more efficient than the white. It suggests too that Africa may hold many potential athletes of outstanding ability.

Nations not competing in the games, or not including women in their teams, were found to be distinguished by

¹ Jokl, E., Karvonen, M. J., Kihlberg, J., Koskela, A., and Noro, L., *Sports in the Cultural Pattern of the World*, 1956, Institute of Occupational Health, Helsinki.

² MacQueen, I. J., *Physiotherapy*, 1956, 42, 83.

³ Smuts, J. C., *Holism and Evolution*, 1926.

comparatively unfavourable rates of child mortality, adult mortality, and morbidity. The astonishing performances of women athletes are apparent from the report: "A track and field team consisting of Mesdames Jackson, Hasenjager, Strickland, Brouwer, Blankers-Koen, Golubichnaja, Sander, Williams, Chudina, Cawley, Brand, Lerwill, Zybina, Ramaschkova, Bagrjanceva, Dumbadze, Zatopkova, and Gorschakova would in 1952 have beaten over 90% of all boys' high school and university teams throughout the world." To give but one outstanding individual example, the women's 400 metre free-style swim won by Miss V. Gyange, of Hungary, in 5 min. 12.1 sec. was faster than every winner of the men's 400 metre free-style swim from the beginning of the games in 1896 up to Weissmüller's world record of 5 min. 6.6 sec. in 1922. But Miss Hveger, of Denmark, has swum the women's world record race in 5 min. 0.1 sec., which would have easily beaten Weissmüller 34 years ago. Physicians who maintain a traditional reserve towards the subject of physical activities and training for women may find it hard to believe that a number of athletic records were established during menstruation, that competitive athletics does not disturb the normal menstrual cycle, and that data on the fertility rates and deliveries of outstanding women athletes are all normal. Moreover, "a large number of the finalists in the women's events of the 1952 Olympic Games were married and had children. Many of them were over 35 and at least two were grandmothers." The safety and greater effectiveness of strenuous weight-resisted exercise for development of the female and adolescent figure compared with relatively ineffectual free exercise has recently been stressed.² It is heartening to learn that "none of the women athletes, none of the 13- and 14-year-old boy and girl competitors and none of the participants of age 60 and above required medical attention."

Considering age in relation to athletic performance, the authors of this report found that many of the youngest participants competed in the cycling and swimming events; it may be significant that these are both non-weight-bearing activities. The long-distance runners, however, were older men, and some of the oldest competitors were horsemen, riflemen, yachtsmen, gymnasts, rowers, and weight-lifters. Several weight-lifters were between 45 and 50; and in the heavyweight class—the class of weight-lifter most popularly, but wrongly, believed to die young—there were competitors older than 55 years.

The size of a country, its climate, economy, and the nutrition of its peoples are other factors affecting its contribution and degrees of success in Olympic competition, yet often enough outstanding individuals can overcome all environmental adversities to beat competitors from more favourable economic and climatic surroundings. The late General Smuts³ believed that progressive historical and social developments follow the integration of small political or geographical entities into larger wholes. This concept of "holism" is embodied in the universal structure of the Olympic

movement, whose call is enthusiastically answered by men and women of diverse social, cultural, and political outlook the world over.

DIAGNOSTIC CENTRE FOR GENERAL PRACTITIONERS

The Secretary of the Department of Health for Scotland, Mr. John Anderson, speaking at the annual conference of the Scottish Association of Executive Councils a fortnight ago, and reported in this week's *Supplement* (p. 127), announced that work was to begin soon on a new general-practitioner centre in Edinburgh. The first of its kind in Britain, the centre will provide for about 100 of Edinburgh's 300 family doctors a range of diagnostic services not normally directly available to them. With its clinical laboratory and x-ray and electrocardiographic departments available for their use, general practitioners will be able themselves to investigate at the centre many cases which otherwise would have to be referred to the out-patient departments of hospitals. The centre is to have five consulting-rooms, and the staff will consist of nurses, a social worker, technicians, and clerks. A senior physician, Mr. Anderson stated, "will act in an honorary capacity as medical adviser in appropriate cases." The doctors to whom the use of the centre will be offered will continue to consult in their own surgeries but will be able to meet by appointment at the centre those of their patients requiring special investigation.

Conversion of the three-story building which will house the diagnostic centre is to cost about £25,000, and the annual upkeep, including staff salaries, is estimated at about £10,000. The Nuffield Provincial Hospitals Trust is contributing £17,000 towards the capital cost and £13,000 towards the running costs for the first three years. The Department of Health will foot the rest of the bill. A management committee, on which the local medical committee, the City of Edinburgh, the University, the regional hospital board, the Nuffield Trust, and the Department of Health will be represented, will run the centre. General practitioners have become wearily familiar with being described as "cornerstones" in the structure of the N.H.S.: in practice they have seen few signs of encouragement to support this high-sounding theory. The sponsors of the diagnostic centre in Edinburgh are to be congratulated for adding deeds to words. If there is any substance in the criticisms of the Select Committee on Estimates (see *Supplement*, page 126) that patients are attending specialist out-patient clinics who could well have been examined and treated by general practitioners, schemes like the Edinburgh one should help to put matters right. It is a development which will be watched with great interest, and, if all goes well, others will certainly follow where Edinburgh has led.

We record with deep regret the death on October 7 of Sir John Parsons, F.R.S., at the age of 89. The leading ophthalmic surgeon of his generation in Britain, he was consulting surgeon to the Royal London Ophthalmic Hospital and consulting ophthalmic surgeon to University College Hospital.

PHARMACEUTICAL RESEARCH

I.C.I.'s NEW LABORATORIES

Lord WAVERLEY, P.C., G.C.B., F.R.S., opened new research laboratories for the pharmaceuticals division of Imperial Chemicals Ltd. at Alderley Park, Cheshire, on October 1. The laboratories cost over £1 million. The inaugural proceedings comprised a luncheon and tour of the buildings on the opening day, and this was followed later in the week by a two-day symposium on drug toxicity.

The purpose of the new laboratories, which stand in open parkland and overlook Radnor Mere (Fig. 1), is the discovery of chemotherapeutic agents of medical or veterinary interest. I.C.I. first undertook the systematic search for new drugs 21 years ago. Since then their work in this field has expanded greatly. The present pharmaceutical research staff comprises about 100 graduate chemists and biologists with about three times that number of laboratory and other assistants.

Pathogen-free Rats and Mice

In order to reduce some of the variables in testing potential new drugs, "pathogen-free" colonies of rats and mice are to be bred—that is, colonies free from the infections and parasitic infestations that otherwise always beset the laboratory animal. This has necessitated most elaborate precautions in the construction of breeding and animal houses and infected animal houses, biological laboratories, and chemical laboratories. In addition there are a central washing-up and media room, a spacious library, conference rooms, offices, and a large canteen.

The breeding unit for the pathogen-free colonies of rats and mice is isolated in a glade in the woods, away from the other buildings. The glade is fenced against rabbits and other large animals, and the only entrance and exit to the unit is through decontamination and changing chambers and a double air-lock with an ultra-violet light barrier and continuous insecticide sprays. The nucleus of the pathogen-free colonies, for which some 100,000 rats and 500,000 mice will be raised annually, is full-term embryos obtained by caesarean section and reared by hand away from their infected dams. All food for the animals is pasteurized, and all equipment sterilized before entry to the unit.

The animal houses in the main block of laboratories are so designed as to maintain the colonies in their pathogen-free state and to prevent cross-infection by experimentally induced disease. When work is done on diseases infectious to man, protection of staff is attained by complete containment of the infected animal in ventilated cupboards (Fig. 2). In addition there are also decontamination locks as in the animal breeding unit, independent air-extraction systems, and other safeguards against cross-infection.

FIG. 1.—Aerial view of north aspect of the central laboratory block, showing Radnor Mere in the foreground and the general appearance of the surrounding parkland. The separate building on the left of the picture is the boiler house and workshop, and the trees behind it screen from view the building for the animal breeding unit.

(Aeroflms, Ltd.)

Among the biological and chemical laboratories are rooms for the safe handling of toxic chemicals, an autoclave laboratory for carrying out chemical reactions under pressure, a radiochemistry unit for labelling compounds with radioactive tracers, facilities for biochemistry and physical chemistry, and laboratories for the study of the pharmacodynamics and toxic effects of new drugs.

Symposium on Drug Toxicity

A special correspondent writes: Biochemists and chemists, pathologists and pharmacologists, and a few clinicians—some 80 in all—were assembled at Alderley Park, on October 3 and 4, for the symposium on drug activity. Professor J. M. McMICHAEL, F.R.S., presided at the first session, and Professor G. PAYLING WRIGHT at the second.

Professor E. J. WAYNE (Glasgow) opened the symposium with a paper on toxic reactions in clinical medicine. He

divided toxic reactions to drugs into the predictable, associated with large doses and generally with an exaggeration of unwanted side-effects such as drowsiness after antihistamines, and unpredictable, less common and more serious, where the response was wholly abnormal and often allergic. Predictable toxicity was best illustrated by Hanzlik's classical demonstration of individual variation in response to salicylates. The therapeutic index, as calculated in animals, was some guide, but could hardly be determined in man, nor lightly transferred from mice to men.

The relatively narrow margin of safety with the longer-lasting barbiturates was, however, common to experimental animals and man. Sometimes a second drug might be added to reduce or prevent side-effects—such as amphetamine with promethazine, and the synthetic chemist was always trying to produce new or related compounds in which undesirable side-effects would be reduced, as in some of the atropine substitutes.

The likelihood that the use of a drug would lead to sensitization phenomena was difficult to assess. Some common drugs were free from this risk, whereas certain chemical groupings—quinonediimines and pyrimidines, for example—seemed to be particularly antigenic. The experienced physician had learned to associate certain symptoms with the probability of drug allergy, and had to decide whether the risk to a patient was justified by the patient's need. Thus he no longer hesitated to use chloramphenicol if it was indicated, but he would not use amidopyrine.

In the discussion it was made clear that no good laboratory test existed for general liability to sensitization to drugs, but that allergic reactions were most likely in patients with allergic backgrounds.

Dr. E. WESTON HURST (I.C.I.) dealt with some sexual differences in the response to drugs. The outstanding example of this was the disastrous effect of chloroform on the kidneys of the male, but not of the female, in certain strains of mouse. This was a hormonal differentiation, abolished by castration, modified by administered hormones, and not seen in the sexually immature, nor was it found in other species. The female mouse was also more fortunate

than its mate in that it was better protected by mepacrine against equine encephalomyelitis and by streptomycin against certain streptococci. It also slept longer after certain barbiturates, but was less tolerant of arsenobenzenes. These sex differences were not a matter of differences in the proportion of body water or body fat. Deficient or modified diets had been found to affect sexual differences in response to toxic substances and also differences between the sexes in rate of growth. Thus penicillamine made the male grow better than control mice, but inhibited growth in the female. No one explanation covered all these odd facts except that males are different from females.

Safety-testing of New Drugs

Dr. G. E. PAGET (I.C.I.) spoke as an experimental pathologist on the morphological evaluation of the toxic actions of drugs. He felt that the pathologist had to plan his experiment to examine such toxic actions as were important in man—no experiment was likely to detect or illuminate all possible toxic actions of drugs, and he regarded the non-

(Elsam, Mann & Cooper (Manchester) Ltd.)

FIG. 2.—This illustrates the protection for workers in the infectious animal house. The animal cages are behind glass, with separate exhaust ventilation passing through bacteriological filters. Cages are transferred mechanically to a glass-fronted manipulator box fitted with built-in gloves.

toxic drug as a contradiction in terms. He thought eight weeks the minimum duration for an experiment, and that at least 20 tissues should be examined in each animal, with emphasis on the liver, kidneys, heart, and gonads. He had found the convoluted tubule the graveyard of many a promising drug. The handling and processing of the tissues were critical, and modern histochemical and biophysical techniques had to be adopted as required. Although pathology was generally less quantitative than other disciplines, and in spite of all the difficulties in transferring the results of animal experiments to man, he believed that such investigations helped the manufacturer to play extremely safe, as he must, in introducing new compounds into therapeutics. Some members of the group doubted the wisdom of so wholesale a histopathological approach to the problem.

Dr. J. T. LITCHFIELD (American Cyanamid Company), described as the man who made complicated statistics look simple, discussed the planning of experiments for the determination of efficacy and safety of new drugs. The first experiment should be limited to, "Is the product interesting?" in the sense that did the drug possess a particular biological property. Thereafter its degree of interest should be determined by establishing dose-response curves and comparative assessments. He thought it a waste of time and effort to attempt the impossible in establishing the absence of a particular undesirable property—e.g., carcinogenesis. "The challenge which must be met lies in the need to predict more efficiently and more accurately both efficacy and potential hazards from drugs and, at the same time, to deal

with an increasingly larger number of drugs. Only by adhering to and fully utilizing basic principles of scientific experimentation can this challenge be met."

Dr. J. M. BARNES (M.R.C. Toxicology Research Unit) discussed the limitations of routine study in the evaluation of toxic action. All therapeutically active drugs had toxic effects at certain dose levels as indicated by their therapeutic indices, but no tests on animals could be expected to give more than a probable answer to questions about the reactions that might arise in man. Both toxicity and therapeutic value might depend upon the drug or upon its metabolites, but not necessarily upon the same metabolite. The risk of liver poisoning from a drug might be assessed by observing how it affected pre-existing liver damage or how it enhanced the toxic effects on the liver of other drugs. LD50 estimations were useful, but depended on the uniformity of the animals examined—perhaps mice and rats were too uniform a population for the detection of possible idiosyncratic reactions, even if large numbers were used. In assessing action on the brain, it had to be remembered that the liver and kidney might protect this most sensitive organ. The Medical Research Council had set up a unit in which the effect of drugs on animal behaviour was evaluated—often a change of gait was observed before such symptoms as tremor. Sometimes highly selective toxicity to such a tissue as the retina was detected with no other evidence of brain damage.

Drug Allergies, Blood Dyscrasias, and Liver Damage

Mr. E. G. DAVIES (I.C.I.) discussed allergic reactions arising from the use of new drugs. He divided drug allergies in animals into immediate, such as bronchial spasm, delayed, such as contact dermatitis and blood dyscrasias like purpuric reactions, aplastic anaemia, and agranulocytosis. Following the Hapten theory, the drug or its metabolite might be conjugated, perhaps with protein, before it became antigenic, although amidopyrine appeared to act unconjugated. While it was possible to produce experimental sensitization to chlorpromazine, so far they had not succeeded with penicillin, a potent sensitizer in man. He thought the production of suitable conjugated antigens might be the most promising line for future work, and that then we might say, with Alice, "Come—that finishes the guinea-pigs—now we shall get on better."

Dr. W. JACOBSON (Cambridge) discussed the toxic action of drugs on the haemopoietic system, where the limited life span of both red and white cells presented special problems if their replacement was depressed in any way. Alkylating agents, folic acid antagonists, and leukaemogenic factors were groups which differed widely in their chemistry within each group, and little was known of how they exerted their toxic actions on the marrow. Folic acid antagonists could arrest cell division in the precursors of normal and leukaemic white cells by competing with the folic acid required for cell multiplication, while leukaemic cells, but not normal leucocytes, could inactivate folic acid antagonists and remove their inhibitory effects on the marrow. It would appear that the cells of acute leukaemia had both the power to build up their own folic acid from a suitable pteridine precursor and to synthesize a folic acid antagonist from a pteridine of antagonistic configuration. Normal cells could do neither.

Dr. P. N. MAGEE (M.R.C. Toxicology Research Unit) described his experimental studies on toxic liver injury. Some hepatotoxins were highly selective, and a single dose of pyrrolizidine (Senecio) alkaloids had produced chronic and apparently progressive liver lesions in the rat which might take weeks or even months to become clinically manifest. A single non-fatal dose of others might produce an acute necrosis with complete recovery. Repeated administration led to fibrosis, and with some, such as azo dyes and dimethylnitrosamine, to tumours.

Dr. K. R. REES described joint experiments with Dr. J. D. JUDAH (both of London) on the action of drugs on subcellular structures, particularly in the liver. They had hoped to find a single enzyme system affected and had used various methods (whole animals during acute necrosis and during the development of bile duct tumours provoked by fed thioacetamide; respiratory studies on subcellular particles such

as brain mitochondria; and liver perfusions) as a means of investigating the processes by which cell death occurred. Liver poisons produced striking accumulations in the liver of calcium and citrate against which antihistamines afforded substantial protection, and depression of respiration in brain homogenates which could be reversed by low concentrations of cobalt or nickel, but not by other metals or by cyanocobalamin (vitamin B₁₂). It was tempting to relate these changes to the demyelination found in cobalt-deficient sheep, but the mechanism of action remained obscure.

EAST AFRICAN PHYSICIANS

The annual conference of the Association of Physicians of East Africa was held at Kampala, Uganda, from June 27 to June 29, under its president Dr. A. D. CHARTERS.

Several speakers drew attention to differences in the age incidence of certain diseases in the African, as compared with the European, and to his apparently greater physical maturity at birth. Dr. A. G. SHAPER, in a study of 155 diabetic Africans admitted to Mulago Hospital, found the peak incidence for males at the fifth decade compared with the sixth in Europe, whereas in females the largest numbers occurred in the third and fourth decades, quite unlike the pattern seen in Europe—and Jamaica—where the maximum incidence in females was after the age of 45. Grouped according to R. D. Lawrence's 1951 classification, 28% of the Mulago series were type I and 70% type II, the majority of both types being underweight. Four cases were classified as the type J recently described in Jamaica. Apart from peripheral vascular disease and renal disease, all the recognized complications of diabetes were seen, though cardiovascular disease was rare. In only one case were there no ketone bodies in the urine during diabetic coma. Dr. Shaper concluded that, in the African, factors other than obesity and parity should be sought to account for the production or uncovering of the diabetic state.

Professor A. W. WILLIAMS, on the basis of a number of field surveys correlating blood pressure levels with age, said that in the African the general trend was towards a less marked rise with advancing years than was usual with Europeans.

Dr. R. F. A. DEAN, who had examined newborn African infants neurologically, said that much of their activity at birth corresponded to that of European children at four to six weeks of age.

Dengue and Trypanosomiasis

Dr. W. H. R. LUMSDEN described work at the Virus Research Institute, Entebbe, on the aetiology of dengue. Even in a homogenous population the clinical picture was very variable, and on clinical grounds it was impossible to arrive at an aetiological diagnosis. Viruses were divided into two main groups depending on the conditions under which they caused haemagglutination. The dengue viruses belonged to Group B, as did yellow fever virus. West Nile virus, which caused widespread human infection in Africa, also belonged to group B; it had been shown to cause dengue-like fevers in Israel and Egypt. Chikungunya virus—a group A virus—had been responsible for a recent dengue-like epidemic in Tanganyika. Other viruses which had been isolated from insects and might well cause dengue-like fevers were also being investigated.

Mr. A. JENKINS offered clinical and biochemical evidence for the occurrence of acute parenchymal liver damage in Rhodesian trypanosomiasis. Its extent varied, and it was reversed by treatment of the trypanosomiasis, although the symptoms and signs sometimes became worse after the initial injection of suramin.

Hookworm and Kwashiorkor Anaemias

Dr. G. JACOB, who had studied the haemoglobin levels of people with hookworms, was able to draw a fairly sharp distinction between those in whom the infestation appeared to be just a simple carrier state and those who had severe anaemia. The latter comprised about 7% of his cases,

though the series was probably weighted in their favour. The suggestion was made that the anaemia was not directly caused by chronic haemorrhage, since the haemoglobin levels did not appear to represent a continuous process of deterioration.

Dr. M. SIMPKISS discussed the anaemia so often associated with kwashiorkor in Uganda, even in the absence of malarial or hookworm infection. When such patients were treated with high-protein diets, ordinarily there was a dramatic fall in their haemoglobin levels. In a series to which he had given intramuscular iron as well as a high-protein, high-calorie diet, there had been an excellent response to treatment and in no case had the haemoglobin fallen.

A number of other papers were also read.

MEDICAL PROTECTION SOCIETY

The annual meeting of the Medical Protection Society was held at Victory House, Leicester Square, on October 2. Sir ERNEST ROCK CARLING began his presidential address by stating that the outstanding feature of the year had been the very satisfactory expansion of the Society's membership in the Commonwealth. They had undertaken a number of cases for members overseas, and had received excellent co-operation from overseas solicitors nominated by their own advisers.

Sir Ernest then warned against three common pitfalls as part of the customary "friendly cautions" to members. If, after a dental extraction, he said, there was any possibility that a piece of tooth had been swallowed or inhaled, a radiograph was absolutely essential. Next he stressed the need for being most careful in selecting sites for injection so as to avoid damage to nerves. And lastly he urged discrimination in the use of relaxant drugs during anaesthetics: "They (relaxants) are dangerous drugs," he stated; "they are apt to give rise to trouble, although they are not dangerous drugs in the strictly legal sense—and they should be treated with very great respect."

Delegation of Responsibility

In discussing the relationship between senior hospital staff and their juniors, the president said: "It is very important indeed for men on the staffs of hospitals to give ample opportunities to their juniors to practise their work, to take full responsibility and become used to it, but nowadays when work is delegated to juniors you expose them to claims for damages for which you cannot take responsibility. They will be involved in claims for damages, so it is very important indeed that the seniors, when doing the right thing—trying to educate their juniors—should make quite certain they do not give them jobs for which a junior has neither the experience nor competence. It has always been a tradition in the profession that the seniors should take without any hesitation responsibility for juniors, and, of course, that continues, but it has partly gone out of our hands and to that extent we ought to be additionally careful how we allot work."

Mr. W. M. MOLLISON, F.R.C.S., the treasurer, said that for the first time since 1951 the Society had experienced a loss; last year there was a deficit of £2,891, due to the great increase in the sums paid out for important cases. The financial position, however, remained strong. The Society's solicitor said that the amount paid out in damages had greatly increased; one of the main elements in the increase was due to the enormous rises in wages and hence of claims for lost earnings; thus a case which a few years ago could be settled for £500 now required £1,000.

Annual Report

The membership of the Society is now over 30,000, of whom just over 2,000 sought advice or assistance during the year of the report (1956). In addition to the financial statement and notes on membership, the report includes notes on a selection of interesting medical and dental medico-legal problems dealt with by the Society during the year.

NEW ACADEMIC YEAR

UNIVERSITY COLLEGE HOSPITAL

The essentially dual character of medicine—at once scientific and humane—and the opportunities of the general practitioner were stressed by Dame JANET VAUGHAN in her inaugural address at University College Hospital Medical School on October 1. Dame Janet Vaughan is principal of Somerville College, Oxford.

New Dental School

Sir CHARLES HARRINGTON, F.R.S., director of the National Institute for Medical Research, speaking in his capacity as chairman of the Medical School council, said that recently the University of London had asked if the School would be prepared to accept a much larger number of dental students. This had necessitated a complete revision of the plans for the new dental school. Moreover, if, as seemed likely, the request was agreed to, the medical school would be deprived of the extension of its research facilities and there would be an acute problem in providing amenities for students. The School had, however, been assured that these difficulties were recognized by the University.

To the new students Sir Charles said that the study of the sick human being would call for many other qualities in addition to those they had acquired in their scientific studies. But there was no need to lose sight of the scientific approach they had learned in their preclinical course. During the clinical training they should try to retain a scientific outlook while acquiring the practical knowledge and understanding of human beings essential to the making of a good doctor.

The Dean, Mr. J. D. F. FLEW, commented in his report that no medical research could progress without money. Money for this purpose was to a great extent dependent on politicians, and medicine and politics did not mix. That was perhaps the greatest lesson to be learned by this generation.

Duality of Medicine

Dame JANET VAUGHAN spoke of the debt which medical education all over the world owed to University College Hospital Medical School. What happened there, although it now formed the pattern at most medical schools in the free universities, was not always what one saw in practice elsewhere. Although there had been a formal separation of the medical school from University College 50 years ago, of the medical school from University College 50 years ago, the clinicians in the hospital inevitably rubbed shoulders with the scientists, philosophers, and historians on the other side of Gower Street, and thus their views of the proper way to teach medicine had the breadth of the university outlook.

The School had been the first in England to establish academic units in medicine, surgery, and obstetrics. To-day most medical schools had such clinical units. Academic medicine had become part and parcel of medical education in this country, and University College Hospital had shown that the care of the patient gained by this dual view of the doctor's work. As students 30 years ago at U.C.H. they had learned that medicine was concerned with the day-to-day needs of patients, and with the precise analysis of the clinical findings in that patient. Medicine, in other words, was a bridge between clinical science, on the one side, and human beings on the other. And this relation between the two facets of life was going to become more and more important.

Dame Janet regretted that she personally never went into general practice. She thought that it was just a newspaper stunt to say that the general practitioner spent all his time signing certificates. From her hospital experience she knew that the spot diagnosis of the rare condition often came from the general practitioner. With treatment in hospital so expensive nowadays, hospitals returned patients requiring complex treatments to the general practitioner and expected him to be able to carry them out. She thought that the pattern of medicine would change and that treatment would come back to the family doctor.

It was said that the heyday of the medical officer of health was past. Such a view was just looking to the past and not to the future.

CHARING CROSS HOSPITAL

The qualities that go to season a man and make him more than just an expert was the theme of Dr. J. F. LOCKWOOD's inaugural address to Charing Cross Hospital Medical School on October 3. Dr. Lockwood is Vice-Chancellor of London University.

Fulham, Their Kingdom of Heaven

The Dean, Professor W. J. HAMILTON, recalled the decision to build the new Charing Cross Hospital and Medical School at Fulham. "For our own part we have always stressed that the Hospital and Medical School must remain in close proximity in order to function as a properly integrated teaching unit, and we now hope that a solution to our particular problem has been found," he said. The number of applications for admission continued to be phenomenal. Only 8% of those who applied could be accepted.

Lord INMAN, chairman of both the Hospital and the School council, who presided, remarked that, as he recalled the many schemes during the past thirty years that had been originated, accepted, and then overruled, he thought of these words: "Through much tribulation you shall enter the Kingdom of Heaven." He hoped they would come to look on Fulham as their Kingdom of Heaven.

What Does Medicine Make a Man?

Dr. LOCKWOOD said the Dean had declared the purpose of the School to be teaching and research. Teaching was certainly a fundamental duty of any university, college, or school, but one had to be careful what the word "teaching" meant in that context. It was only part of the function of a university to fill its undergraduates with an abundance of facts. The university must make them as expert as it could; but, if that was all it achieved, it failed to a large degree. Bacon had said that the object of reading should be "to weigh and consider." Bacon also said that history made a man wise; poetry made him witty; mathematics, subtle; natural philosophy, deep; moral philosophy, grave; logic and rhetoric, able to contend. How many medical students asked themselves seriously the question: What did medicine make a man? It was a question they should ask themselves regularly and repeatedly.

Nowadays there was a plethora of experts, and they were consulted on every conceivable topic. Experts were useful within their limitations, but experts lived in society, and human relationships were the basis of society. From time to time there had been comments upon the ignorance of the learned. Hazlitt had referred to it, and a fine old rustic once put it: "Well, I likes educated people, but the wuss of it is they be so durned ignorant." Did the man and woman who went through the medical school come out with any kind of curiosity, with any kind of philosophy? Would they play their part in the great human society?

The qualities looked for were many. Judgment was vital in the conduct of life and in human relationships. The capacity to assess evidence—to distinguish what was relevant from what was not and then to bring the mind to bear on that evidence after it had been appraised—did not come without a long and hard training in the processes of thinking. Another quality was absolute integrity. Judgment and integrity alone were not enough, however; there must also be courage and resolution to support them. Along with these, enthusiasm was needed, but enthusiasm must be controlled, not what someone had called the "distemper of enthusiasm."

"The man who does not do more work than he is paid for is not worth what he gets," wrote Abraham Lincoln. It was a salutary reminder at the present time when all seemed so concerned about what their remuneration should be. Lincoln was emphasizing a point too often forgotten, that the real satisfaction of work—and hard work did no one any harm—lay in doing the best one could within one's own limited capacity.

A vote of thanks to Dr. Lockwood was proposed by Dr. A. DOYNE BELL.

ROYAL FREE SCHOOL OF MEDICINE

Mr. Justice LLOYD-JACOB discussed professional negligence in his inaugural address to the Royal Free Hospital School of Medicine on October 4. Sir FRANCIS LASCELLES, chairman of the School Council, was in the chair.

Need for Leisure

The Dean, Dr. KATHARINE LLOYD-WILLIAMS, said that it was a matter of constant anxiety in the medical schools that students should have enough time and leisure to get the best out of their time at the university. She thought that the General Medical Council's new recommendations allowed more latitude for experiment. For students of medicine the first eight terms of their course, spent entirely on academic work, really corresponded to the three years' university course of other disciplines; it should be a period when, as well as obtaining a basic knowledge of his subject, the student should acquire a philosophy of life and learn to exercise his powers of reasoning and develop his personality. In the clinical years it was inevitable and right that the training should be to a large extent vocational, though in a profession like medicine the training was one which continued for the rest of one's life.

Negligence, a Failure of Neighbourliness

Mr. Justice LLOYD-JACOB said that for generations the law had applied the maxim that a man must so use his own property as not to damage his neighbour. Particularly since the advent of legal aid had effectively opened the Courts to the poorest, the tort of negligence had come to be seen as a failure of neighbourliness.

He was told that within the medical profession some alarm, and possibly despondency, had been caused by recent decisions in cases which had called into question the discharge of their special duties by surgeons, physicians, housemen, technicians, and nurses. It must always be borne in mind that decisions in negligence cases were determined upon evidence, and in medical cases this meant expert evidence from doctors. Courts admittedly were fallible instruments for the ascertainment of truth, but, if the criticism was directed to the finding of fact, this was an allegation of inaccuracy on the part of medical experts. If the complaint was directed against the standard of care upon which the Courts insisted, his lordship said he must express his firm conviction that the criticism was misconceived. "In entering upon these great professions, we assert a right freely to exercise such talent as we have in the manner of our choice," continued Mr. Justice Lloyd-Jacob. "But we do well to acknowledge the tremendous responsibility we necessarily shoulder in so doing." Cleric, doctor, and lawyer, carrying on their professional duties, were alike required by conscience and common law to do them in all good-neighbourliness.

Dr. FRANCES GARDNER proposed the vote of thanks.

Motoring News

NEW CARS AT MOTOR SHOW

Once again the autumn is upon us and with it the familiar series of exhibitions in London. The Earls Court Motor Show begins on October 16, the 42nd occasion on which it has been held. Since the war many manufacturers have given up announcing their new models during the Motor Show, and 1957 will be no exception. Publicity and advertising men believe that the sensational news about their new models is lost in the welter of bright lights and gimmicks publicizing so many accessories and new developments. The introduction of new models is now being carried out at a more leisurely pace throughout the winter season, with a few additions or alterations in the popular car field during the next few weeks.

Two firms have recently announced a reduction in price of their cars before the show; they are Berkeley and Bond.

The Berkeley is now available for £499 18s. and the Bond for £279, these being the cheapest versions of each. Two of the faster Continental models being exhibited will be the Alfa Romeo Guilletta "Sprint" 1300 and the Mercedes Benz 300SL Roadster; two other recently announced Mercedes models also being shown will be the 300 Automatic and the 220S saloon with hydro-automatic clutch. Volkswagen will be having their usual range of exhibits, and the improved de luxe and standard model cars will be shown. The first of these was brought into Britain about a month ago; the improvements are confined to larger rear window, altered instrument panel, glove locker, and changes in the engine cooling air intake.

There will be no changes in the Hillman, Sunbeam Rapier, and Sunbeam III models, though the last-mentioned will not be shown at Earls Court. Certain arrivals, however, will be the new Vauxhalls, the Velox and the Cresta, which are completely new in external appearance, being lower and longer and fitted with the improved six-cylinder power unit delivering nearly 83 b.h.p. at 4,400 r.p.m. on a 7.8 to 1 compression ratio. The major changes concern the new shape and roomier interior, improved dashboard, and a more comprehensive choice of upholstery. Fords will not be announcing any new cars at present and their exhibits will be unchanged as from last year, but with detailed improvements to the bodywork of most models. Austins will also be unchanged, with a comprehensive selection of saloons and limousines, and Austin Healey sports cars will be shown. There will be no other changes in the B.M.C. range at present, though the Morris Oxford "all-steel" four-door Traveller can be seen on stand 155. This model is priced at £998 17s. and was introduced in August this year. An addition to the Riley range will be the new small 14-litre car, but this will not be shown at Earls Court, the release date being early in November. On the Allard stand there will be a new Gran Turismo model on the Palm Beach tubular chassis, for which a Jaguar 2.4, 3.4-litre or Ford Consul Zephyr engine may be specified. A drop-head coupé Alvis with Graber body will grace stand 135, together with a standard model 3-litre saloon. The new coupé is at present available only for export markets, but as production increases it will be made available for buyers in this country also. On the Aston Martin stand can be seen a new model designated the DB mark III; it is similar in appearance to previous models except for a modified radiator grille, but has an entirely new 3-litre engine developed from those fitted to the current Aston Martin racing cars.

Light-car enthusiasts may find that one of the most interesting exhibits is the Fiat 500, the new air-cooled twin-cylinder economy car to come from the Fiat factory at Turin. This can be seen on stand 134 together with other conventional Fiat models. On stand 127 the Meadows "Frisky" can be seen; there will be two models, a "Friskysport" 3-seater open sports model and a saloon with accommodation for two adults and three children.

The Standard Motor Company are introducing a new Ten and also a larger model similar to the Vanguard but at lower cost; both of these will be on stand 146. There will be no change in the Triumph sports cars, which can be seen on stand 168. For those who crave high speeds and an orthodox design a visit to the Porsche stand is a must, for the new 1958 models will be added to the existing fixed-head coupé, drop-head cabriolet, and roadster. The new models will be known as the detachable hardtop and detachable cabriolet, and are designed for the owner who favours an open car but can have the top fitted in a matter of seconds if the weather becomes unfavourable.

As opening day draws nearer more new models will be announced to await, resplendent in multicoloured hues, the admiring glances of many onlookers. With the number of visitors to Earls Court increasing each year, however, would-be purchasers are tending to inspect the cars at leisure in their dealers' showrooms when they become available instead of signing away large sums in the confusion of the exhibition.

IAIN GELLATLY.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Christmas Gifts Fund Appeal

SIR,—I am writing this appeal in the interim period between the resignation of Lord Webb-Johnson and the assumption of office by Sir Henry Tidy, our newly elected president. Although we are now able to give far larger grants than in the past, it is difficult for your readers to realize what extraordinary joy and happiness the Christmas gift brings to our beneficiaries.

I appeal most earnestly to all members of the medical profession to help to bring Christmas cheer into the homes of many of our less fortunate doctors. Please send your contributions marked "Christmas Gifts" to the Secretary, Royal Medical Benevolent Fund, 1, Balliol House, Manor Fields, Putney, London, S.W.15.—I am, etc.,

R. M. HANDFIELD-JONES,
Chairman of the Committee of Management,
Royal Medical Benevolent Fund.

London, S.W.15.

Vaccination Against Influenza

SIR,—When the 1918 pandemic struck Hong Kong I examined the lungs of people picked up dead in the streets, and the picture in all was the same. A sticky exudate crammed with Pfeiffer's bacilli and pneumococci with very large capsules filled the air cells and bronchioles, choking the victims to death. When grown on blood agar the Pfeiffer's bacillus colonies were many times their normal size when growing near a pneumococcus colony. Thus it was the virulent symbiosis between the Pfeiffer's bacillus and pneumococcus that was doing the killing. Presumably the organisms travelling with the virus can be very important in immunization. There was a definite Pfeiffer's bacillus epidemic. This organism was very rare before the epidemic, was very common in throats during and after the influenza epidemic, and disappeared a few weeks after the epidemic had gone.—I am, etc.,

Salisbury, S. Rhodesia.

C. M. HEANLEY.

Influenza Publicity

SIR,—Unfortunately, the declaration suggested by Dr. G. Fielding (*Journal*, September 28, p. 763) that influenza is "quite harmless, without evidence of serious complications" can be just as damaging as the opposite over-stressing of its seriousness. It raises the problem of coping with a fairly common pattern of behaviour. Some young people maintain a light-hearted view of illness, influenza especially. There is a protective quality in such an approach, until it becomes a pathological self-sufficient contempt for outside influences. One undesirable side-effect of this attitude is the aggravation of illness by refusal to recognize it, a stubborn insistence on continued physical effort after illness has already taken hold of the person. Moreover, when such a person does succumb he is apt to be overcome at one and the same time by the new experience of illness, by the nonsense of his earlier attitude, and by fear of the consequence. Altogether this may amount to panic, and when there is panic it needs to be seen and to be understood. It is unlikely that a visit of less than 20 minutes will help. But, given time and thoroughness, a turning-point in the downhill progress can often be arrived at. There must be many over-worked doctors who would find it difficult, even if they had time and the literary propensity, to express clearly in a few pages all that is required of them, all that they devote themselves to, in the care of their influenza patients. So it is puzzling that any doctor can dispute the necessity for his patients to request his attention for influenza. On the other hand, it is easy to see that through sheer overwork he may be compelled to leave some of them unvisited in an epidemic.—I am, etc.,

Bristol, 8.

AGNES WILKINSON.

Peroxide and Cancer

SIR,—From Dr. R. L. Worrall's letter (*Journal*, August 24, p. 470) it might appear that my experiments using hydrogen peroxide to destroy tumours in rats¹ were carried out as a result of a suggestion made by him.² This is not so. In fact, these experiments were begun long before this, following a study of the catalase-peroxide system in living cells which I have made over the past ten years.

It is pertinent to recall that as long ago as 1928 Magat³ succeeded in curing tumours in mice by using organic peroxides. Dr. Pakenham-Walsh (personal communication) suggested using hydrogen peroxide by local injection in 1932, and in fact succeeded in curing rodent ulcers in 1947.⁴ Dr. Motawei⁵ has for the past three years been using hydrogen peroxide by local infiltration and by intravenous drip with some success and has confirmed Dr. Pakenham-Walsh's findings. Intravenous hydrogen peroxide is being tried in several countries either alone or with agents—e.g., sulphonamides—which inactivate or depress the level of catalase *in vivo*.

The development of energy by oxidation of organic substances involves a chain of reactions many of which are unknown or but poorly understood; however, somewhere in the chain there must be reaction with molecular oxygen and there is clearly an opportunity for hydrogen peroxide to be formed in the ensuing processes. Hydrogen peroxide is formed as a result of many enzymatic reactions, and there seems to be general agreement that it is a metabolite normally produced and destroyed by a wide variety of animal, plant, and bacterial cells. The fact that it is difficult to detect *in vivo* is due to the presence of that very powerful enzyme catalase. One of the main functions of this substance is its so-called catalatic action in converting hydrogen peroxide into water and oxygen. This is the most rapid enzymic-catalysed process known. Catalase also has a peroxidatic action—i.e., catalyses the oxidation of a variety of substances by means of hydrogen peroxide—and many investigators are of the opinion that this function may be more important than the essentially wasteful catalatic action. The peroxidatic action, together with the formation of free radical intermediates, is the probable way in which catalase operates when the hydrogen peroxide is in low concentration, as is usual in most cells. If the hydrogen peroxide concentration rises markedly then the toxic action will be eliminated by the catalatic action.

There can be no doubt from the large volume of work done during the last 64 years on this subject that catalase is very intimately related to the respiratory activity of most living cells. Owing to the almost universal distribution of this enzyme in cells it is not surprising that hydrogen peroxide, which is formed in minute quantities, remained undetected for so long a time, and it is understandable that this was first done with *Streptococcus pneumoniae*—i.e., bacteria devoid of catalase.⁶⁻⁸ Following on this fundamental observation McLeod and Gordon⁹ suggested a scheme of bacterial classification based on the catalase content of the cells and their degree of sensitivity to hydrogen peroxide, and postulated that the strict anaerobic bacteria which are almost all devoid of catalase die in the presence of oxygen, first demonstrated by Pasteur,¹⁰ because they produce hydrogen peroxide, which is lethal to them. A great deal of experimental evidence has been produced in support of this, culminating in the actual detection of hydrogen peroxide in oxygenated cultures of certain anaerobes.^{11,12} Hydrogen peroxide has also been detected in some moulds¹³ and this also appears to explain the action of penicillin B.¹⁴ The probability of hydrogen peroxide production in animal tissues, notably spermatozoa, also deficient in catalase was suggested by MacLeod,¹⁵ and this was later shown to be the case.^{16,17}

It is clear, therefore, that living cells deficient in catalase will produce hydrogen peroxide which may be lethal to them and which can be detected. All other cells possessing adequate amounts of catalase probably produce hydrogen peroxide in larger amounts, but this is rapidly destroyed or used to oxidize various substrates. Indeed, it is more than likely that there is a specific catalase-peroxide balance for each type of cell, whether bacterial, plant, or animal. If this balance is interfered with, either by diminution of the catalase content or by exposure to increasing amounts of hydrogen peroxide, then death or abnormality may occur.^{18,19}

The normal level of catalase in different tissues must be a very important factor in connexion with tumours in man and animals. If it is found that there is a definite catalase-peroxide threshold for different tissues in different individuals,²⁰ this may well predetermine the effects of carcinogenic agents and also will

markedly influence the effectiveness of hydrogen peroxide (or free radicals) or agents which inhibit catalase, or combinations of both, in the treatment of similar tumours in different persons. Indeed, it has already been shown that there is a wide range in the catalase index values of erythrocytes in normal individuals and animals.^{21, 22} This has a direct bearing on the so-called threshold in man for the effects of fission products from test explosions of atomic weapons.

The successful treatment of cancer by way of this mechanism, valuable and attractive though it may be to man, is dealing only with the end of a chain of events which started with the initiation of the change-over from normal to malignant, and, in any case, hydrogen peroxide should theoretically behave like many other anti-cancer agents and itself be carcinogenic. A far more important aspect of this work and a far greater problem is the control of the factors in the life of man which predispose to cancer. All physical and chemical agents which, either by irradiation, ingestion, injection, or inhalation, cumulatively decrease the concentration of catalase or increase the production of hydrogen peroxide (or free radicals) undoubtedly will predispose to tumour formation. We know and we are now aware of the dangers of ionizing radiations in this respect not only from bombardment in the field of medicine but also in the field of war. There has been much interest recently in connexion with the rise in the incidence of cancer of the lung. If this is due to the action of carcinogens on the cells lining the respiratory passages, it is clear that here where the oxygen concentration is at its highest there is the best chance for interference with the catalase-peroxide system, and it may well be that the apparent lack of an increase in the incidence of tumours in the upper respiratory tract is related to the fact that most of the epithelial cells in this region are protected by an overlying layer of bacteria, many of which are strongly catalase-positive.

There can be no doubt that the catalase-peroxide system is of the greatest fundamental importance in all living cells, and provides us not only with the key to the cause, treatment, and prevention of cancer but also opens up the attack on many other diseases, as rightly pointed out by Puig.²³ A detailed discussion of this mechanism in relation to neoplasia will be found in the proceedings of the recent International Symposium at Trieste.²⁴—I am, etc.,

Placentography in Management of Placenta Praevia

SIR,—We were delighted that at least two readers had been stimulated by our article (*Journal*, August 31, p. 490). Along with Mr. W. G. Mills (*Journal*, September 14, p. 641) we readily deprecate any unnecessary caesarean sections, however perfect the surgical technique. The decision as to the method of delivery can be indicated by clinical and radiological investigations, and, though the portion of placenta over the internal os is infarcted and does not bleed (which is so much the better), the remainder of the placenta will

obviously be occupying the lower segment of the uterus and lead to a high free presenting part and/or unstable presentation. Radiological investigation would then have been indicated and would have confirmed the diagnosis of a major degree of placenta praevia. The rare problem of a succenturiate lobe near the internal os, raised by Dr. P. J. Olney (p. 641), must be accepted as a possible hazard, but these are usually small and the presenting part would not be displaced. In the practical management of cases of placenta praevia the relationship of the presenting part to the brim of the pelvis is of greater importance than the relationship of the edge of the placenta to the internal os.

We do look for local sources of antepartum haemorrhage, and with greater confidence if we already know there is a normally sited placenta. Placentography has been shown to be extremely accurate in all the series so far in revealing upper segment placentae. In the usual conservative management of these cases a gentle speculum examination is carried out a few days after the cessation of vaginal bleeding.

Though we have not yet encountered the rare carcinoma of the cervix as a source of antepartum haemorrhage, we shall continue on the alert for it. But one of us (H. B. W.) has experienced torrential haemorrhage on three occasions when gently palpating at an examination under anaesthesia in cases of antepartum haemorrhage, and in the few seconds taken to change one's gloves and proceed with the caesarean section a considerable quantity of blood was lost, with consequent danger to mother and child. We believe that the approach outlined in our paper will help to avoid this in the future and afford greater safety to the mother and foetus.—We are, etc.,

M. ISRAELSKI.

HAROLD B. WATSON.

Birmingham.

Homoeopathy

SIR,—Dr. T. D. Ross in his letter on homoeopathy (*Journal*, September 28, p. 764) states that it is a matter of regret that so many eminent teachers of medicine to-day dismiss homoeopathy with some scoffing remark at infinitesimal doses. He also maintains that to get students and young doctors to look into the subject is extremely difficult, because their minds have been already closed to it by the *ipse dixit* of high authority.

My experience as a medical teacher leads me to hold the opposite opinion. I have frequently been asked by students and young research workers for my views on homoeopathy, and I keep a special file of relevant references and reprints which they peruse with very active interest. Their enthusiasm has stimulated me on several occasions over the past 10 years to approach homoeopaths and to ask them to undertake a controlled experiment in order to substantiate some of their claims. I have never felt that I would be short of willing assistants from the medical undergraduate population, or indeed from among my fellow scientists should their specialized knowledge be required. For various reasons, these experiments never took place in spite of very active interest on my part.

However, I am glad to say that, within the past few months, one group of homoeopaths is undertaking some preliminary experiments in co-operation with a few of the young doctors whose minds are not so readily closed by "high authority." The assistance of Dr. Ross in finding other homoeopaths willing to co-operate in simple controlled experiments will be welcomed.—I am, etc.,

Cambridge.

F. W. CAMPBELL.

Psychopaths

SIR,—The problem raised by the failure of the Royal Commission on the law relating to mental illness and mental deficiency to define the term psychopath can be solved in one way only. Eliminate the use of the word by making new definitions for the several types which it covers. The derivation of its roots is made from words which cover almost the whole field of psychiatry. One cannot use a blanket as a pointer.—I am, etc.,

Sydney, Australia.

JOHN A. MCCLUSKIE.

Physique and Mental Illness

SIR,—The ostensible purpose of Dr. S. E. Finlay's first letter (*Journal*, July 20, p. 160) was to inquire for "any satisfactory explanation" of certain differences which he claimed to exist in the relationship between physique and mental illness and academic performance at Leeds and Oxford. In my reply (*Journal*, August 10, p. 351) I pointed out that the differences he claimed were based on very small samples. In the case of mental illness, the sample of only 71 students contained but three patients with "schizoid personality or schizophrenia." That the much larger number at Oxford contained 40% of mental hospital admissions, but at Oxford contained 40% of mental hospital admissions, many with severe schizophrenic breakdown, led me further to suggest that the selection of Oxford and Leeds samples was not, in any case, comparable. To attempt to compare them directly with a view to testing the notion that physique and mental illness are related in any particular way is pointless. In Dr. Finlay's further letter (*Journal*, September 21, p. 710), still arguing from the same limited data, he simply says he finds it difficult to believe that the difference in selection is the entire explanation. The evidence so far is that Sheldon *et al.*^{1, 2} described the occurrence of hebephrenic schizophrenia in young men of endomorphic-ectomorphic somatotype. The findings, both among students and non-students, reported from Oxford (*Journal*, June 29, p. 1485), together with later studies using separate diagnostic categories, certainly support Sheldon's work in this respect, not to mention earlier descriptions of the physique of schizophrenics which may be found in the literature.—I am, etc.,

R. W. PARNELL.

Oxford.

Hospital Confinement

SIR,—We were amazed to read the letter by Dr. John Frampton (*Journal*, September 14, p. 644). Decent lighting, lithotomy position, sterilized instruments, anaesthesia, local or general, can all be obtained in the patient's home if a little effort is expended (kneeling not excluded). We have found in fourteen years of general practice that "home-made" episiotomies and sutures do excellently at home. What is missing? Only a sister to mop the sweating brow and hand the instruments.—We are, etc.,

JOAN WAGSTAFF.

HELEN WAGSTAFF.

London, E.4.

SIR,—I notice that most of your correspondence on this subject is in favour of home delivery for "normal" cases. Doubtless this is an argument between general practitioners who, in the main, under the N.H.S. have no hospital appointments. We too in Canada found ourselves being gradually excluded from hospitals. There is now, however, a definite trend in the other direction—a trend chiefly promoted by the College of General Practice of Canada. I don't believe there is any argument in Canada on this subject. It is agreed that hospital confinement for all should be the objective. There seems no doubt that the patient and her baby are safer in a hospital environment. What of the doctor? One of your contributors to this discussion cites a necessity for more training for the G.P. obstetrician. We feel that this training is best obtained in the active participation of the G.P. in a hospital. It is there that he can discuss his problems with consultants and watch his betters at work.

I am impressed and heartened to learn in your pages that in the U.K., as in Canada, women are clamouring for hospital admission. In the long run this public enthusiasm will force the provision of the necessary facilities. Only an informed public can exert sufficient pressure to force the provision of hospital beds so desperately needed in Great Britain. My experience two years ago of working in a hospital area in south-west England providing 645 beds for a population of 500,000 was an eye-opener. 2,000 beds for this population

can be considered a minimum in this country. Finally I enclose some statistics.

Year	Live Births	Births in Hospitals	Maternal Mortality	Stillbirths	Neonatal Mortality	Infant Mortality
		Percentage of Births	Rate per 1,000 Live Births	Rate per 1,000 Live Births	Rate per 1,000 Live Births	Rate per 1,000 Live Births
1940	244,316	45.3	4.0	27.2	30	56
1945	288,730	63.2	2.3	23.1	29	51
1950	371,071	76.0	1.1	19.3	24	41
1955	441,681	86.6	0.8	15.6	19	31

These figures were compiled by the Dominion Bureau of Statistics, Ottawa. It will be seen that our figures compare favourably with yours, and that the recent great improvement here parallels the increase in hospital confinement over home confinement.—I am, etc.,

J. H. S. GEGGIE.

Wakefield, Quebec.

SIR,—That 50% of primiparous perineums need suturing is an argument against, not for, hospital confinement. Hospitals harbour sepsis, homes don't.—I am, etc.,

ANDREW SMITH.

Newcastle upon Tyne.

British Medicine Abroad

SIR,—Your leading article (*Journal*, August 3, p. 281) states that British textbooks are falling behind American in sales overseas—e.g., in India. This is certainly not so in Madras as regards medical books, apart from some for which there is no real British equivalent. Not only do three of the British publishing houses have branches here, but the British Council is very influential in this respect. Their library has an excellent medical section which is kept very up to date, and it is to this that my postgraduate students, who are drawn from all over India, appear to turn first, perhaps because its small size makes it easier to use than the university or public libraries. The United States Information Service has nothing comparable to offer, although it may be that the British books being so readily available to borrow makes them more seldom bought.

Business men tell me that the sale of British pharmaceutical products here is increasing, but I would have thought that Swiss and German brands were selling better. Many of these are weird mixtures of drugs apparently thrown together by drawing lots, and British firms would probably find no home sale for such things. As for laboratory equipment, the trade here has been captured almost entirely by the Germans, with a few pockets left for the Americans and Japanese. This is a pity, as not only is there an immense demand for such equipment, but much of the German material is of old-fashioned design and poor workmanship. The retailers have filled their import quotas with such stuff and nothing else is obtainable, with rare exceptions. It is also relatively expensive. A few things are now being made well in India—e.g., autoclaves—but even for these such things as the pressure gauges are imported.—I am, etc.,

Madras, India.

R. E. REWELL.

Sensitization to Tulle Gras Dressing

SIR,—In support of the view recently expressed in your columns by Dr. C. M. Ridley (*Journal*, May 25, p. 1224) and Dr. W. M. Jordan (*Journal*, September 7, p. 591) that balsam of Peru is a harmful ingredient of petroleum jelly gauze dressings, I would like to quote the following 25 cases treated in the medical departments of a large steelworks.

During the period 1950–6 inclusive, 9,140 burns were treated by the following routine—thorough cleansing with 1% cetrimide followed by dressing every five days with a proprietary petroleum jelly gauze dressing; 25 cases (0.27%) exhibited a skin sensitivity with an irritant rash, which was on occasion more troublesome than the original burn. All the cases were patch-tested with both 1% cetrimide and the dressing, and 16 cases were found to be sensitive to

BARBARA C. EDWARDS.

Dr. G. L. ALEXANDER (Bristol, 8) writes: I am at the moment relieving an old friend in his private practice in a West African capital city, on which the Asian 'flu descended on August 29. Whatever it may have been elsewhere, it is not a trivial infection here. One morning a man charged in with what looked like a dead child in his arms, aged about 4. It was not quite dead, but completely comatose and flaccid. Nothing obvious to account for this; it was not like a cerebral malaria. I asked the mother, "Could it have got hold of any sleeping tablets or other narcotics lying around the house?" She swore there was no such possibility. It was passed on to the central hospital. Later in the day I saw the medical specialist, who told me the child had come round quite soon after arrival there. The mother had then admitted that, thinking the child was sickening for the 'flu, she had given it a tablespoon of neat schnapps. It was merely dead drunk. Of course—I should have thought of that. But I still have such an innocent mind.

Obituary

E. L. COLLIS, C.B.E., D.M., M.R.C.P.

Professor E. L. Collis, an authority on the health and welfare of industrial workers, particularly miners, and emeritus professor of preventive medicine in the University of Wales, died in hospital at Forres, Morayshire, on October 1. He was 86 years of age.

Edgar Leigh Collis was born at Stourbridge on November 25, 1870, the son of W. B. Collis, J.P. From Stourbridge Grammar School he went on to Charterhouse, and thence to Keble College, Oxford. A notable sportsman in those days, he was president of the Oxford University Swimming Club and represented the university in athletics against Cambridge in 1892 and 1893, tying for first place in the hurdles in the latter year. After gaining first-class honours in the Natural Science School at Oxford he went to St. Thomas's Hospital for his clinical studies, qualifying in 1896 and graduating B.M., B.Ch. in the following year. He proceeded to the D.M. in 1919, and became M.R.C.P. in 1920. For the first ten years or so of his professional life he was a general practitioner in Stourbridge, where he was certifying factory surgeon and on the staff of the Corbett Hospital. In 1908 he joined the staff of the Home Office as a medical inspector of factories, and soon became a leading authority on pneumoconiosis, the subject of his Milroy lectures in 1915. During the first world war he worked as director of health and welfare at the Ministry of Munitions, and in 1918 was appointed a member of the Industrial Fatigue Research Board. About this time, too, he became a member of the Miners' Welfare Commission, on which he served for over thirty years.

[Barratt's Photo Press, Ltd.]

In 1919 Collis was appointed Talbot Professor of Preventive Medicine at the Welsh National School of Medicine at Cardiff, and in this post he was able to continue his study of pneumoconiosis and to foster plans for improving working conditions in the mines. By this time his reputation as an authority on industrial hygiene was an international one, and besides being Harben lecturer in 1924—his subject being "Phthisis and Industrialism"—he gave a course of lectures at Harvard University in 1926. The author of various Home Office white papers and articles in the *Encyclopaedia Britannica* and medical journals, he was co-author with Professor Major Greenwood of a textbook entitled *Health of Industrial Workers* and was associate editor of the *Journal of Industrial Hygiene and Toxicology*.

Professor Collis retired in 1933 and was made emeritus professor. He went to live in Lossiemouth, Morayshire, where he became a justice of the peace. Appointed C.B.E. in 1937, he was honoured in 1954 by the Society of Apothecaries, which conferred on him the Diploma in Industrial Health, *honoris causa*. He married Barbara Shields, daughter of Principal Fairbairn, of Mansfield College, Oxford, and she survives him.

Dr. THOMAS BEDFORD writes: By the death of Professor Collis we have lost one who took a prominent part in laying the foundations of modern industrial medicine. As one of H.M. Medical Inspectors of Factories he had already made important contributions to the study of the pneumoconioses before war broke out in 1914, and he had also made various investigations on behalf of Home Office departmental committees, including the study of heat stress in hot industries. It was therefore appropriate that, when early in the war the Minister of Munitions set up the Health of Munition Workers Committee, Collis was appointed a member of it, and that later, in 1917, he became Director of Welfare and Health in the Ministry of Munitions. The members of the wartime Committee were convinced of the urgent need for the application of physiological science in industry, and urged that when the war ended provision should be made for continuing studies such as they had initiated. As a result, in 1918 the Industrial Fatigue Research Board was created, and Collis was one of its first members. In that capacity he was able to advise on the organization and direction of research into the physiological and psychological problems of industry.

For about two years, from 1919 to 1921, he was my chief, and thereafter we maintained close touch with each other until some years after he had retired from his chair at Cardiff. I cherish happy memories of that association, for he was kind and considerate, and ever ready to advise a junior worker. A discussion of some problem never failed to bring stimulating suggestions from him, and if there were criticisms they were constructive. Collis's wide knowledge of industry made him a particularly valuable adviser on field investigations, and after a chat with him difficulties always seemed slighter than they had appeared before. He had a strong sense of humour, and a tour of a factory with him could be amusing as well as instructive.

Collis was deeply interested in the human problems of mining and served as a member of the Miners' Welfare Commission from 1921 to 1950. For nearly twenty years he was British editor of the *Journal of Industrial Hygiene and Toxicology*. He never lost his interest in industrial medicine, and in spite of his advanced age he was a regular contributor to the *Bulletin of Hygiene* until the time of his death. During the last war he derived amusement as well as pleasure from his appointment as lieutenant-colonel in the Home Guard when he was about 70 years old. Soon after he was commissioned he was in London attending a meeting of the Miners' Welfare Commission, and he rang me up to exchange greetings. When I asked how he was spending his time he chuckled into the telephone: "Don't tell anybody, but they've made me a colonel." His passing will bring deep regret to all those who are fortunate enough to have known him.

RUTH BENSUSAN-BUTT, M.D.

Dr. Ruth Bensusan-Butt, who practised for many years in Colchester, died there on September 18, aged 80. With her death the Colchester district has lost a well-loved figure in both its medical and municipal life. She was the town's first woman doctor; she was probably also the first woman in the town to drive a car and the first to take an active part in local government.

Ruth Bensusan was born in Annerley, Surrey, on May 9, 1877. Her family moved to Upper Norwood when she was still a child, and the latter part of her education was at the Sydenham High School. Later she matriculated from the Tutorial College, Holborn, and went on to the London School of Medicine for Women, where she passed the second M.B. in 1900. She then studied in Zurich, Dublin, Newcastle, and at the Royal Free Hospital in London, graduating M.B. in 1904 and B.S. in 1905. After working as a locumtenent for a time and holding some posts as an assistant, she became house-surgeon at the Children's Hospital, Derby, in 1906. Then followed three years of general practice in Rome, in partnership with her lifelong friend, Dr. Mary Taylor. She proceeded to the degree of M.D. in 1908. In 1910 she married Mr. G. C. Butt, who bought an accountancy practice later that year in Colchester, where Dr. Bensusan-Butt put up her plate and in due course built up a large practice.

J. N. F. writes: Many of the immense changes that have taken place during Dr. Bensusan-Butt's professional life,

both medical and social, were the result of the work of women like her. She was an untiring supporter of the Labour Party, and throughout her life as a successful G.P. she never ceased to do all she could do to improve the living and working conditions, as well as cure the illnesses, of those who brought her their troubles. Many amenities which the people of Colchester now take for granted owe their initiation to her efforts; notable among these is the Maternity Hospital opened as a Borough Maternity Home in 1932. She served on the local board of guardians from 1912 to 1930, and on the borough council from 1922 to 1952, being elected an alderman in 1945. She was an active and enthusiastic member of the Colchester Medical Society, of which she was a past president, of the Medical Women's Federation, the Socialist Medical Society, the Colchester branch of the Inner Wheel (of which she was founder president), the Business and Professional Women's Club, the Mile End Townswomen's Guild, and of the B.M.A. (apart from a period after her resignation in protest against the Association's attitude to Lloyd George's National Health Insurance Bill). Although she retired from all except a very small part of her practice in 1954, she never lost interest in any of these organizations until the time of her death, and she never ceased professional work altogether until her final illness.

All who knew her will remember her with affection; her greatest characteristic was her seemingly inexhaustible fund of disinterested kindness. She was never out of temper or (apparently) tired; and many hundreds of people will have happy memories of her beautiful house and garden, in which, however busy she was, she frequently found time to entertain her innumerable friends of all kinds and ages. She leaves two sons and a daughter, who is in medical practice as a psychiatrist.

Dr. M. E. CUMMING, M.B., Ch.B., F.R.F.P.S., D.P.H.

Dr. Edward M. E. Cumming, one of the best-known general practitioners in the western district of Glasgow for the past 34 years, died suddenly on September 26 aged 65.

Edward Mitchell Erskine Cumming was born at Bishopston, Renfrewshire, on April 13, 1892, and was educated at Whitehill and Glasgow University, graduating M.B., Ch.B. in 1918. Three years later he took the D.P.H., and in 1922 he was elected a Fellow of the Royal Faculty of Physicians and Surgeons. Before this he had been a demonstrator under Sir William Macewen at Glasgow Western Infirmary and house-surgeon and house-physician at Glasgow Royal Infirmary. On his return from service in the R.A.M.C. in Italy, where he worked for a time under Sir Ronald Ross, he became a member of the staff at the Bellahouston Hospital of the Ministry of Pensions: his association with this Ministry remained unbroken for nearly forty years, and as chairman of boards he rendered valuable service, his opinions being appreciated equally by pensioners and staff. In 1923 he joined the partnership of the late Dr. Farquhar Gracie and of Dr. Hector M. Calder in Partick and district. Among the appointments held by him was that of certifying factory surgeon, and he was a member of National Service medical boards. In addition, for a number of years he was a member of the local panel and medical committees. The Partick Medical Society found in him a wise counsellor. ever ready to welcome and advise younger colleagues. A very hard-working doctor, ever jealous of the dignity and honour of his calling, he carried in his daily rounds the practice of his Christian principles into the homes of his patients, by whom he was deeply loved. For the past 25 years he had been an elder in Wellington Church. For relaxation, he enjoyed all aspects of country life and found great pleasure in his Perthshire garden amongst the hills.

Dr. Cumming married Dr. Rita M. L. Couper, who survives him, together with a son and two daughters: his son and one daughter are medical students and his other daughter is a teacher. Those who were privileged to be his

colleagues deeply regret his passing and extend to his widow and family their heartfelt sympathy.—H. M. C.

R. J. P. writes: For over one-third of a century Edward Cumming in a large and successful general practice maintained unchanged the fine characteristics that impressed themselves on his fellow students at college and his colleagues in the Army and in hospital—tremendous energy, abounding zest and joy of living, coupled with straightforwardness and a deep personal religious faith. He was one of the most sociable of men. After the first world war he may have had thoughts of continuing hospital work, but he took his D.P.H. and then considered the field of public health. In the end, however, he chose general practice, which better suited his individualistic, self-reliant, and vigorous temperament. Highly regarded by his fellow practitioners and consultants alike, as well as by those he came across in the industrial field, his work bore the stamp of the real clinician, and he enjoyed to an unusual degree the confidence, esteem, and affection of his numerous patients and a wide circle of friends. He passed away when his powers were still undiminished and his reputation as a doctor at its height, for, although years were rolling on, there was little evidence of his slacking off. But he was attacked by the prevalent influenza, and, burdened by the added load imposed by the current epidemic, succumbed with unexpected suddenness after only a few days. All who knew him will say there has passed away one of the outstanding exemplars of the family doctor as we would wish him to be.

Cumming was happy and fortunate in his family life. He married Margharita Couper, who had been a fellow resident with him in Glasgow Royal Infirmary, and their home in Glasgow was always a place of welcome. When he could find time, he took great delight in retreating to their highland cottage on the banks of the river Dochart in Perthshire, where he found the peace and quiet that refresh and reinvigorate.

M. D. STAUNTON, M.B., B.Ch.

Dr. M. D. Staunton died suddenly at his home at Swinford, Co. Mayo, on September 2 at the age of 69.

Michael Douglas Staunton was born at Swinford on June 8, 1888. He studied medicine at the Catholic University Medical School and at the Mater Hospital, Dublin, qualifying L.A.H. in 1911. In the following year he obtained the degrees of M.B., B.Ch. of the National University of Ireland. On qualifying he was appointed dispensary doctor at Swinford, and held the appointment continuously up to the time of his death. He is survived by his widow and six children: all his children have entered the medical profession.

FERRIS N. SMITH, M.D., F.A.C.S.

Mr. J. POTTER writes: I was sorry to learn of the death of Dr. Ferris Smith, and I should like to add some words of appreciation to those of Sir Harold Gillies (*Journal*, September 28, p. 768). I shall always remember my visit to see Dr. Ferris Smith at Grand Rapids. He made every effort to make my visit worth while, and had collected a large number of cases for operation and follow-up of his multiple excision work during my visit. I was thus able to see cases that he had described in his writings and examine them personally. His great aim in life was that of perfection. With this aim in view he spent the last years of his life in constant improvement of his multiple-excision technique. He told me of his great appreciation of Sir Harold Gillies for his help when he worked with him at Sidcup during the first world war. Like Sir Harold, he had a pioneer spirit in launching out new techniques, with the aim of perfecting plastic surgery. Besides his work he had many hobbies. He showed me examples of his woodwork, the magnificent furniture that he had made. As a gardener he had completed a lot of experimental work with fruit trees at his country home. It is tragic that Mrs. Smith died whilst nursing him during his last illness. They were

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending September 21 (No. 38) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

† Includes primary and influenza pneumonia.
§ Includes puerperal pyrexia.

Medical News

National Heart Hospital Centenary.—Guests at the Centenary Festival Dinner of the National Heart Hospital, held at the Apothecaries' Hall on October 2, had the privilege of sharing in what was primarily in the nature of a family gathering happily celebrating an event of which it was justly proud. At the same time, none could be unaware that it was also an occasion of great significance in the world of medicine. The story of the growth of this now internationally famous hospital was told in our pages recently (*Journal*, June 29, p. 1528), and many of the past and present members of the board of governors, and the medical, nursing, administrative, and technical staffs who had shared in the making of its more recent history, were present at the dinner, over which Mr. J. M. Oakey, chairman of the hospital, presided. Notable among them was Captain ROBERT WHITNEY, for 45 years secretary of the hospital, who was presented with a gold cigarette-case as a token of esteem from the past and present governors and medical staff. The guest of honour was Mr. IAIN MACLEOD, M.P., Minister of Labour and National Service, who was accompanied by Mrs. Macleod, to whom Mr. Oakey extended a special welcome in proposing the Minister's health. The toast of the hospital was proposed by Captain WHITNEY and that of the medical, administrative, nursing, and technical staffs by Sir WILLIAM ARBUTHNOT LANE, Bt. Dr. MAURICE CAMPBELL replied. All the speakers referred to the outstanding and urgent need for extending the hospital accommodation to provide facilities for modern surgical treatment of heart disease. Sir CHARLES HAMBRO proposed the toast of the guests, for whom Sir HAROLD BOLDERO and Sir JAMES PATERSON ROSS, P.R.C.S., replied.

Middlesex Hospital Medical School.—Dr. H. L. MARRIOTT was chairman at the annual dinner held at the Savoy Hotel on October 4. Proposing the toast of the Middlesex Hospital and Medical School, he reviewed the activities of the past year, mentioning particularly the success of the exchange scheme with Toronto. Looking further back, he spoke of the extraordinary developments that had taken place during the years he had been at the Middlesex, but he attributed the reputation of the hospital among patients to two simple things—kindness of the nurses and excellence of the food. Professor B. W. WINDEYER, dean of the Medical School, responding to the toast, said that they were turning down eight applicants for admission to the school for every one accepted: last year they had had 737 applicants for 80 places. He thought the heavy medical curriculum took its toll on the mental freshness of too many students, and the G.M.C.'s recommended revisions were therefore to be welcomed. The Clinical Research Institute was one of the school's most important activities, and a grant of £11,000 made by the Wellcome Foundation would be used to enlarge its capacity. Professor Windeyer then described the progress of the scheme to rebuild the Medical School, and announced that Lord Astor of Hever had made a further gift of £50,000 towards the cost of this. It was impossible to estimate the debt they owed to Lord Astor, Professor Windeyer continued, for his generosity had been unbounded. The new grant would bring them nearer to achieving the projected Astor College, a hall of residence for 150 students. Dr. G. J. R. MCHARDY, senior Broderip scholar, also spoke in reply to the toast, and Professor A. KEKWICK proposed the chairman's health.

Research in the Antarctic.—An Anglo-American physiological expedition is expected to leave for the Antarctic next month to study human acclimatization to cold. They will be taking part in Operation Deep Freeze II of the International Geophysical Year. In spite of the common belief that one grows accustomed to cold, very little objective evidence for this has so far been found. Studies have hitherto been hampered by lack of methods for measuring

metabolism and body temperature continuously over periods of days at a time. Dr. L. G. PUGH and Major J. M. ADAM, R.A.M.C., will carry out studies of this nature on themselves and members of other expeditions already in the Antarctic. They will use apparatus developed by Mr. H. S. WOLFF at the Medical Research Council's division of human physiology. Samples of blood plasma will also be collected for lipid analysis. In winter the blood and tissue lipids of hibernating animals have a lower melting point than in summer owing to their fatty acids becoming more unsaturated. The results of Dr. J. E. LOVELOCK's preliminary investigations of the blood lipids of persons exposed to intense cold during the recent British North Greenland expedition suggest that similar changes occur in man. Further, changes have been found in the fatty acid composition of the plasma lipids of patients with coronary disease similar to those observed in the winter during the Greenland expedition.

Common Cold Vaccine.—Dr. H. W. PRICE, the trial of whose vaccine against a "common cold" infection was reported last month in America (*Journal*, September 28, p. 773), writes as follows: "I feel these results have received much more publicity than they warranted. While I do feel that the J.H. virus is a true cold virus and is a promising lead in the attack on the common cold, it is only an opening wedge in the solution of this problem. It should certainly be emphasized that this vaccine is no cure-all for the common cold. It should also be emphasized that, although 30% of the colds we studied over a two-year period were due to the J.H. virus, we still need to learn much more about the natural history of this agent over a longer period of time before we can evaluate its importance in causing a large percentage of common colds." The J.H. virus and its relationship to the common cold was discussed in an annotation last week (*Journal*, October 5, p. 813).

International Hospital Federation.—The Federation has accepted an invitation from Mr. J. S. MACLAY, Secretary of State for Scotland, to hold its eleventh congress in Edinburgh in 1959. The congress, which will probably take place in June, will provide an occasion for people interested in hospitals in the various countries represented in the Federation to meet each other and exchange information and views. The Federation's membership is drawn from nearly all the countries in the world except the Iron Curtain countries. Its main objects are to foster the international exchange of information on hospital work and practice, to promote hospital study tours and conferences, and to conduct research on hospital matters.

Changes in Welfare Foods.—The issue of free orange juice to children over the age of 2 years is to cease from November 1, and the vitamin-D content of national dried milk and welfare cod-liver oil is being reduced. This milk and welfare cod-liver oil is being reduced. This accords with recommendations of the Joint Subcommittee on Welfare Foods (*Journal*, August 3, p. 284). Manufacturers of proprietary dried milks and infant cereals have also been asked to adopt the levels of fortification recommended by the Subcommittee. The vitamin-D content of national dried milk is being reduced from a minimum of 280 international units per dry ounce (28 g.) to an average of 100 i.u., that of welfare cod-liver oil from 200 to 100 i.u. per gramme.

Radioactive Lamb.—English lamb sold for consumption has been found to have a higher radioactivity than New Zealand lamb, according to the annual report of the scientific adviser to the London County Council for 1956. The report concludes that pastures in New Zealand have been less affected by fission debris than in Great Britain. The material was present in small amounts relative to the radioisotopes natural to the animal, and was mainly in the bone.

Broadmoor Institution.—Dr. P. G. McGRATH has been appointed medical superintendent at Broadmoor Institution, in succession to the late Dr. S. G. James, who died earlier this year. Dr. McGrath, who is 41, was previously deputy physician superintendent at Glengall Mental Hospital, Ayr.

Dr. A. Buchanan Barbour, D.M.S. of British European Airways, has been appointed to the medical committee of the International Air Transport Association for a period of two years.

COMING EVENTS

University College Hospital Medical School.—Post-graduate demonstrations, October 17 and 18. Annual dinner, October 18, at the Savoy Hotel; spouses invited. Details from the secretary, Old Students' Association, University College Hospital Medical School, University Street, London, W.C.1.

Royal Eye Hospital.—October 22, at 3.30 p.m., at Southwark Cathedral, a Thanksgiving Service to commemorate the Centenary Year. The Bishop of London will preach.

Glasgow University Club, London.—Annual dinner, November 7, 7 for 7.30 p.m., at the Trocadero Restaurant, London, W.1. Details from Dr. J. F. HEGGIE, Department of Pathology, North Middlesex Hospital, London, N.18.

Mental Deficiency.—The National Association for Mental Health will hold a conference on "The Challenge of Mental Deficiency" on November 7-8, to be opened by the Minister of Health. Full details from the association at 39, Queen Anne Street, London, W.1.

St. Thomas's Hospital.—Old Students' Dinner, November 8, at 7 for 7.30 p.m., at the Royal College of Surgeons, London. Details from Mr. A. P. C. BACON, St. Thomas's Hospital Medical School, London, S.E.1.

Royal Society of Tropical Medicine and Hygiene.—A banquet to celebrate the Society's golden jubilee will be held in the Hall of the Royal College of Surgeons of England on November 12. PRINCE PHILIP has graciously consented to honour the Society by his presence.

NEW ISSUES

British Journal of Pharmacology and Chemotherapy.—The new issue (Vol. 12, No. 3) is now available. The contents include:

- THE DISTRIBUTION OF ACETYLCHOLINE IN THE MALAYAN JACK-FRUIT PLANT, *ARTOCARPUS INTIGRA*. R. C. Y. Lin.
- THE EFFECT OF DINITROPHENOL, HYPOXAEMIA AND ISCHAEMIA ON THE PHOSPHORUS COMPOUNDS OF THE DOG HEART. G. Fawaz, E. S. Hawa, and B. Tutunji.
- THE MECHANISM OF DINITROPHENOL HEART FAILURE. G. Fawaz and B. Tutunji.
- THE EFFECT OF DIURETICS ON THE WATER EXCRETION OF PROTEIN DEFICIENT RATS. K. E. Blackmore and H. Schniedner.
- THE METABOLISM OF EXOGENOUS AND ENDOGENOUS ANTIDIURETIC HORMONE IN THE KIDNEY AND LIVER IN VIVO. H. Heller and S. M. A. Zaidi.
- THE EFFECT OF INHALATION OF 30% CARBON DIOXIDE ON THE PERIPHERAL CIRCULATION OF THE HUMAN SUBJECT. L. McArdie, I. C. Roddie, J. T. Shepherd, and R. F. Whelan.
- THE BLOCKING ACTION OF CHOLINE 2:6-XYLYL ETHER BROMIDE ON ADRENERGIC NERVES. K. A. Exley.
- EFFECTS OF CHOLINE 2:6-XYLYL ETHER BROMIDE UPON THE SUPRARENAL MEDULLA OF THE RAT. R. E. Coupland and K. A. Exley.
- SOME ACTIONS OF SUBSTITUTED CHOLINE PHENYL ETHERS, PARTICULARLY OF CHOLINE 2:6-XYLYL ETHER. N. D. Edgc, D. F. J. Mason, and J. H. Wyllie.
- THE ENZYMIC HYDROLYSIS OF IMIDAZOLEACRYLYLOLCHOLINE (MUREXINE) AND IMIDAZOLEPROPYLOLCHOLINE (DIHYDROMUREXINE) BY VARIOUS CHOLINESTERASES. M. E. Grellis and I. I. A. Tabachnick.
- TWO KINDS OF TRYPTAMINE RECEPTOR. J. H. Gaddum and Z. P. Picarelli.
- THE ACTION OF SUBSTANCES ANALOGOUS TO DIAMINODIPHENOXYALKANES AGAINST SCHISTOSOMA MANSONI. J. H. Gorvin, C. G. Raison, W. Solomon, O. D. Standen, and L. P. Walls.
- THE EFFECT OF CARRIER STRONTIUM ON THE ABSORPTION OF ORAL DOSES OF RADIOACTIVE STRONTIUM IN RATS. G. E. Harrison, H. G. Jones, and A. Sutton.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Sunday, October 13

COLLEGE OF GENERAL PRACTITIONERS: NORTH-WEST ENGLAND FACULTY.—At Preston Royal Infirmary, 2.30 p.m., annual general meeting. 5 p.m., first annual Pfizer lecture by Professor W. I. C. Morris: Brotherly Love.

Monday, October 14

DURHAM UNIVERSITY.—At Lecture Theatre, Royal Victoria Infirmary, Newcastle upon Tyne, 5.15 p.m., Professor Erik Stromgren (Denmark): Psychogenic Psychosis. ● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. G. B. Dowling: clinical demonstration. INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Mr. V. C. Thompson: clinical demonstration. INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., clinical lecture by Mr. N. Asherson: Otosclerosis. INSTITUTE OF NEUROLOGY.—5 p.m., film by Dr. Andre Thomas: Neurological Examination and Reaction of the Newborn Babe and Young Infant. Commentary by Dr. Susan Autgaerden. KENT AND CANTERBURY HOSPITAL.—8 p.m., clinical meeting. LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5 p.m., Heath Clark Lecture by Professor G. R. Hargreaves: Psychiatry and the Public Health—(1) Psychiatry and its Origins. (b) At University College, 5.30 p.m., special university lecture in psychology by Professor A. R. Luria (Moscow): Role of Speech in Normal and Abnormal Behaviour.

Tuesday, October 15

INSTITUTE OF CARDIOLOGY.—At Barnes Hall, Royal Society of Medicine, 5 p.m., St. Cyles Lecture by Dr. A. Rae Gilchrist: Clinical Aspects of High Grade Heart Block. INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. P. J. Hare: Sweat Production and Anomalies. LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5 p.m., Heath Clark Lecture by Professor G. R. Hargreaves: Psychiatry and the Public Health—(2) Psychiatry and Society. MANCHESTER REGIONAL DERMATOLOGICAL ASSOCIATION.—At Clinical Sciences Building, York Place, 8.30 p.m., in conjunction with North-west England Faculty of College of General Practitioners. Lectures for general practitioners. Dr. J. Curry: Parasitic Diseases of the Skin; Dr. J. G. Coburn: Tumours of the Skin. ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Dr. F. Dudley Hart: Spondylitis. ST. MARY'S HOSPITAL MEDICAL SCHOOL (WRIGHT-FLEMING INSTITUTE THEATRE).—5 p.m., Professor J. Chassar Moir: Sir James Y. Simpson, A Battle Against Bigotry. SOCIETY FOR THE STUDY OF ADDICTION.—At Medical Society of London, 8 p.m., Dr. P. B. Bradley, Ph.D.: Studies on the Effects of Drugs on the Electrical Activity of the Brain and on Behaviour. WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. T. Rowland Hill: Neurological demonstration.

Wednesday, October 16

BRITISH MEDICAL STUDENTS' ASSOCIATION (LONDON REGION).—At Chemistry Theatre, University College, W.C., 5.30 and 7.30 p.m., films: (1) Children of Hiroshima; (2) Shadow of Hiroshima. DURHAM UNIVERSITY.—At No. 1 Lecture Theatre, Medical School, 5.15 p.m., Professor Erik Stromgren (Denmark): Planning of the Psychiatric Services in Denmark (2). HARVEIAN SOCIETY OF LONDON.—At 11, Chandos Street, W., 8.15 p.m., some contributions from several overseas visitors. INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Dermis and Subcutaneous Tissue. INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. N. Lloyd Rusby: Presenting Manifestations of Intrathoracic Cancer. ● INSTITUTE FOR THE STUDY AND TREATMENT OF DELINQUENCY.—At St. George's Institute, 7.30 p.m., Miss Norah Gibbs, M.A.: Psychological Aspects of Adolescence. INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Dr. W. N. Mascoll: Gonococcal Urethritis. LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5 p.m., Heath Clark Lecture by Professor G. R. Hargreaves: Psychiatry and the Public Health—(3) Psychiatry and Medical Administration. MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 8.15 p.m., annual dinner. POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. J. D. N. Nabarro: Diabetes and Carbohydrate Metabolism (1). ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—3 p.m., Professor D. M. Dunlop: Surgery of the Diabetic. WILLESDEN GENERAL HOSPITAL MEDICAL SOCIETY.—At Department of Physical Medicine, 8.45 p.m., Dr. Richard Asher: Face Values.

Thursday, October 17

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Beveridge Hall, Senate House, W.C., 5.30 p.m., Dr. Julian Huxley, D.Sc., F.R.S.: Some Biological Aspects of Cancer. ● HUNTERIAN SOCIETY.—At Medical Society of London, 6 to 8 p.m., annual party. HYPNOTHERAPY GROUP.—At Royal Society of Medicine, 8 p.m., discussion to be opened by Dr. Nevil Leyton, Dr. Gerald Slot, and Dr. Denys Kelsey: Migraine. INSTITUTE OF PSYCHIATRY.—At Maudsley Hospital, 3 p.m., Dr. W. H. Thorpe, F.R.S.: Drive and Instinct in Animals. LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5 p.m., Heath Clark Lecture by Professor G. R. Hargreaves: Psychiatry and the Public Health—(4) Psychiatry and the Family Doctor. MANCHESTER MEDICAL SOCIETY: SECTION OF ANAESTHETICS.—At Staff House, Manchester University, 7.45 for 8 p.m., presidential address by Dr. Margaret O'Grady: Reviewing the Past with Regard to the Changing Hazards. NORTH-EAST LONDON CLINICAL SOCIETY.—At Prince of Wales's General Hospital, Tottenham, N., 2.30 p.m., meeting. ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—7.30 p.m., presidential address by Brigadier J. S. K. Boyd, F.R.S.: Dysentery: Some Personal Experiences and Observations. ROYAL STATISTICAL SOCIETY: STUDY SECTION.—At Library Room, Bristol University, 5.45 p.m., Dr. J. Knowlenden: Assessment of Therapeutic and Prophylactic Procedures. SCIENTIFIC FILM ASSOCIATION.—At Mezzanine Cinema, Shell-Mex House, Strand, W.C., 6.30 p.m., meeting jointly with Royal Medico-Psychological Association. Program of Psychiatric Films from France.

Friday, October 18

DURHAM UNIVERSITY.—At No. 1 Lecture Theatre, Medical School, 5.15 p.m., Professor Erik Stromgren (Denmark): Psychogenic Psychosis. ● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. G. B. Dowling: clinical demonstration. INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Mr. V. C. Thompson: clinical demonstration. INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., clinical lecture by Mr. N. Asherson: Otosclerosis. INSTITUTE OF NEUROLOGY.—5 p.m., film by Dr. Andre Thomas: Neurological Examination and Reaction of the Newborn Babe and Young Infant. Commentary by Dr. Susan Autgaerden. KENT AND CANTERBURY HOSPITAL.—8 p.m., clinical meeting. LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5 p.m., Heath Clark Lecture by Professor G. R. Hargreaves: Psychiatry and the Public Health—(5) Psychiatry and Public Health Practice. POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Dr. R. A. Shooter: Control of Staphylococcal Cross Infection. ROYAL MEDICAL SOCIETY, EDINBURGH.—8 p.m., dissertation by Mr. J. A. Gray: Bronchogenic Carcinoma.

Saturday, October 19

BIOCHEMICAL SOCIETY.—At Physiology Lecture Theatre, Guy's Hospital: Medical School, S.E., 2 p.m., 366th meeting. INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—11.30 a.m., Dr. Chevalier L. Jackson: Thyrotomy and Partial Laryngectomy. SOUTH-EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY.—At Farnborough Hospital, Farnborough, Kent, 10.30 for 11 a.m., (1) Dr. George Brownlee: Host Resistance in Tuberculosis; (2) Dr. D. G. Madigan: Results of Treatment of Tuberculosis with Corticosteroids. (3) Film: Dynamics of the Tubercle. WEST MIDLANDS PHYSICIANS ASSOCIATION.—At Birmingham General Hospital, 11 a.m., autumn meeting.

Sunday, October 20

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—12.30 p.m., seminar for general practitioners by Mr. Anthony Radcliffe: Common Ear, Nose, and Throat Conditions. MANCHESTER UNIVERSITY: FACULTY OF MEDICINE.—At Theatre 1, Clinical Sciences Building, York Place, 11 a.m., in conjunction with North-west England Faculty of College of General Practitioners. Lecture demonstration for general practitioners. Professor C. Fraser Brockington and Dr. J. M. Greenwood: Old Age.

APPOINTMENTS

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—E. R. F. Mellon, M.D., D.P.H., D.P.M., Consultant Psychiatrist, St. Andrew's Hospital, Norwich; C. D. Linton, M.B., Ch.B., D.Obst.R.C.O.G., D.A., Senior Anaesthetic Registrar, Norfolk and Norwich Area; W. M. E. Tweed, M.D., F.R.C.S., D.Obst.R.C.O.G., Registrar in Obstetrics and Gynaecology, East Suffolk and Ipswich Hospital Group; A. G. Kirk, M.R.C.S., L.R.C.P., Registrar in Psychiatry, St. Andrew's Hospital, Norwich.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Cooper.—On September 22, 1957, at the Oakville-Trafalgar Memorial Hospital, Ontario, Canada, to Elizabeth (formerly Kirk), wife of Dr. Michael A. Cooper, a son. Primrose.—On September 30, 1957, at Thorpe Combe Maternity Hospital, Walthamstow, London, to Dr. John and Mrs. Margaret Primrose, of 22, Castle Avenue, London, E., a daughter—Mary.

DEATHS

Berndt.—On September 20, 1957, Siegfried Fritz Berndt, M.D., of Borrowdale, Regent Road, Loston, Bolton, Lancs, aged 62. Brown.—On September 20, 1957, Evelyn Kempson Brown, M.R.C.S., L.R.C.P., late of Cranbourne, Dorset, and Ludham, Norfolk. Cooke.—On September 16, 1957, at Horsham Hospital, Sussex, Clement Cooke, M.D., aged 64. Geany.—On September 26, 1957, John Joseph Geany, M.B., B.Ch., of Rosemount, Ashton-under-Lyne, Lancs, and 439, Mill Street, Bradford, Manchester, aged 59. Gilroy.—On September 26, 1957, at Cadenham Grange, Cadnam, Hants, Ernest William Gilroy, M.D., late of Hemel Hempstead, Herts, aged 81. Graham.—On September 25, 1957, at Bournemouth, Hants, Joseph Graham, M.C., M.B., Ch.B., late of Kirk Hospital, near Doncaster, Yorks. Harris.—On September 15, 1957, Frederic Rosenberg Harris, T.D., M.R.C.S., L.R.C.P., Lieutenant-Colonel, R.A.M.C., T.A., retired, of 2, Upton Park, Slough, Bucks. Ingle.—On September 29, 1957, Charles Durban Ingle, M.R.C.S., L.R.C.P., of Somerton, Somerset. Maxwell.—On September 9, 1957, at Eaton Socon, Beds, the result of a car accident, John Smart Maxwell, M.B., F.R.C.S.Ed., of 46, North Bar Without, Beverley, Yorks. Reid.—On September 23, 1957, Alan Raeburn Reid, M.B., Ch.B., of 31, Downs Road, Clapton, London, E. Staunton.—On September 2, 1957, at his home, Swinford, Co. Mayo, Michael Douglas Staunton, M.B., B.Ch. Tamplin.—On September 16, 1957, at Portsmouth, Hants, Edward Cowper Tamplin, M.C., F.R.C.S.Ed., D.L.O. Tempny.—On September 25, 1957, Edward Tempny, M.B., B.Ch., of The Red Lodge, Oakwood Lane, Leeds, Yorks. Vaughan.—On September 18, 1957, at Devoran, Cornwall, Richard Greenville Vaughan, M.R.C.S., L.R.C.P. Walker.—On September 13, 1957, at the Royal East Sussex Hospital, John Walker, M.C., L.R.C.P.&S.Ed., L.R.F.P.S., of 23, Edmund Road, Hastings, Sussex, aged 64. Walker.—On September 28, 1957, at The White House, Constantine Bay, Padstow, Cornwall, William Percival Walker, M.B., Surgeon Commander, R.N. (retired). Winkfield.—On September 12, 1957, at Les Blanc Bois, Guernsey, C.I., William Bertram Winkfield, M.R.C.S., L.R.C.P., Lieutenant-Colonel, R.A.M.C., retired, aged 85.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Influenza and Pregnancy

Q.—It used to be taught that influenza was a serious cause of abortion, and that, in addition to the general effect of a high temperature, the toxin of the disease stimulated uterine contractions. Is this still thought to be so? If so, would it be wise to attempt to immunize pregnant women against Asian influenza, or is there any danger that the immunizing agent might itself cause the damage that one was seeking to avoid?

A.—The teaching in question was probably based on observations made during the 1918–19 epidemics of influenza. Statistics collected at that time are still quoted in nearly all the larger textbooks on obstetrics. These go to show that the mortality amongst pregnant women was at least double that amongst non-pregnant women, and reached a figure as high as 50% in those cases where the disease was complicated by streptococcal pneumonia. Abortion and premature labour occurred in approximately 25% of cases, and in 50% if pneumonia supervened. Evacuation of the uterus was more likely in late than in early pregnancy and was itself associated with a higher maternal death rate. The foetal mortality was between 20 and 40%, being mostly caused by prematurity. Sometimes, however, the foetus died in utero (especially during labour) and this was variously ascribed to (i) maternal pyrexia, (ii) anoxia, (iii) absorption of toxins, or even transfer of the infection across the placenta. A few writers commented that the labour was often rapid and relatively painless, but I can find no reference to this being the result of the action of the toxin on uterine muscle. As a guess, it is more likely to have been related to a state of anoxia; a similar phenomenon is still seen in cases of severe heart disease, for example.

Prior to the severe epidemics mentioned, the general view was that the ordinary mild influenza had no special effect on pregnancy or labour, and this has been the experience since. Moreover, although it has been looked for, there is no evidence that influenza as it ordinarily occurs causes foetal malformation when contracted in the early weeks of pregnancy. Since in the present epidemic the influenza appears to be of a mild form, there seem no good grounds for fearing that it will have any materially adverse effect on pregnant women. Even in the 1918–19 epidemics the ill effects were mostly confined to those cases complicated by secondary streptococcal infection of the lungs—for which at that time there was no efficient therapy such as we have to-day.

Vaccination against influenza is not likely to be harmful to a pregnant woman, but, since its value is uncertain and any protection afforded does not reach a maximum until at least one month after the first injection, there do not as yet appear to be any special indications for attempting to apply it to pregnant women.

Pega Palo

Q.—What is known about a plant called pega palo, which grows, I understand, in the West Indies? Has it any medical value?

A.—The plant referred to is *Boerhavia scandens* L. (*Commicarpus scandens* L. (Standley)) which has the common name of pega pollo in Puerto Rico.¹ It belongs to the family Nyctaginaceae, which includes the more widely known plants bougainvillea and *Mirabilis jalapa*.

Boerhavia scandens occurs in the West Indies as far south as Antigua, Curaçao, the Bahamas, and continental America from Arizona to Peru. It grows up to 4 ft. (1.2 m.) tall and is somewhat shrubby, with the stems erect, scrambling,

or climbing. "Leaves cordate to ovate, usually entire; flowers in umbels with long pedicels, yellowish or whitish-green; fruit oblong, rough with papillae, longitudinally 10-striate, glutinous with glands near the apex secreting a viscid fluid."² The Spanish word *pega*=glue, *pollo*=pullet, *palo*=stick; "glue-stick" would be a suitable common name for the plant in fruit, and it may be that pega palo is more correct than pega pollo.

In Jamaica³ the plant is called "rat ears" and "easy-to-bruck." It is used as a home remedy for the treatment of colds and "is also considered to be an excellent treatment for marasmus in children." In Africa and India⁴ other species of *Boerhavia* (notably *B. diffusa* L.) are considered useful "bush medicine," and infusions are used as "emetics, cathartics, diuretics, febrifuges, vermifuges, expectorants; astringents in the treatment of dysentery, gonorrhoea and wounds; and as valuable in the treatment of asthma and dropsy."

Chemically the family as a whole is little known, but the *Boerhavia* species are said to contain a little-studied alkaloid, punarnavine C₁₇H₂₃ON₂.⁴ The plant does not have any medicinal value which is recognized by the medical profession. It is consequently used only for home remedies in the countries where it grows; here it is freshly gathered and infused with hot water.

Emotion and Cardiac Infarction

Q.—What part does emotional upset play in the long-term aetiology and the precipitation of cardiac infarction? What is known of the mechanism of such effects?

A.—There is no clear evidence that emotional upset plays any part in the aetiology of cardiac infarction. The increase in death rate from coronary disease is probably real and not only due to increased awareness of the disease and improved diagnosis, and the concurrence of this increase with new conditions of stress has led some authorities into the belief that there is a cause-and-effect relationship; however, it is probable that many other variables are involved, including perhaps a slow change in dietary habits.

The fairly frequent association of an attack of cardiac infarction with preceding emotional tension or a period of special stress seems to indicate that such psychic factors may precipitate an attack, but even this is doubtful.

Physical Exertion and Coitus after Gynaecological Operations

Q.—How soon after gynaecological operations such as hysterectomy, colporrhaphy, and Fothergill's operation may patients drive a car, bicycle, run and jump, and resume coitus?

A.—Opinion in these matters has changed considerably in the last 10 to 15 years, although there may still be some gynaecologists who take a more conservative view than the one expressed below.

After total hysterectomy or a major vaginal procedure such as is mentioned, the patient can sit out of bed for a few minutes on the first day; take a few steps on the second; and thereafter gradually increase her physical activity according to her inclinations and well-being. This is true even for operations such as a repair of a complete perineal tear. Patients naturally vary in their physical and nervous resilience to surgical procedures, but all tire easily for several months and should be warned to rest when necessary and not to try to force the pace. Within the limits of this common-sense advice, they can really undertake anything of which they feel capable after three weeks. At that time they can usually undertake light household duties and within one or two months can safely drive a car or ride a bicycle. The

last activity will depend to some extent on tenderness of any perineal scar. Strenuous activity such as is involved in the playing of certain games and lifting heavy articles should be forbidden for a total of two months from the time of operation.

Coitus can be resumed when the vaginal incisions are completely healed and free from tenderness. These conditions are usually satisfied in six weeks, but it is wise always to examine the patient vaginally (including inspection of the vaginal walls and vault with a good light) before allowing coitus to be resumed. It is important that coitus should not be commenced too soon—otherwise tenderness may lead to vaginismus and permanent dyspareunia. On the other hand, it should not be deferred any longer than necessary, because the patient is usually at an age when climacteric atrophy is likely and contracture of the vagina is prevented only by regular coitus.

Diarrhoea after Short-circuiting Operation

Q.—A patient of 40 has a long-standing ileo-colic anastomosis (lower end of ileum to transverse colon near the hepatic flexure) performed to relieve intestinal obstruction after perforation of the appendix. Since the operation he has suffered intermittently from diarrhoea and finds this rather a nuisance. Recent barium enema examination and sigmoidoscopy reveal no cause for the diarrhoea. What is the probable cause of the attacks of diarrhoea, and what treatment is recommended?

A.—Though not specifically stated, it may be presumed that the ileo-colic anastomosis was side-to-side, thus short-circuiting and isolating a loop of bowel. Steatorrhoea is a not infrequent sequel to this situation, owing, it is thought, to an altered bacterial flora causing abnormal fatty acids to be formed and thus interfering with normal fat absorption. The isolated loop must be replaced in circuit by taking down the anastomosis, and the attacks of diarrhoea will then cease.

Placental Implants for Ocular Conditions

Q.—Is there any good evidence that placental implants have any value in the treatment of eye conditions? Claims are made for such treatment on the Continent.

A.—Claims for the value of placental implants in the treatment of degenerative affections of the eye are not based on any substantial experimental or clinical evidence. It is perhaps not an exaggeration to say that the method has fallen into disuse after an ephemeral popularity. The use of placental implants is part of the more complex problem of the value of tissue therapy generally, for which again there is no substantial supporting evidence. Much of the work appears to have been based on incidental clinical impressions, and this applies to amnion implantation as much as to other forms of tissue therapy.

Wasp Stings

Q.—A farmer is sensitive to wasp stings, a typical reaction consisting of increasing drowsiness and severe palpitation leading to collapse in about ten minutes; he remains in a stupor for some hours and is not fit again for several days. He is completely insensitive to bee stings. For the last three years he has had long desensitization courses with wasp extract, but complains that the final few doses make him very ill with similar symptoms to a sting. This of course prolongs the course, as the doses have to be adjusted. Can you suggest any alternative treatment that might obviate the need for desensitization?

A.—Ephedrine might be taken as a prophylactic whenever there is a risk of being stung by a wasp. Immediate self-treatment should be isoprenaline sulphate, 20 mg. sublingually, and an antihistaminic. Then, if symptoms progress, subcutaneous adrenaline, slow intravenous aminophylline (if angioneurotic oedema or bronchospasm develops), and finally, if necessary, intravenous hydrocortisone could be given.

Hyposensitization in such cases is advocated and supported by various authorities.¹ It would be wise, however, to avoid doses which make the patient "very ill." If severe symptoms occur the next dose should be reduced to that of the last preceding one to cause no symptoms and subsequent increases should be made much more slowly.

The nature of wasp venom was the subject of a recent annotation.²

Culture of Candida

Q.—What is the most satisfactory medium for the culture of *Candida albicans*? I have seen advertisements for Nickerson's medium for this purpose. What is its constitution and how is it rated?

A.—Sabouraud's medium. The methods of preparing it will be found in any textbook of general bacteriology or mycology which has an adequate technical section. This medium contains an exceptionally large amount (4%) of a fermentable sugar (glucose or maltose) and is of exceptionally acid reaction (pH 5-5.5). Bacteria dislike this degree of acidity exceedingly, but fungi thrive on it: hence apparently pure cultures (or nearly so) of *Candida albicans* can be obtained from material containing many and various bacteria, such as not only mouth and throat swabs but even faeces.

According to its manufacturers, Nickerson's medium is "an acidified sulphite medium containing metallic salts in a nutrient broth base." It has been patented by Dr. Walter J. Nickerson, of the United States, and its formula cannot be disclosed. The claim made for it is that it is completely selective for *Candida*.

Progressive Myopia in a Man of 60

Q.—What are the likely causes of progressive myopia in a man of 60? This year, for the first time, small myopic crescents were observed in the fundi and small black spots floating in the left anterior chamber. His urine and blood pressure are normal, and his only complaint poor vision.

A.—Lens sclerosis is the commonest cause of progressive myopia about the age of 60. This would account for the patient's complaint of poor vision. Forward bulging of the cornea in keratoconus and keratomalacia may also produce curvature myopia associated with irregular astigmatism.

The small crescents of choroidal atrophy or recession are more likely to be due to atrophic change than to axial myopia, with which they are generally associated in the progressive myopia of young people. The small black spots observed in the left anterior chamber may have been due to a resolving hyphaema or a mild iridocyclitis.

Correction.—In our report of the first annual meeting of the Society of Social Medicine (*Journal*, October 5, p. 818) the final sentence of Dr. ALICE STEWART's reply to Dr. ETHEL DUNCAN should have read: "There was, however, a high incidence of mongolism among the leukaemia cases, but not among those with cancer at other sites." We regret that Dr. R. SUTHERLAND, of the Department of Social Medicine at Leeds, was wrongly given the title of professor. Dr. LILLI STEIN now works at the Maudsley Hospital, not Edinburgh.

AN OUTBREAK OF ENCEPHALOMYELITIS IN THE ROYAL FREE HOSPITAL GROUP, LONDON, IN 1955

BY

THE MEDICAL STAFF OF THE ROYAL FREE HOSPITAL

On July 13, 1955, a resident doctor and a ward sister on the staff of the Royal Free Hospital were admitted to the wards with an obscure illness. By July 25 more than 70 members of the staff were similarly affected, and it was plain that there was in the hospital an epidemic of a highly infectious character, producing amongst other things manifestations in the central nervous system. Because of the threat to the health of patients, and because of the large number of nurses involved, the hospital was closed on that date and remained closed until October 5. By this time the epidemic was almost over, although sporadic cases appeared up to November 24.

Between July 13 and November 24 292 members of the medical, nursing, auxiliary medical, ancillary, and administrative staff were affected by the illness, and of these 255 were admitted to hospital; 37 were nursed at home or admitted to other hospitals from their homes. It is remarkable that, although the hospital was full at the onset of the epidemic, only 12 of the patients who were already there developed the disease.

The course of the outbreak by admissions is shown in Fig. 1, and the location of the different establishments involved is shown in the Map (Fig. 2). When the epidemic began there was free intercommunication between various communities in the group, and in particular between the Royal Free parent hospital in Gray's Inn Road and its branch hospitals at Lawn Road and Liverpool Road. There were numerous opportunities for cross-infection. Both before, during, and after the epidemic in the group, the medical staff saw a number of similar cases occurring sporadically in North-west London. Eight such cases have been described (Ramsay and O'Sullivan, 1956).

Establishments shown in the accompanying Map are: Royal Free Hospital, Gray's Inn Road; North-western Branch, Lawn Road, Hampstead; Liverpool Road Branch, Liverpool Road; Nurses' Annexe; Royal Free Hospital Medical School; Nurses' Preliminary Training School; Hampstead General Hospital; Elizabeth Garrett Anderson Hospital; Elizabeth Garrett Anderson Maternity Home; Eastman Dental Hospital.

Clinical Manifestations

The clinical picture has been drawn from observations on 200 of the cases admitted to hospital, in which the diagnosis seemed certain and the records complete.

Few instances of single isolated exposure were found among the cases which occurred in the hospital staff, but there were a number of cases among the relatives and friends of staff who had paid single visits to one of the hospitals. There were also several instances of either

husbands or wives of staff who contracted the disease in their homes. The sum of their evidence suggests that the incubation period was seven days or less and five to six days for the majority.

The disease when fully developed showed features of a generalized infection with involvement of the lympho-

FIG. 1.—Graph showing dates of admission.

reticular system and widespread involvement of the central nervous system. It varied from case to case, both in its content of symptoms and signs and the speed with which it evolved. Inevitably, in the course of a severe epidemic where the slightest departure from health is viewed with suspicion, mistakes in early diagnosis were made. However, experience was gained rapidly, and certain symptoms occurring early in the illness were soon realized to be characteristic.

The initial manifestations in the 200 cases are recorded in Table I. The earliest symptoms were usually malaise and headache, frequently associated with disproportionate depression and emotional lability. Early

symptoms fluctuated markedly, often disappearing for a day or two, only to recur more severely. A mild sore throat was also usual. Headache, frontal or occipital, though often transient, was sometimes persistent and

occasionally severe. Nausea, with anorexia, was frequent. Transient abdominal pain, vomiting, and diarrhoea were far less common.

The symptoms so far described are common to the prodromal phase of most infections, but the intensity of the malaise, particularly when related to the slight pyrexia in this disorder, requires emphasis.

Within the first week of the disease usually all the characteristic symptoms had appeared. Occasionally all the symptoms were present from the very beginning. In a few, however, the fully developed picture did not develop until the second or third week. This consisted of pain in the neck, back, or limbs, and of "dizziness." The pain was out of all proportion to the general constitutional disturbance and was sometimes present when fever was absent. It was usually confined to one limb, one side of the body, or to both legs, and, as with other symptoms, pain exhibited marked changes in intensity from day to day. Pain below both subcostal margins was common. At times the severity of these pains was such as to require the strongest analgesics for their control.

FIG. 2.—Map showing location of the different establishments.

Dizziness, usually meaning a transient feeling of imbalance on sudden movement but in about an eighth of the cases a true vertigo, characterized the disease early in its course. Sometimes this vertigo was very marked, being readily induced by slight movement of head or eyes.

A clear division of symptoms into those appearing early and late is not possible; in some cases objective neurological manifestations, usually more characteristic

of the second and subsequent weeks of the disease, were seen in the first week of the illness.

In those in which no neurological manifestations were present, physical abnormalities in other systems were few. Abnormal signs other than those in the central nervous system are shown in Table II.

Pyrexia rarely exceeded 100° F. (37.4° C.), and there was only a slight tachycardia. The pharynx was usually mildly injected, but in a few cases there was more marked involvement with vesiculation. In almost all cases superficial lymph nodes were enlarged and tender, and the tenderness was often extreme. The commonest group to be involved was the posterior cervical. The liver was enlarged in just under a tenth of the cases, but no instance of unequivocal splenic enlargement was encountered.

During the second and third weeks many of the patients became more severely ill. In addition to the intensification of the earlier symptoms, particularly of the pain, vertigo, and prostration, other neurological symptoms and signs developed. Of the cases, 148 (74%) showed objective evidence of affection of the central nervous system, and the neurological manifestations formed a characteristic picture that distinguishes this disease from other infections of the nervous system.

Frequently the patients complained of hypersomnia, of nightmares, and of panic states, and sometimes of uncontrollable weeping. In addition to neck rigidity, photophobia was also sometimes seen. Frequently an amnesia developed for these symptoms. Even when the clinical picture seemed fully established there was the same fluctuation in the day-to-day intensity of the symptoms, as in the earlier stages.

Table III indicates the incidence of involvement of the cranial nerves.

The fundi and visual fields were not affected, but transient blurring of near vision, probably due to ciliary weakness, was encountered. Pupils were sometimes unequal, and might be defective in reactions to light and accommodation. External ophthalmoplegia was common, usually affecting one or both sixth nerves and occasionally the third nerve. Total external ophthalmoplegia with ptosis occurred in one patient.

Paraesthesiae or pain with sensory impairment in a trigeminal distribution was present in 6 patients. Facial palsy occurred in just under a fifth of the cases, and was occasionally bilateral, when it was associated with other

brain-stem manifestations. Vertigo, already mentioned as an early symptom, sometimes persisted and occasionally became very severe. It might be associated with tinnitus or perceptive nerve deafness, and fine nystagmus was frequently present. Bulbar palsy occurred in 11 patients; two of these required tube-feeding. Respiration was never impaired to such a degree as to require assistance.

The limbs and trunk were involved in almost all the cases in which there was invasion of the nervous system (Table IV).

TABLE IV.—Incidence of Motor and Sensory Signs in Limbs and Trunk (148 Cases)

	Cases	%
Limbs and trunk	144	97
Abnormal tendon reflexes	112	76
Motor weakness	102	69
Sensory disturbances	82	55
Muscle spasm	18	12
Myoclonus	5	3.4
Micturition disturbances	39	26

Motor weakness was more common than sensory disturbances. Initially paresis was accompanied by slight hypotonia, and might be associated with severe and prolonged painful muscle spasms. These spasms often occurred in limbs in which objective sensory disturbance was marked. The slightest attempt at active or passive movement often invoked extreme pain. The usual initial distribution of weakness was hemiplegic, or less commonly monoplegic or paraplegic, but later the remaining limbs were often affected to some degree. Loss of power in the affected limbs was more marked distally than proximally, and in some the paralysis might be complete. Weakness occasionally showed a segmental distribution, predominantly in the upper limbs. The tendon jerks were preserved; early on they tended to be sluggish, but in established cases they were slightly exaggerated. In only two cases were frank extensor plantar responses encountered; an absent or equivocal response was common in the disease. Wasting of muscle was exceptional, but was well marked in the tongue and thenar eminence of one severely affected nurse, and in the muscles below the knee in another.

Sometimes early on, but more commonly during recovery from weakness, a peculiar jerking could be observed in a limb on voluntary movement. This is considered to be a distinctive and characteristic feature of the nervous involvement in this form of encephalomyelitis.

Irritative phenomena observed in addition to spasm were fasciculation of muscle and myoclonic movements, which all became more prominent when the patient was disturbed by physical examination or nursing treatment. Bladder dysfunction occurred in about a quarter of the patients. This consisted of difficulty in initiation of micturition, and sometimes resulted in retention, requiring tidal drainage for a few days.

Spontaneous pain was the commonest sensory manifestation, and has already been mentioned, but its part

in the clinical picture cannot be overemphasized. It was usually felt diffusely throughout a weak limb, and was associated with marked muscle tenderness. The pain was sometimes of segmental distribution in the upper limb, or frequently involved the lower thoracic and upper abdominal segments as in Bornholm disease. In such cases there was extreme tenderness in the subcostal regions, and attempts at palpation might evoke resentment due to pain. It was sometimes difficult to decide whether such pain was of visceral or muscular origin. Numbness and coarse tinglings were other sensory symptoms which occurred chiefly in the limbs. Objective sensory loss was usually maximal peripherally, and its distribution frequently coincided with the motor weakness. Cutaneous sensory loss was more prominent than loss of joint sense and vibration sense, but hemianaesthesia for all forms of sensation occurred in a number of patients with a hemiplegia, though the face usually escaped. Radicular sensory loss was sometimes found in the upper limbs. Cutaneous hyperaesthesia or hyperpathia was common and severe, and might be associated with sensory loss to the same limb. In no case was an ataxia of cerebellar type seen.

The clinical impression was that this disease produced a diffuse disorder of the nervous system with a combination of irritative and paralytic signs, which were frequently transient. Weakness of a hemiplegic distribution suggested an upper motor neurone dysfunction, but, as is not uncommon in encephalomyelitis considered to be of virus origin, the reflex changes were slight and prone to fluctuation. Even in patients with paralytic picture, reminiscent of vascular lesions, did not take place. In two patients with paraplegia reduction of reflexes has persisted.

It was thought that the disturbance of function of the lower motor neurone was irritative rather than destructive; peripheral nerve reflex conduction measurements were normal.

Course of the Disease

The course of the disease has been most variable. The mildest cases which showed no evidence of invasion of the nervous system became symptom-free within a month and the patients were able to return to work. On the other hand, in others the illness was more protracted, its duration depending largely on the severity and extent of the nervous manifestations.

Table V indicates the duration of hospital in-patient treatment.

TABLE V.—Duration of Hospital In-patient Treatment

2-3 "	15	7.5
3+ "	14	7

Throughout the foregoing account of the clinical manifestations of the disease emphasis has been placed upon the tendency for day-to-day variation in the intensity of symptoms and signs. Long-term observation of cases showed a similar variation. There might be periods of two weeks in which the symptoms were mild and fever had disappeared. Such periods were often followed by marked recrudescence of old symptoms and sometimes the appearance of fresh neurological manifestations. In such relapses further fever and tender enlargement of glands occurred. Relapses occurred in some cases after patients had been fit enough

to return to their homes or had been transferred to convalescent homes. The protracted illness, with a large element of doubt in the mind of the victim as to the ultimate prognosis, naturally engendered considerable anxiety and depression. Functional manifestations in a few cases overlaid the organic picture, particularly in those cases longest in hospital.

In the large majority of cases recovery of neurological function has been complete, but it has been a slow process. Extreme fatigue and general aches and pains have made the rehabilitation period extremely tedious and long. Even after a six-weeks period of convalescence, which was soon found to be necessary in those who were in bed for more than a month, these patients, with the best will in the world, were often able to work for only four hours a day, and minor residual symptoms are still very common. In four cases marked disability is still present at the time of this report. One nurse, whose right hand was paralysed from the onset, has now developed cogwheel rigidity with choreo-athetoid movement in the same arm when voluntary movement is attempted in that arm. Two nurses need leg callipers to aid their weakened lower limbs in walking, and the fourth, who showed some wasting of both lower limbs, still needs crutches.

Complications

One patient developed jaundice: clinically and biochemically the findings were similar to those in infective hepatitis. Three other patients who had slight enlargement of the liver, but not jaundice, also showed some biochemical evidence of hepatitis.

Other complications were few and were not considered to be directly related to the disease. A small outbreak of streptococcal sore throat affected a group of nurses. Two patients developed the clinical picture of inhalation pneumonia. Urinary infection developed in certain of the patients with retention of urine. This infection responded to treatment.

Psychiatric Aspects

Many of the patients suffered from various psychological symptoms, most of which were of a depressive nature with sometimes a hysterical overlay. All of them cleared up fairly quickly without any special psychological treatment.

Six cases were of a more serious nature. They comprise three severe depressive reactions, one anxiety state, one schizophrenic, and one paraphrenic. There was an additional patient with severe depression who subsequently committed suicide by taking an overdose of "carbrital." The three other cases of depression responded quite well to electric convulsion therapy (E.C.T.) and were treated as in-patients.

The anxiety case was the only patient who was not a member of the hospital group staff, and she was treated as an out-patient, her chief symptoms being vertigo, emotional upset, and anorexia. She responded quite well to treatment and supportive psychotherapy, and was discharged after two months; she had a mild relapse, however, in November, 1956.

The two more serious cases of psychotic manifestation, the schizophrenic and the paraphrenic, had to be certified and committed to a mental hospital. They have now been discharged; one is back at full-time work and is very well, and the other is improved and doing part-time work. In both these cases E.C.T. was given in the mental hospitals.

It is of interest, therefore, that the common denominator in these mental illnesses seems to be one of depression which has reacted quite well to E.C.T.

Another factor which is fairly consistent is the time-lag between the onset of the disease and the onset of these more serious psychological manifestations. This was from two to three months. We do not think it should be said that the disease is in any way a causal agent, but it does appear that with certain individuals the disease has been responsible for precipitating an underlying latent psychosis or psycho-

neurosis. So far as we are aware, there is no evidence of any delinquent behaviour as was seen as a sequel to the cases of encephalitis lethargica after the first world war.

Case Histories

As has already been pointed out, a large number of the cases were extremely mild, and in 52 (26%) no neurological manifestations developed. Such a mild case is the following:

A nurse aged 25 was admitted on July 27, 1955, with seven days' history of headache, sore throat, nausea, and pain in the legs. She also had lassitude, and on the morning of reporting sick felt giddy, and she complained of pain in both subcostal regions, which were tender on palpation. She was afebrile. The throat was slightly inflamed; the tonsillar glands and those in the left posterior triangle, axillary, and inguinal regions were enlarged. Aching pains in the limbs continued. On the fourth day after admission she had a severe headache with pain in the back. By the ninth day she was feeling better and was able to get up. She returned to work five weeks after the onset.

Sixty-six cases showed severe and widespread involvement of the nervous system. Such cases needed a long period in hospital, considerable nursing care, and much encouragement. Such an example was that of a nurse aged 21, among the earliest of our admissions.

This patient was admitted on July 18. She complained of depression for eight days, a slight sore throat for four days, and pain in the neck and feet for two days. On the day of admission she also complained of pains in the back and over the chest. She developed double vision and severe vertigo, and this vertigo was accompanied by nausea. Yet she showed no fever, and, apart from some pharyngitis and slight enlargement of the cervical glands, there was no other abnormality whatsoever. On the following day, however, she began to experience difficulty in micturition. On the fifth day she noticed tingling in all limbs and the temperature rose to 99° F. (37.2° C.), with a pulse of 100. This mild pyrexia continued throughout her illness. She also showed some neck rigidity, but Kernig's sign was negative. There was marked tenderness in the subcostal regions, but the liver was not at that time palpable. The inguinal and axillary glands were tender. There was diplopia on lateral deviation of the eyes to the right and on elevation. The tendon reflexes were increased in the right upper limb only. The abdominal reflexes were absent. There was some weakness of the right leg, and the right knee-jerk was increased, but both ankle-jerks were diminished. At that time the left plantar response was extensor. There was some sensory loss below the right knee. The micturition difficulties increased and tidal drainage had to be instituted for four days. On the tenth day the liver became palpable and tender. During vertigo persisted and the nausea was most distressing. The second week she complained of aching pain in the left arm, and this was accompanied by fasciculation in the muscles of the forearm. At that time a patchy erythema was noticed. In the third week, although there had been some general improvement, a weakness of the left arm and left leg was noticed, with sensory impairment over the whole of the left arm. A period of gradual improvement followed, but five and a half weeks after admission there was a recrudescence of the right-sided weakness.

She was discharged to convalescence at the end of the second month, but a month later she complained of palpitations on exertion and that her left leg remained weak. The tendon jerks were diminished in the left arm, and there was now some weakness of both lower limbs with an increase of the left tendon jerks. She began to do part-time work a few weeks later, and it was six months from the onset of her illness before she was able to engage in full-time work. The increase of tendon jerks in the left lower limbs persisted, and the left plantar response was unobtainable.

Fifteen of the patients showed a hemiplegic distribution, and the following case is an example of the severer group.

A nurse aged 26 was admitted at the height of the epidemic with seven days' history of malaise and frontal headache, with pain in the left lumbar region. The day before admission she experienced attacks of vertigo, bilateral tinnitus, and nausea, with some blurring of vision. There was no fever, but the patient looked ill, complained of photophobia, and showed slight mental inaccessibility. The cervical and inguinal lymph nodes were enlarged, and there was bilateral subcostal tenderness. The day after her admission she became drowsy and complained of double vision: this was due to left external rectus paresis. There was transient hypalgesia of a bilateral trigeminal distribution, and there was also hypalgesia along the distribution of the right fifth

and sixth cervical segments. This was accompanied by tenderness of the muscles of the right arm, and the jerks in that arm were diminished. On the following day the left arm was found to be hypotonic. On the next day, four days after admission, she developed a complete flaccid right-sided hemiplegia, also affecting the lower face on that side. The tendon reflexes became exaggerated and the plantar response was a weak extensor. There was hemi-analgesia, and hemi-anaesthesia for all forms of sensation, but the face was spared. This sensory loss included joint sense as well. Seven days after admission she complained of

FIG. 3.—Photograph of foot in spasm.

Fig. 4.—Photograph of foot in spasm.

with acute dorsiflexion of the foot and digits. The spasm persisted for five weeks but ceased to be painful, so that the patient was able to walk on the affected limb. During the ninth week there was an episode of behaviour disorder with screaming, followed by stupor for 45 minutes. She then improved steadily, and was discharged home five months after the onset, with a right hemiparesis, maximal in the arm, and residual relative hemiparesis with sensory loss of cortical type in the hand. The tendon jerks in the left leg were slightly increased; the left plantar response was a doubtful extensor. She has since returned to full duty, but a slight right hemiparesis with impairment of all forms of sensation in the upper limb, without reflex abnormalities, persists 18 months after her illness.

Sixty-two of the cases showed signs with a predominance within the spinal cord. The following case is such an example:

A nurse, aged 21, was admitted on August 9, complaining of diffuse aches and pains, frontal headache, and a slightly stiff

neck. She had had a sore throat on the previous day. She showed a temperature of 99.2° F. (37.3° C.), pulse 72, and respiration rate 18. She did not look ill. Enlarged tender glands were found in the anterior and posterior triangles of the neck and in the inguinal regions; there was also tenderness in the left subcostal region. Physical examination revealed no other abnormality. Three days later the frontal headache was more severe, and was accompanied by vertigo. On the fifth day she was allowed up to toilet, for she had lost all her symptoms. Next day her headache and vertigo returned, but there were still no abnormal signs in the nervous system. On the seventh day she had severe backache and neck stiffness, and Kernig's sign was positive. There was also tenderness below the right and left subcostal margins, and she experienced difficulty in initiating micturition. The low-grade pyrexia persisted.

Two weeks after admission she developed very severe pain in the arms and complained that they felt heavy. On examination, power in the left arm was much diminished, and the muscles were tender. The left supinator jerk was absent. The legs were slightly hypertonic and the muscles tender. The tendon reflexes were increased, but the plantar responses were flexor. Sensation, except for some transient loss of sensation in the left forearm, was normal. Once more the condition improved, and in the third week she felt reasonably well, although still complaining of slight headache and pains in the lower limbs. Power was still diminished in the left upper limb, and tone in both lower limbs was increased, but the plantar responses were flexor. Fasciculation was noticed in the legs, and myoclonic jerks developed. From day to day there was considerable fluctuation both in power and in reflexes in arms and legs.

In the fourth week difficulty in micturition was more pronounced, but it did respond to carbachol. At this time there was a diminution of sensation to cotton wool from the waist downwards, and postural sense was also impaired. She still complained of muscle pains, although power began to improve. In the fifth week, although her general condition appeared to be fairly good, complete paralysis of the left leg occurred, and tendon reflexes were absent. The weakness of the left arm was still present, and a patchy sensory loss was noted in both arms. From this time there was a general improvement, in spite of minor relapses, until after three months she was fit to be discharged to a convalescent home.

After a month away she was readmitted. She had severe backache and complained that she suffered "cramps" during her stay at the convalescent home. On examination at this time there was again photophobia, the neck muscles were weak, power in the upper limbs was reduced, but the reflexes were brisk and equal. There was patchy anaesthesia over the shoulders and sensory ataxia in both arms. The left leg was held in flexion. There was gross impairment of power on the left; on the right side the movements were a little stronger, but the reflexes were brisk and equal. There was also patchy anaesthesia over the lower limbs. During the second admission there was irregular pyrexia up to 100° F. (37.8° C.) for periods up to five days. Her general condition improved more rapidly than previously, and by the sixth month from the original admission she was able to be mobilized. Lumbar backache continued to be troublesome, but it was possible to discharge her two weeks later.

Management

Rest proved the sheet-anchor in the management of the acute stage. Rest, as absolute as was practicable, was prolonged beyond the febrile period and beyond the stage when the neurological complications had already improved. Attempts to reduce this rest period were always followed by a relapse. The evil effects of premature exertion, even a prolonged neurological examination, became apparent to all.

A confident and, above all, a reassuring attitude on the part of the medical and nursing staff proved of increasing value. This is not surprising when the patients in the main were nurses knowing we were dealing with an unknown disorder.

In the convalescent recovery stages occupational and diversional therapy proved most helpful.

Drug Treatment

The clinical picture did not suggest that antibiotics would be of any value. In a proportion of cases suffering such complications as urinary infections, streptococcal sore

throat, or chest infections, antibiotics were used. No influence on the course of the basic disease could be demonstrated.

Faced with the problem of a seemingly new disease entity caused by an unknown agent, treatment resolved itself into general management, drugs being used solely for the relief of symptoms. All symptoms proved remarkably drug-resistant. Trunk and limb pain, headache, muscle spasm, and vertigo failed to yield to orthodox preparations.

For pain, aspirin and its compounds proved as serviceable as the more potent preparations. Ergotamine tartrate was found to be more helpful when the headache was severe than the customary analgesic drugs. For the vertigo, promethazine and related compounds were also tried, but relief was not constant. Antispasmodic drugs were also used for muscle spasm, but the relief was inconstant.

In a few cases where dysphagia was a complication, tube feeding was instituted, and in a few intravenous therapy had to be resorted to for a short period.

For the commonest urinary problem—that is, difficulty in initiation of micturition with a tendency to retention—carbachol was effective in the big majority, though catheterization with prophylactic chemotherapy was required in some. In two severely affected cases tidal drainage had to be used.

Convalescence

Convalescence was slow. The policy was soon adopted to allow as many weeks convalescent leave as had been spent in the ward. Any attempt to shorten this time was met by a relapse. Nearly all patients confessed that, on leaving hospital, to their surprise they felt very unwell for some time. Some suffered recurrences of limb pain, headache, and physical weakness. On their return all were placed on half duty, but in many the half-duty time had to be extended on account of their persistent ill-health. Even now, many still complain, in addition to weakness and readily induced fatigue, of vertigo, recurrent headache, depression, double vision, and pain in an arm or a leg. This persistence of symptoms long after the infection is over is a notable feature.

Physiotherapy

Physiotherapy was instituted in the acute stages of the disease. This consisted of passive movements to all the joints of the affected limbs, aimed at maintaining full joint range and preventing contractures. Passive movements also had the effect of relieving muscle spasm. Muscle spasm also responded to heat, the most effective form being electric pads or radiant-heat lamps.

After the acute stage had passed, graduated active exercises were begun, but these had to be kept to a minimum to avoid invoking painful muscle spasm and cramps. Excessive activity rapidly produced fatigue. Some patients exhibiting marked neurological signs and persistent muscle spasm were placed in warm baths for their exercises. This proved a most effective measure, as it produced relief of the muscle spasm and thereby facilitated active movements. In the re-education of the weak limbs in some patients orthopaedic appliances were utilized, including long leg and below-knee braces.

Special Investigations

Haematology

A total of 750 blood counts were examined from over 400 confirmed or suspected cases. Analysis of the counts from a selected group of 138 nurses was reviewed by three independent observers; these results are considered to be representative of the patients as a whole.

Haematological changes were not specific. There was a tendency for a low-normal neutrophil count, with a high-normal lymphocyte count, during the first week of the disease. This change was seen in about half the cases. Abnormal lymphocytes of the type described on numerous occasions in a variety of virus diseases (Leibowitz, 1953)

were seen, such as vacuolation of cytoplasm of adult lymphocytes, and the presence of Türk or plasma-cell-like forms with coarsely reticulated nuclei and deeply basophilic cytoplasm. But the changes characteristic of infectious mononucleosis were not found, nor did the white count as a whole correspond with the picture seen in that condition.

In most cases the E.S.R. was normal. In three cases only did it exceed 20 mm. in the hour (Westergren). There was no anaemia.

Paul-Bunnell Test

The Paul-Bunnell test for heterophil antibodies with absorption with guinea-pig kidney and ox cells was performed on 121 cases. A total of 250 tests were done. In only four were antibodies of the infectious mononucleosis type present. In two of these cases the unabsorbed, and guinea-pig-kidney absorbed, titres were only 1/40, with a titre of less than 1/20 after ox-cell absorption. In one other case there was an unabsorbed titre of 1/320, 1/160 after guinea-pig-kidney absorption, and 1/40 after ox-cell absorption. In the fourth case there was an unabsorbed serum titre of 1/1,280; after guinea-pig absorption this was 1/640, and after ox-cell absorption less than 1/20. In these four cases repeated tests were done, and no change in titre occurred. It is justifiable to assume that these four positive results are possibly due to residual antibodies after a previous infection.

Chemical Pathology

Flocculation Reactions.—No abnormality in the thymol and colloidal-gold reactions was found in the sera of 119 patients. The sera of three patients who had slightly enlarged and tender livers gave weak positive reactions. One patient who developed jaundice at the height of this condition had a serum bilirubin of 9.5 mg. per 100 ml., thymol turbidity of 24, colloidal gold of 4; and alkaline phosphatase of 10 K.-A. units per 100 ml.

The Electrocardiogram

Routine electrocardiograms were recorded in a random sample of 42 patients.

Thirty-nine patients had no significant abnormality in their records. In seven of them, either there was complaint of palpitations or tachycardia had been noted, but in only one record was the rate above 84 a minute, and in this patient there was a sinus tachycardia of 115 a minute.

Three patients had abnormal electrocardiograms. In two there were abnormal T waves in two or more leads, and in one the Q-T interval was prolonged. Only one of these patients complained of palpitations, and in no instance was a tachycardia recorded. Two of these patients now have entirely normal records. The third, whose initial record showed isoelectric T waves in lead I and inverted T waves in lead V₃, still had an abnormal electrocardiogram eighteen months after the onset of her disease. The most recent record shows improvement, however, in that the T waves in leads I and V₃ are upright, though of low voltage. This patient still has extensive neurological abnormalities.

Prolongation of the Q-T interval and T wave abnormalities may be evidence of biochemical as well as histological changes in cardiac muscle. Only one of the three patients with abnormal records was among the more seriously ill nurses.

Electrodiagnostic Investigations

Electrodiagnostic investigations were carried out on 28 cases (Richardson, 1956). All the 28 cases referred for these investigations showed marked motor involvement. A few were examined in the early stages. The majority were examined on a single occasion between one and two months after the onset of the disease. Five with severe and prolonged motor involvement were examined at intervals for 12 months.

Nerve-muscle Excitability Measurements.—These were determined by the plotting of strength-duration (I/T) curves

of the involved muscles. With the exception of isolated muscles in one case, which showed incomplete denervation, none of the muscles tested showed any evidence of lower motor neurone degeneration. Nerve-conduction measurements were all within normal limits.

Electromyography.—Electromyography in the early stages of the disease occasionally showed some irregularly occurring fasciculation potentials of normal motor-unit-potential form. The myoclonic spasms were recorded as bursts of asynchronous motor-unit potentials. With the onset of paralysis the most important sign was abnormality in the recruitment of the motor units. Thus, in normal willed muscle contraction, the motor units begin activity one by one, each joining the discharge at rates of up to 20–30 a second, separately and asynchronously, but building up into an interference

FIG. 5.—Recording from severely involved tibialis anterior muscle on maximal sustained volition.

FIG. 6.—Recordings with concentric needle electrode and maximal sustained volition. A, From weak tibialis anterior muscle. B, From normal contralateral tibialis anterior muscle. Calibration 50 cycles. 300 microvolts.

pattern. Further, small motor-unit potentials initiate the contraction, and only with an intense effort or on fatigue are large motor-unit potentials normally recorded. In contrast, the affected muscles in this disease showed a severe reduction in the number of motor-unit potentials on volition, and some were of long duration and polyphasic (Fig. 5). Further, in the less severely involved, and particularly during recovery, the motor-unit potentials were grouped (Fig. 6). The result of this grouping was a tremulous contraction with a frequency of 5–10 a second which rapidly fatigued. The combination of a severe volitional disturbance with retention of nerve conduction, without signs of lower motor neurone degeneration but with a reduction in the number of motor units on volition and its occasional initiation by large polyphasic potentials, is suggestive of a so-called myelopathic lesion (Bauwens, 1955). This term is used to describe involvement of the motor unit at the level of the cord, a finding common to vascular lesions of the cord, anterior poliomyelitis, and other conditions. However, prolonged paralysis from these lesions is usually accompanied by signs of lower motor neurone degeneration. The peculiar grouping of motor-unit potentials has not been described in them or any other myelopathic lesions. Its origin remains obscure.

Histopathological Material

No specific changes were observed in the very limited material available for histological examination. This consisted of a small lymph node, excised two weeks after the onset of the disease, which showed well-marked reactive hyperplasia of non-specific type; and post-mortem tissue from a further two patients, both of whom had died from other causes several months after attacks of the epidemic disease.

In one of these fatal cases post-mortem examination showed an ovarian carcinoma with multiple metastases and a terminal clostridial peritonitis and septicaemia. Microscopical examination of the brain, spinal cord, and peri-

pheral nerves showed no abnormality except for that attributable to either the septicaemia or carcinomatosis.

The second fatality, due to acute "carbital" poisoning, occurred in a woman, aged 32, who had the epidemic disease seven months before death, and who had had definite clinical evidence of organic disease of the central nervous system for the last seven months of her life. In her case it was considered on clinical grounds that she had disseminated sclerosis as well as the epidemic disease. Post-mortem examination revealed small circumscribed grey or yellowish plaques in the white matter of the cerebral hemispheres, mainly paraventricular in distribution, in the brain stem and in the spinal cord, particularly in the cervical segment.

Microscopical examination showed multiple small well or fairly well demarcated areas of demyelination with associated microglial and astrocytic proliferation and a variable degree of gliosis. There was no evidence of primary neuronal damage, and no viral cell-inclusions were seen. Occasional cellular foci composed of lymphocytes and cerebral histiocytes, mainly perivascular in distribution, were present in the leptomeninges overlying the brain, but this was not a marked feature except in one section taken from the hypothalamus which showed intense perivascular cuffing.

The distribution and character of the lesions in the central nervous system, with the exception of the changes in the hypothalamus, were typical of disseminated sclerosis, and a histological diagnosis of disseminated sclerosis in a fairly early phase was made. The lesion in the hypothalamus in this case may represent the effects of a superadded viral encephalitis, but such an explanation is conjectural, and it is more probable that the intense perivascular cuffing represents an unusual but not unknown reaction associated with disseminated sclerosis.

Other Investigations

In 16 patients radiographic examination of the chest showed no hilar-lymph-node enlargement. The cerebrospinal fluid was examined in 18 cases, and no abnormalities were discovered.

Estimations of the serum cholinesterase in seven cases were normal. The electrophoretic patterns also showed no abnormality in any of these sera. Cholinesterase was 1.0 μ l./ml./min. (normal) in a cerebrospinal fluid examined during a severe relapse.

Epidemiology

Sex, Age, and Occupation.—The case incidence in relation to sex, age, residence, and occupation is shown in Table VI. Residence in hospital and occupational risk (nursing) are factors which contributed to a high case incidence. A comparison of the number of times that nurses were in personal contact with other nurses, as opposed to other members of the staff, showed that the chances of exposure were at least 4:1. Since nurses form about half of the average hospital population the high case incidence did not necessarily indicate that nurses as a group of young women were peculiarly susceptible to the infection.

Mode of Spread.—The explosive character of the outbreak suggested the possibility that the infective agent was disseminated through a common vehicle, but investigations relating to water, milk, food, food handlers, and launderers were negative. There is at present no evidence that the infection was spread either by arthropods or by animals. In this connexion the possibility of toxic trace chemicals in paints, insecticides, and detergents was also considered.

At present the aetiology of the disease remains unknown, and the mode of transmission has not been elucidated.

Evidence of case-to-case infection accumulated during the epidemic, though individuals were often exposed to infection on two or more occasions.

A detailed report of the epidemiological aspects has been published (Crowley *et al.*, 1957).

TABLE VI.—Attack Rate Among Hospital Workers in Various Categories

Hospital Staff	Population at Risk	No. of Cases	Attack Rate per 100 People
Royal Free Hospital group	3,500	292	8.3
Men	950	27	2.8
Women	2,550	265	10.4
Domicile:			
Non-resident	2,740	128	4.7
Resident	860	164	19.0
" men	20	4	20.0
" women	840	160	19.0
Occupation:			
Nurses	800	149	18.6
Medical and ancillary medical staff in contact with nurses	400	54	13.5
Resident domestic workers	240	33	13.7
Others	2,060	46	2.2
Age:			
18 to 35	—	247	—
over 35	—	45	—

* About one-third of the population is probably 35 or over, and two-thirds are over 18 and under 35.

Studies on the Aetiology

Sera from a number of patients were tested for antibodies to the viruses of influenza A, B, C, psittacosis, A.P.C., herpes simplex, mumps, and louping-ill, and to *Rickettsia burnetii*; and sera from six typical cases with neurological signs were tested against encephalomyocarditis virus, all with negative results. Tests for toxoplasmosis and leptospirosis were also negative.

All attempts at the Virus Reference Laboratory to isolate an agent from specimens of blood, throat washings, and stools collected in the acute stage of the disease have been negative in fertile hen eggs, suckling mice and rats with or without cortisone treatment, adult mice, suckling hamsters and ferrets, guinea-pigs and monkeys with or without cortisone treatment, following intracerebral, intranasal, and intraperitoneal inoculation. Two monkeys also received intraspinal and intrasciatic inoculations. Negative results have also been obtained with the same materials in tissue cultures of HeLa cells (nine experiments), monkey kidney (10 experiments), human embryo brain (2), liver (1), spleen (1), kidney (6), and human infant kidney (3). Experiments are continuing in additional animal species and tissue cultures.

Experiments conducted at the London School of Hygiene with throat washings from cases of the disease suggested that the washings might contain an agent capable of infecting suckling mice and of causing a cytopathic effect in cultures of human amniotic epithelium. The response in neither system was clear-cut, and the results could not be used at the time to discover the nature of the agent or to decide whether it was causally related to the disease in man.

Discussion

A number of outbreaks in recent years of obscure forms of encephalomyelitis have been reported (Lancet, 1956). Those outbreaks which had most features in common with this disease were the epidemics in Iceland in 1948-9 (Sigurdsson *et al.*, 1950), Adelaide in 1949-51 (Pellew, 1951), New York State in 1950 (White and Burtch, 1954), the Middlesex Hospital, London, in 1952 (Acheson, 1954), Coventry in 1953 (Macrae and Galpine, 1954), and Durban, South Africa, in 1955 (Alexander, 1956). A small epidemic recently reported in Berlin in 1954 (Sumner, 1956) does not seem so closely related as those outbreaks already mentioned.

These forms of encephalomyelitis may show a high infectivity in closed populations, particularly among nursing

staff in hospitals; or in schools, as in the Iceland outbreak. Institutional epidemics have usually been associated with a number of cases in the general population, with the exception of the Middlesex Hospital epidemic, during which no similar illness was present in adjacent boroughs. In all the epidemics in which the sex incidence has been reported there has been a female preponderance. The peak incidence of cases has occurred in the summer, with the exception of Icelandic disease. The clinical features described in these outbreaks resemble each other in many aspects of the clinical course, and, although no contact has been traced between these widely separated epidemics, a common infective agent would seem to be the cause.

A prodromal stage of malaise, sore throat, headache, nuchal pain, lassitude, sometimes with gastro-intestinal symptoms, has occurred in every epidemic except in the Icelandic disease, in which headache and malaise occurred but visceral disturbances were absent.

Relapses also have been a common feature, and the course has lasted up to several months except in the Middlesex and Coventry outbreaks, in which the duration of the disease was usually a month and did not exceed two months. Pyrexia has been absent or slight, and when slight has lasted a few days or even several weeks. Paralysis usually appear a few days after the onset of the illness, but may occur simultaneously or be delayed as long as a few weeks. Loss of voluntary power may be severe although disturbances of tone and reflex changes tend to be slight. Muscle tenderness, spasm, and fasciculation are common signs, and sometimes myoclonic jerks may be observed. Wasting of muscle, particularly of the proximal muscles of the upper limbs in Icelandic disease, has been exceptional in other epidemics.

Sensory symptoms consist of pain, which is often severe, and paraesthesiae with objective findings of cutaneous hyperaesthesia or sensory loss and sometimes impairment of postural and vibration sense. Micturition difficulties are not infrequent except in the Iceland outbreak, when they occurred in two patients only. The frequency of involvement of the cranial nerves varies in different epidemics, but ocular pareses, symptoms referable to the eighth nerve, and facial weakness predominate, though bulbar pareses may occur.

In all the United Kingdom epidemics the cerebrospinal fluid has been normal, but a slight pleocytosis was observed in four cases in the Adelaide outbreak and in two cases in the New York State epidemic, and an increase of globulin in the later stages in some of the Durban cases. The Icelandic epidemic differed in that the cerebrospinal fluid which was examined in eight cases showed an increase of cells in five cases and an increase of protein in four. Two of these four had normal cell counts.

The clinical identity of the epidemic of the Royal Free Hospital Group with the Coventry and Durban outbreaks was confirmed by visits from the Medical Superintendent from the Whitley Hospital, Coventry, and by the Neurologist from the Addington Hospital, Durban, who examined our cases and considered that the disorder was the same as they had encountered in their respective outbreaks. Neurologists from the Middlesex Hospital were also impressed by the clinical resemblance of our patients to their series, but were of the opinion that the manifestations of the disorder in the Royal Free Hospital Group outbreak were more severe and prolonged.

The major point of difference between the Royal Free Hospital Group epidemic and other outbreaks has been the prominence of lympho-reticular involvement, although in retrospect enlargement of the cervical glands was found in some of the Durban cases (R. W. S. Cheetham, personal communication, 1955) and also had been observed in two cases at the Middlesex Hospital, and four cases in the New York State epidemic.

One of the most important problems in diagnosis has been the differentiation of this condition from poliomyelitis. The resemblance has been commented on by Macrae and

Galpine (1954) and more recently by Ramsay and O'Sullivan (1956). Initially the Middlesex Hospital outbreak also was thought to be a manifestation of poliomyelitis. Patients exhibiting paralysis after a short prodromal illness in the summer months might well be diagnosed as cases of poliomyelitis, but if the clinical features of this form of encephalomyelitis are familiar the resemblance is superficial. In the early stages vertigo and painful stiff neck are common, and although the posterior cervical muscles are tender, there is usually no true neck rigidity and Kernig's sign is negative. Malaise is disproportionate to the slight or absent fever, which is another distinguishing feature.

At the stage when neurological manifestations have appeared, distinction between this disease and poliomyelitis is not difficult. Sensory manifestations, migrating myalgia, and often fleeting paralyses, more often of an upper motor neurone distribution, distinguish this form of encephalomyelitis from poliomyelitis, in which the sensory manifestations are exceptional and myalgia and motor weakness do not tend to migrate. Motor weakness of a lower motor neurone distribution in poliomyelitis is associated with progressive loss of tendon reflexes, whereas in the present illness, even if paralysis persists and progresses, the reflexes can usually be elicited and may be exaggerated. Poliomyelitis, except in the early stages of infection, shows none of the tendencies of partial remission and subsequent exacerbation which characterize many of the cases described above. The relapsing lympho-reticular manifestations referred to again tend to distinguish the diseases even if the neurological picture proves confusing. The normal cerebrospinal fluid would also differentiate the condition, as in poliomyelitis abnormalities are present in the cerebrospinal fluid in at least 90% of cases.

The presence of a vesicular stomatitis in some patients, combined with painful spasm of the muscles of the trunk, was suggestive of a Coxsackie infection, but the absence of a meningeal reaction in the cerebrospinal fluid, and the failure to identify the causal virus, excluded this diagnosis. The normal cerebrospinal fluid was also evidence against a parenchymatous invasion by other organisms causing a lymphocytic meningitis such as Armstrong and Lillie's virus.

The complaint of sore throat with generalized lymph-node enlargement, leucopenia, and the presence of abnormal lymphocytes led to a diagnosis of infectious mononucleosis being suspected in the early stages of the epidemic. However, the typical blood count did not develop, and the Paul-Bunnell test remained negative in the great majority of cases.

The arthropod-borne encephalitides have not yet caused an epidemic of encephalomyelitis in the United Kingdom. A few sporadic cases of louping-ill due to tick-bites have occurred as an occupational disorder in veterinary surgeons, shepherds, and abattoir workers. Louping-ill as a possible cause of the epidemic of encephalomyelitis under consideration was excluded by serological tests.

A mild form of tick-borne meningo-encephalitis has been endemic in Slovenia for some years, causing epidemics in 1947 and 1953 without deaths, and has been described by Kmet and his colleagues (1955). The disease affected rural workers and caused an acute diphasic illness of short duration with marked meningeal signs and changes in the cerebrospinal fluid. Serological tests by Pond and Russ (1955) have identified the viruses of these epidemics, and of a similar virus meningo-encephalitis in Austria, as members of the tick-borne group. Mosquito-borne forms of virus encephalomyelitis such as Western equine encephalomyelitis produce epidemics in the United States and Canada in districts with surface water due to flooding. There is a case mortality of 8-15%, and the cerebrospinal fluid shows abnormalities. On epidemiological grounds it seems most improbable that any of the arthropod-borne infections have been the cause of this London epidemic.

The question naturally arose whether the Royal Free Hospital Group outbreak was a reappearance of encephalitis lethargica in an epidemic form. Epidemiological features,

cerebrospinal fluid findings, and case mortality are points which distinguish the epidemics. Von Economo (1931) regarded encephalitis lethargica as a disease with maximal incidence in the first quarter of the year, of low infectivity and without any sex predominance. Changes in the cerebrospinal fluid were not uncommon, the case mortality was 40% in the acute stage with 30% resultant invalidism in survivors. The symptom-complexes of encephalitis lethargica described by Walshe (1920) have considerable interest because of their polymorphism, which he attributed to the irritative and paralytic action of the infective agent. Although of a much less severe character, this double action was observed in the neurological manifestations of the Royal Free Hospital Group infection. There has been no mortality attributable to the latter disease, and encephalitic Parkinsonism has not been a feature of it nor of any of the other similar outbreaks mentioned in this review.

A distinctive feature of the cases under consideration has been the peculiar nature of the motor weakness. It has only occasionally resembled a lower motor neurone type. Although often of an upper motor neurone distribution the positive elements of hypertonia classically associated with lesions of the pyramidal tract, though present in a mild degree initially, have not persisted even in the presence of a severe residual hemiplegia or paraplegic weakness. An extensor plantar response has been present as a transient phenomenon indicating disturbance of function of the pyramidal tract, but has not persisted as a frank abnormality of the cutaneous reflexes, and the abdominal reflexes have only been minimally disturbed. Another characteristic feature has been the peculiar jerking quality of volitional movement which was present in the milder cases throughout and was particularly noticeable during recovery from severe weakness. The associated electromyographic changes suggested that the peculiar grouping of motor-unit potentials with a hemiplegic weakness is a manifestation of long motor tract involvement.

The occurrence of hemiplegia without spasticity due to cortical or deep subcortical lesions has long been recognized, and the evidence for another descending pathway for the control of hypertonus has been discussed by Walshe (1919, 1942), who concludes that this problem cannot as yet be answered in man. The presence of hemiplegia, spontaneous pain, and disorder of all modalities of sensation on the same side, as occurred in one case, would suggest that structural damage was situated in the deep subcortical region. Another distribution of signs which not uncommonly occurred was a crural monoplegia or paraplegia combined with hyperpathia and diminution of posterior column sensibility. Muscle irritability, spasm, and sometimes myoclonic jerks made it difficult to assess the reflexes in this type of case. The posterior region of the cord which receives the sensory inflow and also probably the termination of the lateral corticospinal tract (Nathan and Smith, 1955), might be postulated as the site for the causal lesions to produce this combination of signs. Campbell and Garland (1956) have described three fatal cases attributed to virus infection under the title of "subacute myoclonic spinal neuronitis" with myoclonic jerks and painful spasms in the legs but without reflex changes. The histological findings were those of an inflammatory lesion of the grey matter of the cord, maximal in the dorsal horns in the thoracic and lumbar regions. Bradshaw (1954) has suggested that the internuncial neurones might be primarily involved in myoclonus, and that the anterior horn cells were only secondarily affected by afferent stimuli.

In the absence of pathological evidence any view regarding the nature of the lesion in the Royal Free Hospital epidemic must remain hypothetical.

Encephalomyelitis of virus origin in any event shows a discrepancy between the widespread impairment of nervous function and histological changes, which even in a fatal case may consist only of round-cell infiltration of the perivascular spaces.

There does not seem much doubt that the outbreaks reviewed in this discussion and the outbreak at the Royal Free Hospital constitute a clinical entity in which encephalomyelitis is the most serious feature. The name recently suggested for the entity is benign myalgic encephalomyelitis (*Lancet*, 1956). This title has certain merits and certain disadvantages; the use of the adjective "benign," although it correctly implies that there is no loss of life, gives a misleading impression of the severity and possible permanency of the neurological manifestations of the disease. The use of the adjective "myalgic" is a valuable reminder of this important and common feature of the illness. The title as a whole, however, fails to indicate that there is involvement of lympho-reticular structures.

Summary

An epidemic illness which affected nearly 300 members of the staff of the Royal Free Hospital Group between July 13 and November 24, 1955, is reported.

The clinical picture is studied in 200 in-patients. There is evidence of involvement of lympho-reticular structures in almost every case and of involvement of the central nervous system in about three-quarters of the 200.

The illness tends to run a fluctuating course. Treatment was symptomatic, but in 20 cases antibiotics were tried without effect. No patient died of the disease.

In the majority of cases recovery is the rule. Severe disability, however, may persist for many months and has persisted in at least four patients who are still disabled at the time of this report.

Laboratory investigations give no aid to diagnosis; haematological changes are non-specific and the cerebrospinal fluid is normal.

Electrodiagnostic investigations failed to show any evidence of lower motor neurone degeneration except in one case. The motor paralysis was accompanied by a reduction in the number of motor-unit potentials recruited on attempted volition, the residual potentials often being polyphasic. Occasionally, particularly during recovery, volition was accompanied by grouping of the motor-unit potentials.

Epidemiological studies suggest that the disease is spread by case-to-case contact and that the incubation period is five to six days.

Extensive investigations with the help of outside laboratories have failed, so far, to reveal either an infective agent or a causative factor.

The relationship of the outbreak in the Royal Free Hospital Group to similar epidemics reported in recent years from almost every quarter of the globe is discussed.

We received help from many sources, and we would like to record our gratitude to the staffs of the Public Health Departments of the Boroughs of St. Pancras and of Islington, the Virus Reference Laboratory, the London School of Hygiene, the M.R.C. Group for Research on Virus Diseases the Ministry of Health, the National Hospitals for Nervous Diseases, the Middlesex Hospital, the Hospital for Sick Children, the Radcliffe Infirmary, Oxford, the Whitley Hospital, Coventry, the Addington Hospital, Durban, the Eastman Dental Hospital, to the late Sir Lionel Whitby, C.V.O., M.C., and to the nursing, auxiliary administrative, and ancillary staff of the R.F.H. Group. The Royal Free Hospital medical staff would also like to put on record the constant service of our Senior Medical Registrar, Dr. P. E. Jackson, in co-ordinating this report.

Figs. 1 and 2 are included by courtesy of the Editor of the *Journal of Hygiene*.

AN OUTBREAK OF ACUTE INFECTIVE ENCEPHALOMYELITIS IN A RESIDENTIAL HOME FOR NURSES IN 1956

BY

DENNIS GEFFEN, O.B.E., M.D., D.P.H.
Medical Officer of Health to the Metropolitan Borough
of St. Pancras

AND

SUSAN M. TRACY, M.R.C.S., L.R.C.P., D.P.H.
Deputy Medical Officer of Health to the Metropolitan
Borough of St. Pancras

The outbreak of encephalomyelitis in the Royal Free Hospital Group began on July 13 and ended on November 24, 1955. During this time approximately 300 persons contracted the disease. This included 8 out of the 40 nurses and staff of the Royal Free Hospital Nurses' Preliminary Training School, N.W.8. The cases here all occurred from the end of July to the beginning of August, 1955.

In order that the report of the epidemic may be complete we record a further small outbreak associated with the Preliminary Training School which started in May, 1956. At this time there were resident 27 students, 3 teaching staff, one warden, and 7 domestic staff, a total population at risk of 38.

The number of notifications from the Preliminary Training School was seven, divided as follows: Student nurses, 5; sister, 1; member of domestic staff, 1. The dates of onset were: May 16, one student nurse; May 20, one student nurse; May 27, one student nurse; May 30, one student nurse; May 31, one sister; June 1, one student nurse; June 6, one maid.

The following is a summary of the illness in these seven patients, including the dates when they were admitted to the Sick Bay of the Royal Free Hospital and transferred or admitted direct to the Lawn Road Fever Hospital.

Case 1

Student nurse aged 18. Onset of illness, May 16; admitted to sick bay May 17; admitted to Lawn Road Hospital on June 1.

Symptoms.—Right earache, general malaise, severe headache, retrosternal pain, dizziness, nausea, and occasional

vomiting. These subsided, but they recurred on May 28 together with a low-grade pyrexia.

Signs on June 1.—A few palpable tender posterior cervical glands, but no other abnormal signs except slow cerebation and a minimal weakness of the right biceps.

Within three days the patient developed pain in her neck and right arm, and was found to have paresis of the right arm and right leg. This persisted, together with nausea, general malaise, and headache, for the next two weeks. She then had a right facial weakness and a weakness of her left arm and leg. The condition deteriorated and she developed photophobia, blurred vision, generalized muscular pain, and abdominal guarding.

At this stage she had to be given an intravenous drip. Her condition slowly improved and by July 12 she was able to walk with help. By the end of August, although her progress was generally maintained, she was still getting short spells of dizziness. This cleared, and she was able to return to duty on September 17, and has worked full-time since then. During most of her illness she was emotionally very labile.

Case 2

Student nurse aged 18. Date of onset, May 20, 1956; admitted to sick bay May 21; admitted to Lawn Road Hospital on June 5.

Symptoms.—Headache and nausea, which passed off, but between May 25 and 28 she had a fall and knocked her head. This was followed by a slight headache and a numb feeling on the left side of her face.

Signs.—Temperature was normal throughout. The throat was slightly injected; some enlarged cervical glands were easily palpable; all tendon reflexes were very brisk.

The patient improved and lost all her symptoms, but on June 25 she developed a frontal headache and paraesthesiae of her left arm; she also felt very tired. The headache and a "creepy" sensation in the left side of her head and excessive fatigue persisted during most of July but disappeared early in August. Patient decided to give up nursing.

Case 3

Student nurse aged 28. Date of onset, May 27; admitted to sick bay May 30; transferred to Lawn Road Hospital June 5.

Symptoms.—General malaise, right earache, nausea and anorexia, dizziness.

Signs.—A few palpable tender posterior cervical glands. She was apyrexial throughout and returned to duty on July 4, and has been working full-time since then.

Case 4

Student nurse aged 19. Date of onset, May 30; admitted to sick bay May 31; transferred to Lawn Road Hospital June 5.

Symptoms.—Headache, general malaise, nausea, pain in right arm and leg.

Signs.—A few palpable cervical glands; slight pyrexia; paraesthesia right foot; tendon reflexes, rather exaggerated.

The signs and symptoms cleared within two weeks and she returned to duty on July 4 and has worked full-time since then.

Case 5

Sister at P.T. school, aged 39. Date of onset, May 31; admitted to sick bay May 31; transferred to Lawn Road Hospital June 5.

Symptoms.—Headache, general malaise, pain in left arm and leg, nausea and anorexia.

Signs.—There were no objective signs except slight diminution of right biceps reflex.

The symptoms continued for about ten days and the patient was discharged home on June 18. She returned to duty on July 4, but was off duty again for one month in October with tonsillitis and general debility. Apart from this absence, she has been well and on duty since then.

Case 6

Student nurse aged 21. Date of onset, June 1; admitted to sick bay June 1; transferred to Lawn Road Hospital June 5.

Symptoms.—Tiredness and anorexia on May 31, followed on June 1 by headache, nausea, and pain in left ear. The headache continued for about a week.

Signs.—There were no abnormal physical signs.

The patient returned to duty on July 4 and has been well and working full-time since then.

Case 7

Woman aged 20 on domestic staff. Date of onset, June 6; admitted to Lawn Road Hospital June 13.

Symptoms.—Headache and giddiness. Left-sided strabismus, but this might have been of long standing. At no time was her temperature raised. Her E.S.R. was 50 mm. in one hour, which fell to 3 mm. in five days. All her reflexes were slightly exaggerated, but had returned to normal by July 7.

She returned to duty on June 27 and has worked satisfactorily since then.

Case 8

Staff nurse of Royal Free Hospital aged 24. She was admitted to the sick bay of the Royal Free Hospital on May 1 with sinusitis. On May 17 she was in contact with Case 1 (it is stated for not more than half an hour). She was discharged on May 19 to a convalescent home. On May 29 she returned to duty at the Royal Free Hospital. On June 1 she vomited twice and developed pains in both legs, and on June 2 complained of weakness in both lower limbs. On June 3 she was readmitted to the sick bay and transferred to Lawn Road Hospital on June 5.

Signs.—June 5. A few small enlarged cervical glands and on the anterior border of the trapezius; anaesthesia of the right side of face and neck to cotton-wool and pinprick. Slight degree of paresis in both arms with complete anaesthesia to cotton-wool and pinprick. Joint and vibration sense absent in the right arm and an area of anaesthesia on the left side. There was general diminution in power in her legs, with anaesthesia to cotton-wool and pinprick and absent joint and vibration sense on the right side. The signs, together with drowsiness and nausea, persisted for about a week, when she became brighter. The anaesthesia of her arms improved slightly, that in the legs persisted. She also had bouts of vertigo and nausea and very acute paraesthesia.

By the end of June her condition had improved, but sensation was still impaired on the right side. By the middle of July she could walk unaided but with a rather spastic tremulous gait, and there was some foot-drop on the right side. She still had anaesthesia of her right and left legs and was very readily fatigued. On July 18 she was discharged for convalescence and returned to duty on October 11. She has been well, and working, since then.

Discussion

Two doctors who were in contact with some of the above eight cases were admitted to hospital. In one case the diagnosis of encephalomyelitis was doubtful, the doctor being in hospital from June 23 to July 10. In the second case the doctor went off duty on June 17 and has not yet returned, her recovery being complicated by an attack of acute appendicitis.

Leaving out the two doctors, it will be seen that, of the eight cases described, one was off duty for 2 weeks, four for 5 weeks, one for 2 months, one for 3½ months, and one for 5 months; this is probably a typical pattern of the disease.

The outbreak was of short duration and it is possible that this was due to quick administrative action following the experience in the group in the previous year. As soon as it became obvious that there was an outbreak of acute infective encephalomyelitis the Preliminary Training School was

disbanded, and all those residents who were not ill were sent home. Close contact was kept with them, and in no case did they or any of their home contacts develop illness. The ward in which Case 8 was working before contracting encephalomyelitis was closed from June 8 to 18 for the admission of all except urgent cases.

There was no spread to patients, although the probationers in training were visiting various hospitals in the group.

All the patients admitted to the sick bay of the Royal Free Hospital, Gray's Inn Road, were transferred to the infectious disease hospital of the group at Lawn Road as soon as the outbreak was diagnosed as acute infective encephalomyelitis, and succeeding cases were admitted directly to Lawn Road.

Every attempt was made to correlate this epidemic with the previous outbreaks in the various hospitals of the group, but no success was achieved. Such pathological examinations as were carried out showed the same negative results as in previous epidemics.

Some idea of the difficulties which arise during an outbreak of this description are typified by the fact that at the time of this small epidemic eight people working in or associated with the Royal Free Hospital were admitted or transferred to Lawn Road as suspected cases of acute infective encephalomyelitis which were not confirmed as such, the final diagnoses being as shown in the accompanying Table.

Patient	Final Diagnosis
A nurse from Royal Free Hospital	Headaches
A radiographer from Royal Free Hospital	Intercostal myalgia
A student radiographer from Royal Free Hospital	Acute exudative herpetic tonsillitis
A casualty receptionist from Royal Free Hospital	Stress syndrome
A patient in Royal Free Hospital with haemorrhage due to duodenal ulcer, and who developed ophthalmoplegia	Acute respiratory catarrh
A cardiologist technician at Lawn Road Hospital	Small cerebral thrombus
A clerk at the Royal Free Hospital	Infectious mononucleosis
	Renal colic and congenital malformation of kidneys

Twelve other individuals associated with the Royal Free Hospital or seen in the out-patient department were sent home as suspected mild cases of acute infective encephalomyelitis. They were followed up. They did not develop typical symptoms of this condition nor did they convey infection to other persons.

During the course of the epidemic a patient from a suburb 10 miles north-west of London presented herself at the out-patient department of the Royal Free Hospital. She was admitted to the Fever Hospital as a typical case of acute infective encephalomyelitis with stiff neck, temperature, and paresis of the muscles of the left shoulder, without loss of reflexes or muscle wasting.

The occurrence of sporadic cases unassociated with the bulk of cases in the limited sphere of the hospital epidemic was a feature of the outbreak in the previous year and, in fact, of outbreaks described in other countries.

Summary

A small outbreak of acute infective encephalomyelitis is described in a residential training school for nurses.

Of 38 individuals resident and at risk 7 developed the disease.

In 6 cases the symptoms were mild—5 recovering within five weeks and 1 within two months.

One case was complicated by serious neurological manifestations, and recovery was delayed for three and a half months.

One nurse from the hospital group concerned was in contact with this more serious case for half an hour and

developed the disease. She showed marked neurological manifestations and was off duty for five months.

Two doctors contracted the disease. In one case the diagnosis was doubtful.

Eight cases of illness in contacts are described in which the diagnosis of acute infective encephalomyelitis was not confirmed.

There were no deaths.

It is possible that prompt administrative action localized and controlled the epidemic.

We would like to pay tribute to the physicians of the Royal Free Hospital Group, who have supplied us with most of the clinical information on which this report is based, and in particular to Dr. Ramsay, physician at Lawn Road Hospital. With his permission we saw all the cases ourselves repeatedly, and it was his kindness in helping us with the clinical details and progress of the patients that enabled us to make this report. We would also express our indebtedness to Sir Daniel Davies, senior physician of the Royal Free Hospital, for his ready help and advice. We would also like to thank Dr. Doreen Nutbourne, who was R.M.O. of the Royal Free Hospital at the time of the outbreak, for her daily co-operation.

UREA, THE FORGOTTEN DIURETIC

BY

CORNELIO PAPP, M.D.

Clinical Assistant, Cardiac Department, London Chest Hospital

AND

K. SHIRLEY SMITH, M.D., F.R.C.P.

Physician and Cardiologist, Charing Cross Hospital and London Chest Hospital

The introduction of mercurial diuretics marked an outstanding advance in the treatment of chronic congestive heart failure. This therapy can generally be relied upon to ease the distress of oedema and other accumulations of fluid. It is nevertheless sometimes found that after a while the diuretic effect wanes, and this development marks a critical stage in treatment. Increasing the dosage of digitalis does not then improve the urinary output; while the patient, who may have been taking the drug for years, has frequently become so sensitive to it that even small amounts cause bradycardia and coupling. Other standard methods of averting fluid accumulation may fail at the same time; thus rigid sodium restriction may worsen the general condition through electrolytic imbalance and the blood urea may steadily rise. Aspiration and acupuncture may bring temporary relief but do not arrest the downhill course. Nor do the newer diuretics solve the problem, since their efficacy is generally inferior to that of mercurial diuretics. These considerations prompted us to reassess, in a systematic trial, the value of urea, the only effective diuretic of the pre-mercurial days, now fallen into disuse.

Friedrich (1892) was the first to use urea for oedema due to various causes; with doses of 3–14 g. he reported favourable results. These were confirmed by Strauss (1896, 1921), and Feilchenfeld (1919). Volhard (1918) used even larger doses (40–60 g. a day) with good success in nephrotic oedema. Crawford and McIntosh (1925) gave the first detailed account of its use in eight cases of congestive heart failure. They were able to double the urinary output with a daily dose of 45 g. Prolonged administration gave rise to anorexia, vomiting,

and lassitude; after stopping the drug for a few days it could be resumed in small doses. They found an increase of urea excretion proportionate to the administered dose, and some increase of chloride excretion. The blood urea rose initially to 60–90 mg. per 100 ml. within a few days; then it remained at this level during the period of administration and fell quickly to normal when urea was discontinued.

Miller and Feldman (1932) reported five patients with cardiac dropsy who were treated with urea intermittently for 1½–3 years and in whom water retention could be prevented by combining this treatment with mersalyl. No signs of renal damage were seen on post-mortem examination. Marvin (1940) believed that the unpleasant taste was practically the only disadvantage of urea. He found it extremely valuable as a diuretic, emphasized its constant effect, and thought it deserved a more important place in therapy. Winternitz (1940) was able to reduce the frequency of mercurial injections or omit these in three cases of congestive heart failure, giving urea at the same time. He preferred one daily dose of 20–40 g. to more frequent smaller amounts. White (1951) thought that urea was worthy of trial when mercurial therapy was found inadequate. Friedberg (1956) and Gross and Jezer (1956) held similar opinions. Current editions of standard British textbooks either make little reference to the use of urea as a diuretic (Dunlop, Davidson, and McNee, 1953), or do not mention it at all (Wood, 1956; Davidson, 1956; Garland and Phillips, 1953), or regard it as not indicated in congestive heart failure (Price's Textbook, 1956).

The main objections to the use of urea have been that it is unpalatable and that it may cause vomiting and gastro-intestinal irritation. Fishberg (1940) believed the congested gastric mucosa to be particularly sensitive to the irritant action of urea, and fluid restriction was difficult to enforce since urea increased thirst. It was said that sooner or later all patients became intolerant to it (Goldring, 1929). Further criticism concerned the diuresis produced by urea. Keith and Whelan (1926) maintained that urea leaves sodium chloride in the tissues, removing only water, and is therefore a poor substitute for mercurial diuretics, which remove both water and sodium. Crozier and Mayrs (1940) thought that owing to its high diffusibility the concentration of urea in oedema fluid soon attained the concentration in the blood, and its diuretic power, based on osmosis, thus became exhausted. Vogl (1953) admitted success in some cases, but felt that the treatment was not dependable on account of the high incidence of nausea and vomiting.

The purpose of our investigation was to find out whether a positive water balance could be restored with urea alone; whether combined treatment with mercurial diuretics enhanced the effect of the latter by increasing urinary output on the day of injection by diminishing the "rebound" the day following injection; whether the diuresis produced by urea is different from that produced by mercurial diuretics; and, finally, if life can be prolonged and made more comfortable for these gravely ill patients.

Material and Method

Our series comprised 17 patients with obstinate and prolonged right ventricular failure in whom anasarca and ascites were the main features and in whom mercurial diuretics had become ineffective in clearing oedema and effusions. Fourteen patients had valvular heart disease, and these had been

in chronic congestive heart failure with auricular fibrillation for years. Ascites often persisted after the oedema cleared; this and the hard and enlarged liver suggested cardiac hepatic cirrhosis. Six of them underwent mitral valvotomy. The operation, which was done as a last resort, was ultimately unsuccessful in all; a second valvotomy in one, however, has produced a good immediate result. In the remaining eight the preponderant lesion was mitral or aortic incompetence, which precluded operation. All had functional tricuspid incompetence. Detailed in-patient data were available in 11 out of these 14; the remaining 3 were treated as out-patients. Two patients had coronary heart disease and developed congestive heart failure immediately after cardiac infarction. Failure persisted for three and six months respectively before the beginning of urea treatment. Hospital admission was possible in one only. One patient had hypertensive heart failure and bronchial carcinoma.

After admission the patients were kept for 10 to 14 days on the usual treatment, consisting of digitalis, mercurial diuretics preceded by ammonium chloride, and sodium restricted regime with fluid intake limited to 30–40 oz. (850–1,130 ml.). Blood electrolytes, blood urea, and urinary chlorides were estimated and effusions aspirated when necessary. The fluid intake and output were charted and the average fluid balance was calculated from a total of at least seven days without and separately from a total of 4 days with mercurial injections—mersalyl, "unephral" ("neptal"), or mercaptomerin ("thiomerin"). If the blood urea was normal 15 g. of urea was then given three times a day after meals, dissolved in 2 oz. (57 ml.) of water (25% solution) or grapefruit juice. This dose had to be reduced occasionally, but with one exception no patient received less than 30 g. a day. The laboratory tests were repeated during treatment, while the basic regime was continued. The same calculation of the average fluid balance was then repeated and compared with the one before urea was started.

We were surprised to find how easily most of our patients took urea. Those who objected to its taste in watery solution were able to take it in grapefruit juice. Anorexia and vomiting occurred in some, mostly when the patient deteriorated; it necessitated withdrawal of the treatment for a few days, and if a second attempt with a smaller dose was unsuccessful treatment was abandoned. There was thus no difficulty in carrying on with the treatment in most of our cases.

Except for two patients, treatment was maintained over periods ranging from 2½ weeks to 7 years (Tables I and II). Cases 6, 7, 10, 11, 12, and 13 were treated from 2½ to 4 weeks; Cases 3, 8, and 16 from 3 to 5 months; Cases 1, 4, 9, and 14 from 6 to 9 months; Case 17 for 1½ years; and Case 2 for 7 years.

Results

Treatment was regarded as successful when a patient who was a bedridden cardiac invalid before urea treatment was able to return to a sedentary occupation or to light housework and could be kept reasonably free of oedema and effusions on treatment by urea coupled with mercurial diuretics. These criteria were fulfilled in three instances: Case 2, who had congestive heart failure following bacterial endocarditis and who has been taking urea for seven years intermittently; Case 17, with congestive heart failure after extensive cardiac infarctions, who took urea for one and a half years and who died suddenly six years later of a further cardiac infarction; Case 14, with trivalvular heart disease, who has been taking urea now for six months.

Temporary improvement was achieved in 11 cases; this consisted in increased diuresis and clearance of oedema and effusions while under hospital treatment. But these patients, when seen subsequently as out-patients, continued to retain fluid. When readmitted and kept under strict control their diuresis improved; but as time went on urea became ineffective, and in the end had to be abandoned on account of nausea and vomiting. Ten of these had valvular heart disease, six of them dying within weeks or months after urea

became ineffective. The only patient who improved was No. 8, who underwent a second valvotomy. The last patient in this group (Case 13) had congestive heart failure following two cardiac infarctions; urea established a positive water balance when mersalyl failed. Treatment was stopped on account of high blood urea. This patient died two and a half weeks later.

Treatment failed in three. One of these (Case 12) had hypertensive failure; the second (Case 15), with valvular

heart disease, refused to take urea after one week; the third (Case 5), also with valvular heart disease, improved during six days of treatment in hospital, but died at home of pulmonary oedema before she could be reassessed.

The detailed results are summarized in Table I. Except for Case 11, all were in negative fluid balance before treatment by urea, the average daily fluid retention varying from 60 to 720 ml. In eight the fluid balance became positive on urea alone (Figs. 2, 3, and 4). In the cases in which it

TABLE II.—Urea Treatment in Four Out-patients in Obstinate Heart Failure

Case No.	Diagnosis	Age and Sex	Duration of Failure	Short History	Daily Dose (g.)	Duration of Treatment	Comment	Result
14	M.S.-A.I. A.S.-T.I. and T.S. A.F. C.H.C.	42 F	7 years on and off	Frequent previous admissions for C.H.F. and gross ascites. Urea started March, 1956. Within 3 weeks lost 6 lb. (2.7 kg.) in wt. and 2 in. (5 cm.) in abd. girth. Approx. daily output doubled—mercaptomerin inj. reduced from two to one a week	45	8 months	Well. Doing light housework. Under observation	Success
15	M.S. and A.I. -T.I.	48 F	1 year	Severe congestive heart failure. Greatly disabled	45	1 week	Urea made her thirsty; became worse—stopped treatment	Failure
16	M.I. and T.I.	51 F	1 1/2 years on and off	Not severely disabled. Needs Hg inj. twice weekly; attempts to omit these failed previously	45	3 months	Much improved; no Hg inj. required since on urea. Under observation	Temporary improvement
17	C.H.F. after cardiac inf. C.H.F. C.H.C.	42 M	3 months	Extensive ant. infarct April, 1947, followed by extensive post. inf. Feb., 1948. 4 months later severe C.H.F.; gross fluid retention in spite of Hg inj. 3 a week. Urea started June, 1948; positive fluid balance restored. Left for abroad, July, 1948. Subtotal thyroidectomy, Nov., 1948. Feb., 1949, T.I., ascites, large liver. Urea resumed. Ascites and oedema disappeared within 14 months. Urea stopped. Ascites again in May, 1949. From May to Nov., 1949, urea intermittently. From then onwards sl. C.H.F. successfully treated with digitalis and occasional Hg inj.	20-40	1 1/2 yrs.	Sodium restriction could never be enforced. In spite of this, dehydration with urea successful. From 1950-5 fully active in sedentary occupation. From 1952 onwards no Hg inj. needed. Well compensated on digitalis and thyroid. Sudden death May, 1955, of further cardiac infarct	Success

remained negative, retention became less, and, while the output after mercurial injections rose considerably during urea administrations (Fig. 1), mercurials were largely ineffective before treatment with urea (Cases 2, 4, 5, 8, and 10). In Case 4 mercurial injections were not required because of the spectacular output on urea alone (Fig. 2). In Case 8 a greater output was obtained for three successive days after

such injection while the patient was taking urea, without the usual great diuresis on the day of injection. In Case 11, the only patient with positive water balance before urea, the average excess output during urea increased from 70 to 135 ml., and he did not need further mercurial injections, which had previously been uncertain in effect. The result obtained with urea was proportionate to the dose: in Case 6, with renal involvement, only one-third of the usual dose was given; she retained less, but still remained in negative balance. Case 1, unable to take the full dose, retained fluid when on 15 g. a day; raising the dose to 25 g. a day produced an excess average daily output of 195 ml. with a correspondingly greater output on injection days. When urea was stopped water retention immediately recurred (Fig. 2). Resumption of urea in smaller amounts resulted in a smaller

FIG. 1.—Case 2 (Table I). Urea in reduced dosage greatly enhances effect of mercurial diuretic, abolishes rebound after injection, but does not suppress entirely the negative fluid balance. N=neptal, 2 ml.; i.p.=intraperitoneally; P=paracentesis, 5.1 litres.

FIG. 2.—Case 4 (Table I). Urea in average doses suppresses fluid retention; no mercurial injections required. Stoppage of treatment results in fluid retention. Resumption of urea with smaller doses restores positive fluid balance, enhances effect of mercurial injections, and suppresses gross rebound present before treatment with urea. T=thimeron, 2 ml. i.m.

output, though it still potentiated the effect of mercurial diuretics. As fluid retention became less, the effect of mercurial diuretics also diminished (Fig. 3). Rebound after mercurial injections was abolished in six patients (see Figs. 1, 2, and 3).

FIG. 3.—Case 7 (Table I). Urea in average doses restores positive fluid balance; only one further mercurial injection required. M=mersalyl, 2 ml. i.m.

Laboratory Data

Diuresis with urea is due to a rise in blood urea after its ingestion. The excess of urea circulating in the blood leads to the filtration of larger amounts of urea from the glomeruli. The rising concentration of urea increases the osmotic pressure in the renal tubules, hindering reabsorption of water. "Urea thus retains water in the tubules for its own elimination" (Wright, 1952). Patients on urea all have a raised blood urea, and the level depends on the amount ingested. In Case 9 the blood urea rose from 26 mg. per 100 ml. to 86 mg. during the administration of 45 g. of urea; Case 1 had a blood urea of 58–67 per 100 ml. while on 30 g., of 42 mg. while on 20 g., and of 26 mg. when on 15 g. a day. In Cases 4 and 14 the blood urea estimated three hours

FIG. 4.—Case 13 (Table I). Spectacular diuresis on urea alone after mercurial injections became ineffective. M=mersalyl, 2 ml. i.m.

after the first daily dose was 49 and 42 mg. per 100 ml. respectively. The rise of blood urea purposefully produced has a significance different from that caused by chronic renal disease, in which it is a sign of the inability of the kidneys to eliminate toxic waste products. The urea retention was well tolerated by our patients; vomiting was looked upon as a sign of intolerance of the congested gas-

tric mucosa to absorb urea, and in these cases the blood urea was normal. In chronic renal disease, however, vomiting is a sign of toxæmia, and the blood urea is high. The diuresis with urea has been thought to be less valuable than that produced by mercurial diuretics, on the ground that only water is eliminated, sodium being left in the body. The daily urinary chloride estimation in Case 7, with a normal blood chemistry, refuted this (Table III). The

TABLE III.—Chloride Excretion on Urea Alone and After Mersalyl in Case 7

Date	Urinary Chlorides (mEq l.)	Urinary Output (ml.)	Daily Urinary Chlorides (g.)
26.7.56	51.7	1,200	3.6

*(M) = 2 ml. of mersalyl injection.

chloride output in this patient was low because she was, as all our patients were, on a sodium-restricted regime. The relative chloride content in the urine after mersalyl was only one-half or less (34.5 mEq/l.) of that she had on some days while on urea alone (77.6 mEq/l.). Owing to the greater urinary output, however, the absolute amount of chloride excreted on the mersalyl day was equal to that excreted on urea days, when output was smaller.

Discussion

Our series was highly selective in that it comprised only patients with a consistently bad prognosis. To see bedridden patients with advanced heart failure and anasarca following bacterial endocarditis, extensive cardiac infarction, or trivalvular heart disease restored to gainful occupation, or to light housework in the cases of women, was remarkable or at least unexpected. Clearly, it was not urea alone which was responsible for this success: digitalis, mercurial diuretics, and sodium restriction all played their part. However, these measures were unsuccessful by themselves; the diuresis produced by urea, the potentiation of the effect of mercurial diuretics, and the abolition of rebound after mercurial injections were the decisive factors which produced the improvement. In Case 17, suffering from heart failure after cardiac infarction, subtotal thyroidectomy was performed, but this would not have been possible except for the diuresis produced by urea at a decisive moment when the patient was waterlogged and when mercurial diuretics had become ineffective. When oedema and ascites reappeared after operation, urea again restored the normal water balance. In Case 2 intraperitoneal unephral injections, during the administration of urea, produced an exceptional diuresis. The same combined treatment was effective in Case 9, but in her the intraperitoneal mercurial was ineffective without the aid of urea administration.

After these striking results it was disappointing to find patients failing to respond to a second or third course of urea. Failure to produce diuresis by urea coincided with a rapid downhill course, and, with two exceptions, all these patients died within one year, many within weeks. If cardiac strength wanes osmotic diuresis is bound to fail, since glomerular filtration becomes deficient. When this stage will be reached cannot be foretold; our findings show that even in the apparently hopeless case a good diuretic response may disclose unexpected cardiac reserves. Whether or not it prolongs life may be questionable, but the clearance of oedema certainly makes life more bearable.

Treatment with urea is far from being pleasant. This substance is unpalatable, but that drawback may be overcome by various devices. Grapefruit juice seems to be the best means of masking the unpleasant taste, though we have not tried giving it in beer or in raw tomato juice as advised by Miller and Feldman. Tolerance remains individual: many of our patients who were able to take urea for months and years did not object to the taste; others refused a second course on account of its unpalatability. Real intolerance was seen in the severely ill who vomited the mixture they had been able to tolerate earlier for weeks and months. While taking urea most patients complained of increased thirst, but on the average they drank about 300 ml. more daily, but only one stopped treatment on account of this. Urea has a sedative action and may produce tiredness; but this was

not a prominent complaint in our series, nor was diarrhoea. The dose may have to be adjusted to the need of the patient; the average dose was 45 g. daily. Less than 30 g. may not by itself be enough to increase diuresis, but it may be enough to potentiate the effect of mercurial diuretics and to abolish water retention the day after injection.

Summary

A new assessment of the diuretic properties of urea has been made. When integrated in action with mercurial diuretics urea has a special place in the therapy of chronic heart failure with oedema.

A group of 17 patients, all suffering from obstinate and prolonged right ventricular failure, has been studied. Fourteen had chronic rheumatic valvular heart disease, and some of these had developed cardiac hepatic cirrhosis with ascites; six underwent mitral valvotomy. Of the remaining three patients, heart disease in two was of coronary origin, and in the remaining one hypertensive.

Urea was administered in doses of 15 g. dissolved in 2 oz. (57 ml.) of water or grapefruit juice thrice daily. Treatment was maintained over periods ranging from two and a half weeks to seven years.

This treatment was found to be advantageous. In about half the patients a negative fluid balance was changed to positive on urea alone. In cases in which it remained negative, fluid retention became less. Urea was found to produce such effects even after mercurial diuretics had become useless. In several patients mercurial diuretics were greatly augmented in their effect when urea was given concurrently.

At worst, urea administration is never harmful, but it may have to be discontinued on account of distaste on the part of the patient or because of nausea and vomiting. At best it may be the means of maintaining in a quiet occupation for several years a patient with grave valvular heart disease in whom this result is unattainable by any other medicaments singly or in combination. Between these extremes are the patients in chronic congestive failure who may receive many months of benefit, at first by prolongation of quiet activity free from oedema, and latterly by mitigation or abolition of distressing oedema and effusions until the last days of the illness.

ESSENTIAL HYPERLIPAEMIA AND IDIOPATHIC HYPERCHOLESTEROLAEMIC XANTHOMATOSIS

BY

PETER BORRIE, M.D., M.R.C.P.

Physician, Skin Department, St. Bartholomew's Hospital, London; Dermatologist, Moorfields, Westminster and Central Eye Hospital and Barnet General Hospital

The purpose of this article is twofold. First, to examine the difference between essential hyperlipaemia and idiopathic hypercholesterolaemic xanthomatosis. Hitherto these conditions have been differentiated solely by the presence or absence of an increase in plasma neutral fat (hyperlipaemia) (Lever *et al.*, 1954; Malmros *et al.*, 1954). Secondly, to examine the significance of the hyperlipaemia when it does occur.

Essential Hyperlipaemia

Essential hyperlipaemia has been defined as a condition in which a primary increase in plasma neutral fat, sufficient to cause turbidity, occurs, usually associated with an increase in the blood cholesterol. It is familial in about a sixth of the cases—hepatosplenomegaly, recurrent upper abdominal pain, and skin lesions occurring, though not necessarily together, in about one-half. The upper abdominal pain is thought to be due to pancreatitis resulting from the hyperlipaemia (Klatskin and Gordon, 1952). Hyperglycaemia, which can be controlled by a low-fat diet, has also been described (Thannhauser, 1950). Approximately a third of the cases occur in children under the age of 10. None of the symptoms or signs depend on any particular critical level of plasma lipids.

Of the 41 cases reported prior to 1954, 19 had cutaneous lesions (11 adults and 8 children). In adults the lesions are remarkably constant in their morphology and are known as eruptive xanthomata (Wijnhausen, 1921; Marcus, 1937; Bloomfield and Shenson, 1947; Thannhauser, 1950; Frank and Levitt, 1951; Hand, 1951; Fulton, 1952; Gadrat *et al.*, 1952; Klatskin and Gordon, 1952). They occur suddenly, in crops, and vary in intensity, sometimes even clearing completely for short periods. The individual lesion is a yellow dome-shaped papule, 1 to 5 mm. in diameter, frequently surrounded by a bright-red halo. Itching may occur when the lesions are erupting and occasionally they are acutely tender. They vary in number from a dozen to thousands and may be grouped or scattered. The commonest sites are the knees, elbows, thighs, and buttocks, but any area of the skin may be affected. They disappear when the patient is placed on a low-fat diet, but recur when the diet is discontinued.

In children the cutaneous lesions may be the same as in adults (Burger and Grutz, 1932; Abegg, 1937; Bernstein *et al.*, 1939; Goodman *et al.*, 1940), but pinhead vesicles, from which a milky fluid can be expressed, have also been described (Holt *et al.*, 1939; Bruton and Kanter, 1951). In one infant aged 17 months transitory orange papules appeared (Crocker, 1951). The lesions were not described in Collett and Kennedy's (1948) case.

The following two cases are typical examples of the condition in adults.

Case 1

A man now aged 46 noticed in 1950 an extremely tender eruption on his elbows, trunk, and feet. He had no other

needed to control the hyperglycaemia. Another uncomplicated example of essential hyperlipaemia had already been reported (Hopgood, 1948). Neither of these cases had skin lesions. The remaining five all had hyperlipaemia and hypercholesterolaemia and both eruptive and tuberos xanthomata, the latter type preponderating. In the two cases treated with a low-fat diet, the former cleared, while the latter did not. Three patients had tendon xanthomata and three coronary-artery disease. One had enlargement of the liver and spleen, but none suffered from abdominal pain. Thus these cases exhibit features of both essential hyperlipaemia and idiopathic hypercholesterolaemic xanthomatosis, and either diagnosis would be equally applicable. The following two cases are further examples of this type.

Case 7

A woman now aged 69 was seen in 1949 with a six-months history of itching of the elbows. On examination typical plane xanthomata were found on the eyelids and tuberos xanthomata on both elbows. The past and family histories were not relevant. The blood cholesterol level was raised, but the appearance of the serum was not noted and the serum neutral fat was not investigated. There was no change in her condition until 1956, when typical eruptive xanthomata appeared on the buttocks. The serum was then found to be milky; total lipids were 2,979 mg. per 100 ml.; cholesterol, 972 mg. per 100 ml.; and phospholipids 750 mg. per 100 ml. There had been no change in the lesions on the eyelids and elbows.

Case 8

A man now aged 42 noticed, in 1949, an eruption on the trunk and limbs. This cleared spontaneously in a few months, but then recurred and persisted. His general health had been good. His mother had suffered from hypertension and died from a cerebral haemorrhage. On examination at that time the eruption was found to consist of discrete yellow pinhead papules, with an erythematous margin. These were present profusely on the buttocks, aggregated into plaques on the feet, and scattered on the upper limbs, back, and thighs. No other abnormality was found. The serum was milky; total serum lipids 3,900 mg. per 100 ml., and cholesterol 1,040 mg. per 100 ml. Paper electrophoresis showed a hyperlipaemic pattern. Polariscopic examination of a skin lesion showed that the lipid consisted of approximately equal amounts of neutral fat and cholesterol.

He was placed on a low-fat diet and the eruption, with the exception of the lesions on the right elbow, cleared in 10 months and has not recurred. The lesions on the right elbow had always been rather larger and more orange coloured than the others, and they continued to increase in size for two or three years and have since remained stationary. For the past two years he has complained of upper abdominal pain, the exact cause of which has not been ascertained.

On examination in 1957 no abnormality was found except for three typical tuberos xanthomata on the right elbow. The serum was still milky, total lipids being 3,400, phospholipids 520 mg., and cholesterol 400 mg. per 100 ml. Polari-

scopic examination of a section from the remaining cutaneous lesion showed it to be composed almost entirely of neutral fat.

Discussion

Essential hyperlipaemia and idiopathic hypercholesterolaemic xanthomatosis have hitherto been regarded as separate entities. This distinction has been based on the presence of a raised neutral fat level in the former condition. However, Cases 4, 5, and 6 in the present series (see Table), and an analysis of those reported by Malmros *et al.* (1954), show that this can no longer be regarded as a valid distinction, since such a hyperlipaemia can occur in both conditions. Further, the cutaneous lesions characteristic of these two maladies, plane and tuberos xanthomata in the case of idiopathic hypercholesterolaemic xanthomatosis and eruptive xanthomata in essential hyperlipaemia, can also occur together in the same patient (Cases 7 and 8 and Lever *et al.* (1954)). The cases of Lever *et al.* also showed tendon xanthomata and cardiovascular disease, characteristic of idiopathic hypercholesterolaemic xanthomatosis, while in Case 8 recurrent abdominal pain suggests the pancreatitis of essential hyperlipaemia. Finally, either of these diagnoses would be equally applicable to Case 7.

On clinical grounds alone these conditions seem to have much in common, and it is tempting to consider them as differing presentations of the same fundamental abnormality. Yet preliminary reports on their response to certain forms of treatment hint at further differences. A low-fat diet is sufficient to cause the complete disappearance of eruptive xanthomata in a few months (Cases 1, 2, and 8) but has no effect on plane or tuberos xanthomata. Recently phenylethyl-acetic acid was introduced by Cottet *et al.* (1954) for the treatment of atheroma. These authors considered that by forming a stable combination with co-enzyme A it might interfere with the endogenous formation of cholesterol. There appears to be no reason, however, why it should not have the same effect on the phospholipids or neutral fat. Cases 1, 4, and 5 were treated with this drug for six weeks, the dose being 2 g. a day for the first two weeks and thereafter 3 g. a day. No effect on the serum cholesterol was seen in Cases 4 and 5 (idiopathic hypercholesterolaemic xanthomatosis with hyperlipaemia), but in Case 1 (essential hyperlipaemia) the serum cholesterol, which had varied between 220 and 400 mg. per 100 ml. for the previous 18 months, rose during treatment to 660 mg. Since stopping the drug it has not again risen above 400 mg. during the ensuing 10 months.

None of the cases in the present series have been treated with a high vegetable fat diet for long enough for any conclusions to be drawn. Malmros and Wigand (1955) caused a rapid reduction in plasma cholesterol in cases of familial hypercholesterolaemic xanthomatosis with this type of diet, whereas in the single case of essential hyperlipaemia so treated there was an increase in both neutral fat and cholesterol. It was thought that this was due to previous treatment with a low fat diet, and on repeating the treatment after a period on a normal diet the cholesterol fell. It is

Details of Cases

Case No.	Diagnosis	Total Lipids	Phospholipids	Total Cholesterol	Neutral Fat	Paper Electrophoresis	Cutaneous Xanthoma
1	Normal	400-700	150-250	150-260	0-200		
2	Essential hyperlipaemia	5,590	550	425	4,498	Hyperlipaemic	Eruptive (N.F.)
3	Idiopathic hypercholesterolaemic xanthomatosis	4,300	580	520	3,044	Hypercholesterolaemic	Eruptive (N.F., cholesterol)
4	"	2,300	470	515	1,161	"	Tuberos (cholesterol)
5	"	1,800	445	520	679	"	Tuberos (cholesterol, N.F.)
6	"	1,920	430	520	814	"	Tuberos (cholesterol)
7	Mixed type	2,979	750	972	969	"	Eruptive and tuberos
8	"	3,400	520	400	2,360	"	1. Eruptive (N.F., cholesterol) 2. Tuberos (N.F.)

All figures represent mg. per 100 ml. and refer to the serum. The normal values are taken from Thannhauser (1950). The neutral fat (N.F.) was calculated on the following formula: neutral fat = total lipid minus (phospholipid + 1.3 × total cholesterol).

ACCIDENTAL COAL-GAS POISONING

LOSS OF SENSE OF SMELL AS A POSSIBLE CONTRIBUTORY FACTOR WITH OLD PEOPLE

BY

H. D. CHALKE, O.B.E., T.D., M.R.C.P., D.P.H.
Medical Officer of Health, Camberwell

AND

J. R. DEWHURST, Ph.D., B.Sc., A.R.I.C.
M.Inst. Gas E.

Central Laboratories, South-Eastern Gas Board

During recent years there has been a progressive increase in the number of accidental deaths from coal-gas poisoning in this country. In 1955, out of a total of 8,000 fatal home accidents, 892 were due to domestic gas and three-quarters of these occurred in persons over 60 years of age. As shown in Tables I and II, which refer to Great Britain, the increase is not accounted for by the greater number of consumers of gas. The figures quoted are taken from the Report on Accidental Coal-gas Poisoning issued by the British Medical Association in 1956 after a careful investigation by a committee appointed by that body for the purpose.

It is clear that impairment or loss of the sense of smell may be one of the factors contributing to the prevalence of accidental poisoning among older persons. With this in view a small pilot survey was initiated in Camberwell by one of us (H. D. C.), and the findings were considered by the B.M.A. Committee. This survey showed that in the case of many of the people tested the sense of smell was negligible and would therefore give no protection. The work was, however, of a preliminary

TABLE I.—Accidental Deaths from Gas Poisoning

Year	No. of Fatalities	Fatalities per 10 Million Consumers (Domestic)
1931	175	No figures available
1935	203	" " "
1938	224	" " "
War years	No records	" " "
1946	441	41.0
1949	497	44.5
1951	589	51.8
1953	751	64.2
1955	892	74.2

Final understanding of the true significance of hyperlipaemia must await further detailed investigations of this type regarding the form the lipid takes in both the plasma and the tissues.

Summary

Eight cases of cutaneous xanthomatosis are reported, seven being associated with an increase in plasma neutral fat.

On clinical grounds, two cases were diagnosed as essential hyperlipaemia, four as idiopathic hypercholesterolaemic xanthomatosis, and two appeared to represent mixed types.

It is considered that the diagnosis of essential hyperlipaemia does not depend solely on the presence of an increase in plasma neutral fat.

The differences between this condition and idiopathic hypercholesterolaemic xanthomatosis, and the significance of the hyperlipaemia, are discussed.

My thanks are due to Dr. E. F. Scowen for permission to study Case 8; to Dr. P. D. Samman for the clinical details of Case 7; to Dr. W. G. Dangerfield for the biochemical and electrophoretic investigations; and to Mr. N. K. Harrison and the photographic department of St. Bartholomew's Hospital.

TABLE II.—Classification of Deaths from Gas-poisoning Accidents According to Age

Year	Proportion of All Fatalities	
	0-59 Years	60 Years and Over
1931	49.2	50.8
1935	42.3	57.7
1938	50.5	49.5
War years	No records	
1946	28.8	71.2
1949	28.9	71.1

1953	32.4	67.6
1955	25.2	74.8

nature, and in its report the Committee pointed out that before definite conclusions could be reached it would be necessary to carry out further work on this problem. The present paper gives the results obtained in a more detailed examination of a further 60 persons over the age of 65—hospital out-patients and in-patients, and residents in an old people's home. Control tests on a limited number of younger persons were carried out at the same time, and these are directly comparable with the results obtained earlier with a total of 160 persons of all ages representative of the working population.

Preliminary Tests

In carrying out tests of this nature with old people it is important to maintain their confidence, and it was therefore thought at first that complicated apparatus must be avoided. The simplest technique appeared to be that normally employed in assessing the sense of smell—a number of bottles containing substances of different odorosity. It was found that medicinal paraffin will take up the typical odour of town gas when a slow current of gas is passed through it for a short period. The level of odour, or odorosity, may be controlled, within limits, by the time of passage of the gas.

Accordingly, two bottles were prepared containing oil odorized to the equivalent of 5 and 15 parts of gas per 10,000 parts of air, and these were submitted to a number of persons together with a selection of other odours, as indicated in Table III. The subjects were asked if they could detect the odours and if they could identify them.

The results obtained were not satisfactory; very few people, whether old or young, succeeded in recognizing the "coal gas." It was concluded that the unexpectedness of "gas" in a glass bottle was confusing, and the technique was modified. The odorized oil was placed in a pair of aspirators connected by a oil-resisting plastic tube and fitted each with a glass filter funnel through which air in the one aspirator could be expelled by raising the other and allowing the oil to flow through the tube. This technique was more satisfactory, nearly 50% of old people readily recognizing the smell of the issuing air as that of gas. Table III sets out the results obtained in one series of tests with 19 old people. The "gas" was equivalent to about 30 to 40 parts of town gas per 10,000 parts of air.

TABLE III.—Ability to Detect and Identify Odours (All Subjects Over 65 Years)

Odour	No. of Subjects		
	Able to Identify the Odour	Able to Detect the Odour but Not Identify It	Unable to Detect the Odour
Clove	3	16	0
Lavender	8	11	0
Onion	8	10	0
Peardrops	3	16	1
Wintergreen	3	14	0
Peppermint	1	18	2
Town gas	8	1	10
All odours but gas	0	17	2
„ seven odours	0	9	10

Determination of the Threshold of Recognition

While this work was going on, a method had been developed in the laboratory for readily determining the lowest concentration of gas which a normal subject could recognize. Experience with this apparatus suggested that it might be possible to use it with old people without imposing upon them the strain of a lengthy test procedure. Preliminary trials confirmed this view, and tests have been completed with a number of old persons in hospitals and in an old people's home.

The apparatus is shown in the accompanying illustration. It consists of two 1-in. (2.5-cm.) brass tubes, 20 in. (50 cm.) long, connected at intervals along their length by a number of smaller tubes containing calibrated capillaries of stainless steel and carrying each its own stopcock. These capillaries have been selected to pass a small known amount of gas when the differential pressure across the capillary is 0.50 in.

Odorimeter for determination of the threshold of recognition of the odour of town gas. Gas from the further wide tube passes in determined quantity through one or more of the cross-tubes into a measured stream of air in the near wide tube, and, emerging from the glass vessel on the right, is smelled by the subject.

(1.25 cm.) of water. Air, purified by active carbon, is blown through the nearer 1-in. (2.5-cm.) tube at 100 c.f. (2.83 cubic metres) per hour, and emerges from the glass vessel on the right. The diameter of this is about 6 in. (15 cm.) so that the linear velocity of the issuing air is approximately 10 ft. (3.05 metres)/min. Town gas is passed through the other wide tube and its pressure is adjusted to be 0.50 in. (1.25 cm.) of water above that of the air, as indicated by the gauge on the right. When one of the stopcocks is opened gas passes into the air stream at the predetermined rate giving the corresponding concentration. With the apparatus used for the bulk of this work the concentrations given by the capillaries were 1, 2, 3, 0, 6, 10, and 16 parts of gas per 10,000 parts of air. As more than one capillary could be used at a time, this permitted concentrations up to 38 parts per 10,000 without modification of the pressure. Higher concentrations were obtained by increasing the differential pressure, but only a very few tests were made with concentrations above 50 parts—taken as the maximum for this report. The blank tube, passing no gas, served as a useful check on reliability.

In carrying out a test the subject smelled first the air with no added gas. Unfortunately, this was not completely odourless, but the level was low and did not seem to affect the results. A selected amount of gas was then added, and the subject was asked if he could detect coal gas. The concentration was then altered and the question repeated. By varying the concentration both up and down it was possible to obtain a reasonably accurate estimate of the "threshold of recognition," or, in the case of "unreliable" subjects, to be certain that they were in fact not detecting the smell at all.

Results Obtained

Four series of tests have been made with a total of 61 persons over the age of 65, and with a few younger persons to act as controls. The results are summarized in Table IV.

It is believed that the values are reliable, but in a few cases the answers were suspect, because, as was to be expected, some subjects were too overawed or too anxious to please. It seems probable that these could not reliably

recognize the odour, and they have been included among those who could not recognize 50 parts per 10,000 parts of air. In Table IV the term "reliable" has been used to indicate those whose threshold was under 50 parts and could therefore be determined. In calculating the means and the standard deviations, only the "reliable" results were utilized.

The control tests with younger persons carried out at the time of the main tests gave the results indicated in the table. They are directly comparable with those obtained with the samples of the normal working population drawn from the office staff at two of the Gas Board's establishments and included in the table under "Other Tests."

TABLE IV.—Threshold of Recognition of Odour of Town Gas (Parts of Gas per 10,000 Parts of Air)

	Threshold of Recognition		Unable to Recognize 50 Parts
	Mean "Reliable"	Standard Deviation	
1. Old persons (over 65):			
A. Hospital in-patients. 9 tested; 6 reliable	24	11	27%
B. Hospital out-patients. 7 tested; 5 reliable	25	9	29%
C. Home X. Convalescents. 26 tested; 17 reliable	29	7	35%
D. Home Y. Inmates. 19 tested; 13 reliable	22	10	31%
All four tests. 61 tested; 41 reliable	24	10	33%
2. Younger persons (under 65):			
A. 6 tested; 6 reliable	7	3	0
B. 4 tested; 4 reliable	9	2	0
C. Observer only	10	6	10%
D. 19 tested; 17 reliable*	9		
All four tests. 30 tested; 28 reliable*	8	5	7%
3. Other tests (under 65):			
61 tested; 61 reliable	6	3	0
49 " 49 "	6	3	0
51 " 51 "	7	4	0

*The two persons who could not detect 50 parts in 10,000 were inmates and not staff.

Discussion

These results indicate that it is probable that approximately 30% of old persons cannot reliably recognize the odour of town gas at concentrations below 50 parts per 10,000 (and perhaps not at all). While of those old persons who can smell town gas, 95% will recognize 45 parts and 50% will recognize 25 parts of gas per 10,000 parts of air.

For younger persons (under 65) the proportion who cannot smell town gas is lower, since over 95% may be expected to recognize 20 parts, and 50% should recognize 8 to 10 parts per 10,000.

The "other tests," with the Gas Board's staff, indicated that neither age below 65 nor sex, nor the practice of smoking, has any significant effect upon the threshold of recognition of town gas.

Conclusions

These results confirm the earlier findings referred to in the B.M.A. report and indicate that the subject is one of importance. Investigation of the sensitivity of old people to other odours might also be of value, since there would appear to be a case for the addition of odorants to town gas to increase the threshold of recognition. Ways and means of doing this are being investigated as part of the research programme of the Gas Council, which has been acquainted with the results of the surveys mentioned in this paper and is actively interested in methods of odorization.

The use of odour as a danger signal for accidental escapes of unburnt gas is clearly unreliable for old people living alone. In this country there are 1½ million one-person households; nearly two-thirds of them are occupied by persons over 60, but the proportion varies widely throughout the country. The carbon monoxide content of domestic gas also varies, and it is possible that the level of odour of the gas is different in different areas. It is suggested, therefore, that further information should be sought in other parts of the country on this ability of older persons to detect and recognize the smell of gas. The results would be of value

for purposes of comparison in relation to local conditions. They would also help to throw further light on the whole question of loss of sense of smell with advancing years. If, as a result of these surveys, the loss of sense of smell is confirmed, it must have considerable bearing on the problem of poisoning by coal gas in the home.

We thank Dr. M. S. Kataria, Consultant Geriatrician to St. Francis Hospital, Dulwich, for his full co-operation in this work and for making some of the tests; also Dr. R. C. Walsh, Medical Officer, the Warden, and the Matron of the Newington Lodge Old People's Home, where many of the tests were made. Acknowledgment is also due to Mr. C. W. Ward, who made the threshold determinations. We duly acknowledge our indebtedness to the B.M.A. Committee, who first drew attention to the need for such an investigation, and one of us (J.R.D.) thanks the Gas Council for permission to publish this work.

FURTHER CONSIDERATIONS ON CEREBROSPINAL FLUID DYNAMICS

BY

DAVID BOWSHER, M.B., B.Chir.

Lecturer in Postgraduate Anatomy, the University of Liverpool

In an earlier paper (Bowsher, 1953) apparent changes of cerebrospinal fluid (C.S.F.) pressure due to change in venous volume were considered in the case in which the fluid was in communication with an open manometer. It was pointed out that the volume of fluid displaced into a manometer, over and above the resting pressure level, when venous compression is applied, is equal to the increase in volume of the subarachnoid blood vessels, and therefore dependent, in height, upon the calibre of the manometer tube. In any such case there will, of course, be a slight rise of true pressure, measured by the increase in height of the column of liquid in the manometer. But this height varies with the calibre of the manometer, whereas the volume of fluid displaced does not, at least within the limits imposed by the increased pressure.

It was considered necessary to study these conditions in the physiological state—that is, when the system is not open to the atmosphere. To this end, two sets of experiments were performed.

Experiments with a Model

A model was constructed consisting of an outer glass cylinder, representing the craniospinal theca. Running through this was a semi-permeable tube of plastic sausage-skin, representing the subarachnoid vasculature. Although this plastic tubing is analogous to blood vessels in that it is permeable to water and is deformable, it is not elastic, and this factor was provided by hard rubber bungs at each end of the glass cylinder (Fig. 1, A).

A flow of water was set up in the inner tubing such that it did not fully fill it, and at the same time the outer tube was filled with water containing sodium thiocyanate. The whole system was then closed.

FIG. 1.—Semi-permeable tube running through a rigid water-jacket, in side (A) and end (B) elevations. Dotted lines indicate position of tube in semi-collapsed and solid line in circular cross-sectional areas, the circumference being the same in both cases. The area between the dotted and solid lines indicates the increase of volume which occurs in change of area.

The flow of water through the inner tube was then increased until the previously elliptical cross-section had assumed a circular shape (Fig. 1, B). The outflow from the inner tube was collected after the flow had been increased, and on testing with ferric chloride was found to contain sodium thiocyanate, thus proving that liquid passes from the outer tube to the inner, even when presumably, at a given moment, the hydrostatic pressure in the inner tube is greater than in the outer.

Experiments with Animals

Isotonic saline containing radioactive sodium (^{24}Na) was introduced into the subarachnoid space of two monkeys. The concentration of sodium in the systemic blood was assessed by counting over the shielded foot and recording continuously from a ratemeter. A steady rate of increase of ^{24}Na in the systemic blood was established. The abdomen was then compressed with a towel. Immediately the rate of absorption of sodium into the blood stream was increased, and rapidly reached a slope parallel to but above the original

FIG. 2.—Diagrammatic representation of absorption curve. Compression applied between arrows produces an increase of absorption following initial compression.

curve (Fig. 2). It is therefore presumed that when the volume of the subarachnoid veins is increased C.S.F. passes into them, presumably in a volume equal to the increase in venous volume. When the veins collapse again the potential space so formed is taken up by newly formed C.S.F., so that there is no sudden drop in the absorption curve implying an equal movement of fluid out of the veins. This may in fact happen locally, but the sensitivity of the recording method used was not sufficient to demonstrate it.

Discussion

While the doctrine of Monro (1783) and Kellie (1824), that the sum volume of blood, neuraxis, and C.S.F. in the subarachnoid space is constant, may not be entirely true, it is so for all practical purposes (Weed, 1929). It is true that the original theory took no account of the elasticity of the system, and hence the discrepancy, but this is so small as to be of no practical importance under normal conditions (Flexner, Clark, and Weed, 1932). This doctrine is invoked to explain the symptoms of chronic hydrocephalus, but it must hold true in the physiological state. Therefore, if the intrathecal blood vessels increase in volume, or if the volume of the whole theca is diminished by compression from without, as for example increase in cross-sectional area of the extradural vertebral venous sinuses (Bowsher, 1954), there must be a diminution in volume of the non-vascular intrathecal contents.

Holbourn (1943) has shown that nervous substance is virtually incompressible within the range of pressures exerted in physiological or pathological conditions; and so, of course, is liquid (blood or C.S.F.). Additional space can be found only by the removal of liquid from the subarachnoid space. When this space is in contact with an open manometer, excess liquid is displaced into the manometer, and a small but true rise of pressure occurs. When, however, the system is closed it is not possible for this type of displacement to occur. Bering (1954) and Sweet *et al.* (1956) have shown that the water component of C.S.F. exchanges extremely rapidly throughout the system; for example, the turnover time of water (as deuterium oxide) in the cisterna magna is of the order of 1.5 to 6 minutes in the resting state. It is concluded that there is an exchange of water across all the (vascular) membranes of the C.S.F.-containing system.

The experiments with a model, described above, suggest that in any manoeuvre whereby the intrathecal vascular volume is increased the wall of the vessel is enabled to move outwards by the passage into the interior of the vessel of liquid originally external to it. One may imagine a molecule of water in the C.S.F., in a static position, coming to be included in the interior of a blood vessel merely by movement of the semi-permeable vascular wall across it—that is, by passing through the vascular wall as a result of expansion of the latter. Scholz and Ralston (1939) have demonstrated the presence of Weed's prussian-blue reagents in the walls of cortical veins, and Bowsher (1957) has shown the same to be true of homogenous protein; Adams (1951) has observed that an inorganic ion (PO_4^-) also passes into these veins.

Ryder, Molle, and Ferris (1944) demonstrated that, while a semi-collapsed tube increased in volume until a circular cross-section is assumed, the increase in its internal pressure is minimal; the pressure is increased only when flow is increased in an elastic tube which is already circular in cross-section. Thus, during the initial volumetric increment of originally semi-collapsed veins of the subarachnoid space there is no internal pressure factor resisting the inward passage of extravascular particles. This has also been found to be true of the semi-collapsed tube surrounded by a rigid water-jacket, as in the model described, though the range is somewhat smaller than in a free tube.

That this increased rate of passage of extravascular particles into blood vessels during volumetric increase of the latter is true of the living system is demonstrated by the animal experiments described above. As soon as the intrathecal vascular volume is increased by abdominal compression there results a very rapid jump in the rate of absorption of Na^+ ions into the systemic blood stream. After this, absorption continues at the same rate as before.

It has been held that when intrathecal venous volume is increased absorption of C.S.F. constituents is depressed or abolished. This may be partly true when the system is in communication with an open manometer, although even in this case it is not wholly so, as has been previously demonstrated (Bowsher, 1953). In the case of a closed system, there is actually an increase in the rate of absorption as the intrathecal blood vessels dilate. Under pathological conditions, when there is a true and significant increase in pressure both of the C.S.F. and of the intrathecal veins, the rate of absorption of C.S.F. constituents is diminished, as has been shown by Bering (1954) for water, and Sweet and Locksley (1953) for electrolytes and protein.

Physiological changes in intrathecal vascular volume occur with the phases of expiration and inspiration, systole and diastole, and with temporary occlusion of the abdominal vena cava, as in coughing and straining. When the C.S.F. is in communication with an open manometer these changes are reflected partly as a true change of pressure, but mainly as a displacement phenomenon (Bowsher, 1953). In the closed system, however, these changes, so long as they do not result in expansion of total circumference of the vascular wall, will cause very little or no change in subarachnoid pressure. Experiments with a capacitance manometer connected with the subarachnoid space have in fact failed to reveal significant pressure changes in the resting state, though artificially induced straining (by abdominal compression) does cause noticeable increase in subarachnoid pressure. It is inferred that what is recorded by such a manometer is the average of intravascular and extravascular subarachnoid pressures, and that, in the absence of expansion (increase of circumference) of the vascular wall, such an average is constant.

The changes in venous volume must be envisaged as showing a sharp rise and a slow decline. In each cycle the volume decrement is made up by the inpouring of newly formed C.S.F. into the extravascular part of the subarachnoid space.

Thus constant rhythmic changes in the volume of the subarachnoid veins are presumably responsible for the mechanical absorption of the constituents of C.S.F. across

their walls. The rate of absorption of any given substance is a measure of the permeability of the vascular wall to such substance. The pressure in the unsupported veins of the subarachnoid space cannot be much below that of the C.S.F., or they would be completely collapsed; but dural sinuses into which they drain are at a lower pressure because they are held open by the rigid and inelastic dura mater. So long as the blood in these sinuses does not occupy the total potential volume of the sinus (as in hydrocephalus) it is possible for their pressure to be below that of their tributary veins. Thus the true pressure gradient exists not between the C.S.F. and the veins which it immediately bathes, but between the unsupported (pial) veins and the dural venous sinuses.

Such a mechanism demands that all the subarachnoid veins be in the same phase of vascular systole or diastole. If, for example, the cerebral veins were dilated while the spinal veins were compressed, and vice versa, there would merely result a flow of C.S.F. from cranial to spinal subarachnoid spaces and back again. This would happen during the phases of respiration of the cranial subarachnoid veins drained into the superior caval system and the spinal into the inferior. But Howarth and Cooper (1949) showed that a radioactive local analgesic injected into the lumbar subarachnoid space is subsequently found in much higher concentration in the azygos vein than in any other systemic veins. Bowsher (1954) demonstrated that in six representative mammals (including man) the intradural and extradural veins of the vertebral canal drain into the azygos system and thence into the superior vena cava. Hence the total venous drainage of the cranial and spinal subarachnoid spaces is into the superior caval system in the thorax, and thus venous volume changes in subarachnoid vessels induced by the phases of respiration will be in the same direction throughout the subarachnoid system.

Summary

A semi-collapsed semi-permeable tube in a rigid water-jacket can increase in volume, up to a circular cross-sectional area, by absorbing the contents of the jacket.

In the closed C.S.F. system, increase in volume of the intrathecal veins results in increased absorption of C.S.F., whereby the total volume of intrathecal liquid is equilibrated.

So long as there is no expansion of the total circumference of the vascular walls in the subarachnoid space, as opposed to change in cross-sectional area, there will be little or no change of pressure accompanying volumetric changes in these blood vessels.

The rhythmic changes in volume of the subarachnoid vessels due to cardiac action, and especially those due to respiration, are an important factor in the purely mechanical absorption of C.S.F.

My thanks are due to Professor R. G. Harrison for his advice and encouragement, and to Professor J. H. Preston, of the Department of Fluid Mechanics, for his advice and the interest which he has shown in this work. This work has been aided by a grant from the Medical Research Council.

SEVERE POST-OPERATIVE THROMBOCYTOPENIC PURPURA

BY

FREIDA YOUNG, M.B., B.S., D.C.P.

Pathologist, Willesden General Hospital

Generalized haemorrhage in the post-operative period, especially after a major operation, is an alarming occurrence. Among a number of conditions which may cause this is thrombocytopenic purpura. Many drugs (Ackroyd, 1955) have been described as able to cause a severe thrombocytopenia, of which the reaction to "sedormid" (Ackroyd, 1949) is the classical example. It has been shown that both phenobarbitone (Andel and Groen, 1937) and allylisopropyl barbituric acid (Wintrobe, 1942) can cause this condition.

In the case here described hypersensitivity to butobarbitone developed; it was rapidly recognized by a positive patch test, and later by the effects of a test dose of the drug. The widespread use of pre-operative sedation, and the ease with which sedative drugs can be obtained, make it imperative that this condition be recognized early, for, though a rare complication, its effects may be fatal.

Case Report

A man aged 65 was admitted to hospital with a four-months history of abdominal pain and loss of weight. He was found to have a carcinoma of the stomach. Examination of the chest revealed no abnormality, and x-ray examination showed no active disease there. His blood pressure was 138/75; haemoglobin, 67% (9.9 g./100 ml.), blood group A, Rh negative. He was transfused with 1 pint (570 ml.) of packed cells, group A, Rh negative, and next day a partial gastrectomy was performed.

At operation a growth 2 by 2 in. (5 by 5 cm.) was found in the pyloric part of the stomach, and enlarged glands were present in the adjacent mesentery, none distant from the stomach. There was no growth in the liver or peritoneum. Histologically the growth proved to be a well-differentiated papillary adenocarcinoma. No growth was seen in the glands present in the operation specimen. For the next few days progress was uneventful.

On the seventh post-operative day a slight blood-stained discharge appeared from the stab wound into which a drainage-tube had been inserted at operation. On the 10th day the sutures were removed and the wound appeared satisfactory. The next day a slight greenish discharge from the wound was noted, and "crystamycin" therapy was started. On the 12th post-operative day a small epistaxis occurred, and the following day a slight blood-stained discharge from the wound was noticed. At this time, also, some purpuric spots in the region of the wound in the abdominal wall appeared; these were thought to be due to bruising resulting from the use of adhesive strapping to cover the wound. On the 14th post-operative day bright-red blood was oozing from the wound and stab hole and from the stitch holes. The blood was fluid and showed no evidence of fibrin formation. Gross haematuria then appeared for the first time. Purpura was now extensive, being evident over the trunk, arms, legs, and heels. Bleeding from the face after shaving was difficult to control.

Haematological investigation at this time showed: haemoglobin 58% (8.6 g./100 ml.); red cells, 3,560,000 per c.mm.; colour index, 0.8; white cells, 19,100 per c.mm. (polymorphs 87%, lymphocytes 8%, monocytes 5%); bleeding-time grossly prolonged (over 10 hours); clotting-time, 10 minutes (room temperature); platelets, 35,000 per c.mm. (method of Lempert); prothrombin index, 100% of normal; capillary fragility test, strongly positive; blood

fibrinogen, 320 mg. per 100 ml. The significant findings were a greatly reduced platelet count, prolonged bleeding-time, and increased capillary fragility. The thromboplastin generation test was not therefore proceeded with.

Inquiry elicited the following: the patient had received 3 gr. (0.2 g.) of butobarbitone on the night of admission, pethidine and atropine pre-operatively, crystalline during the post-operative period, with further 3-gr. (0.2-g.) doses of butobarbitone on the third, fourth, and fifth post-operative days. Patch tests as described by Ackroyd (1955), containing butobarbitone, penicillin, and streptomycin, were accordingly applied.

A slow drip transfusion was started and continued for the next 48 hours, and vitamin K₁ therapy was begun. The next day the patch test with the butobarbitone was found to be positive; the rest were negative. Sternal puncture was performed, but no malignant cells were found in films or sections of the marrow aspirate. In the meantime haemoptysis had appeared, the wound continued to ooze bright-red blood without any fibrin formation, and the urine still contained a large amount of blood. Although the fibrinogen levels had been determined on successive days, the level never became low enough to account for the haemorrhage, and the normal prothrombin time also excluded the possibility of haemorrhage due to fibrinopenia. The platelets continued to decrease, levels of 63,000 and 49,000 per c.mm. being found on successive days.

Since it was now clear that the bleeding diathesis was due to a platelet defect, and since this was likely to be due to hypersensitivity to butobarbitone, treatment with prednisolone was begun.

Twelve hours after the first dose of prednisolone was given the platelets were 31,000 per c.mm.; six hours later they were 164,000 per c.mm. Fibrin clot appeared in the blood on the dressing of the wound. Within 48 hours of starting prednisolone therapy the urine was clear macroscopically and contained only scanty red cells in the spun deposit. The haemoptysis had ceased. Thereafter there was a steady improvement in the patient's condition. The platelet level, bleeding-time, and capillary fragility tests became normal. All bleeding ceased, and the wound healed satisfactorily. Prior to his discharge to a convalescent home, three weeks after the bleeding episode had started, the patient was given a test dose of approximately 1/20 of a tablet (5 mg.) of butobarbitone, with no effect on his platelet level, as shown below:

9.30 a.m.	..	Platelets, 255,000 per c.mm.
9.40 a.m.	..	Test dose 1/20 tablet butobarbitone.
10.40 a.m.	..	Platelets, 245,000 per c.mm.
11.40 a.m.	..	" 251,000 "
12.40 p.m.	..	" 250,000 "
2.40 p.m.	..	" 261,000 "
3.40 p.m.	..	" 239,000 "
4.40 p.m.	..	" 234,000 "

Accordingly, the following day, half a tablet, or 47 mg., of butobarbitone was given, which caused a small but definite drop in the platelet level, as shown below:

9.30 a.m.	..	Platelets, 259,000 per c.mm.
	..	Test dose 1/2 tablet butobarbitone given.
10.40 a.m.	..	Platelets 259,000 per c.mm.
11.40 a.m.	..	" 290,000 "
12.40 p.m.	..	" 233,000 "
2.40 p.m.	..	" 219,000 "
3.40 p.m.	..	" 175,000 "
4.40 p.m.	..	" 170,000 "
5.40 p.m.	..	" 272,000 "
6.40 p.m.	..	" 285,000 "

The urine deposit contained scanty red cells.

One month later the bleeding-time, clotting-time, platelets, and capillary fragility tests were all normal. A gain in weight of 3 lb. (1.4 kg.) was recorded, and the patient felt well.

Discussion

The appearance of a haemorrhagic condition after operation may be due to the presence of a congenital defect of the clotting mechanism, or an acquired defect. In the present

case it seemed unlikely that the defect could be congenital, since no haemorrhage had occurred for 10 days following operation.

Fibrinolysis has been described (Dyggve, 1947; Soulier *et al.*, 1952) as a cause of post-operative haemorrhage, but this was discounted by the presence of a moderately reduced but nevertheless significant blood fibrinogen level and a normal prothrombin time. Fibrinolysis due to general dissemination of carcinoma was made unlikely by the absence of malignant cells in the sternal marrow.

The most significant finding was a gross reduction in the platelets, accompanied by a prolonged bleeding-time and increased capillary fragility. It is well recognized (Williams *et al.*, 1955) that thrombocytopenia occurs and is sustained for three to four days after surgical operation, and that the pre-operative platelet level is regained by the seventh post-operative day, so that it appeared that the thrombocytopenia in this case could not be due to the operation *per se*. Massive transfusions have been shown (Krevans and Jackson, 1955) to cause thrombocytopenia, and to be unaffected by cortisone therapy, but the transfusions have to be of at least 5 litres and given rapidly. The present case had received 560 ml. of blood by slow drip.

A positive patch test seemed to implicate butobarbitone as the sensitizing agent in producing the thrombocytopenia, and this was confirmed by subsequent test-dosing when the patient was well and had recovered from his haemorrhagic episode.

Since this case showed an immunological response, large doses of prednisolone were given, with remarkably dramatic results.

Summary

A case of thrombocytopenic purpura developing post-operatively is described.

The cause has been identified as due to sensitization to butobarbitone.

Prednisolone was found to be remarkably effective in controlling the condition.

I have pleasure in acknowledging the help and advice of Professor J. V. Dacie, particularly in regard to the marrow examination; to Mr. George Quist for permission to publish the case; and to Miss Geraldine Payne for technical help.

A day-school for physically handicapped children—The Franklin Delano Roosevelt School—was opened in London on October 3 by Sir EDWARD BOYLE, Parliamentary Secretary to the Minister of Education. The school, an L.C.C. establishment in Avenue Road, Hampstead, is stated to be the first day-school for physically handicapped children to be built in London since the second world war. Originally an all-age school in Paddington, which was reorganised and divided in 1944, the school was renamed the Franklin Delano Roosevelt in 1950; the transfer to the new building was made in January this year. The new school is for 160 boys and girls, whose ages range from 2 to 16. Among the pupils are children suffering from cerebral palsy, heart diseases, anterior poliomyelitis, tuberculosis of the bones and joints, and haemophilia. In addition to the headmistress, Mrs. E. K. SELICK, there are eight full-time teachers and one part-time, and a part-time nursing sister. A remedial exercises room is provided, in which visiting physiotherapists give treatment; speech therapy is also available when required. Children attend the school from west and north-west London, Middlesex, and Hertfordshire.

ARC-WELDERS' LUNG

BY

BERTRAM T. MANN, M.D., B.Sc., D.P.H.
F.C.C.P.

Consultant Chest Physician, Royal Halifax Infirmary

AND

EDMOND R. LECUTIER, M.B., Ch.B., F.R.C.S.

Consultant Thoracic Surgeon, Bradford Royal Infirmary

Arc welding is an important and expanding technique used in many branches of the engineering and shipbuilding industries. The equipment employed consists of covered electrodes with a core of metal and a heavy cellulose or mineral coating. At the high temperature (1,500° C.) generated during welding operations the metal core and flux of the two electrodes spread over the welded metal. The greyish-white vapour which arises during operations has been shown to consist of oxides of iron, calcium, sodium, lead, aluminium, manganese, tin, cadmium, copper, titanium, magnesium, and silica, as well as nitrogen peroxide, ozone, etc. It is the inhalation of these fumes which produces the radiological changes in the chest of arc welders, first described by Doig and McLaughlin in 1936.

During the past twenty years a number of workers in Britain (Doig, 1949), Germany (Koelsch, 1941; Humperdinck, 1942), Belgium (Mignolet, 1950), and the U.S.A. (Nayer, 1942) have observed abnormal x-ray patterns, usually taking the form of a deposition of fine nodules (Sander, 1944; Sutherland and Fawcitt, 1945), in the lungs of welders. Some authors (Collen *et al.*, 1944; Collen, 1947; Doig, 1949, 1954) have expressed the view that there is no statistical evidence to suggest any special hazards in this occupation, that the radiological changes are reversible (Britton and Walsh, 1940), and that such workers are asymptomatic. In consequence the impression has gained currency that the iron oxide fumes are inert (Doig and McLaughlin, 1936, 1948; Groh, 1944), and that the radiological findings are benign (Enzer *et al.*, 1945; Pendergrass and Leopold, 1945; British Medical Journal, 1948; Wyers, 1949; Poinso *et al.*, 1953). Oddly enough, there is very little pathological evidence (Enzer and Sander, 1938; Charr, 1955) to uphold this view of the complete innocence of arc-welders' lung.

The following case should ensure a fresh appraisal of the medical problems associated with this occupation.

Case Report

The patient, aged 49, had been employed as an arc welder for over 25 years. The dimensions of the shop in which he was engaged were 50 by 30 ft. (15 by 9 metres). Seven other welders worked in the same room and the ventilation was unsatisfactory. The patient was provided with an arc-welders' screen, which gave protection from the glare and heat, but had never used any form of respirator. The electrodes were of mild steel, although the covering was a proprietary preparation containing ? asbestos and silica. The

work consisted mainly of welding boilers. At no time did the patient engage in fettling, though his work involved cleaning the welded slag with a wire brush.

On leaving school he spent six years as a jewellery salesman, and since then his only occupation has been arc welding. His personal and family health was good, although during the previous 18 months he was short of breath on exertion and on going up inclines. He complained of slight cough and mucoid sputum. His appetite was good and his weight constant.

Clinically, nothing of note was detectable on pulmonary or cardiovascular examination. He was Mantoux-positive to 1:100 O.T.; E.S.R., 2 mm. per hour. Radiologically there was an increase in vascular markings, accompanied by a fine stippling of nodules 1 mm. in size, scattered mainly throughout the lower two-thirds of both lung fields. These micro-nodules were uniform in density, were discrete, and showed little tendency to merge into the pulmonary vascular background. An opacity 3 by 1.5 cm. was found in the apical segment of the right upper lobe. The patient was admitted to hospital for investigation.

A tomogram of the opacity showed it to be non-homogeneous. Maximal voluntary ventilation and timed vital capacity were about 70% of their predicted values. Fifteen sputa were negative for acid-fast bacilli on direct smear and culture.

A diagnosis of right apical pulmonary tuberculosis associated with arc-welders' lung was made.

Operation.—Right upper lobectomy was performed on April 16, 1956. At operation the lung had an unusual "feel" like pitting oedema, and there was a noticeable lack of tissue retraction on expiration. The lobe was immediately prepared by the Gough and Wentworth technique.

Histological Examination.—Large sections were cut and stained by Perls's method for iron pigment. Professor Gough reports: "In the lower part of the lobe the emphysema is of the focal type related to the dust, but in the upper part it has become confluent with whole lobules involved in the lesion. The granuloma is presumably tuberculous, modified by the iron dust, as so often happens with benign pneumoconiosis. From the large sections it is not possible to determine how much of the iron is exogenous and how much from the body, but, undoubtedly, a good deal of the iron is from the inhaled dust."

Histological examination revealed the presence of pneumoconiotic bodies, which were quite as marked as those to be observed in asbestosis. These deposits appear to be similar to those described by Schilling (1956) in byssinosis, but, whereas in cotton disease the bodies are round or oval, the striking feature in arc-welders' lung is the large size and complexity of the bodies. Professor Gough, in a personal communication, reports that "the appearances indicate that the dust is one to which the body is reacting, so that the dust cannot be regarded as inert."

Petrological Analysis.—Incineration of a large section revealed that the material was partly combustible, the residue consisting of a dark-brown material due to the presence of iron oxide.

Chemical analysis of the lung tissue for iron was performed by Dr. Nagelschmidt, of Sheffield. The emphysematous portion had 22% Fe₂O₃ and the tuberculous portion 13% Fe₂O₃. This amounts to 4.2% dry lung for the first and 1.6% for the second sample. Thus it would appear that the iron content of this patient's lungs is at least 100

Spectrochemical Analysis (g.%)

Portion of Lung	CaO	Na ₂ O	PbO	Fe ₂ O ₃	Al ₂ O ₃	Mn ₂ O ₂	SnO	CdO	CuO	TiO ₂	MgO	SiO ₂	B ₂ O ₃	Bi, Sb, As, NiO, Ag ₂ O, ZnO, Co ₂ O ₃ , Cr ₂ O ₃
Emphysematous part dried lung	0.02	0.02	0.025	2.0	0.3	0.04	0.02	0.01	<0.005	0.2	0.02	0.05	<0.01	No indication
Ashed emphysematous lung	0.05	>2.5	0.1	>2.0*	>1.0	0.1	0.1	0.04	0.005	0.5	0.05	0.1	<0.01	" "
Tuberculous part of lung	0.02	0.2	<0.025	2.0	0.3	0.02	0.01	0.01	<0.005	0.5	0.02	0.1	<0.01	" "
Ashed tuberculous part of lung	0.02	>2.5	0.05	2.0	0.3	0.02	0.02	0.01	0.005	0.2	0.01	0.1	<0.01	" "

It will be noted that both the emphysematous and the tuberculous portions of lung have a very high iron content. The remarkably high iron content found in the emphysematous portion of ashed lung (*) is interesting and strongly supports the results of chemical analysis reported above.

times greater than normal values (Rechenberger and Schairer, 1947). Spectrochemical analysis of four samples of lung ash was kindly carried out by the Bragg Laboratory, Sheffield, with the results shown in the Table.

Discussion

Arc-welders' lung arises because of inhalation of the smoke and fume of iron oxide. It is the high temperature of the arc which produces the oxidation of the iron. After the inhalation of these tiny particles, $1\ \mu$ in size, into the lung alveoli they are arrested in the peribronchial and perivascular lymphatics, and in lymph nodules, and it is this deposition of tiny radio-opaque iron particles which gives the characteristic x-ray appearance.

Our patient, though suffering from only cough and shortness of breath, showed evidence of considerable focal and lobular emphysema, a marked loss of lung elasticity on thoracotomy, and a maximum voluntary ventilation and a timed vital capacity of about 70% of their predicted values.

In the past the general consensus of opinion has been that the condition of arc-welders' lung is benign and innocent. This view has been based on the frequent clearing of miliary radiological shadows in the chest x-ray picture, and on the absence of major pulmonary symptoms. Indeed, this also has been our own experience in the past. However, it may well be that prolonged exposure to iron fume (in this case over 25 years) in an enclosed space with little or no protection from the fumes does produce secondary emphysematous changes which are considerable and permanent, and are responsible for the irreversible lung damage reported in this patient.

Summary

A case is recorded of arc-welders' lung in association with a tuberculoma, in a man engaged in arc welding for over 25 years.

Radiologically an increase in the pulmonary vascular pattern, with micro-nodular shadows, mainly concentrated in the lower two-thirds of the lung fields, was observed.

At operation a distinct loss of lung elasticity was noted, and this was confirmed by respiratory physiological investigation. The pathological appearances of the excised lobe, in addition to the deposition of iron, revealed a considerable degree of emphysema. Chemical and spectrochemical analyses show the lung to have an iron content at least 100 times greater than normal values. Evidence strongly suggests that arc-welders' lung is not always the innocent or reversible condition which has been suggested by all previous workers.

We wish to record our grateful appreciation to Professor J. Gough for his kindness in cutting and preparing the sections, and for his advice in reporting on the histological specimens; also to Dr. Nagelschmidt for the chemical and petrological analysis of the sections.

FRACTURE OF NECK OF FEMUR SURVIVAL AND CONTRALATERAL FRACTURE

BY

I. M. STEWART, M.B., F.R.C.S.Ed.

Clinical Research Assistant, Eastern Region (Scotland)
Orthopaedic Service

As a consequence of the increased proportion of aged in the population fractures in the elderly are more frequent. The classical example, fracture of the neck of the femur, continues to pose new problems. The following survey indicates fresh implications of this common injury.

During the four years from 1952 388 patients have been studied. The initial two-year period has already been reported (Stewart, 1955). In that paper the first absolute incidence was recorded. The present report is a sequel occasioned by a fresh problem—namely, the readmission of significant numbers of patients with a second fracture of the same variety on the opposite side.

Present Series

The series represents the total unselected incidence of fractures of the neck of the femur in one area. No patient was refused admission. A standard routine of management was practised throughout. Surgical treatment was given to 95% of the cases. After internal fixation the patients were encouraged in immediate mobilization, but weight-bearing was prohibited until there was evidence of bony union.

In the period under review 27 patients sustained the fracture, first on one side and then on the other (see Table). The contralateral fracture followed return to activity and, with one exception, did not occur spontaneously during confinement to bed or chair. It seemed to be a consequence of non-weight-bearing, and occurred only when weight was again borne freely. The interval between fractures in 24 patients varied from a few months to ten years, with the majority close to the average of two years and a few months. This is also about the time taken to regain the degree of activity which determined the original fracture. Reactive remodelling of bone declines with age (Lacroix, 1951), and the elderly patient may not respond rapidly enough to the stimulus of resuming walking. As with stress fractures in general, this particular fracture results from the repeated application of a strain with a rapidity which outstrips the capacity for reactive remodelling by the bone. Characteristically, force is absent from the production of the injury.

There is further evidence, as shown by the symmetry of the bilateral cases, that the final dissolution of the bone has simply occurred at its weakest point. The two exceptions (Cases 5 and 8) may merely prove the rule. Less obvious is the reason why the right hip was the first to prove unequal to demands in a similar proportion. It has been said, in relation to other mechanical failings of the weight-bearing skeleton, that this is a "right-footed world" (Goff, 1954). The precedence of right before left may be no more than the result of "best foot foremost" in the conflict with gravity. The femoral neck becomes so vulnerable that the most trivial factor may tip the balance to either side.

Discussion

Solution of continuity in the neck of the femur can certainly follow disuse. Restrictions imposed by the first fracture, and ageing physique, deprive the weight-bearing bones of the stresses normally expressed by the cancellous architecture of the femoral neck in accordance with Wolff's law. Fractures of the neck of the femur are a not infrequent spontaneous occurrence in bedfast or paralytic patients. This is exemplified in the case of a male who complained of hip pain while incompletely confined to bed in hospital

Bilateral Fracture of Neck of Femur in 27 Cases, in Chronological Order of Second Fracture

with pulmonary tuberculosis; bilateral fractures of the neck of the femur had occurred without any incident being recognized. Two other bilateral cases also sustained supracondylar fractures of the femur during non-weight-bearing mobilization. Since it has been shown that the incidence of the injury is related to the senile state of the bone (Stewart, 1955), the inference is that the inactivity enforced by the first fracture leads to more rapid degenerative changes.

The misfortune of the first fracture is responsible for the vulnerability to the second. A higher incidence of second fracture among survivors of the first, as compared with the incidence of the first in the population at risk, indicates the degree of relevance. The exact incidence of second fracture is not yet known. Even the estimation of survival becomes problematical in these age groups; it is impossible in the individual. When the appropriate bilateral cases are related to the survivors from the known population the incidence is approximately twenty times that of the first fracture.

A second fracture on the same side is rare. The final healing of any fracture can only follow the principles of Wolff's law: the healed neck of the femur, having thus

once more become adapted to stress, is the less likely to undergo classical fracture again.

Dietary deficiency can be postulated as relevant to senile bone change; but in animal experiments bone has been found resistant to dietary restriction of calcium (Bell, Cuthbertson, and Orr, 1941). The second fractures arose after a period of hospital dietary likely to have corrected deficiencies.

Patients with fractures of the neck of the femur are usually thin; they are often described as emaciated. The weight-bearing requirements of the skeleton have thereby again been reduced to an inadequate level. Such fractures, however, do occur in the obese and entail particular technical difficulties, including comminution. It has been noted that heavy patients have not only applied their own weight to produce the fracture, but have also more frequently done so in some accident from which violence was not entirely absent.

A word or two may be said concerning the fate of the fracture. The local result is often undecided for about two years. This is also the time taken to produce a contralateral fracture if such is to occur. The final processes in repair depend on the very factors the absence of which determines the vulnerability of the other hip. The point is thus not surprising.

The foregoing comments cannot justify the taking of physical liberties with the first fracture. If, however, the incidence of contralateral fracture is proportional to the prohibition of walking until union, a warning is none the less implied. There is no ready alternative to the normal stimuli for maintenance of skeletal strength. Elderly people do not take kindly to the use of crutches even when the use of both legs is once more vouchsafed. They cannot reasonably be expected to use them with one sound leg. Meantime, reliance can only be placed on intensification of maintenance exercises.

Deterioration of skeletal strength must be borne in mind when decreased activity is prescribed for the ageing. The concept of occupational therapy has been developed to make exercises palatable, and, indeed, is popularly so understood. However, there is not yet popular understanding of the need to encourage activity in old age. This may be due to the lack of some comparable plan to make it as acceptable. Preventive medicine could contribute to this defect in prophylaxis.

Conclusions and Summary

Clinical investigation of the bilateral cases described appears to confirm that the incidence of fracture of the neck of the femur is determined by the senile state of the bone. Furthermore, the susceptibility of senile bone to this fracture is in particular related to a low level of physical activity. The patients who sustained fractures of the femoral neck first on one side and then on the other probably exhibit the highest degree of predisposition. The symmetry, timing, and production of these second fractures exemplify the failure of skeletal reactivity as determined by the ageing process. Such cases thus clarify the aetiology of fractures of the femoral neck. They indicate also the obstacles to their prevention.

Details are given of 27 cases of fracture of the neck of the femur where survival has already been followed by a similar fracture in the opposite hip; the exact incidence of such second fractures, however, is not yet known.

Certain inferences are drawn from the bilateral cases relating to aetiology and prophylaxis.

The greater part of this work was carried out while I was holding a Clinical Research Fellowship of the Scottish Hospitals Endowment Research Trust. I am further indebted to Mr. I. S. Smillie, Lecturer in charge, Department of Orthopaedic Surgery, Queen's College, St. Andrews University, for his stimulation and

assistance. I am grateful for the co-operation of the other surgeons of the Regional Orthopaedic Service, on whose cases this investigation is based: Mr. J. Hutchison, Mr. I. D. Sutherland, Mr. G. Murdoch, Mr. R. D. Muckart, Mr. G. L. Clark, and Mr. C. S. Campbell.

Medical Memorandum

Fatal Outbreak of Botulism among Labrador Eskimos

This is an account of a fatal outbreak of botulin poisoning among a group of Eskimo hunters in Northern Labrador. The men concerned belonged to the township of Nain and moved out from there in the middle of November, 1956, to the autumn sealing station at Ungadlek. The party consisted of six men, two women, and some children. The sealing station was a hut which had not been used since the spring of that year.

A favourite Eskimo diet called *utjak* was asked for. This is prepared by placing seal flippers, complete with fur, in a container, and leaving this with a lid on it behind the stove for a variable period of several hours to several days. One of the women did not like the food and refused to make the meal. Her husband insisted, whereupon she said that the wooden cask was leaking and she could not use it. He then brought an empty gasoline cask, which had previously been used for tainting sealskins, and told her to use that to prepare the meal.

Sealskins are "tainted" by being left in a cask beside the stove until the hairs are removed from the skin. The gasoline cask had been used for that purpose a year previously. It was now used to prepare *utjak* without being cleaned. In this cask meat was "cooked" for ten days at a temperature that probably fluctuated between 20 and 40° C. The seals used for the meal were fresh, and other parts of the seals had been eaten at other times.

The meal was consumed at about noon on December 10. One man thought it tasted bad, and vomited almost at once. He was the only man to survive. Between two and three hours later a girl aged 6 died. Her speech was peculiar, she seemed to be paralysed and unable to move her tongue. At this point the survivor left to get help, and further clinical details are scanty. In all cases there appeared to be difficulty in swallowing, regurgitation of fluids through the mouth, abdominal pain, and distension. The first man, aged 46, died at 4 p.m. (necropsy was carried out on his body); the second, aged 42, died soon after. Then next morning (December 11) the third man, aged 21, died, and the fourth man (aged 34) died a little later. The last man to die (aged 42) was the heaviest, weighing about 170 lb. (77 kg.)—in contrast to the others, who weighed 120–140 lb. (54.4–63.5 kg.). He died on December 13.

There was one other survivor—a girl of 8. She took the meal, and suffered from nausea, vomiting, diarrhoea, and headache. She arrived back at Nain on December 15 and was admitted to the nursing station early the following morning with diarrhoea (stool green and black), abdominal distension, nausea, abdominal cramps, and frontal headache. She vomited three times after admission, was kept on fluids by the nurse in charge, and recovered completely in a few days.

The two women did not eat the food and were unaffected.

The man who survived (aged 22) ate only one or two mouthfuls, and vomited almost at once. He walked nine miles to Black Island, where he was reported to have arrived covered with sweat and his abdomen so distended that his top trouser button and his jacket buttons would not fasten. The next day he travelled by dog sledge 25 miles to Nain. He felt better then and went to his home, complaining only of some stiffness in his throat. A few days later he felt pain

in his chest, was admitted to the nursing station, and then transferred by aeroplane to the hospital at North-West River with lobar pneumonia. He made a rapid and uneventful recovery. No other physical abnormality was discovered on examination.

As soon as news of the tragedy was received at Nain an aeroplane was summoned. It arrived at Nain, but was delayed thereafter for several days by bad weather. This aeroplane brought the body of one of the victims to North-West River, where necropsy was performed.

NECROPSY REPORT

The body was that of a well-built Eskimo. Some discoloration of the skin of the abdomen was seen, and there was a notable dilatation of the superficial vessels over the whole body. No pathological changes had occurred within the mouth. The peritoneal cavity contained no free fluid. The stomach was filled with a paste-like material flecked with blood. There were petechial haemorrhages in the gastric mucosa, particularly towards the cardia, also a few haemorrhages in the duodenum. The rest of the gut was normal, as were all other abdominal viscera. The bladder was filled with cloudy urine. The bladder mucosa appeared normal. Signs of old tuberculosis were seen in the right lung and pleural cavity, otherwise the thoracic viscera showed nothing abnormal.

The brain was normal both macroscopically and microscopically. The meninges were normal to the naked eye, but histological examination showed multiple thromboses in small vessels. Otherwise the histology of all organs showed no abnormality apart from vascular congestion in the upper alimentary tract.

Samples of the seal flipper from the food consumed, together with samples of the gastric contents and urine from the body examined, were sent to the Public Health Laboratory at St. John's, Newfoundland. In direct smears from the seal flipper a Gram-positive bacillus with terminal spore, morphologically resembling *C. botulinum*, was demonstrated. Subsequent exhaustive bacteriological investigation failed to yield culture of this organism or its toxin. However, the confirmatory bacteriological investigation of part of the sample of the flipper, carried out at the Department of Bacteriology in the University of British Columbia, demonstrated type E toxin of *Clostridium botulinum* in a concentration of roughly 1,000 m.l.d. per g. of flipper, and also a toxic strain of *Cl. botulinum* type E.

COMMENT

In the eyes of the Eskimos the cause of the tragedy lay in using a metal cask. Many Eskimos have said that to have used a gasoline tank showed *issumaki* (little thought). They have a definite superstition that metal should not be used for cooking seal meat. This dish is always made in a wooden cask.

In 1954 a similar tragedy occurred in the same region. Information concerning this is now scanty, but it seems to have followed the same pattern as the Ungadlek tragedy. The Eskimos were warned at that time of the dangers of eating rotted meat.

An incident is recounted by a Moravian missionary who was travelling in winter many years ago with Eskimos in the same region. They came to a house which had been derelict for many weeks. In a wooden cask, with a cotton cover, were rotting seal flippers. The delighted Eskimos put their arms into the cask, stirred them round, and ate the contents in handfuls. There were no ill effects.

I am indebted to the Rev. W. Peacock, superintendent of the Moravian Mission in Labrador, for much of the above information. Also to Dr. J. E. Josephson, Director of Public Health Laboratories, St. John's, Newfoundland, and Dr. C. F. Dolman, Head of the Department of Bacteriology and Immunology in the University of British Columbia, for the result of bacteriological investigations, and to Dr. Gordon Thomas, of the Grenfell Mission Hospital, St. Anthony, Newfoundland, for the brain histology.

JOHN C. BROCKLEHURST, M.D.

Reviews

CONVERSION AND BRAIN-WASHING

Battle for the Mind: A Physiology of Conversion and Brain-washing. By William Sargant. (Pp. 248+xxiv; illustrated. 25s.) London: William Heinemann. 1957.

The tyrant may destroy and enslave, may govern and even bring material prosperity to the conquered, but he may yet be brought to despair through failure to invade the last stronghold of freedom—for a man's thoughts may still remain his own. There have been tyrants, however, whose order the lives of millions in accord with their ideologies and explanations of the purpose of life. But the complete tyrant, be he a man or an impersonal apparatus of state, seeks a total victory. He prefers to achieve his conquests by first capturing the mind with his propaganda, but he is often driven to physical subjugation in the hope that the mind can then be brought under control. A survey of the history of this struggle indicates that conversion to new beliefs can come with surprising suddenness if the time is opportune, but also that freedom of thought can sometimes survive even the most rigorous inquisition, can revive and flourish again.

The scientific study of this process, with the control of mind as its objective, is a necessary backroom activity for all organizations which seek to conquer the mind, whether the empire is political, religious, or commercial. Dr. Sargant's aim has been to approach the subject from the point of view of physiology and to bridge the gap between objective dog and subjective man. His comparison of such entities as transmarginal inhibition and religious ecstasy results at times in a kind of semantic bathos which will not please those who try to keep up with the Koestlers in matters of belief, but this is a risk he has knowingly taken. The fields from which the contributory material is derived are those of religious conversion, the effects of mental stress as seen in war neurosis, the effects produced by specific stresses in the Pavlovian dog, the phenomena of interrogation, and in the psycho-analytic transference. An excellent chapter on the equivalent of brain-washing in ancient times has been contributed by Robert Graves, and the later history of political and religious interrogation is also reviewed in the light of recent research. The general effect is to bring to realization the fact that what happened almost by chance in the Spanish Inquisition and in the hands of the secret police of Czarist Russia can now be brought about quite deliberately. Most of the descriptive material comes from religious sources, and includes a fascinating analysis of Wesley's own conversion as well as an account of a variety of evangelical movements and religious cults in many countries. These are illustrated by some very good photographs of ecstasy and trance in a religious setting.

On the subject of brain-washing itself the author is a little disappointing, as he has had to fall back on such material as the questioning of the illiterate and backward Evans in the Christie case and an account of the outdated Yeshov method of interrogation. Nevertheless, it is made quite clear that artificial conflict can be induced in brain and mind, emotion generated and transferred to objects of the interrogator's choice, artificial guilt installed, and a state of suggestible inhibition created in an individual who has been made uncertain of his own identity—for these are the principles of brain-washing. Dr. Sargant has chosen to interpret most of his facts in terms of the psychopathology of Pavlov's later years, and from this has attempted to create a unifying hypothesis. Whether or not he has succeeded, he makes a good case for a far greater interest in this doctrine which has been carefully built up in the last thirty years while the West has been on its Freudian spree. This book may annoy those who are already committed to an existing system of religion or psychopathology, and even those who would

cling to an older concept of human decency; but it is based on observations from which the citizens of the free world can avert their heads only at their peril.

ALEXANDER KENNEDY.

MEDICAL ETHICS

Medical Ethics: A Guide to Students and Practitioners. Edited by Maurice Davidson, M.A., D.M., B.Ch.(Oxon.), F.R.C.P.(Lond.). (Pp. 165+viil. 20s.) London: Lloyd-Luke (Medical Books) Ltd. 1957.

This book sets out to guide the young practitioner on the conduct of a doctor towards his patient, his colleague, and the State. It is comparatively easy for experts to instruct on the legal aspects of a doctor's conduct, on the working of the General Medical Council, and on the history of the Hippocratic oath. It is not so easy even for distinguished contributors such as Dr. Hugh Clegg, Lord Cohen, and Professor McCance, who write as clearly as they think, to advise on the moral code or philosophy of life of a doctor. Many ethical problems though insoluble in theory are quite manageable in practice. It would be a poor general practitioner who could not prevent Dr. Dawson's epileptic engine driver (quoted by Dr. Clegg) from driving a train without ever divulging a professional confidence against his patient's wish. It is part of a doctor's job to manage as well as treat his patient. Again, Lord Cohen's destitute, crippled old lady with pneumonia requires nursing care as well as penicillin. It is the doctor's duty to procure both. If he fails in either the patient may die, but this is a practical rather than an ethical problem. Professor McCance's approach to the ethically difficult field of experimental medicine is robust and courageous. He experiments on himself before trying it out on the patient; but, as he says, all treatment is experimental. A surgeon can hardly be expected to operate on himself first. Treatment is often a choice of evils. To choose wrongly is not unethical; the reason for the choice may be. Dr. Maurice Davidson, who edits this book, is anxious about the neglect of the art of medicine and of the doctor's family. It is a mistake to assume that medicine as an art is not practised in the National Health Service, or that the doctor's wife is half-witted.

This book is stimulating. If it does not provide all the answers, that is not surprising, as the questions have been asked for thousands of years. Perhaps we must be content with the motto quoted by Dr. Douglas Guthrie: "To cure sometimes, to relieve often, to comfort always."

C. W. WALKER.

FREUD ON HYSTERIA

Studies on Hysteria. By Joseph Breuer and Sigmund Freud. Translated from the German and edited by James and Alix Strachey. (Pp. 335+xxxi. 25s.) London: The Hogarth Press and the Institute of Psycho-Analysis. 1956.

Of not many books can it be said with assurance that they bear the stamp of immortality. This new translation by James and Alix Strachey of Freud's *Studien über Hysterie* (originally published in Vienna in 1895) belongs to this imperishable category. Read in conjunction with his volume of letters to Fliess (*The Origins of Psycho-analysis*, English translation 1954) it gives the reader an account of the invention of what the editors justly describe as "the first instrument for the scientific examination of the human mind." Here indeed is psychological history in the making. Before our eyes concepts that are nowadays almost household properties are given birth or adumbrated in prodigal sequence: "repression," "the unconscious," the beginnings of "free association" and of the "interpretation" of dreams, "conversion," "cathexis," "overdetermination," "censorship," "the transference," "defence," "resistance," and the "principle of constancy" which underlies every "dynamic" psychology worthy of the name. To which list Breuer adds "trauma," "catharsis," "abreaction," and many other concepts, including that of the determining force in conversion of the original "hypnotic state"—a theory which Freud later

discarded completely. Equally intriguing is the fact that Breuer, who was later to abjure this conviction, lays more emphasis in his contributions on the sexual factor in hysterical pathogenesis than does Freud, who very soon after the publication of these studies was to raise it to the status of a cardinal agent. Even more fascinating is the insight these papers give into Freud's unique combination of therapeutic and theoretical intuition, which, reinforced by the patent courage of his convictions in the face of unforeseeable obstacles, was to give rise to the monumental structure and endless range of his psycho-analytical theories. From the point of view of the modern therapist his analyses may seem strangely "dated." On the other hand, modern psychoanalysts, those inheritors of a more elaborate and lengthy technique which in some instances they have developed to the point of pretentiousness, may well take to heart the rapidity with which in most cases Freud was able to achieve successful results.

A memorable book, of which the translation, editing, and annotation are alike faultless.

EDWARD GLOVER.

SYMPOSIA ON MICROBIOLOGY

Microbial Ecology. Seventh Symposium of the Society for General Microbiology, held at the Royal Institute, London, April, 1957. Edited by R. E. O. Williams and C. C. Spicer. (Pp. 388+viii. 32s. 6d.) Cambridge: For the Society for General Microbiology at the University Press. 1957.

Biological Aspects of the Transmission of Disease. Edited by C. Horton-Smith. (Pp. 184+viii. 21s.) Edinburgh and London: Oliver and Boyd. 1957.

Each of these two volumes contains the papers presented at a symposium recently held in London, and their subjects are closely connected. Microbial ecology was the subject chosen for the seventh symposium of the Society for General Microbiology, and, in accordance with the usual practice of that society, the full text of all the papers was available to members in the form of this volume before the meeting took place. Two of the papers are by contributors from the United States, and the remaining 15 derive from this country. Some deal with the influence of physical and chemical factors on microbic survival in natural environments; in this connexion the effect of light is discussed only in relation to the requirements of photosynthetic organisms, and not as an agency of some hygienic importance in the destruction of pathogenic species. Relationships between micro-organisms are exemplified by papers on the predacious fungi, on bacteriophage, and on the natural functions of antibiotics, of which it is somewhat cautiously concluded that they do exist. Later papers deal with aspects of relations between micro-organisms and their plant and animal hosts, and include two by authors who contributed on similar subjects to both symposia. F. C. Bawden, whose subject here was the role of plant hosts in microbial ecology, reminds us that the transmission of plant disease has been much facilitated by the unnatural practice of growing large areas of a single crop; C. H. Andrewes, discussing the ecology of viruses, refers to the capacity for antigenic variation in the influenza virus as a factor in its epidemic spread, another and formidable example of which has appeared since his paper was written.

The Institute of Biology was responsible for the symposium on biological aspects of the transmission of disease, an object of which was to bring together botanists, zoologists, and human and veterinary pathologists on common ground. This volume contains 22 papers, and reports of discussions on 14 of them and on the subject as a whole which seem to have included some lively exchanges; Bawden's account (p. 158) of a conversation between donkeys pestered by flies and its bearing on a fundamental question in evolution is particularly commended to the reader. The papers deal with every mode of transmission of microbic disease, direct and indirect, by way of air, water, soil, and various vectors and intermediate hosts. They contain a large variety of information some of which must be unfamiliar to almost any reader: how many animal pathologists, for instance,

are aware that "45 different fungal diseases of 34 plant and one animal species are transmitted by over 100 species of insects belonging to at least six orders"? Insect vector of mammalian disease receive much attention, particularly with reference to the behaviour of the parasite within the vector and the precise mode of transmission, which, as C. A. Hoare points out in connexion with trypanosomiasis, may be contaminative, inoculative, or mechanical. O. D. Standen deplores the neglect of malacology, the study of which offers some hope of controlling schistosomiasis; and W. C. Moore gives particulars of regulations in force to deter the international transmission of plant diseases. No doubt almost everything in these papers is to be found in the books and journals of various specialties, but the combination of such varied material within a common theme makes a uniquely instructive volume.

L. P. GARROD.

COAGULATION OF BLOOD

Human Blood Coagulation and its Disorders. By Rosemary Biggs, B.Sc., Ph.D., M.D., and R. G. Macfarlane, M.A., M.D., F.R.S. Second edition. (Pp. 476+xxv. 42s.) Oxford: Blackwell Scientific Publications. 1957.

The second edition of this book will be warmly welcomed. Since the appearance of the first edition four years ago much progress has been made in the understanding of blood clotting, and the present volume has been extensively revised to incorporate much of this new material. The plan and format of the book are essentially unchanged. After an introductory chapter on historical aspects of blood coagulation the authors deal serially in a lucid and readable manner with the complicated aspects of the various participating materials: thrombin, fibrinogen, fibrin, prothrombin, tissue extracts, Factors V and VII, thromboplastin, and the natural inhibitors of clotting. Though these chapters have headings that are almost the same as formerly, a comparison of the two editions shows how extensively the authors have enlarged and modernized the present volume. The chapters on clot retraction and anticoagulant drugs have needed fewer changes. That on fibrinolysis is especially interesting and important by reason of the authors' numerous contributions to this subject. In Part II the clinical aspects of coagulation defects are reviewed, and these chapters will prove valuable for all who are concerned with the care of patients, whether in the ward or the clinical laboratory. The theoretical and practical aspects of hypofibrinogenaemia, haemophilia and its related conditions, thrombocytopenia, and hypoprothrombinaemia are well discussed, and a chapter on artificial anticoagulant and haemostatic drugs will prove notably useful for the safe management of patients under these forms of therapy. Finally an excellent series of appendices giving synonyms for the terminology of coagulation as used in different countries, the current methods for investigating unknown coagulation defects, and the methods for the preparation, assay, and technical uses of many of the reagents and factors employed in the laboratory all add greatly to the value of the book.

Many clinical and laboratory haematologists will be deeply indebted to the authors for so clear and authoritative a monograph. It will be in great demand both for post-graduate teaching and as a constant bench companion in clinical and research laboratories.

HELEN PAYLING WRIGHT.

New and Nonofficial Remedies, an annual publication of the American Medical Association's Council on Pharmacy and Chemistry, contains evaluations of new drugs based on the available scientific data and on reports of investigations. Descriptions of drugs are presented in the form of monographs, giving chemical or biological identity, actions and uses, side-effects, and dosage, including methods of administration. *New and Nonofficial Remedies*, 1957, is published by the J. B. Lippincott Co., and is available in Britain from the Pitman Medical Publishing Co., Ltd., 45, New Oxford Street, London, W.1 (pp. 528+xxv; 30s.).

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 19 1957

EPIDEMIC MYALGIC ENCEPHALOMYELITIS

A number of outbreaks of an illness in which encephalomyelitis is a prominent feature and which, in the early stages, could be confused with poliomyelitis have recently been observed in different parts of the world. From published reports it is clear that no clue to the cause has yet been obtained, so that any assumption that such outbreaks are of the same aetiology is purely hypothetical. Nevertheless, in many of the outbreaks the clinical and epidemiological pattern is so similar that it seems justifiable at the present to consider them as a clinical entity. Mention was made of these outbreaks in a review of virus meningitis and encephalomyelitis in the columns of this *Journal* earlier this year,¹ and in the opening pages of this week's issue there appears a report from the medical staff of the Royal Free Hospital on the 1955 outbreak which affected all the hospitals in the Royal Free Group and which became known throughout London and beyond as "Royal Free disease." This authoritative account will be of value in putting into perspective the perplexing features of this infection.

Much of epidemiological interest has already been discussed in a report published earlier this year by N. Crowley, M. Nelson, and S. Stovin² from the Royal Free Hospital. The first cases occurred in July, 1955, and by the end of November over 300 cases had been seen at eight hospitals comprising the Royal Free teaching group. Of these 300, 292 were members of the nursing, medical, domestic, and ancillary staffs. Although the main hospital in Gray's Inn Road was closed ten days after the start of the outbreak, only 12 patients developed symptoms; and in an area very much aware of the "disease" only a few sporadic cases were encountered. The earlier cases at Gray's Inn Road were followed by secondary cases appearing over the next 10 to 12 weeks among the staff at the associated hospitals, all of which were situated within a few miles of each other (in the Metropolitan Borough of St. Pancras and its immediate neighbourhood). A noticeably higher attack rate was observed

among resident staff (19%) than in non-residents (4.7%) and among nurses and the domestic workers and orderlies closely associated with them. Senior nurses seemed to be particularly badly hit, but student nurses at the preliminary training school were also affected. In a further paper published this week, (p. 904) Drs. D. Geffen and Susan M. Tracy report a further outbreak at the same training school in May, 1956, with features similar to those of the previous year. On this occasion the training school was closed, and no secondary spread was reported. Thus the disease appears to be highly infectious in closed populations, and hospitals evidently provide suitable soil for such infections as those observed at the Middlesex Hospital³ and at Coventry a few years ago.⁴ An outbreak among nurses in a private psychiatric hospital in Washington, D.C., is yet another example⁵: In this there were 41 cases, of whom 39 were nurses, 29 being student nurses. Only one patient was affected. A report⁶ from Iceland of a similar infection indicated that schoolchildren were predominantly affected by the disease.

Fully developed cases of this disease, as seen at the Royal Free Hospital, showed signs of a generalized infection with widespread involvement of the central nervous system and enlargement of the superficial lymph nodes. But marked variations were encountered from case to case not only in severity but in the evolution and whole course of the disease. The signs and symptoms in individual patients varied from day to day, particularly during the subacute stage. In this latter respect, and indeed in many others, myalgic encephalomyelitis differs from poliomyelitis, but, even so, the distinction between the two may not always be clear-cut, particularly in the early stages. The commonest prodromal symptoms of the patients at the Royal Free Hospital were headache, malaise, sore throat, and occasionally gastro-intestinal disturbance—symptoms common to a number of infectious diseases, but here the malaise and headache often appeared to be out of proportion to the moderate fever. In most cases the major illness developed as an aggravation of these symptoms with, in addition, the development of pain, muscle weakness, and other signs of involvement of the central nervous system. In the early stages paresis was accompanied by hypotonia and severe pain on movement; the weakness was often hemiplegic in distribution, later becoming more extensive but constantly fluctuating. True flaccid paralysis of the lower-motor-neurone type, with wasting and loss of tendon reflexes as seen in poliomyelitis, was not observed. Reflexes were usually normal, occasionally exaggerated. Another unusual feature was a peculiar jerking on

voluntary movement seen in some patients. The severe pain associated with muscle tenderness was a striking characteristic of the infection; and, coupled with this, many patients tended to become emotionally unstable. Evidence of involvement of the central nervous system was found in 148 cases (74%), and an equally high proportion (73%) had enlarged lymph nodes, particularly the posterior cervical group. Convalescence was remarkably slow, with a fluctuating course during which many of the previous symptoms recurred. Even after six weeks' convalescence many patients were having difficulty in getting back to a full day's work. The outbreak reported at Washington had very similar clinical characteristics, particularly during the course of the subacute stage. Several patients examined six months later had weakness of muscles and became easily fatigued. In another outbreak which occurred during 1956 in a small community in Florida about 150 cases were seen by local physicians.⁷ Though the clinical picture resembled that of the Royal Free disease, the incidence of cranial-nerve lesions was low and the lympho-reticular system was unaffected.

The spinal fluid was normal in the patients seen during the outbreak at the Royal Free Hospital, and except for minor discrepancies this seems to be a constant feature in all these outbreaks. But all laboratory investigations to determine the cause have been unsuccessful. Many of the Royal Free cases were investigated by up-to-date virological methods, as indeed were those in the Washington series, but no conclusive evidence of a virus or other infectious agent has been found. For the time being, therefore, the aetiology remains a matter for conjecture. The nature and position of the lesion in the central nervous system is also not known, but the infection, irritative rather than destructive in nature, is evidently widespread. Electromyographic studies point to a myelopathic lesion without degeneration of the lower motor neurone, but in the absence of histological material the pathology will remain unknown.

SUBLIMINAL ADVERTISEMENT

Some public anxiety has been caused by claims that it is possible to influence people's choice by exposing them to advertisements of which they are not aware. This is done by projecting the advertisements for very brief periods on the screen during a cinematic performance. What are the grounds for believing these claims? And what are the dangers to political life and mental health if such a method falls into unscrupulous hands? The credibility of the claims may be examined under two heads. First, is it possible for visual stimuli, though too brief to be reported by the

subject, yet to affect his behaviour? Secondly, if it is possible for them to affect his behaviour in a laboratory situation, are they a good means of conveying suggestions, like the hypnotic trance? There is a great deal of evidence on the first question.

It seems at first sight paradoxical, especially to those trained on the physiological notions of threshold, that external stimuli which are subliminal or subthreshold should have any effect at all on the central nervous system. It would seem that if the energy of a stimulus is really below the threshold in intensity and duration for the firing of a receptor, it is absurd to expect any change in the behaviour of an organism. Unfortunately the notion of threshold is not clear-cut, and it is complicated by the existence of random activity or "noise" in the end-organs themselves. Thus a receptor-organ will emit many messages which are not due to the arrival of signals from outside. A "decision" has to be made each time, by assessing probabilities, whether any message reaching the central nervous system is really a message arriving from outside the receptor or just a random discharge generated by the receptor itself. That is why a person, when in a sensitive condition, may be aware of stimuli when there are none, because the decision he has to make on statistical grounds will occasionally be wrong when a spontaneous random discharge passes the criteria set for accepting a message as veridical. These criteria are changeable. R. C. Oldfield¹ has demonstrated that there are fluctuations in sensory threshold, and C. I. Howarth and M. G. Bulmer² have shown that these fluctuations are closely related to the number of rejections or acceptances of stimuli in the preceding series. It is unlikely that the number of times a subject has said "Yes" or "No" can affect the physiological condition of an end-organ; much more probably the subject has in some way shifted his criterion of what he is to take as "seeing." Further work at the Institute of Experimental Psychology, Oxford, by Howarth and Treisman³ supports even more clearly the view that the criterion is one of probability; they have shown that if a stimulus is expected, because of a warning signal at a fixed interval beforehand, the threshold for it is lowered.

It might be argued that these effects take place at a comparatively low level in the nervous system and that the messages which are there rejected are unlikely to affect behaviour greatly. But there is another line of evidence which complicates the notion of threshold still further. This has been produced by

⁵ Stein, K. B., *J. Personality*, 1953, 21, 467.

experimental psychologists trying to find out whether affective processes measurably influence and modify perception. Recent work in this field has been reviewed by N. Jenkins.⁴ Some of this work indicates that thresholds of awareness can be raised or lowered in response to the pleasant or threatening nature of the material displayed. This evidence suggests that the "decision" to see a stimulus like a word must be made at a high level and yet without conscious awareness. The factors determining a change of threshold are evidently rather complex. For instance, K. B. Stein⁵ found that some neurotics consistently raised their threshold for aggressive material, while others lowered it. Other factors, such as the familiarity of the material, also influence the threshold. While this field remains incompletely investigated and some of the results conflict, we must to some extent suspend judgment, though it is probable that subception—as this unconscious perception of stimuli is called—does in fact occur.

If subception does occur, is it a good channel for conveying suggestions? First, it is difficult to make certain that people apparently influenced by a subliminal advertisement did not consciously see it. Visual thresholds are highly variable and memory highly labile. Moreover, if the buyer is questioned, he may feel that the question whether he saw a persuasive advertisement has a derogatory implication. None of us like to admit even to ourselves that we are buying a soft drink not because we are thirsty but because we have fallen victim to the guile of a copywriter. Secondly, even if such an unconscious means of conveying suggestions is available, it is unlikely that messages of any complexity could be sent. Disruptive stimuli can be suppressed before they reach a certain length or intensity; after this they produce annoyance and discomfort. Again, unfamiliar and unexpected messages are corrupted and contorted into the familiar if a more leisurely examination is precluded. It is to be expected, therefore, that only exceedingly simple messages for which conscious advertising has paved the way would have any effect. Even so, this threat to free choice deserves impartial investigation. If the threat is real, steps could be taken to protect the public; if not, the public could be reassured.

WOUND HEALING

Several distinct processes combine to re-establish continuity of divided tissues. Skin wounds of animals are convenient for studying them, and by varying the conditions of site, injury, and treatment three phases of healing can be separately investigated¹—contracture, replacement of connective tissue, and cover by epider-

mis. Important recent advances in knowledge have been concerned particularly with contracture and the metabolism of growing connective tissue.

Healing by contracture is particularly evident in full-thickness wounds of the loosely bound skin of rabbits. R. E. Billingham and P. S. Russell² have shown that these wounds contract to half their initial area in seven to ten days. They describe a remarkably constant specific rate of contracture such that the wound diminishes daily by a regular proportion of its area. This compound decremental rate is little affected by the size of the wound, but circular wounds and those in older animals contract more slowly than others. An interesting finding is that the rate is unaffected by the presence of a prior wound elsewhere in the same animal. Contracture is prevented by full-thickness skin grafts and is slowed by cortisone and by ionizing radiations. Evidence is accumulating that contracture is not directly caused by collagen fibres: its timing and extent are not parallel to the quantity of new fibres, and M. Abercrombie and colleagues³ make the alternative suggestion that the mesenchymal cells of the regenerating connective tissue may have contractile properties similar to those of smooth muscle.

Investigating the metabolism of newly formed connective tissue, J. E. Dunphy and colleagues⁴ emphasize the importance of "humoral" rather than "cellular" factors in healing. This antithesis may be too emphatic, since cellular activity is clearly essential for healing, and the more that is known of this activity the more it is found to have a chemical basis. By making chemical analyses of growing granulation tissue at different stages of healing, these workers have demonstrated an initial phase of accumulation of polysaccharide during the apparent "lag" stage of healing. When this accumulation has reached its maximum, collagen, as measured by the proline content of the tissue, begins to increase, and in parallel with this the tensile strength of the wound also rises. Animals starved of protein show retardation of wound healing with fewer fibroblasts, diminished accumulation of mucopolysaccharides, and retarded synthesis of collagen. This picture can be almost entirely corrected by the addition of methionine to the protein-free diet. If a normal protein diet is given but no vitamin C, fibroplasia and accumulation of polysaccharides are fairly normal but maturation of the collagen is faulty. Further details of these "humoral" changes are provided by the work of D. S. Jackson⁵ and H. G. B. Slack⁶ using the connective tissue overgrowth induced by the sulphated polygalactose carrageenin.⁷ In this tissue they demonstrated the early accumulation of sulphate and polysaccharide (presumably in combination) and a parallel formation of a collagen which is soluble in neutral salt solution. This is thought to be the precursor

of the insoluble collagen fibres. Analysis of the polysaccharide into different fractions shows that there is a salt-soluble polysaccharide whose concentration parallels that of the salt-soluble collagen, and a papain-soluble polysaccharide whose concentration parallels that of insoluble collagen. The two former materials may be precursors of the final complex of insoluble collagen and sulphated polysaccharide present in connective tissue. Findings based on study of the tissue induced by carrageenin may not be entirely reliable evidence of what goes on in normal wound healing. For instance, the connective tissue so induced is reabsorbed after a period of a few days. Nevertheless, it clearly offers a convenient experimental approach.

Since wound healing is a complex of several processes, it is not easy to relate experimental data to clinical problems. The most common wounds in surgery are those which have been sutured. In such wounds contracture is negligible, and by apposition of the edges the surgeon makes any extensive replacement of connective tissue unnecessary. Some alternative procedures for surgical apposition of wounds have been recently investigated by S. Borgström and P. Sandblom.⁸ They found little difference in wound healing whether mattress, through-and-through, interrupted, or continuous sutures were used, or whether the spacing of the sutures varied widely. The only feature which they found made a significant difference to the rate of recovery of tensile strength was the presence of tissue tension. It would thus appear that in the treatment of fresh wounds free from gross mechanical, chemical, or infective interference the surgeon has a wide choice of suturing techniques, any of which will give good results.

PREVENTION AND TREATMENT OF TETANUS

Tetanus is one of the few infections that still have a high mortality. It is mercifully rare, but this also means there are few who have much experience in its treatment. There is thus much to be learned from a symposium¹ on this subject at the Mayo Clinic: this includes a paper by N. A. Christensen and D. L. Thurber analysing a series of 91 cases treated there between 1911 and 1954. Four grades of the disease are recognized, ranging from mild (7 cases in which spasm was confined to the jaw, face, and neck) with no mortality to 13 fulminating cases with a mortality of 100%. That the degree of severity varies inversely with the length of the incubation period was fully confirmed. Age is also a factor: mortality was high in the first and after the fourth decade, and lowest in the second and third. Modern treatment has improved the outlook. The mortality was 58% up to 1925, 57% until 1934, but only 39% in the ensuing ten years and 27% in the last. For this last ten years the Clinic has had a "tetanus team" consisting of "consultants in internal medicine, pediatrics, neurology, orthopedics, plastic surgery, anesthesiology, bacteriology, clinical pathology, biochemistry and physiology, together with the medical

director of the Rochester Health Department." This sounds a somewhat cumbersome list, but at least it should now be acknowledged that the treatment of tetanus is not the exclusive province of the surgeon, as has been too easily assumed in the past. If any one specialty has a preponderating claim it should surely be medicine, since drugs, notably sedatives and perhaps to a less extent antibiotics, play the leading part in treatment. Unfortunately the authors give few details of the regime of treatment they use at present, but they mention that curare has given disappointing results, and that control of spasms is achieved by giving retention enemas containing tribromoethanol ("aver-tin") and amylene hydrate. Penicillin is given routinely for its action on *Cl. tetani* and presumably also as a preventive of pneumonia; and corticosteroids are being tried with some success to combat exhaustion, to mitigate the effects of complicating infection, and to suppress any reaction to antitoxin.

A paper by E. D. Henderson discusses the indications for surgical treatment. He takes the view that excision of the causative lesion is a worth-while procedure and may be advisable even though it entails an amputation. N. A. Christensen discusses prophylaxis, and defines four categories of individual who should be actively immunized with toxoid. These are the specially exposed, including some industrial workers as well as soldiers; all with evidence or history of allergy, in whom consequently treatment with antitoxin may present difficulties; all who have been given tetanus antitoxin; and, finally, those who have recovered from the disease itself, since it seems that permanent immunity does not result. It is suggested in this and other papers that active immunization should be carried out even more widely than this, as by inclusion in "child health programs," or even universally—"Every farmer, every rancher, every laborer, every person who rides in an automobile, indeed everyone would benefit." A difficulty in this would be to sustain immunity. The Army gives an annual booster dose: the "present custom" in the U.S.A. is to give one at intervals of four or five years, and it is suggested that this could be extended to 10 years. If this could be firmly verified, universal immunization would be much more nearly practicable. Instructions are also given for the management of patients with tetanus-prone wounds, according to whether or not they have been previously immunized, and for the administration of antitoxin when necessary. The intradermal method of testing sensitivity to horse serum is advocated, and elaborate instructions are given for the desensitization of patients to whom antitoxin must be given, under cover of an antihistamine, corticotrophin, and adrenaline. In these matters the recommendations differ from those of L. J. M. Laurent and H. J. Parish² in this *Journal* some years ago, although the policy for the prevention of tetanus in the individual casualty recommended more recently by these authors and N. H. Moynihan³ is similar to that advocated in the Mayo Clinic symposium.

ACHONDROPLASIA

Those achondroplastic children who survive infancy are, apart from their short stature, normally fit and intelligent. Not uncommonly they are gifted acrobats. Achondroplastic dwarf jesters were favoured at the courts of kings, and nowadays the troupe of clowns at Bertram Mills's Circus usually includes two or more achondroplastics. The condition is well represented in statues from ancient Egypt portraying the popular deity Bes.

The fertility of achondroplastics is low. Most affected women can have children only by caesarean section, and the men are less likely to marry than normal men. The constant recurrence of the type suggests that their numbers are kept up by fresh gene mutations. The great majority of achondroplastics who survive infancy are probably affected by a dominant gene mutation. They are born to normal parents and their sibs are normal. They appear sporadically in a way which does not at first sight suggest genetic determination. But when children are born to parents of whom one is achondroplastic the dominant genetic determination is shown by approximately half of them being affected.

Conditions determined by dominant mutations are important because they give the most direct estimate of mutation rates. The first national survey of achondroplasia was reported by Mørch in 1941 from Denmark.¹ He found 86 living achondroplastics in a population of about 3,793,000—that is, about 23 per million. A second national survey recently reported by A. C. Stevenson from Northern Ireland² revealed 39 in 1,387,000—that is, about 28 per million. Of the 86 Danish patients, 12 had a parent affected, and so 74 were presumably the result of fresh mutations. None of those with normal parents had an affected brother or sister. Of the Ulster patients, only one had an affected parent and there were two pairs of brothers or sisters with normal parents. The Danish estimate of the mutation rate from surviving achondroplastics born to normal parents is about 20 per million and the Irish about 27 per million. These estimates, which do not differ significantly, are based on the assumption that the life expectancy of achondroplastics due to dominant mutation is the same as that of the rest of the population. Mørch did not think this was the case. He noted that infants recognized as achondroplastic in maternity hospitals had a high mortality, perhaps only 1 in 4 or 5 surviving the first year. He assumed that those achondroplastics dying in infancy had the same cause as the remainder, and accordingly considered that the mutation rate was best estimated from the incidence at birth, 7 in 94,075—that is, 74 per million in the Rigshospital. Stevenson found an even higher incidence in the Royal Maternity Hospital—9 in 31,753 births, or 283 per million—but he stresses that the cases may be selected for admission to hospitals and thus give a relatively high incidence

¹ Mørch, E. T., *Chondrodystrophic Dwarfs in Denmark*, 1941, Copenhagen.

² Stevenson, A. C., *Amer. J. hum. Genet.*, 1957, 9, 81.

³ Slatis, H. M., *ibid.*, 1955, 7, 76.

⁴ Grebe, H., *Z. Kinderheilk.*, 1952, 71, 437.

among hospital births. Further, he follows H. M. Slatis³ in suggesting that the aetiology in many of the achondroplastic children stillborn or dying shortly after birth might be different from that in the survivors. These children dying in infancy should not, he thinks, be included in estimates of the mutation rate. One indication of the different aetiology is that the few achondroplastic children who have an achondroplastic parent do not appear to have a high infant mortality. Another indication is that pregnancies resulting in these children who die in infancy are often complicated by hydramnios. A third is that, as Mørch noted in the Danish series, the average age of fathers of surviving achondroplastics is unusually high; this is also true of the Irish cases, but it is seen to a much smaller (and non-significant) degree in the Irish hospital series. Stevenson suggests that many of the hospital cases may not be genetically determined at all, and he also notes that many of the surviving patients were not recognized as being achondroplastic in hospital.

The occasional families of achondroplastics in which the parents are normal, but there are two affected sibs, are difficult to reconcile with causation by a dominant gene mutation. It is possible to suppose that the mutation affected an appreciable section of one or other parent's gonad. But in one of the Irish families with two affected children, and also in a German family reported by H. Grebe,⁴ the parents were first cousins. This strongly suggests that a recessive gene may also cause achondroplasia. Probably these recessive types will be clinically differentiated in time, but no such differences have yet been found.

To sum up, most cases of achondroplasia surviving infancy are due to a dominant gene, while a small fraction, at the moment clinically indistinguishable, are probably due to a recessive gene. Most are stillborn or die in infancy and show features which distinguish them from the survivors. These are of unknown causation. It is preferable to use only the surviving patients when estimating mutation rates.

BENIGN CONGENITAL HYPOTONIA

Many readers must have been confronted with the problem of the limp or floppy baby which fails to pass its normal milestones successfully, but few will have seen an appreciable number of these cases, for they are by no means common. On full examination it will usually be found that this symptom is one feature of an underlying general condition such as mental deficiency or cerebral palsy. But in some cases no such cause is discoverable, and it is in this group that full investigation of the lower motor neurone system is necessary in order to establish the diagnosis. This step is important not from the point of view of treatment, which in most cases is of no benefit, but rather to assess the prognosis. It may vary from a rapidly progressive disease of a few months' duration (in Werdnig-Hoffmann's infantile spinal atrophy), to a slowly progressing disablement (in

many myopathies), or gradual improvement to partial or even full recovery may take place, as in benign congenital hypotonia. Unfortunately the prognosis is complicated by the fact that these diseases do not always run a typical course. Thus, there are thought to be three variants of Werdnig-Hoffmann's disease, one beginning in intrauterine life, burning out, and leaving a disabled child¹; a second ending fatally after a less rapid deterioration, about 3-8 years; and a third variant in which the disease ceases to progress, leaving the child with considerable impairment of muscular function.^{2,3} Similarly the myopathies vary considerably in the rate at which the patient deteriorates, and sometimes he may be left with little disability.

These separate conditions, therefore, have variable and overlapping natural histories which admit of no clear distinction. It is due to this fact that difficulties in terminology have arisen, and no textbook, either of neurology or pathology, gives a similar definition of amyotonia congenita. H. Oppenheim's⁴ original description was simple and explicit and corresponds exactly to the condition now referred to as benign congenital hypotonia. Unfortunately both he and later writers included cases under this diagnosis which manifestly did not conform to the original criteria. It is for this reason that a new term has been created by J. N. Walton⁵ for a previously described condition. This is displeasing to the traditionalists, but has the merit of cutting across the existing confusion of thought. Consequently amyotonia is now used to describe a symptom rather than a pathological entity.

Two main surveys have been carried out—by S. Brandt,² who reviewed 131 cases, and by Walton,³ with 109 cases all previously labelled amyotonia congenita. In both series the case histories were reconsidered with special reference to the progress and outcome of the disease, and on review the majority were thought to have had Werdnig-Hoffmann's disease and another considerable proportion to be suffering from general diseases outside the lower motor neurone system.

Out of this large series Brandt was left with six (4.6%) and Walton eight (7.3%) patients who eventually made a full recovery, and these were considered to be undoubted examples of benign congenital hypotonia. Recently Walton⁵ has given a detailed report on his eight patients and nine others who made an incomplete recovery but who nevertheless, he feels, belong to the same category. It is interesting that electromyography in five of these cases suggested a myopathy, a finding in line with the view of F. E. Batten⁶ and J. W. Aldren Turner^{7,8} on the nature of this disorder.

This type of review is open to certain criticisms in that the same observer did not see every patient at both the

beginning and later stages of the condition and that the diagnosis was sometimes made on the natural history of the process, which has already been shown to be variable. Nevertheless it has been most valuable in provoking interest in the early diagnosis of these conditions. Modern electro-diagnostic techniques (strength-duration curves and electromyography) are far in advance of the outmoded faradic-galvanic test, and similarly the specialized histological methods for studying the motor end-plate area give more accurate information than was previously available. At the present time these methods of investigation give reliable differentiation between myopathy and Werdnig-Hoffmann's disease soon after the symptoms have become apparent and thus enable a more reliable prognosis to be given than was possible in the past. Benign congenital hypotonia is so much rarer, however, that insufficient experience has yet been gained of the characteristic pathological and electrical patterns in this condition. This gap in our knowledge can be overcome only by full investigation and careful follow-up of all children presenting with the symptom of amyotonia.

FIRST CHAIR OF PAEDIATRIC SURGERY

In honour of Lord Nuffield's eightieth birthday the Nuffield Foundation has offered two special gifts—a sum of £80,000 for the endowment of a chair of child surgery at the Institute of Child Health and the Hospital for Sick Children, Great Ormond Street; and a grant of £15,000 to enable the Central Medical School, Fiji, to establish a department of social and preventive medicine. In announcing these gifts, Mr. L. Farrer-Brown, director of the Foundation, said that they had tried to select two schemes—one at home and one in an overseas part of the Commonwealth—which had qualities making them singularly appropriate as the subject of the Foundation's birthday tribute to its founder. The magnificent gift to the Institute of Child Health makes possible the establishment of the first chair of child surgery in Britain. It is believed that there is only one other such chair in the world—at the Children's Medical Centre, Boston. One of the earliest grants made by the Nuffield Foundation was in 1944 for the endowment of the Nuffield chair of child health at the Institute, and the setting up there of an academic surgical unit will be a further milestone in its progress. The professor of child surgery, who has yet to be appointed, will also be a member of the staff of the hospital. As head of the new surgical unit he will be responsible for co-ordinating postgraduate surgical teaching at the Institute. The unit will also engage in planned investigations into methods of diagnosis and treatment.

Professor Andrew M. Claye, professor of obstetrics and gynaecology in the University of Leeds, has been elected President of the Royal College of Obstetricians and Gynaecologists. He was a vice-president of the College during the late Sir Charles Read's presidency.

INFANTILE FUNDUS LESIONS IN RELATION TO MENTAL CAPACITY*

BY

JAMES H. DOGGART, M.D., F.R.C.S.

Surgeon, Moorfields, Westminster, and
Central Eye Hospital, London

Developmental abnormalities and other congenital defects of the eye often remain unsuspected in the early weeks or months of life because newborn babies do not as a rule undergo detailed intraocular examination. For research purposes a clinic may go out of its way to scrutinize the ocular fundi and media in every infant, but in ordinary out-patient and office practice the need seldom arises. We know that the macula is not fully developed at birth, even in healthy full-term children, so that nurses, parents, and others in close contact with infants do not usually feel perturbed about a baby's blank stare—unless that vacant look persists beyond the time when a healthy baby should be taking in his entourage with a purposive stare. If later on we discover a bilateral macular coloboma or any other fundus lesions ample to account for defective sight we can as a rule tell the parents that nobody could have prevented the trouble, and that no treatment, however promptly it had been given, could have made the eyes normal.

Before mentioning some of the diseases in which fundus lesions may give a clue to the mental state, let us consider what kind of situation makes a parent or doctor wish to have an infant's eyes examined.

1. Ophthalmoscopy may be done as a routine precaution in the absence of any unfavourable signs. Perhaps there is a history of eye trouble in other members of the family, or perhaps the parents are full of fear through having often heard eye defects discussed.

2. An explanation may be sought for abnormal signs in the eyes. For instance, one eye may be smaller than the other, or possibly there is nystagmus, proptosis, squint, inequality or peculiar shape of the pupils, or opacity of one or both lenses.

3. The victims of certain disease-states are prone to suffer from ocular complications, so that ophthalmoscopy may serve to clinch the diagnosis, as in Tay-Sachs disease or in toxoplasmosis. Then again, the family doctor may seek to know whether the optic disks are atrophic in cases of hydrocephalus, oxycephaly, or other deformities of the skull and face.

4. There is the important group of infants who make their mothers anxious because they do not gaze concentratedly at things, and fail to follow objects with their eyes by the time they are expected to do so. In the early stages suspicion is more likely to settle upon the faculty of sight, although in fact the blank expression often turns out to be a sign of mental defect; and this brings us to the important question whether we can make a reasonable forecast of the future intelligence by observing patients during infancy.

Early Recognition of Mental Defect

Medical opinion is far from unanimous concerning the chances of early assessment. Kirman (1953) said: "It is only very seldom that a child of less than 2 can safely be diagnosed as definitely mentally defective." His view

*Read at the 30th Annual Spring Congress of the Gill Memorial Eye, Ear, and Throat Hospital, Roanoke, Virginia.

agreed with that of Bowlby (1951), who wrote: "Mental tests have no predictive value in the first 18 months of life." Gesell's (1943) attitude was radically different from that of Kirman and Bowlby. He came to the conclusion that nearly all cases of mental deficiency can be diagnosed in the first year of life—except those which arise from secondary causes in later infancy.

Does the truth lie midway between these extremes? I think not. In my opinion Gesell's conclusion is far more realistic. It is, of course, true that from time to time the mind of an apparently defective infant will develop far better than at one stage we could have hoped, because medicine is far from being an exact science. Every experienced physician, and many a layman as well, can cite instances of a patient being given a few weeks more to live, and then perhaps recovering from the allegedly fatal illness and enjoying rude health a year or two later. These happy turns of fate are some compensation for all the suffering which we meet in everyday practice, but they do not alter the general prognosis by more than a small fraction. The same principle applies to infants' intelligence. Early asphyxia or some other form of birth trauma can hold up a baby's progress, so that he may for a while seem defective and yet later catch up; but in most backward infants the stigmata are not only evident but also lasting.

Here it must be emphasized that Gesell's view was based upon a vast amount of clinical material. He and his colleagues examined in detail and made follow-up observations on many thousands of infants and children. We cannot shut our eyes to the fact that uniform backwardness during the first year of life nearly always means permanent defect of mind. Backwardness in a few isolated aspects may be manifest without there being any lowering of the general level, but general backwardness is nearly always ominous.

Criteria of Mental Development

At the Great Ormond Street Hospital for Sick Children a few years ago I was wading through some not easily legible notes about a child who had been referred to me, and I found myself asking: "What are these milestones he keeps talking about? Must the children have them?" "Oh, sir," said the resident registrar, or deputy clinical supervisor of lower age groups, or whatever the modern title is for what we used to call H.P. (house-physician), "it isn't milestones, it's milestones and it's development." "What's development?" I replied, somewhat pedantically, I fear; "but," I went on, "never mind. Development is religion, and I don't want to interfere with that." "Time which antiquates antiquities," to borrow Thomas Browne's expression, has also accustomed and reconciled me to this usage of "milestones," which now seems to be one of the favourite words of paediatricians.

These milestones or stages in normal development form a useful series of criteria, so long as they are not too rigidly interpreted as a measure of the infantile mind. For instance, a mentally alert baby's failure to pass this or that milestone can be due to blindness, muscular weakness, or skeletal defect. Therefore a milestone test is valid only when it is reckoned in the light of all available facts about the baby's physical state. With this precaution in mind, and remembering also that milestones are merely a series of averages or approximations, we are entitled to regard each milestone as a useful gauge; and it is now generally agreed that in former times too much attention was paid to the dates of tooth-eruption and closure of the anterior fontanelle as yardsticks of infantile progress.

Unfortunately we cannot always obtain accurate information about the previous milestones, because parents are often unreliable when they come to recount their own child's progress. A fond mother can see a smile flit across her baby's heavenly countenance when in fact he is only being blown into facial spasm by wind bombinating around his abdomen. Incidentally the time-table of development as recounted by the father may wildly conflict with what the mother has

worked out. Even so, we should never omit to take a careful history when we try to estimate an infant's mental level.

An average healthy baby of 2 weeks can momentarily hold up his head when he is held sitting. At 4 weeks he should be able to look fixedly at his mother when she talks to him, and a smiling response to her blandishments is likely to dawn when he reaches the age of 6 weeks. By this time he should be able for a few seconds to lift up his head in the line of his trunk when he is held in the prone position by a hand placed under his abdomen. At 3 months he should be able to turn his head in the direction of a sound that interests him, and at this stage he can usually clutch an object placed in his hand. At 6 months or slightly sooner he should be able to crawl a little distance towards a desired object, and to sit unsupported in a pram, though probably another month will elapse before he can sit without support on a flat surface like the floor. If his hands are held at 10 months he can, after a fashion, walk (or at least do a rock 'n' roll), and launch into a solo stagger by the end of his fifteenth month. Overt drooling usually finishes at the age of 1 year, although many non-certifiable persons continue, figuratively speaking, to drool for the rest of their lives.

Persistence of a blank stare well beyond the age of 6 weeks usually makes the mother anxious, but in many instances it is some outside person, often the doctor, who first suspects abnormality. Naturally the lack of expression upon an infant's face will be all the more striking to someone who has not been watching him every day. At first the mother is unlikely to suspect any mental trouble unless the baby was born with some gross defect or has been attacked by a severe convulsive illness. When she comes to realize that by this time her baby should have been watching things and beginning to follow them with his gaze, she will as a rule hit upon defective sight as the explanation; and at this stage an ophthalmologist will probably be sought.

Ophthalmoscopy

Whether it be a question of trying to differentiate between ocular and mental defect, or of obtaining some neuro-retinal clue to general diagnosis, or of allaying suspicion when the question of an eye lesion has been raised, I am strongly in favour of examining infants under general anaesthesia. The suggestion is not always well received, but there are powerful arguments in favour of it unless the baby is too ill—in which case we must do what we can without such aid, and aim at a general anaesthetic later on. During my earlier years in ophthalmology I wasted a lot of time trying to get precise information about babies' fundi without anaesthesia. After a quarter of an hour's patient concentration I often found the utmost I could honestly report was: "Nothing abnormal detected."

But this is not enough with the kind of patient that I chiefly have in mind. I am thinking of the situation that arises when the family doctor has reason to suspect eye trouble or mental defect, or both, to account for backwardness in development. In such circumstances ophthalmoscopy can often yield information without which it is impossible to build up a realistic prognosis. Unless we can make a thorough survey of the fundi we run the risk of missing signs which the parents ought to be told with the least possible delay. Therefore it is not enough to say: "Nothing abnormal detected." We should either describe what we find wrong, or else simply say: "Fundi normal."

In most cases the examination under general anaesthesia need not be repeated. If the fundi are established as normal, well and good. Many of the abnormal things detected are permanent, non-progressive, and not amenable to topical therapy; nevertheless it is important that they should be recorded, and taken into consideration when an infant's future is being planned. Before the second world war I used to make an occasional examination under general anaesthesia in the out-patient department, but that was never a satisfactory arrangement. It is not always easy to find an anaesthetist at short notice, and there are many obvious

objections to the ophthalmologist administering the anaesthetic, although I must admit that I have often functioned in the dual role. The greatest objection of all against out-patient general anaesthesia is the risk to the baby afterwards. I never met with any tragic outcome, but I believe there is a danger, even if it be slight, in sending a small baby out into the streets and crowded vehicles just after a general anaesthetic. Under in-patient conditions, however, the risks of a few minutes' anaesthesia are almost nil, unless life is already at a very low ebb, in which case the examination would of course be postponed. My own practice is to get the baby into hospital the day before the anaesthetic, and then he can go home the day after examination if no additional investigations are contemplated.

At the beginning of the examination under general anaesthesia we should inspect the anterior segment of each eye with the aid of a loupe, because fundus lesions are no uncommonly associated with other defects of the eye. Then we note the main features of the optic disk, follow the main vessels out to the periphery, and scrutinize the macular region. Many people like to insert a speculum to facilitate ophthalmoscopy, but I hardly ever do so nowadays, because the exposed cornea so soon desiccates. That necessitates either taking the speculum in and out at intervals, which is a nuisance, or repeatedly instilling drops of normal saline, which is not only a nuisance but also blurs the ophthalmoscopic picture. Without a speculum, I can easily hold the eyelids open with two fingers, and I keep the baby's cornea moist and lubricated by means of his own natural secretions. That is to say, my fingers draw the lids closed every few seconds. A colleague criticized my method on the ground that the baby's eyes are usually elevated under general anaesthesia. "The main advantage of a speculum is," he said, "that it enables you to apply your fixation forceps to draw the eye down." My retort was that a properly anaesthetized baby's eyes seldom shoot upwards, and I hardly ever resort to fixation forceps for this examination.

Interpretation of Ophthalmoscopic Signs

I have already referred to Tay-Sachs disease and toxoplasmosis as examples of diseases with ocular complications. The phakomatoses also form an interesting group in which eye defects may link up with intracranial lesions. Another fascinating subject is rubella, but I cannot dwell on all these things here.

My next task is to underline some of the commoner fallacies and mistakes associated with the ophthalmoscopic examination of babies.

1. Whenever I delve into my memories of other people's notes on infantile fundi, one impression stands out clearly; it is: *For every genuine abnormality that escapes detection, at least a dozen imaginary ones are described.* I wish I could more often meet with that simple comment "Fundi are normal," but I am driven to conclude that many people are afraid to commit themselves so far, lest some other person should afterwards discover a lesion; or else they misinterpret something so as to make it fit in with what they vaguely remember from a textbook. Incidentally some observers evidently cannot believe that a blank stare is compatible with a pair of normal eyes; but surely there is nothing paradoxical about the association. In gross widespread injury or maldevelopment of the brain we should naturally expect the occipital lobes and various other regions concerned with vision to be implicated, so that there is no need for us to invent optic atrophy to explain the lack of sight in an infant thus afflicted.

2. *Optic disk pallor* is a potent source of confusion. It is widely recognized that the colour of healthy optic disks can vary within wide limits, but there are still many people who do not appreciate the extent of that variation, and many others who fail to realize that the average infantile disk is paler than that of a child or adult. Therefore many babies have been wrongly described as suffering from optic atrophy. It is in fact impossible to know the degree of a

partial optic atrophy until the subject is old enough to perform visual acuity and visual field tests.

3. *Blurred Disk Margins.*—Although it has been repeatedly pointed out that mere blurring does not mean swollen disks, this error keeps raising its head. Genuine swelling is always accompanied by corroborative signs, which I need not here describe in detail, but I should like to stress that many a perfectly healthy child is running about without any distinct margin to his optic disks.

4. *Congenital connective-tissue vestiges* on and near the optic disk are in most cases harmless, but they often create alarm and uncertainty among inexperienced users of the ophthalmoscope.

5. *Retinal hypoplasia* is normal in the early months of extrauterine life. Thus the pattern of the chorio-retinal vessels stands out distinctly in a larger proportion of babies than it does in children's or adult's fundi. Moreover, the macular stippling may be disquietingly conspicuous even in the absence of any degenerative change.

Correlation of Fundus Signs with the Other Medical Data

As the optic nerve is part of the central nervous system it is not surprising that optic atrophy or hypoplasia should so often be associated with low-grade mentality. Such major defects can arise from faulty genes, from intrauterine disease, or from birth injury, and we cannot always get conclusive evidence about the factors which have been responsible in one particular instance. From the standpoint of prognosis, however, these cases of blindness associated with gross mental defect present a relatively simple problem; and the doctor's main task is to console the parents and to give them advice about the baby's upbringing.

At the opposite extreme are various minor defects not likely to interfere with ordinary activities and not requiring any action other than a note in the medical records. Between these extremes a wide range of clinical problems still arise, demanding careful consideration by all concerned. Optic atrophy or gross macular degeneration affecting each eye obviously necessitates education by special methods, even if the patient is mentally normal and free from other physical defects, but in practice many borderline situations arise. I have already referred to the late starter who is suffering from slowly mending birth trauma to the brain, and who ultimately turns out far better than we could at one stage expect.

Another possibility to bear in mind is delayed myelination of the optic nerve, described by several French authors under the heading of "la pseudo-atrophie grise du nerf optique." Myelin is essential for the conduction of light-impulses, so that retarded myelination is in certain cases the reason why a baby apparently blind goes on to develop normal sight. Therefore no attempt should be made to give final or comprehensive advice about the disposal of infants as soon as any defect is apparent. It is, of course, important that some kind of prognosis, however provisional and incomplete it may be, should be given to the parents without delay. Most parents will appreciate how many uncertain factors must be weighed, and they will go on hoping for progress until the position clears.

It is impossible to lay down a set of rules governing the disposal of handicapped infants, whether the handicap be visual or mental or combined. From one point of view the mother is far and away the best person to look after a child with a disability, but that solution is not always feasible. The mother may lack the necessary qualities of patience and courage; or, on the other hand, she may tend to devote herself so utterly to a helpless infant that she has to neglect the rest of the household. The family doctor with all his knowledge of the home background is obviously better qualified than the ophthalmologist to give advice about disposal, but many problems can best be settled by joint discussion.

One of the questions often raised by the parents of a defective child is the advisability of having other children; and the answer depends mainly on the nature of the defect. Tay-Sachs disease, epiloia, and Schilder's disease are strongly familial, and in such conditions we can emphatically advise against any future pregnancy. Mongolism, on the other hand, is most unlikely to occur twice in the same marriage, although isolated instances are on record. In cases of primary amentia with no history of any similar trouble in a near relation the chances of another baby being affected are probably not more than 5%; but 5% is a lot when one considers the appalling consequences, and most couples would hesitate to take the risk. Now that so many statistics have been carefully worked out by experts in the field of heredity, the advice of a geneticist will often be helpful in answering queries about further children.

Concerning the relationship between fundus lesions and mental capacity, I want to make one final point, and that relates to a baby's future visual acuity. We must avoid giving too gloomy a forecast about the sight unless fundus lesions are very severe, because it is astonishing how resourcefully some children learn to interpret blurred images if their mind is bright.

PRESENTATION TO LORD INMAN

SERVICES TO CHARING CROSS HOSPITAL

To mark his 36 years' work for Charing Cross Hospital and Medical School, Lord INMAN was presented with his portrait at a ceremony at the Royal College of Surgeons on Tuesday. Lord Inman is chairman of the hospital. The presentation was made by Lord Justice MORRIS, a fellow member of the board of governors, and Mr. JOHN ADAMSON, the deputy chairman of the board, president. The portrait, which will eventually hang in the board room at Charing Cross Hospital, is by Mr. Norman Hepple, A.R.A., and a replica of it was given to Lady INMAN.

A Notable Administrator

In 1921, at the early age of 29, Lord Inman, then Mr. Philip Inman, was appointed house governor of Charing Cross Hospital from 583 applicants. At the time he was chief officer of the Hospital Saturday Fund.

In the days of the voluntary hospitals the chief administrative officer had a dual function. Not only had he to manage the hospital but he had also to obtain the income necessary for its existence. Charing Cross was one of the relatively few hospitals able to balance its accounts, thanks to its house governor's great success in raising funds. From the time of his appointment until the inception of the National Health Service, Lord Inman was instrumental in raising £1.5m. for the hospital.

When in 1936 the then chairman of the hospital died, the hospital council invited Mr. Inman to succeed him. Shortly after his appointment as chairman of the hospital,

Mr. Inman was also made chairman of the medical school. In any hospital few have held both offices, and never, it seems, has a former hospital administrator done so.

When in 1948 the National Health Service was introduced, Lord Inman, as he had then become, was made chairman of the newly appointed board of governors, a post he has retained ever since.

EPIDEMIOLOGICAL METHOD IN MEDICAL AND SOCIAL RESEARCH INTERNATIONAL STUDY GROUP

[FROM A SPECIAL CORRESPONDENT]

The International Corresponding Club for Preventive and Social Medicine held a "study group" meeting in Holland from September 1 to 6. The chief aim was to show how epidemiological methods could be used in aetiological research, particularly on non-communicable diseases, and also for assessing a community's health needs and services. Another aim was to show that this sort of research need not necessarily be expensive. Indeed, it was striking to hear how much had been accomplished in Britain and Scandinavia often on meagre budgets. One speaker from Norway had carried out an extensive survey at a cost of £25.

Fifty-nine doctors, representing 44 university departments in 20 countries, attended the meeting. Grants towards its cost were provided by the Rockefeller Foundation and the National Foundation for Infantile Paralysis.

First Get Your Data

On the first two days the use of existing records and "getting your own data" were debated. In the mornings illustrative epidemiological studies were presented, such as on bronchitis (Dr. D. D. REID), leukaemia (Dr. ALICE STEWART), cancer in nickel refiners (Dr. W. R. S. DOLL), ulcerative colitis (Dr. J. H. USTVEDT, Oslo), heart disease (Dr. D. G. BJÖRCK, Malmö), infectious hepatitis (Dr. K. RASK, Prague), and venereal disease (Dr. A. J. NELSON, Vancouver), and in the afternoons their implications were discussed.

Although occasional study of existing morbidity or mortality records collected for some other purpose can be made to yield useful epidemiological facts, usually such scrutiny, it was agreed, should be regarded as a preliminary reconnaissance only. It might point to precise questions and allow a hypothesis to be formulated, but a specially designed survey would then be needed to test the hypothesis. For example, examination of the mortality statistics for a given occupation might suggest that the occupational conditions concerned were of aetiological importance. But only by studying in detail a sample from this occupational group and comparing it with a control sample could causative factors be identified. The actual procedure was described by Dr. I. HIGGINS, who had used a whole community to study the incidence of bronchitis in foundry workers. Dr. C. M. FLETCHER stressed the importance of precise definitions of symptoms and diseases if serious differences of judgment between observers were to be avoided. The suggestion was made that some organization such as W.H.O. might concern itself with establishing clinical standards and definitions of disease to facilitate international epidemiological studies.

There was general agreement that, while hospital records are rarely much use in assessing the incidence of a disease in a community, they can be most helpful in collecting a group of cases for study by matching with a control series. The control group could be another group of hospital cases, although because of some danger of bias it was better, where possible, to use a group of "normals" from the general population. Hospital cases were also very suitable for long-term prospective investigations of the natural history of a disease. Dr. REID, in summing up the discussions on the use of existing data, advised his audience to be "paranoid in their suspicions," to listen carefully for "the screams of

tortured data and the sound of axes being ground," and to remember the dictum that "all generalizations are untrue—including this one."

Estimating Community Health Needs

There then followed a session on the use of epidemiological methods to evaluate community health needs and services. Dr. H. HILLEBOE (New York State) described how a health department, provided it had adequate funds, could carry out valuable epidemiological studies—for example, on the causes of road accidents. It might on occasion undertake such studies in response to public opinion and political pressure, but it should be careful to make no promises about results or the time needed to complete a study. Dr. L. BRESLOW (California), reporting investigations of the use made of health services, had found, for example, that the proportion of children receiving poliomyelitis inoculations (which could be obtained free of cost) increased as the family income increased; similarly in an English housing estate Professor J. H. F. BROTHERSTON (Edinburgh) had found that children from smaller families and with better-educated parents had more National Health Service consultations with their general practitioners than those from larger families and with less well educated parents—findings which suggest that more health education is needed if the best use is to be made of available medical services.

The application to the general population of screening tests—other than mass radiography—has probably been more widely practised in the U.S.A. than in Britain. Dr. BRESLOW said that in America a blood-sugar screening test had disclosed much unsuspected diabetes in the obese, in relatives of diabetics, and in mothers of large babies, and had thus shown where further efforts at detection and early treatment should be made. One of the more important effects of epidemiological studies of health needs and services had been to direct the attention of public health services towards the current problems. Professor E. K. CRUICKSHANK described how epidemiological methods had been used to elucidate the causation of two diseases peculiar to Jamaica, "vomiting sickness" and veno-occlusive disease of the liver. The former had been shown to be due to eating the fruit "ackee," which produces an acute hypoglycaemia, and the latter to drinking bush tea made from an infusion of *Crotalaria retusa*.

In summing up the session, Dr. BRESLOW said that social medicine must concern itself with social forces. Epidemiological method could be applied in three ways to assess health needs and services. First, the incidence of disease in a population and its health needs could be discovered by a proper inquiry using the whole population as a base line; secondly, an epidemiological approach might disclose the weakest link in the chain of disease causation and so make possible preventive action; and, thirdly, the method could demonstrate the value, and use made, of existing medical services.

Epidemiology in Psychiatry and General Practice

Epidemiological methods had as yet been little used for aetiological studies in the mental health field, it was conceded, though they had been used to some extent to measure community needs. Professor T. McKEOWN (Birmingham) said that a survey of all patients in Birmingham mental hospitals had shown that 12.4% needed no hospital facilities, 74.7% only limited hospital facilities, and 12.9% full hospital facilities. He thought one implication of these findings was that large isolated mental hospitals were unsuitable for dealing with mental illness. New cases of mental illness should be admitted to a building in the same curtilage as the general hospital. This might help to improve treatment, stimulate research, and solve some of the present staffing problems in mental hospitals. Dr. D. A. SUNIER (Leyden) described a survey of mental illness in Israel. In summing up this session, Professor McKEOWN advocated more epidemiological studies of the aetiology of mental illness. The starting-point should be to define the role of heredity, thus clearing the decks for study of the environmental factors. The standard epidemiological approach should be first employed to

establish any correlations with age, sex, social class, maternal age and parity, and birth order. Inquiries in this field presented special difficulties, and he advised a critical approach on a limited scale rather than extensive surveys with ill-defined objectives.

The last session was devoted to "General Practice as a Field for Epidemiological Research." Dr. W. N. PICKLES, from his 45 years' experience in Wensleydale, described how careful observation and recording could yield information on the transmission of infection. Dr. R. F. L. LOGAN reported studies from the Darbishire House Health Centre in Manchester. By using "a new tool," the photo-electric colorimeter, a large number of cases of microcytic anaemia in women coming to the Centre were discovered. Another new tool there was a social worker, who "being human was more difficult to learn to work with." Of 155 problems referred to her, 22 concerned employment, 17 the care of the elderly or dying, and 9 housing or pregnancy; but 72—or almost half—were problems of mental or emotional ill-health.

In summing up this session, Dr. R. SCOTT (Edinburgh) suggested that the general practitioner's closed or "captive" community offered an ideal field for epidemiological research. The present renaissance of general practice in Britain was associated with an active interest in epidemiology, and a number of such studies by general practitioners had been carried out or were in progress. General practice was especially suited to the study of disease in the earliest and the latest stages. Dr. Logan had suggested that different doctors attracted different types of patient, and epidemiological methods might be extended to study the relationships between doctors and their patients.

NEW ACADEMIC YEAR WESTMINSTER HOSPITAL

At the inaugural session of the Westminster Medical School on October 7 the Dean, Mr. H. E. HARDING, drew attention to the plight of many young doctors when National Service ends in 1960. The guest speaker, Sir ERIC HARRISON, High Commissioner for Australia, discussed the effects of political pressures on Medicine under the heading, "Medicine and Politics." Sir ERNEST ROCK CARLING presided in the unavoidable absence of the chairman of the School council.

Resettlement of National Service Doctors

Mr. HARDING said that the end of National Service in 1960 was bound to create a medical manpower problem in the Armed Forces. However critically the recommendations of the Waverley Committee were read, they did not directly envisage the end of National Service. Nor could he find that any responsible body had concerned itself with the problem of resettling over two years the enormous numbers of young doctors to be released. It was known from experience in implementing the Medical Act, 1950, that for the first year after qualifying there were enough pre-registration posts. But the post-registration posts of quality were also filled, and in fact they provided experience for a number of Dominion and Colonial doctors at this level.

He was therefore very much concerned for the well over a thousand young doctors who might have to be resettled in a two-year period. Most of them on release would want to refresh their experience of civilian hospital practice before planning their careers. They represented an enormous potential of medical skill, and the problems of their future employment could only be determined by national policy after careful inquiry. The National Health Service, with its fixed establishment, close budgeting, and present planning, had given no assurance that the problem was any less than he had postulated.

Political Pressures and Medicine

Sir ERIC HARRISON said that, while the improved standards of health throughout the world were a great boon to humanity, they also created very great problems of their

own. The proportion of old people in the population was increasing, and this had led to greater political pressure for increased pensions, and, as production was not increased, inevitably to rising taxation.

This pressure for bigger and better social services was one of the political problems of the century. When a community expected to receive, from creation to cremation, assistance and protection from the Government, that community should be prepared to accept the responsibility of providing the assistance and protection. But it did not. People seemed to think that the Government had an inexhaustible supply of free money and that, as a Government, it could create wealth. They forgot that it was not possible to take more out of a pint pot than one put in. Inevitably in this age of party politics this led to the welfare state; Governments tended, in line with public opinion, to provide more and more of the things people once provided for themselves. To supply such increased services, high taxation was imposed, and this limited personal savings for the future and brought more demands. So a vicious spiral was entered. This was where the bureaucrat took over. Once the welfare state obtained, one could expect government by regulation, and then one could expect a complete breakdown of the services that one was so proud of and that rendered so much to the community. If Governments were to do more and more, then in heaven's name let them act in such a way as to preserve a certain amount of independence of human spirit and not commit the error of creating complete dependence on the Government.

The medical profession should be concerned about this problem. Whatever progress had been made, whatever the achievement, they believed in Australia that there could be no proper medical service unless it preserved freedom of choice, the personal relationship, and some obligation of self-help. The Australian health service stood as an example of what could be achieved by co-operation between the medical profession and the Government.

Mr. A. BRIANT EVANS proposed the vote of thanks.

Nova et Vetera

THE ROYAL EYE HOSPITAL 1857-1957

The South London Ophthalmic Hospital, later to be named the Royal Eye Hospital, was opened by John Zachariah Laurence on October 12, 1857. The early years of the nineteenth century had witnessed the establishment of many such special institutions for the treatment of eye diseases. They were created in the face of determined opposition from the leaders of the medical profession, but survived and prospered, particularly in the growing industrial centres. This dependence on a commercial environment was well illustrated in London, where by 1856 there were already twelve eye hospitals in the old-established urban areas to the north of the river. Industrial development on the south bank had proceeded only since the middle of the eighteenth century. In 1857, when the population of metropolitan Surrey and Kent was nearing half a million, Laurence was making the first attempt to satisfy an obvious need when he inaugurated the South London Ophthalmic Hospital.

The new hospital was fortunate in many respects. The site at St. George's Circus was a convenient one at the heart of contemporary road developments in South London. Laurence ensured the initial reputation of his venture by associating with it such eminent names in the medical profession as Carsten Holthouse, Wharton Jones, and James Copland, while the chairman of the hospital, Henry Maudsley, was an important local business man. Thereafter the quality of the staff, both administrative and medical, was exceptionally high. Laurence himself can justly claim to be one of the founders of British ophthalmology, and two of his greatest achievements emanated from the Royal Eye Hospital. In 1864 he brought out the *Ophthalmic Review*,

the first ophthalmological journal of modern design in English and the forerunner of the *British Journal of Ophthalmology*. In the volume for 1866 he published the first description of the familial occurrence of retinitis pigmentosa, associated with dystrophia adiposa genitalis, now known as the Laurence-Biedl syndrome. When Laurence died in 1870, at the age of 42, his successor as surgeon at the hospital was Robert Brudenell Carter (1828-1918), a man of forceful character, who contributed brilliantly to the literature on refractive errors, medical ophthalmology and operative surgery, and served with distinction on the General Medical Council and the editorial staffs of the *Lancet* and *The Times*. Malcolm McHardy (1852-1913), who followed Carter as surgeon in 1877, evolved the use of the electromagnet for the removal of magnetic intraocular foreign bodies. He performed the operation at the hospital in 1877. McHardy worked long and devoted hours in his clinics, where his blunt manner and diverse interests combined to make him extremely popular with patients.

Men of such calibre piloted the Royal Eye Hospital with success through its early years. The need for its services By 1870 the number of new cases was 3,486, but as late as was so great that the problem of space was soon pressing. 1876 there were still only eight beds available for in-patients. In 1875 the erection of a new building was made possible when the hospital was found to be the residuary legatee under the will of the late Mr. Richard Mount, of Wingham, Kent. This legacy of £27,000 was forthcoming in 1886. Difficulties over the lease of the site were numerous, and it was not until December 15, 1892, that the new building was opened. During this period, after several changes of name, the hospital was finally designated the Royal Eye Hospital.

The opening years of the twentieth century were spent in consolidating and expanding the work of the hospital. The number of new cases became stabilized at about 25,000 a year, and this required skilful organization of both staff and accommodation. Out-patient clinics were run both morning and afternoon for six days a week. The obligation to use the extensive material available for teaching purposes was accepted and the first organized facilities for instruction were created in 1906. Supervision of the eyesight of school-children was regularized in 1910 in an agreement with the London County Council, by which 2,000 children were to be seen at the hospital during the year by four salaried clinical assistants, each working one half-day a week. This formed the basis for an excellent service that has continued without interruption since that date.

Throughout the first world war, despite depletion of staff, the hospital remained open and the number of out-patients treated was almost as high as ever. By 1934 the freehold of the existing site together with that of an adjacent area had been purchased; for the first time plans could be made for large-scale rebuilding and expansion, but these were necessarily shelved in 1939 on the outbreak of the second world war. On May 10, 1941, severe damage was suffered from incendiary bombing, but the resultant loss of accommodation was made good by the transfer of the in-patient department to a house at Surbiton, and by the use of 64 beds at Lambeth (L.C.C.) Hospital. In recent years research activities have been intensified. In 1943, by agreement with the Royal College of Surgeons, a Joint Research Chair in Ophthalmology was established, and the opening of the Courage Laboratory in 1954 has substantially increased the facilities for clinical research at the hospital.

The people of South London and the specialty of ophthalmology are both indebted to the Royal Eye Hospital for its 100 years of service in the face of considerable difficulty.

To commemorate the centenary, Professor Arnold Sorsby has written a short history of the Hospital, upon which the foregoing note is based, and a Thanksgiving Service is to be held at Southwark Cathedral on October 22.

F. M. SUTHERLAND.

Preparations and Appliances

MODIFICATION TO BONNEY-REVERDIN'S NEEDLE-HOLDER

Mr. BRAITHWAITE RICKFORD, surgeon to the Chelsea Hospital for Women, writes: For a long time this instrument has proved to be unsatisfactory, particularly in hospital practice, where it is used very frequently. The modification here illustrated comprises an alteration to the head of the needle and the socket of the holder. In the past this joint has been

made round, so that after considerable wear there has been a tendency for the needle to slip in the holder. The head of the needle has been made square to fit into a square joint in the holder, thus obviating the tendency for the rotation present in the original instrument. With this modification it is possible for the needle to be placed in three stable positions.

The instrument has been made for me by Messrs. A. L. Hawkins and Co., Ltd., of 15, New Cavendish Street, London, W.1.

AID IN NECK MANIPULATION

Dr. L. S. CALVERT, Welton, Brough, E. Yorks, writes: It has always been difficult for a single-handed practitioner to manipulate the various conditions of the neck which require such treatment. The difficulty arises in keeping the patient fixed on the couch without somebody else holding the feet. I therefore devised this apparatus to fix a patient's feet to the

bottom of the couch. The fitting and adjustment take only a matter of seconds. Each foot is fitted, over the shoe, with a leather "spat"; the spat is done up with two straps at the back of the heel. From the spat in the line of the tibia are two long adjustable straps, which are passed through a staple screwed to the end of the couch. The length of the strap adjustment makes it possible to treat tall or short people.

Mr. W. Henson, surgical aid specialist, 29, Wright Street, Hull, made this appliance to my specification.

Correspondence

Because of heavy pressure on our space correspondents are asked to keep their letters short.

Complications of Influenza

SIR,—We were impressed by your leading article on the pulmonary complications of influenza (*Journal*, October 12, p. 872). Recently we have had the opportunity of dealing with a considerable number of patients suffering from this complication of influenza, and our experience may be of interest to your readers. In our cases pulmonary involvement developed within a few days of the commencement of "flu," frequently during convalescence, and even at times when the patient was already ambulant. One of the most striking observations was that when pulmonary complications supervened they were frequently associated with toxæmia and especially drenching perspiration quite out of proportion to the degree of pyrexia. As you rightly remark, mild central cyanosis is a not uncommon feature, and presumably this is due to pulmonary insufficiency caused by a combination of parenchymal, pleural, and bronchiolitic involvement.

We too have been impressed by the paucity of pulmonary findings. Some degree of impairment of percussion note was invariably observed, but undoubtedly the most constant clinical feature was the presence of crepitations on the affected side. In at least 25% of our patients there was radiological confirmation of pleural involvement, and investigation revealed that this ranged from pleural thickening to straw-coloured effusion and even staphylococcal empyema. Considerable pleural involvement was accompanied by a swollen, tender, mobile ipsilateral axillary gland. The common radiological patterns were those of segmental or bronchopneumonia, either unilateral or bilateral, usually basal in distribution, and accompanied by abscess formation in one case. In one patient, a female aged 35, a dense shadow radiating upwards and outwards from the left hilum was observed.

Your leading article mentions the serious problem of influenza pneumonia in chronic bronchitic patients, and we entirely endorse this comment. However, we feel that an even more crucial diagnostic problem was the exclusion of bronchial neoplasm in two middle-aged chronic bronchitics who developed influenzal infection. Bronchoscopy revealed marked localized engorgement and swelling of the mucosa of the affected bronchus, which seeped yellow frothy pus and after bronchial aspiration revealed red, thickened segmental carinae.

Haematological findings were not remarkable. Cold agglutinins were consistently negative, the sedimentation rate was always elevated, and a mild to moderate degree of leucocytosis was observed. Convalescence occurred slowly over a period of 4-5 weeks, and even when patients were completely asymptomatic some radiological changes, especially pleural thickening, persisted. Finally, we entirely agree that the tetracyclines were in most instances inadequate and parenteral penicillin gave superior results in the treatment of the pulmonary complications of influenza.—We are, etc.,

BERTRAM MANN.
M. A. PASHA.

Halifax.

SIR,—During this present influenza epidemic we have had in one acute female medical ward, within the space of three weeks, nine cases of valvular disease of the heart with complications secondary to influenzal infection. Of the nine cases, six were mitral stenosis and three aortic incompetence, and the complications ranged from congestive cardiac failure (two of these patients died having shown virtually no response to treatment) to pneumonia and severe bronchospasm. The number of cases involved seems to be more than can

be accounted for merely by chance, and one wonders if the passive congestion in these conditions might act as a suitable culture medium for this particular virus. It would be interesting to hear if the connexion between these two conditions has been observed anywhere else.—I am, etc.,

Liverpool, 1.

N. C. R. W. REID.

Influenza Epidemic

SIR,—In your timely annotation (*Journal*, September 28, p. 757) on the present influenza epidemic you make some interesting statements regarding immunization, together with an opinion. The assertion that a vaccine can only protect 30-40% of those vaccinated is too much at variance with the results obtained in the American armed forces to be entirely acceptable. The "restricted conditions" in the American armed forces can hardly explain a protection rate of nearly double that which you quote as being the best possible. It seems that the American vaccine is considerably more effective than you expect the home-produced vaccine to be. You also say that enough vaccine is not likely to be available. One would wish to feel that steps are being taken as a matter of urgency to increase our sources of supply at home or to import supplies of the American vaccine. In this connexion one cannot help remembering with some dismay the Ministry's performances with regard to the Salk vaccine.

With regard to the opinion you express that, so long as the influenza remains mild, general vaccination is unnecessary and perhaps unwise, this is rather a surprising thing to say. If vaccination affords any protection at all, surely the greater proportion of the population protected the better. It is a matter of epidemiology that you do not require 100% of those at risk to be immune to prevent a disease attaining epidemic proportions. You also qualify your opinion by the phrase "so long as the Asian influenza remains mild." But if a sudden access of virulence happens mass vaccination will then certainly be too late to save many of its victims. Those of us whose memories go back to 1918 remember that dreadfully lethal epidemic which began in late October and which was preceded in June, July, and August by an epidemic of a minor infection which was then labelled "Spanish" influenza. The symptoms of this were trifling and the illness transient, but the major outbreak which succeeded it was a thing of horror. The death rate (unlike that in ordinary influenza) was greatest in the young and robust. Death often occurred within a few hours of the onset of the attack with all the signs and symptoms of an acute toxic pneumonia. Attacks presenting a similar clinical picture have already been reported in the present epidemic. As there is a possibility (to put it no higher) of history repeating itself, I suggest that protective measures for the general population should be instituted now, and not, as you imply, when a virulent infection has begun to spread. The old Hippocratic maxim, "The occasion is fleeting," is as applicable to prevention as it is to treatment.—I am, etc.,

Carshalton, Surrey.

CHAS. E. THORNTON.

Influenza in Schools

SIR,—It is a matter of concern that epidemic influenza is affecting schoolchildren by the thousand, this being the second occurrence within recent years. Preventive measures lie in the hands of the local M.O.H. If no measures are taken, the disease can spread with alarming rapidity and produce complete dislocation of school life. If part measures are enforced—e.g., banning assemblies, physical training, school meals, etc.—the influenza spreads more slowly, taking a course of about three or four weeks to affect 50% to 75% of all pupils. There is growing evidence that the most successful measure is partial or complete closure. As it is, there is a lack of uniformity in the action of M.O.H.s which could be overcome by guidance from the Ministry of Health. I consider that the matter as it stands is a challenge to the medical profession.—I am, etc.,

South Shields.

F. H. ROBSON.

Use and Abuse of Blood

SIR.—Mr. A. Ruscoe Clarke (*Journal*, September 28, p. 721) has given a valuable review of the modern management of haemorrhage and shock, and stresses the vital part played by blood transfusion. The gist of his paper is "larger transfusions earlier" associated with (in his unit) "a careful attempt to establish a more accurate approach to transfusion indications at various stages." In his concluding remarks, Mr. Clarke mentions the question of supplies of blood: "... in Britain there are big reserves of voluntary donors yet untapped. The difficulties are organizational. If blood is needed it can be obtained." We are in full agreement with his principles of treatment. They are indeed substantially those taught for some years past to the personnel of the Sheffield Regional Hospital Board's resuscitation unit. It is, however, disappointing to find no reference to the use of plasma.

For some time now we have been increasingly aware that the voluntary donations of blood distributed by the transfusion centres are not always used to best advantage. In some cases they are gravely abused. At all levels of hospital staff there seems to be from time to time a too casual attitude towards transfusion. It is encouraging to learn that in one hospital at least the use of blood is governed by a careful assessment of needs. We wish it were possible to believe this to be so in every hospital. Almost every day we hear of excessive demands and unnecessary transfusions. Mr. Clarke equates the risks of blood transfusion with those of anaesthesia. No one would treat a simple headache with a general anaesthetic rather than tab. codein. co., yet simple iron-deficiency anaemia is nowadays a frequent indication for blood transfusion. The question is not simply one of supplies. It is also one of a rational approach to the use of supplies already available. Blood must be available for traumatic cases. It must be available for haemolytic disease of the newborn. Any traumatic case requiring "transfusion of eleven bottles of blood" may be unlucky if the present irresponsible usage continues. A baby requiring replacement transfusion with AB Rh-negative blood (the frequency of which is approximately 0.5%) may die in order that an adult can be sent home a few days earlier than would be possible with iron therapy.

One of the primary functions of a blood transfusion service is to provide blood. Any criticism of our hospital colleagues very often results in retorts such as, "If we ask for it, it's your job to get it." Apart from the difficulty of justifying some of these demands, the question of supply is not nearly so simple as Mr. Clarke suggests. About 2% of the population are blood donors. The difficulties of raising the public response in any community above this level are tremendous. It must be remembered that of Mr. Clarke's "big reserves" large numbers are too old, too young, pregnant, or not in sufficiently good health. The remainder are either apathetic or restrained by fear. Even among the willing minority approximately 5% are found to be anaemic and as high as 8% unsuitable to be donors owing to a history of jaundice. Most urban communities are probably now producing as many donors as can be expected. Further expansion can only take place in fresh fields, such as the rural districts, where the practical difficulties of recruitment and bleeding of donors are very great. That expansion has been achieved in this region is amply demonstrated by the increase in the number of donors bled from 42,458 in 1950 to 66,246 in 1956 (an increase of 56%). Even this rate of expansion is apparently inadequate to meet the ever-increasing demands of the hospitals, and it is doubtful if this can be maintained to yield 90,000 donors in 1962. We are also governed by the Exchequer. Adequate organization for donor recruitment is existent—the difficulties are psychological, educational, and financial.

Fundamentally, blood is not provided by the transfusion service. It comes from the voluntary efforts of a small altruistic section of the population. These efforts must not be wasted.—We are, etc.,

Sheffield, 10.

C. BOWLEY,
J. DARNBOROUGH.

Mental Health of Students

SIR.—Dr. S. J. G. Spencer (*Journal*, September 21, p. 710) is surprised at the suggestion (*Journal*, September 7, p. 567) that incipient psychosis might be noticed sooner in college than at home. Two clinical observations, however, support the idea. The first is the frequency with which the parents of young psychotics deny the abnormalities of their offspring when they finally come to out-patient clinic or hospital as a result of some extreme psychotic act or the insistence of outsiders. The second is that unfamiliar situations bring out a display of psychotic signs in patients who can still manage routine behaviour in well-known surroundings.

Dr. Parnell reported in 1951¹ that Oxford University students had a greater suicide rate than the national average for young men. He also showed that a considerable number of students had nervous breakdowns necessitating at least a term off work. Can we now say whether students in general have a higher incidence of mental ill-health than do other young men, and if so in which diagnostic categories—for example, schizophrenia, psychotic depression, obsessional neurosis—the excess comes? Is it equally true for all students, or only for those at some universities? This kind of information might throw light on the extent to which university life really is a special stress. Even if it turned out that the depressions, anxiety states, personality disturbances, and psychosexual difficulties and so on occur only about as often as in the general population, a student mental health service would of course be fully justified, but the question of special vulnerability of students should be clarified.

Dr. Spencer lays a good deal of emphasis on American findings, but it is doubtful whether they have any international relevance. American universities and student recruitment are very different from the British, and the position of the psychiatrist in American society is a very special one. The American literature tends to a notorious over-optimism towards treatment of all kinds, but particularly perhaps to the effectiveness of psychotherapy. Without precise diagnosis, which means a prediction of what course the spontaneous untreated illness will run, and without a reasonably long follow-up period after the end of treatment, any judgment of the value of treatment is bound to be extremely subjective. Many, without going as far as Professor H. J. Eysenck, now agree that psychotherapy lacks scientific validation. How much of it is wrongly aimed or misconceived, how much time and energy is being wasted at present in useless hocus-pocus—and how psychotherapeutic techniques are to be improved in speed and effectiveness—will not be learned until the mystery, the atmosphere of faith and dogma, can be set aside and some dispassionate hard and careful work done. In the meanwhile what psychotherapy has to offer is very far from certain.—I am, etc.,

Birmingham, 15.

Penicillin V in Staphylococcal Infections

SIR.—We were interested in the article by Mr. J. I. Burn and his colleagues (*Journal*, July 27, p. 193) reporting a trial of penicillin V in staphylococcal sepsis in the casualty department of St. Bartholomew's Hospital, London, and in particular in the similar response to treatment of lesions caused by strains both sensitive and resistant to penicillin. The lesions they treated were perhaps small, 66% being 5 sq. cm. or less in size, although 60% showed evidence of systemic reaction to the infection by virtue of lymphadenitis. In view of this, the results they observed, as they themselves state, may have been those of the natural course of the disease influenced by treatment, for no untreated group was studied to compare with them. In addition no mention was made of whether any of the patients had received any antibiotic treatment immediately prior to admission to the trial. Such therapy might also have influenced the results. However, a recent similar small trial conducted in the casualty depart-

ment of St. Thomas's Hospital before the above article was published has produced similar results, and we are prompted to report our findings briefly here.

Oral novobiocin 500 mg. twice daily and oral penicillin V 125 mg. three times a day (the latter being the form of penicillin and dosage now used routinely in the department) were given to alternate patients, both for five days. We studied only adults and only those from whom a specimen of pus was available for bacteriological examination before treatment, those who had not received chemotherapy for the lesion elsewhere, and those considered to need such treatment. Since most of the patients attending hospital had already received some such treatment, only 17 who were given novobiocin and 13 penicillin were finally available for study. No patient required a change of antibiotic, and none more than the five-day course. The lesions treated were abscesses, carbuncles, cellulitis, and finger infections. All were infected with *Staph. pyogenes* alone, but, while all the strains isolated initially were sensitive to novobiocin, seven of those treated with penicillin were resistant to this antibiotic *in vitro*. The criteria used for initial assessment and for judging the response to therapy were very similar to those described by Mr. Burn. The median size of the lesions treated with novobiocin was 25.5 sq. cm. and that in both the penicillin-sensitive and penicillin-resistant groups 12.5 sq. cm. (the patients who received penicillin were divided into these two categories for analysis depending upon whether the organism isolated initially was sensitive or resistant). The novobiocin group was otherwise similar to the penicillin-sensitive group, except that the former consisted of slightly younger and less well localized lesions, and these required less surgery. These disparities were reflected in a slight delay in healing of the cases treated with novobiocin, but the difference was neither large nor significant. No toxic effects were observed with novobiocin in this dosage and duration of administration, and it was our impression that it was as effective as penicillin in the treatment of staphylococcal sepsis. In two cases the infecting organism developed some resistance to the antibiotic during treatment, but there was no apparent delay in healing in these cases.

The two penicillin groups were comparable initially, but a difference was observed between them in response to therapy. This was most apparent in the time a discharge persisted after starting treatment—median day 9.3 for the resistant group as against 4.5 for the other. However, all the patients in the trial improved promptly following the initiation of antibiotic therapy as judged by the relief of fever, lymphangitis, and local pain, tenderness, and erythema. A change of the antibiotic was not required and serious complications were absent from this small series; moreover, they are nowadays rarely seen in the large number of septic cases routinely treated with penicillin in the department.

In view of these facts it would be hard to believe that penicillin does not affect the natural course of the disease, even when the causative organisms are resistant *in vitro*. Thus penicillin still seems to be effective in the treatment of the type of staphylococcal lesion seen in a casualty department, despite the advent of resistant strains. It would be interesting to observe and compare a series of cases not treated with an antibiotic, in an attempt to prove this contention, but presumably this would be neither wise nor ethical in cases now accepted as requiring such treatment. How far these findings are a function of the relatively localized type of lesion treated and how far they are applicable to more generalized infections we are not in a position to say. The value of such trials must therefore be questioned when an attempt is made to argue the general from the particular, and it would be unwise to try to assess from them the probable response of other infections caused by resistant staphylococci. It is possible that the few resistant organisms present at the edge of a small septic lesion produce insufficient penicillinase to destroy all the penicillin in their environment, in which case they would be killed, but the balance might well be in favour of the staphylococci in a more severe and widespread infection.

We would like to thank Mr. R. H. Boggon, under whose care these patients were treated, for permission to report our findings, and Dr. M. Barber for constant advice, help, and encouragement.—We are, etc.,

J. E. MIDDLETON,
J. B. SELF.

London, S.E.1.

Herpes Zoster and Chicken-pox

SIR.—In view of recent letters on the subject of chicken-pox, the following case may be of some interest.

The family concerned live in a delightful house surrounded by extensive grounds in rural Cornwall. A son, aged 8, returned home from boarding school on July 30. He had his second poliomyelitis injection on August 27, though this seems of no moment. On September 1 he developed a typical herpes zoster, which worried him very little, and has resolved normally with a little residual discoloration and scarring. There was never any sign of a generalized rash. On September 14 his two brothers, one, aged 6—on holiday from a local school—and the other, aged 14 months, simultaneously developed chicken-pox rashes with mild constitutional symptoms.

The interesting features seem to be: (1) the typical zoster at the age of 8, and (2) the time interval of the development of the chicken-pox rashes, bearing in mind the negligible possibilities of infection from any outside source. There was no local epidemic at the time. Though I have at times felt inclined to attribute a case of chicken-pox to infection from an adult zoster, I have never previously had a case showing such clear evidence of the infectivity of a varicella herpes zoster.—I am, etc.,

Falmouth.

C. F. TURNER.

Acute Haemorrhage from Peptic Ulcer

SIR.—I read with interest your annotation (*Journal*, September 21, p. 693), and, while agreeing that "barium-meal examination is frequently impracticable in a severely anaemic subject," it can be carried out soon after transfusion. We have recently performed modified barium-meal examinations as soon as possible after admission. In some cases the delay has been up to 24 hours to allow for transfusion. The examination is carried out in the ward, using a mobile apparatus. The patient is given three-quarters of a cup of barium to drink; prone and supine films are subsequently taken. The patient is disturbed as little as possible, and, while there have been no complications to date, the results have been encouraging, as in over 50% of cases a lesion has been demonstrated. A report on this work is in course of preparation for publication.—I am, etc.,

Leeds.

DERMOT F. CANTWELL.

Thrombo-embolism in Pregnancy

SIR.—Mr. M. B. Wingate's memorandum (*Journal*, September 21, p. 685) prompts this brief report of an analysis of 20 case histories of thrombo-embolism associated with pregnancy that occurred in the obstetric unit of St. John's Hospital, Chelmsford. During 1955 and 1956, 2,520 patients were delivered in the unit, and certain clinical impressions were formed which this analysis proved to be wrong. The incidence of superficial and deep ante- and post-partum crural venous thrombosis was 0.8%. There were eight cases of deep vein thrombosis (two bilateral), and twelve of superficial vein thrombosis; in four patients the process began at the 16th, 23rd, 28th, and 38th week of pregnancy, three superficial left and one deep left. Puerperal deep vein thrombosis occurred on the 1st, 3rd, 5th, 11th, 14th, and 17th days after delivery; the right leg was affected six times, and the left four. There was one case of major, but not fatal, pulmonary embolism which occurred eighteen days after lower segment caesarean section at the 38th week of pregnancy for severe toxæmia in a primigravida aged 41.

Analysis of possible associated factors was as follows. Age.—Varied between 21 and 41 and evenly distributed. Parity.—Nine were primigravidae, 3 had had previous miscarriages, 1 had had previous ectopic pregnancy, and multiparity ranged between 1 and 6. Anaemia.—Only 7 cases with a haemoglobin of below 70%, and lowest haemoglobin was 60% (Haldane). Antenatal rest.—Five patients only had antenatal rest. Blood groups.—Eight O.IV Rhesus-

positive; 2 A.II Rhesus-negative; 4 B.III Rhesus-positive; 4. A.II Rhesus-positive; 1 O.IV Rhesus-negative; 1 AB.I Rhesus-positive. *Varicose veins*.—Only mentioned in six patients. *Sex of child*.—Seven girls and 13 boys—among cases of deep thrombosis, 4 boys and 4 girls. *Weight of baby*.—Varied between 4.2 and 8 lb. (1.9 and 3.6 kg.). *Infection*.—A possible factor in nine cases. *Fertility*.—Of 11 para-0, fertility poor in six—i.e., all married more than 5 years, and longest 13 years; of 9 multiparae fertility poor in one. *Toxaemia*.—Six cases of toxaemia—this is not a significantly high number in St. John's. *Placenta*.—Fourteen normal and healthy to the naked eye; 3 small or infarcted; 2 battledore; 1 unusually thick chorion. *Third stage loss*.—Varied between 2 and 30 ounces (57 and 852 ml.) with two cases of post-partum haemorrhage. *Duration of pregnancy*.—Fifteen at term; 4 premature; 1 post-mature. *Artificial rupture of membranes*.—Seven cases—this is twice the number expected, but the number is so small that it is not truly significant. *Duration of labour*.—Ranged from 5 hours to 67 hours, with normal distribution of curve. *Method of delivery*.—11 normal; 2 B.B.A.; 3 forceps; 2 breech; 2 caesarean section.

The conclusion is that there is no constantly recurring factor in this series. We should be interested to know if the calf veins were examined at necropsy in the case reported by Mr. Wingate.—We are, etc.,

ANTHONY C. PEARSON.
J. THEO. WHITLEY.

Chelmsford, Essex.

Preparation of Skin for Electrocardiography

SIR,—I have always understood that special jelly is essential in the preparation of the skin before applying electrodes during electrocardiography. The procedure is messy and it involves considerable cleaning, both of the skin and of the electrodes, after the tracing is taken. This takes a considerable time and it is apt to be a nuisance. Some months ago I began to wonder whether jelly is really necessary. I have come to the conclusion that it is not. Satisfactory contact can be achieved by lightly rubbing the selected areas of skin and the electrodes with a small piece of damp sponge, leaving them slightly moist. Alternatively a small piece of moist gauze can be placed between the electrode and the skin. This procedure gives just as good results. The saving in cost is negligible, but the saving in time and effort is considerable.—I am, etc.,

London, W.1.

JAMES MAXWELL.

Snake-bites

SIR,—Despite the valuable work my colleague Dr. Abdul Wahab Ariff has done on Malayan snake-bite, I must dispute his statement (*Journal*, August 31, p. 525) that certain sea-snakes in Malaya are aggressive even when unprovoked—if he means they will attack human beings unprovoked. In the literature, personal experience of snakes in captivity, and talking to numerous Malayan fishermen, I have not encountered a single authentic incident suggesting unprovoked aggression to mankind. I would be interested if any reader can quote a convincingly authentic record of unprovoked attack on man by a land-snake.

On reconsideration, I quite agree with Dr. W. B. Roan-tree (*Journal*, July 27, p. 236) in doubting the figure of 250,000 victims receiving antivenene each year. In a recent survey, Keegan¹ was only able to record a total of 19 institutes producing antivenene in the world. However, as antivenene production increases and poor communications, antipathy, etc., are overcome, the number of snake-bite victims receiving hospital treatment will continue to mount. The fate of the victims will not then necessarily be decided at the time of the bite. The outcome may be influenced for the better—or for the worse. The latter is unfortunate in a condition whose danger is greatly exaggerated. I do not think it is sufficiently realized that poisonous snake-bite is not synonymous with snake-bite poisoning. For example, in 311 out of 1,038 patients admitted to four hospitals in north-west Malaya during 1955-6, the snake biting was identified as *Ancistrodon rhodostoma* (Boie). Potentially it

is a dangerous viper, 25 patients developing a general haemorrhagic syndrome (9 fatal). Yet of these 311 *A. rhodostoma* victims no less than 116 had trivial or no symptoms of poisoning. This happy finding is, of course, due to negligible venom being injected at the bite. In no way can it be attributed to antivenene, because the one used during 1955-6 was not made with *A. rhodostoma* antigen.

For considerations to be published later I believe that, in Malayan snake-bite, antivenene should not be given (1) if the bite is known to be by a snake for which available antivenene is ineffective (at present this includes sea-snakes and probably all vipers); (2) if there is no clinical evidence of significant envenomation; (3) if the patient is not seen until 12 or more hours after the bite. For various reasons these contraindications to antivenene would not apply to snake-bite in some other countries, but they are probably applicable to England. Even contraindication (1) may be valid, because Schöttler² was constrained to describe Pasteur ER—the antivenene commonly available in England—as so low-titred it cannot be used as a standard for the therapeutic efficiency of antivenenes. So far as I am aware, it is not refined, the danger of serum reactions being correspondingly greater.

Undoubtedly, suitable antivenene therapy can be an important (sometimes life-saving) factor in certain types of snake-bite poisoning, but its limitations are often ignored and there is a tendency to overstress its value. As a result, and general measures of equal or more importance may be neglected. Suitable antivenene is only likely to affect the systemic toxaemia—and only if circulating within a very few hours of the bite.³ In experimental viper poisoning it does not diminish the extent or severity of local necrosis⁴ (even if given before the venom is injected). In treating patients with severe viper poisoning, I believe far the most important single measure is adequate blood transfusion. Many pints may be needed—unfortunately, a counsel of perfection in most hospitals treating these victims. For the local lesions the watchword should be "masterly inactivity," as suggested by Mr. R. T. Burkitt (*Journal*, July 20, p. 159). Necrosis developing in hospital may be extensive—indeed, frightening to those unfamiliar with snake-bite—but in my experience it is nearly always confined to superficial tissues. If secondary infection is controlled, it is quite remarkable how well these lesions heal with a conservative regime.—I am, etc.,

Dietary Fat and Coronary Disease

SIR,—Your leading article on dietary fat and coronary disease (*Journal*, July 13, p. 89) needs another few comments. You claim, "There are no figures available to show that subjects with a high level of serum cholesterol maintained over a long period succumb to coronary disease more often than those with a lower value. This is the crucial observation that needs to be made. It could in fact be postulated that a raised blood cholesterol is the result rather than the cause of a coronary artery disease." There is a high incidence of coronary thrombosis among those suffering from hypercholesterolaemia. Here the hypercholesterolaemic state is clearly a precursor of the coronary disease. One may of course argue that the two conditions are due to the same underlying congenital disorder. I agree that the sequence high fat—hypercholesterolaemia—hypercoagulability has not been proved. Hypercoagulability is extremely difficult to demonstrate. I do not think that any method to-day will give information of real value. But experience in human beings is, to my mind, very convincing. In Norway the incidence of thrombo-embolic complications after operative procedure has been investigated, and it has been shown¹ that thrombo-embolic complications went down to zero in the two largest surgical wards of Oslo City Hos-

pital during the war years, and went up again with cessation of food restriction. Ignoring these facts, one can certainly with confidence enjoy a breakfast meal with eggs and bacon and probably a large helping of butter.—I am, etc.,

Oslo.

Scorpion Stings

SIR,—I was interested in a letter in your correspondence columns by Dr. M. McA. Holmes (*Journal*, August 10, p. 353) on the treatment of scorpion sting.

When I was in practice in south-west Africa I found that the intramuscular injection of "prontosil soluble" was often a life-saving measure in this condition: 5 ml. is injected intramuscularly in children up to the age of 5 years. I first used this measure empirically in 1937.¹ Since then I have used this substance successfully in several cases. Subsequent work seems to have provided a rational basis for this treatment. In 1938 Stanley Cobb *et al.*² and Osgood and Robinson³ described the anticonvulsive action of vital dyes, prontosil soluble being one of them. They were found to be particularly effective against chemical convulsants. R. B. Aird, in a paper read to the American Psychiatric Association at San Francisco on June 6, 1938, concluded from the experiments on dogs that the effect of these dyes was obtained by the alteration of the endothelial barrier to "convulsive metabolites."—I am, etc.,

The Misnamed Stethoscope

SIR,—We as a profession have been perpetuating for generations what is surely an error in calling our commonest instrument a stethoscope: we would, I hope, be less informed on chest disorders if we looked down it. The name stethophone is suggested—to right an ancient wrong. Who ever heard of a proctophone?—I am, etc.,

Southsea.

F. R. LANGMAID.

Overdosage of Chloroquine

SIR,—In 1955 I reported a fatality due to chloroquine overdosage.¹ Since then I have performed necropsies on two further children who had been given intramuscular chloroquine, following which they collapsed and died within 20 minutes of the injection. Post-mortem examinations failed to reveal any organic disease or other cause of death. In each case the amount of chloroquine injected was in excess of the manufacturer's recommendations—that is, 5 mg./kg. body weight. The second death was an infant, aged 5 months, weight 7 kg., who received 3 ml. of "nivaquine" (equivalent to 120 mg. chloroquine base), this amount being 3 to 4 times the recommended dosage by weight. The third patient was a boy, aged 17 months, weight 11 kg., who, it was stated, received 2.5 ml. of nivaquine (equivalent to 100 mg. chloroquine base). This amount is approximately twice the correct dosage by weight. His death was all the more tragic in that there was no clinical or laboratory evidence that he was actually suffering from malaria, nor indeed was he unable to take medicine by mouth.

In the manufacturer's literature the dosage for children is also stated in simple fractions of the adult dose—up to 1 year, $\frac{1}{4}$ to $\frac{1}{2}$ of the adult dose, the latter being 200 to 400 mg. Thus if the lower adult dose is used in the calculation an infant would receive 25 to 33 mg. and on the higher adult dose 50 to 66 mg., the latter figures being $\frac{1}{4}$ to 2 times the dose when estimated by weight in the case of a 7-kg. infant. As injections of any substance should only be given on the advice and authority of a medical practitioner, the pharmaceutical manufacturers should avoid the dangers of rule-of-thumb dosage. Any medical practitioner should possess or have easy access to a weighing machine and be capable of calculating the correct dose.

These deaths have naturally caused local practitioners some anxiety in the administration of chloroquine parenterally. This is a good example of a first-class drug being brought into disrepute owing solely to its use in a haphazard fashion. It is hoped that the manufacturers will emphasize the danger of overdosage in the instructions accompanying this drug.—I am, etc.,

Medical Association for the Prevention of War

SIR,—I hope you will allow me to make some observations on behalf of the Medical Association for the Prevention of War in reply to criticisms put forward in your correspondence columns (*Journal*, August 31, p. 528).

When this association was founded in 1951, a clause was inserted in its constitution proclaiming the independence of the association and its disavowal of any political or religious affiliation. We confirmed our independence of Communist influence when we refused to accept any invitation to act with the British Peace Committee; when we refused to accept as conclusive the evidence offered during the Korean War in support of the allegations of germ warfare by the United States; and when we protested to the Soviet Ambassador at the time of the Hungarian uprising. We draw attention to the eminent and independent speakers and writers who have contributed to our work, and to our work itself, which has consistently abjured any political activity, and has restricted itself to matters relating to medicine, medical ethics, and peace.

Communists and non-Communists have been active in this association, just as they are in trade unions and in the United Nations; they have worked amicably together and learned from each other, but Communist influence has never dominated our discussions nor dictated our policies. We are aware that it is with the Communist-controlled States that we have to live in peace, and it would appear to us highly impractical to suggest that any association such as this could start its campaign for peace by proclaiming even ideological war against so large and powerful a section of the human race.—I am, etc.,

AUDREY HENSON,

Acting Hon. Secretary.

London, W.1.

Medical Association for the Prevention of War.

Solubility of Gentian Violet

SIR,—The letter from Dr. W. G. Dawson (*Journal*, September 21, p. 711) on G.P. responsibility in gynaecology brings to light an interesting point regarding the solubility of gentian violet in water. It seems to be quite commonplace to prescribe 2% aqueous solutions of gentian violet, yet theoretically its solubility is far less than 2% in water.

The *British Pharmacopoeia*, 1948, gives the solubility of medicinal gentian violet in water as 1 part in 150 parts (approximately 0.67%) at 15.5° C., while the *B.P.*, 1953, gives it as 1 part in 200 parts at 20° C. (approximately 0.5%). Gentian violet was also the subject of a monograph in the *United States Pharmacopoeia XIII* of 1947, where the solubility is given as 1 in 30 to 1 in 40 (2.5% to 3.3%), but the monograph has been omitted from subsequent editions. It seems apparent that this greater solubility is probably due to a mixture of the hydrochlorides of methylosaniline, while the *British Pharmacopoeia* is more specific in stating the formula of hexamethylparosaniline hydrochloride.

Now, although the solubility seems to be in the region of 0.5% to 0.7%, some drug houses issue standard preparations of solution of medicinal gentian violet ranging in concentration from 0.5% to 1%. But a concentration of 2% seems to be feasible only by the addition of either alcohol (in which gentian violet is very soluble) or glycerine (in which it is soluble to the extent 1 in 30).

Although the point raised is relatively unimportant and mainly of academic interest, it seems pertinent to mention it owing to the frequency with which 2% and even 5% aqueous solutions are prescribed.—I am, etc.,

Uxbridge, Middlesex.

P. J. KEEN.

Psychosis Due to Isoniazid

SIR,—I have read Dr. S. L. O. Jackson's excellent paper on psychosis due to isoniazid (*Journal*, September 28, p. 743) with interest; but I am wondering whether he would allow me one quibble? He observes that, "It is particularly important to consider an isoniazid reaction in any patient showing an unexpected and peculiar mental change, especially where there is no past history of mental instability" (italics mine). In view of recent observations¹ demonstrating the fact that patients suffering from "toxi-infective" conditions and "toxi-organic" syndromes (characterized by interference with mental processes, exaggeration of temperamental traits, or preponderance of emotionally charged material in awareness), and those in whom a depressive psychosis proper has already become established, benefit from treatment with intramuscular vitamins, would it not therefore be a wise precautionary measure to institute vitamin injections before embarking on isoniazid therapy, and to continue them for as long as the isoniazid is given, in all patients who have a history of mental instability? Isoniazid may well prove the last straw for a patient whose enzymic activity is precariously balanced, and hence I would advocate considering the possibility of an isoniazid reaction in any patient showing an unexpected and peculiar mental change, especially where there is a history of mental instability—the isoniazid, as it were, adding insult to injury.

Similar considerations would apply when contemplating isoniazid therapy in chronic alcoholics, in view of the observations by Armstrong and Gould,² and Dr. Jackson's experience with the two cases he mentions in this paper.—I am, etc.,

Bognor Regis, Sussex.

AUDREY F. ROBERTS.

Detention of Voluntary Patient

SIR,—Recently a coroner was reported as saying that a mental hospital had broken the law by not enforcing the 72 hours' notice of discharge required of a voluntary patient when giving in his notice of departure, in order to make other necessary arrangements to detain the patient.

I would be very glad to have an authoritative ruling on the following questions: (1) What law was broken? (2) What rights has a hospital to compel a patient to stay for the requisite 72 hours? It is true he has signed a voluntary patient form on admission agreeing to do this, but what validity has this in law? Is it a contract? If it is not, what is it? And even if it is a contract, has the hospital, or the doctor in charge of a case, the right to enforce what is presumably a civil contract? Has he the right to detain anyone not certified against his will? In the case of a voluntary patient who escapes from the hospital there has been a court ruling that the hospital has no power to make him return; in the case of a patient who insists on leaving without staying the requisite 72 hours I have never been able to discover what actual legal rights of detention exist. In the mental hospital I attend the view is that if the patient is in a closed ward one is under no obligation to open the doors for him, but if he is in an open ward there is no right to detain him by forcible restraint, which may entail removing him to a closed ward if he insists on going. I should be very interested to hear your readers' views on this question.—I am, etc.,

London, W.1.

W. LINDESAY NEUSTATTER.

Malformation of Ears and Genito-urinary Tract

SIR,—I enjoyed reading Dr. D. Hilson's most interesting paper (*Journal*, October 5, p. 785). It is worthy of note that in a series of 25 cases of Turner's syndrome reported by Lissner *et al.*,¹ one case had malformed ears and another had coarctation of aorta, double left kidney, pelvis, and ureter. I believe that the defects in the syndromes of Turner

and Klinefelter are genetic and that the genes involved may lie on the same chromosome. The defects could be produced by deletion of loci in consequence of inversion cross-overs, and some such defects would be inherited in the manner of an autosomal dominant. I and my colleagues have reported² unusual rhesus blood group findings in Klinefelter's syndrome. The rhesus loci might lie on the same chromosome and would show genetic linkage. The defects described in Dr. Hilson's cases appear to be inherited in the manner of an autosomal dominant, and it would be of value to look for linkage between these defects and the rhesus blood groups.—I am, etc.,

Glasgow, C.4.

Ophthalmoscopic Sign of Death

SIR,—The full title of this communication is "A Teleological Interpretation of the Ophthalmoscopic Sign of Death—Segmentation of the Blood Columns in Retinal Vessels." What I mean by this is an interpretation of the ophthalmoscopic sign of death (segmentation of the blood columns in retinal vessels) as part of an inborn vital reaction towards obstructions, irritations, or injuries, as if serving a definite purposeful aim of relief or cure. This method of reaction has doubtless been acquired by a long process of trial and error through countless generations, according to the Darwinian doctrine of the "survival of the fittest."

Teleological aspects can be discovered when considering almost any sign or symptom however remote they seem to be—for instance, at first sight, who would think that there could be any connexion between segmentation of blood columns in retinal vessels and a conservative vital reaction against impending death? But there is, according to my explanation, as follows. It seems that our blood vessels act in such a way that sudden obstruction in a main artery of a limb is followed by dilatation of all the blood vessels of that limb, including even the capillaries, with the object of removing the obstruction if possible, but at all events of producing collateral circulation. This explains the occasional swollen red appearance of a leg threatened by senile gangrene. I believe that cases of Weir-Mitchell's "erythromelalgia" are sometimes to be explained as a reaction towards arterial obstruction of some kind.

When the heart suddenly ceases to contract, and the blood flow throughout the body stops, the body takes this as signifying that there is an obstruction at some part of the circulation, but unfortunately the "obstruction" in this instance is at the commencement of the circulation, and so, instead of all the blood vessels dilating in a limb, the blood vessels, more or less in the whole body, or the upper part of the body, have to dilate in a final effort to furnish a collateral circulation. This endeavour must of course inevitably fail unless the heart commences to contract again, either spontaneously or aided by cardiac massage, etc.

This whole consideration is chiefly of academic interest and explains the pink flushing of the face sometimes observed as well as the phenomenon of segmentation in blood columns in retinal vessels. This latter is apparently due to dilatation of the vessels forming a vacuum which cannot be completely filled up by the blood content. The absence of any segmentation of retinal blood columns in certain cases may be due to death having been very slow in taking place in those cases.

Although these considerations help one, I think, to understand what takes place under the circumstances alluded to, without helping very much in the treatment, there are other conditions in which a correct understanding of the teleological aspects can help directly in the treatment, but I cannot deal with these at the moment.—I am, etc.,

London, N.W.1.

Obituary

Sir JOHN HERBERT PARSONS, C.B.E., D.Sc.
LL.D., F.R.C.S., F.R.S.

No man in his generation exercised a greater influence on British ophthalmology than Sir John Herbert Parsons, whose death occurred on October 7 at the age of 89. As ophthalmic surgeon to two principal London hospitals, adviser to Government departments, or consultant to the Forces he brought to bear upon the science and art of this branch of medicine a mastery of theory and practice and a broad and imaginative outlook. His invaluable investigations on sight-testing for the Board of Trade prepared the way for his outstanding work on colour vision. He served on numerous commissions and departmental committees dealing with illumination and the correlation of ophthalmological knowledge with the modern developments of industry. In the war of 1914-18 he was appointed ophthalmic consultant for the home troops, with the rank of temporary colonel A.M.S., and he gained ex-

[Press Portrait Bureau]

perience of the visual problems which confronted all three Services. In 1919 he was appointed to the Advisory Medical Council of the Air Ministry and three years later to the similar council of the Admiralty. This was the first occasion on which a Government department had appointed an ophthalmic surgeon to its chief medical committee, the function of which was to advise the Director-General of the Medical Services on questions of difficulty. At the time of the Munich crisis in 1938 he was made civil consultant to the R.A.F., and just before the second world war he was appointed by the Secretary of State for Air the only ophthalmic member of a committee to investigate and advise the Minister on the medical aspects of all matters concerning personnel which might affect the safety and efficiency of flying.

John Herbert Parsons was born at Bristol on September 3, 1868, and was educated there, going to the University College, Bristol, where he won the Gilchrist, John Stewart, and Sharpey scholarships. Later he won the first entrance scholarship to Bristol Royal Infirmary. Having taken the B.Sc., with honours, of London University in 1890, he completed his clinical training at St. Bartholomew's Hospital, qualifying in medicine in 1891 and graduating M.B. in 1902. After qualification he continued to work as a physiologist, having been appointed assistant to the Professor of physiology at University College, London, of which he later became a fellow. One of the first papers

he wrote for the *Journal of Physiology* was "On the Electrical Variations in Muscle and Nerve." For five or six years Parsons was in general practice in Finchley, and during this time he began to concentrate his interest on ophthalmology, working as clinical assistant at the Royal London Ophthalmic Hospital, City Road (Moorfields). Having taken the F.R.C.S. in 1900 he gave up general practice and began the study of his chosen specialty in its widest aspects. In this he was helped by the award of a B.M.A. research scholarship in 1900. Not content to learn the rudiments of the science of optics, he set himself to acquire a thorough knowledge of normal vision, with all that it entails of physics, chemistry, physiology, neurology, and psychology, as well as of clinical ophthalmology. The advance of ophthalmology, as he understood it, depended upon an extended knowledge of the physiology of the eye and of vision. Thus he claimed that further advance in the treatment of cataract, for example, would not consist in new refinements of technique but in a new understanding of the biochemistry of the lens. In this early stage of his career he wrote two books, *Elementary Ophthalmic Optics* (1901) and *Ocular Circulation* (1903).

In 1904 Parsons won the B.M.A.'s Middlemore prize—he was again Middlemore prizeman in 1914—for the best essay or work in any department of ophthalmic medicine or surgery. In 1907 he was awarded the Nettleship gold medal for his important monograph, issued in four volumes from 1904 to 1908, on *The Pathology of the Eye*. In 1903-4 he was Arris and Gale lecturer to the Royal College of Surgeons, and in 1904 he was elected to the staff of Moorfields, the mecca of ophthalmologists from all parts of the world, where he had previously been curator and librarian. The vacancy at Moorfields which he filled was caused by the death of A. Q. Silcock, who was the last general surgeon to serve on the staff of that hospital. Parsons also became ophthalmic surgeon to University College Hospital. He gave eminent service to both these hospitals until the age fixed for retirement, when he joined the consulting staff of both. For a time he was ophthalmic surgeon to the Hospital for Sick Children, Great Ormond Street. With all this hospital work went a continually enhancing reputation as a consultant.

Parsons joined the Ophthalmological Society of the United Kingdom in 1900, and for more than 40 years he was a constant contributor to its *Transactions*. His name appears more than 50 times as the reader of a paper or the participant in discussion during the years 1901 to 1910. His first contribution was the description of a case of coloboma of the optic disk. He became president of the Society in 1925. He was secretary of the Section of Ophthalmology of the British Medical Association, 1905, vice-president in 1913, and president in 1923 and again in the centenary year, 1932. In 1936-8 he was President of the Royal Society of Medicine, the first ophthalmologist to be elected to that position since the amalgamation. He was also greatly interested in the British Council of Ophthalmologists, a body which arose out of some annotations he himself wrote in the *British Journal of Ophthalmology*, of the editorial committee of which journal he was chairman from 1917 to 1948. In the important Convention of English-speaking Ophthalmologists held in London in 1925, he was chairman of the Scientific Business Committee. In 1919 he delivered to the Oxford Ophthalmological Congress the Doyné memorial lecture, taking as his subject "Preventive Ophthalmology," and in 1925 to the Ophthalmological Society the Bowman lecture on "The Foundations of Vision." In 1929 he visited America and delivered an address at the opening of the Wilmer Ophthalmological Institute at Baltimore on "Anomalies of Normal Vision," and in 1936 he was again in the U.S.A. as the guest of the American Academy of Ophthalmology and Otolaryngology, when he delivered an address on "Ophthalmology and Research." During this visit to New York the Lucien Howe medal of the American Ophthalmological Society was presented to him in recognition of his services to this branch of medicine.

During his whole career his pen was kept fully employed. An early labour was his translation in 1904 of J. Boldt's *Trachoma* from the German, and in 1905 of V. Hanke's *Treatment of Diseases of the Eye*. He also edited the translation from the French of Felix Lagrange's *Les Fractures de l'Orbite par Projectiles de Guerre*, one of the Military Medical Manuals published during the first world war. In 1915 he wrote his *Introduction to the Study of Colour Vision* for the Cambridge Psychological Library. In it he pointed out that the vast literature on colour vision consisted almost entirely of papers written to support some particular theory, and that it was peculiarly difficult to obtain a general and unbiased view of the subject. In that publication and in others he did good service in separating the established facts of colour vision from the theories with which the whole subject was surrounded, but it led him into a well-remembered controversy with Dr. Edridge-Green, whose theories he had challenged. The study of vision introduced him to the adjoining and overlapping territory of psychology, on which he wrote in a very understanding way. His *Mind and the Nation: A Study of Applied Psychology* appeared in 1918. But his great work was his manual for students and practitioners, *Diseases of the Eye*, which reached its twelfth edition in 1954, having been originally written in 1907. Among the several handbooks of ophthalmology by British and foreign authors, this standard work has ranked very high. Parsons was terse both in speech and in writing; he had the gift of putting all the known facts of a subject into small compass. He wrote an *Introduction to the Theory of Perception* in 1927, and a few years ago his last book appeared; it was a neuropsychological study entitled *The Springs of Conduct*.

In 1910 Parsons served as a member of the Departmental Committee on Sight Tests set up by the Board of Trade; in 1913 he was appointed to the Home Office Committee on Factory Lighting, and in 1920 to the Ministry of Health Committee on the Causes and Prevention of Blindness. He was a member of a Glass Workers' Cataract Committee set up by the Royal Society in 1906; chairman of a Committee on Eyestrain in Cinemas appointed by the Illuminating Engineering Society in 1919, and a member of the B.M.A. Special Committees on Tests for Motor Drivers (1929-31), and on Miners' Nystagmus (1935-6 and 1938-40). His interest in the industrial aspects of ophthalmology was stimulated by his experience at Moorfields during the war of 1914-18, when there came to his clinic almost every morning four or five cases of eye injury due to preventable accident, mostly among munition workers. Another subject to which he drew attention, in a paper read at the Annual Meeting of the B.M.A. in 1914, was the need for care of the eyes when reading newspapers. He suggested that publishers and printers might do well to consult the ophthalmologist on the legibility of a fount of type, the proper spacing of words, the length of line, and the "leading" of a printed page. He also drew attention to the fact, which perhaps no one had noted before, that the violinist has to read his score at twice as great a distance as the pianist, yet printed music is all of a standard size. Throughout the whole of his professional life he exerted a strong influence on ophthalmological research, and he was largely responsible for instituting the Faculty of Ophthalmologists.

Parsons was appointed C.B.E. in 1919 and was knighted in 1922. Elected a Fellow of the Royal Society in 1921, he served on its Council in 1926-7, and he was a member of the Medical Research Council from 1928 to 1932. He received the honorary D.Sc. of his old university, at Bristol, and the honorary LL.D. of the University of Edinburgh, and he was an honorary member of the American Medical Association. The Illuminating Engineering Society, of which he was a past president, made him an honorary member in 1954. In the evening of his life Sir John Parsons received a tribute from his colleagues which gave him the greatest pleasure. The occasion was his 80th birthday, in 1948, when Sir Stewart Duke-Elder presented him with his portrait, painted by Mr. John Gorlay, on behalf of the Faculty of Ophthalmologists and the Ophthalmological Society of the

United Kingdom. Making the presentation, Sir Stewart said that every ophthalmologist treated his patients better because of what Parsons had taught and written: alike in clinical work, fundamental research, and publication and teaching he was *facile princeps*. The *British Journal of Ophthalmology* also celebrated Sir John's 80th birthday by publishing a special issue in his honour.

We are indebted to Lord ADRIAN, O.M., F.R.S., for the following appreciation: Sir John Parsons gained his commanding position in ophthalmology by an unrivalled knowledge of the physiology and pathology of vision, a clear grasp of essentials, and a sincerity and composure which won the confidence of his patients and of the countless advisory bodies on which he served.

His book on colour vision, published in 1915, was soon established as the authoritative account. It was not written to support some particular theory and is still an excellent summary of all the evidence relating stimulus to sensation. His wider interests in neurology are shown in his *Introduction to the Theory of Perception*. Here he allowed himself to speculate on the lines laid down by Head and Rivers, but it is sober speculation with sound biology to illustrate it. He brought about many improvements in the organization of teaching and research in his subject, for he had clear ideas and a strength of purpose which was seldom defeated. Ministries and scientific bodies relied on his advice, backed by expert knowledge and decisive as well as honest. We admired his understanding of scientists and their problems and were proud of his friendship.

F. A. J. writes: Parsons was one of a number of outstanding personalities in English ophthalmology over the turn of the nineteenth into the twentieth century. He followed Bowman, Nettlehip, Marcus Gunn, Treacher Collins, and Holmes Spicer, to mention a few of the Moorfields stalwarts, and he brought to bear on his chosen specialty a brain of rare ability, well worthy of his distinction of the Fellowship of the Royal Society, so rarely awarded to a clinician. But Parsons was much more than a clinician: his mind was on the look-out for advancement by research, and his results were brilliant, as evidenced by the details given in his biography. His reputation was world-wide, and his fame was a major factor in the position of British ophthalmology and its associated sciences in the colonies and abroad.

As a teacher he was on a plane by himself, but his lectures were often on a level which left the average student behind and appealed to the few. In the same way his out-patient sessions tended to become postgraduate discussions, to the great advantage of his senior students. To those seeking after truth he was always accessible. His writings were on the same scale, on a high scientific plane not always easily comprehensible to the uninitiated, but of value to the intelligent reader. His elementary textbook, however, was a very practical value, and went through many editions.

His personality was a most attractive one, and, to those like myself who had the privilege of an increasing acquaintance, the longer the intimacy lasted the greater the respect and affection in which he was held. His opinion of men and morals was critical, strict, and freely stated; and, though sometimes severe, his standard was high—if it were followed by a larger number of citizens the world would be a better place. He was an excellent committee man, and on decisions of policy his advice was widely sought and was given with frank discussion and definite conclusion.

His long life has now ended, and we who knew him are grateful for his stimulating companionship.

J. S. MAXWELL, M.B., F.R.C.S.ED.

Mr. J. S. Maxwell, orthopaedic surgeon to the Hull (A) Group Hospital Management Committee and the East Riding Hospital Management Committee, died in a road accident on the Great North Road at Eaton Socon, Bedfordshire, on September 9 at the age of 45.

John Smart Maxwell was born on April 2, 1912, and received his medical education at Edinburgh University,

where he graduated M.B., Ch.B. in 1935. After graduation he held resident appointments at the Rochdale Infirmary and later spent one year in general practice with his brother, William Maxwell, at Porth, near Cardiff. In 1937 he returned to Edinburgh, where he worked in the surgical tuberculosis wards at the City Hospital, under the direction of Mr. C. F. W. Illingworth, who is now Regius professor of surgery at Glasgow. In 1938 Maxwell was elected a Fellow of the Royal College of Surgeons of Edinburgh. After a year as surgical registrar at the Royal Cumberland Infirmary he obtained the post of surgical registrar to Mr. Cochran at the Princess Margaret Rose Hospital in Edinburgh, but was not able to take up the appointment because of the outbreak of war. He immediately volunteered for service in the Army, and soon after joining the R.A.M.C. as a lieutenant was promoted major and posted to the Military Hospital at Catterick. In 1941 he was sent to India as orthopaedic specialist and was stationed at No. 1 British General Hospital at Karachi and later at No. 3 Indian Base General Hospital at Poona. In early 1944 he was asked to organize and establish a new orthopaedic division at 128 Indian Base General Hospital at Secunderabad. When the new division was established he was promoted lieutenant-colonel and he remained in charge of it until his demobilization in 1945.

On returning to the United Kingdom, John Maxwell became surgical registrar at Hairmyres Hospital and later assistant to Mr. E. H. T. Hambly at the Prince of Wales's General Hospital, Tottenham, where he remained for one year. In 1947 he was appointed assistant orthopaedic surgeon at the Bradford Royal Infirmary, and in 1950 he became orthopaedic surgeon to the Hull (A) group of hospitals and to the East Riding hospitals.

S. M. writes: During the seven years that he worked in Hull John Maxwell's reputation as a fine orthopaedic surgeon and also as a fine, sincere, and kindly doctor increased steadily. He was held in high esteem by his colleagues and by his patients. Earlier this year he was elected to the East Riding Hospital Management Committee. In the early part of the war he married Alice Strang. The life of a wife of an aspiring consultant is far from easy, but Alice Maxwell contributed in no small way to John's success by her constant devotion and encouragement. Two sons were born during the war, and they and his widow survive him. John Maxwell died when he was approaching his prime and when his fine gifts had become apparent. He leaves a gap in the orthopaedic ranks which will not easily be filled. His experience in bone injuries was extremely wide, and his skill in their management was apparent to all. His particular interest was in congenital deformities, and he had given his time and his advice freely to the care of spastic children. He had a fine physique and a most courteous manner, and was a pillar of strength to those who sought his help and a particularly staunch supporter of his juniors.

W. J. J. CZYZEWSKI, M.D., D.M.R.D.

Dr. W. J. J. Czyzewski, who was consultant radiologist at Willesden General Hospital and assistant radiologist at Oldchurch Hospital, Romford, died on August 12 at the age of 47.

Waclaw Jan Jozef Czyzewski was born on August 31, 1909, and received his medical training at the University of Lwow, qualifying in 1934. He then specialized in obstetrics and gynaecology in the hospitals attached to the university, holding appointments equivalent to registrar and senior registrar. He obtained the degree of M.D. at the University of Lwow in 1938. On the outbreak of the second world war he joined the Polish Forces, and after the fall of Poland managed to escape through Rumania. During the rest of the war he served—both with the R.A.M.C. and the Polish Forces assembled in this country—in Nigeria, in the Middle East, and in Italy. Towards the end of his Service career he became

interested in radiology, and after demobilization in 1947 studied for his D.M.R.D. at the Postgraduate Medical School at Hammersmith. After obtaining the diploma in 1950 he held a registrar appointment at the Southend General Hospital and was senior registrar to Chase Farm Hospital, Enfield, in 1951-2. In the latter year he was appointed to Oldchurch Hospital, Romford, as assistant radiologist, and in 1956 obtained the post of part-time consultant radiologist to the Willesden General Hospital. He contributed to *Abstracts of World Medicine* in the years 1948-54, abstracting from the French, German, Swiss, and Italian literature. An original paper by him on the subject of hysterosalpingography was recently published in the *British Journal of Radiology*. Dr. Czyzewski is survived by his widow.

OLIVER ST. JOHN GOGARTY, M.D.
F.R.C.S.I.

Dr. J. H. MELLOTT writes: Though Ireland has produced some of the most famous men of letters, specially prolific around the 1920's, Dr. Gogarty, whose generous obituary notice you published on September 28, only four days after his death in America, was the most colourful personality of them all. I had the great pleasure and honour of his friendship for over 35 years, and I probably knew him better than most. Introduced to him by a mutual friend while I was a resident at the Richmond Hospital in Dublin, he took me under his wing, and fascinated me as he had many others. He was the E.N.T. surgeon there, and a brilliant one at that, famous for his infectious unpunctuality. Though not a great crime in Ireland, he might turn up for his 9 o'clock session at 12 or 1 o'clock, his face splattered with blood to give the impression that he had been operating elsewhere all morning. His movements were as quick as his lightning replies to patients about their various complaints, replies which caused roars of laughter even among the nervous ones waiting their turn. He had at that time a fetish that all nose and throat trouble was due to infected antra, and he published a paper on the subject in the *British Medical Journal* which caused a lot of discussion and interest. He spoke and lectured about it so much that he established a sort of cult, especially among budding vocalists, that unless the antra were washed out or, better still, a radical operation performed, the timbre of the voice would suffer. The late John McCormack would not take his advice about his tonsils, but his antra were duly punctured. Gogarty's fee for this type of surgery was high, but he was most generous and would take me or some other penniless student to assist him at private nursing homes and afterwards would slip a fiver into one's hand. It was not long before I realized that his first love was the greater pursuit of *belles lettres*. Operating one morning, he was quite unable to conceal his childish delight at the reception his play *The Enchanted Trousers* had received at its first performance at the Abbey Theatre the night before. I am sure the patient was suitably impressed.

Though very Irish in temperament and character he was never antagonistic towards England and the aristocracy. He revelled in this British way of life, and when he came to practise in Grosvenor Street, London (first during the week-ends and then continually), he could count on a lot of big names for entertainment. He got to know everybody worth knowing, even to telling the late ageing Duke of Connaught, on learning from him of his great age, that he was "threatened with immortality." He was the most versatile person it is possible to imagine, and everything he did was magnificently accomplished. He of all men certainly deserved Dr. Johnson's epitaph on Goldsmith: "Nullum quod tetigit non ornavit." Poet, author, playwright, lecturer, surgeon, athlete—he was an outstanding performer in all. Archery was another hobby he excelled in. Typical of him that he was one of the first Irishmen to own a Rolls-Royce, in which he would parade the fashionable Grafton Street at the proper hour in the afternoon. He explained that he did

this so that people who saw him knew what to expect when consulting and operating fees were to be considered.

Though he had, so to speak, the world at his feet, Gogarty was nevertheless a very lonely man. Since he went to America in 1940, I saw him only when he came to London on a few occasions, but we corresponded fairly regularly, and I attribute his loneliness to two factors. Firstly, he was so mentally alert that he could not get all he wanted to say out quickly enough, and in a conversation, when he let anybody speak, I am sure he did not hear what was said but was agitating his brain for further outbursts of intellectual wit. Secondly, through his biting wit and severe castigations he estranged many friends and acquaintances, and even those who had been spared up to date had no reason to think that they would be immune in the future. He himself had intense personal and racial prejudices. De Valera and George Moore were enough to incite him to bitter scorn, and his racial antipathy cost him a few thousand pounds in the famous libel action brought against him in Dublin. Those two factors, I think, left him devoid of friendship in the true sense.

By all standards he was a great man. Someone has said that greatness is not the same as virtue, but that there is always virtue in it. Sincerity was not one of Gogarty's greatest virtues, and many people realized this. May he sleep peacefully if only for the amount of laughter and amusement he caused.

G. H. C. OVENS, O.B.E., M.B., F.R.C.S.

The obituary of Professor G. H. C. Ovens was printed in the *Journal* of October 5 (p. 830).

G. H. J. writes: Gerald Ovens's death will come as a great blow to the old friends of his time at St. Mary's, for no one who knew him, though separated from him by long tracts of time and space, would be likely to forget him. Gerald was a serious man, modest and reserved, but he was so single-minded, so loyal and devoted to his friends, his work, his students, and his hospital, and so quietly confident in them that he got the best out of them all. As if to deprecate his thoroughness Gerald developed a little pose, his only one, of at times being one of life's spectators: "Really it's most absurd," he would say with a chuckle equally at anything which appealed to his keen sense of humour or which he felt was a little substandard. Though latterly his work kept him so much abroad, he was devoted to the English countryside and knew it well in all seasons; even the winter did not entirely stop his picnics. Though registrars were not two-a-penny in the 'thirties, that was about the prevailing rate of their pay, and Gerald's old car was for more than one of his friends the only chance of a week-end look at Avebury, the Kent orchards in bloom, or the daffodils on the Mendips. He loved the old village churches, and that their other significance was not lost on him was shown by his whole life. No one who knew him years ago will be surprised to know that he passed through the difficult end of his journey without comment. He would have thought any other line of conduct "just too absurd."

J. S. R. G. writes: With the death of Professor Ovens on September 19, the University College of the West Indies mourns the loss of its first professor of surgery and dean of the faculty of medicine. He will be remembered as the author of the plans for the University College Hospital and its medical school. He was an exceptionally gifted teacher, and his textbook *Approach to Clinical Surgery*, published in 1953, has become an accepted work for medical students everywhere. His interest in medical students was paramount in his conception of the duties of dean of the faculty of medicine: he was always available to them for advice and help, and many are grateful for the efforts he made to help them at the start of their careers. During the last three years, since his first heart attack, he continued to work on the subject which lay closest to his heart—the founding of a medical school which would attain the high standard of excellence which he required in everything he did.

Medico-Legal

POST-OPERATIVE TETANUS DEATH

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On August 28, 1957, William Edwin Weeks, of Pimperne, Dorset, a basket-maker 53 years old who had been blind from birth but had otherwise always enjoyed good health, tripped over a low wall while pushing a wheelbarrow and fell, sustaining a comminuted fracture of the left os calcis.

He was admitted to the Royal Victoria Hospital, Bournemouth, on the same day, and two days later Mr. Ross Smith performed a triple arthrodesis. Following the operation plaster-of-Paris was applied, and when this was removed on September 13 the wound was found to be healed and the stitches were removed. A new plaster was put on, and on September 18 a walking-heel was ordered for this and it was decided that he could be discharged shortly. In fact he was kept in hospital for a few days longer than usual because it was thought that, being blind, he might find walking difficult. His temperature and pulse rate after the operation had shown no sign of infection.

On September 21 Mr. Weeks told the staff nurse that he had a pain in the side of his face which he thought was caused by a draught from the window during the night. He said that it felt like neuralgia, and was given aspirin. He was discharged on the afternoon of September 23, and had made no further complaint of pain, and he was not observed to have any difficulty in eating, although one of his fellow patients did not think that after September 21 he opened his mouth as wide as usual. Everyone found him a model patient who was not given to complaining.

On the morning of September 24 Mr. Weeks was visited at home by his family doctor, Dr. Kenneth Wilson, of Blandford.

Dr. Wilson, who had previously seen a number of tetanus cases, mostly during the first world war, saw at once that the patient's neck, face, and jaw muscles were rigid, and immediately realized that he had well-established tetanus, including the unmistakable risus sardonicus. Mr. Weeks, who was able to speak, told Dr. Wilson that he had a first felt his jaw to be stiff on September 20 and had had a little difficulty in eating since then. Dr. Wilson had him readmitted to hospital at once, and he was given 100,000 units of tetanus antitoxin and 1 mega unit of penicillin intramuscularly. He was given 30 mg. "laudolissin" (laudexium) intravenously as a muscle relaxant. There followed a degree of collapse and difficulty with breathing so that a tracheotomy was performed, but he died at 1.20 a.m. on September 25.

Dr. T. K. Owen, consulting pathologist to the Royal Victoria Hospital, who carried out the post-mortem examination, gave evidence at the inquest held by the Bournemouth deputy coroner that there was no wound on the heel before the operation. Swabs taken from the operation wound grew germs resembling tetanus bacilli, and in his opinion it was almost certain that the germ entered the wound at the time of the operation or by contact with something used in the operation. Death was caused by respiratory failure following tetanus. It was extremely rare for an operation wound to become infected by tetanus with the precautions normally taken to sterilize instruments and dressings, and it was not usual to inject an antitetanus serum unless there was a pre-operative wound. Dr. Owen knew of no previous case of post-operative tetanus in the hospital, and the sterilization unit in use was very modern and only recently installed.

The deputy coroner recorded a verdict of death by misadventure.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending September 28 (No. 39) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1957					1956

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Influenza

Deaths from influenza in the great towns in the week ending October 5 were as follows, with the figures for the previous week in parentheses: England and Wales 442 (282), Scotland 75 (28), Northern Ireland 5 (0), and Eire 1 (0).

Towns with 10 or more deaths from influenza were as follows: Darlington C.B. 10, Dewsbury C.B. 15, Leeds C.B. 13, Sheffield C.B. 15, Bolton C.B. 19, Liverpool C.B. 25, Manchester C.B. 25, Oldham C.B. 16, Salford C.B. 13, Stockport C.B. 11, Birmingham C.B. 22, Stoke-on-Trent C.B. 11. In Glasgow there were 43 deaths, and in the Administrative County of London 31.

The accompanying graph shows numbers of deaths in the 160 great towns of England and Wales from early September to the latest date for which figures are available.

The regional distributions of deaths from various causes in England and Wales were as follows in the week ending October 5:

Region	All Causes	Influenza	Pneumonia	Bronchitis
Northern	361	36	34	22
E. and W. Riding	756	81	71	49
North-western	1,307	158	170	111
North Midland	400	32	30	17
Midland	620	56	45	35
Eastern	298	7	15	14
London and S.E. (including Greater London)	1,743	41	79	63
Southern	242	9	11	15
South-western	266	10	14	7
Wales	183	14	25	18

The following Table shows the age distribution of deaths from influenza in the 160 great towns of England and Wales:

Week Ending	0-	1-	15-	25-	45-	65+
Sept. 14 ..	1	9	3	4	14	16
" 21 ..	2	18	8	17	39	37
" 28 ..	3	25	22	47	102	83
Oct. 5 ..	2	36	28	57	159	160

During the week ending October 1 new claims on the Ministry of Pensions and National Insurance amounted to 540,896: this was about 130,000 more than the previous week and about four times as many as during the corresponding week in 1956. Although the incidence of influenza has increased in most regions, the rate of increase has begun to decline in the north.

Week Ending October 5

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 305, whooping-cough 383, diphtheria 3, measles 1,328, acute pneumonia 1,880, acute poliomyelitis 116, dysentery 262, paratyphoid fever 4, typhoid fever 6.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1948-56 (influenza, 1952-6) are shown thus - - - - -, the figures for 1957 thus ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

In England and Wales the chief variations in the notifications of infectious diseases during the week ending September 28 were falls of 160 for whooping cough, from 724 to 564, 98 for food poisoning, from 240 to 142, 74 for acute poliomyelitis, from 198 to 124, 63 for measles, from 1,044 to 981, and a rise of 665 for acute pneumonia.

The number of notifications of whooping-cough was the smallest since 1940: a small fall in the incidence occurred in most areas during the week, the largest being 40 in Devonshire, from 51 to 11. The notifications of scarlet fever numbered 305, being 16 less than in the preceding week, and only small changes were recorded in the local trends. Only 1 case of diphtheria was notified, 2 fewer than in the preceding week. A rise in the incidence of acute pneumonia occurred throughout the country: the largest rises were 162 in Yorkshire West Riding, from 164 to 326, and 102 in Lancashire, from 177 to 279.

The number of notifications of acute poliomyelitis was 124—26 fewer for paralytic and 48 fewer for non-paralytic cases than in the preceding week. The largest returns were Essex 9 (Dagenham M.B. 2), London 8 (Islington 2, Lambeth 2), Middlesex 8, and Warwickshire 8 (Coventry C.B. 3).

The notifications of dysentery numbered 202 and were 28 above the total for the preceding week. The chief feature of the returns was a new outbreak of 34 cases in Somerset (Bathavon R.D.). The largest of the other returns were London 32 (St. Pancras 13), Lancashire 27 (Heywood M.B. 10), and Yorkshire West Riding 17.

Eire in Second Quarter

The birth rate during the second quarter of 1957 in Eire was 22.8 per 1,000 of the population, which was 0.5 below the rate for the preceding second quarter. The infant mortality rate was 32 per 1,000 registered births and the neonatal mortality rate was 21; both these rates were 1 below the rate for the preceding June quarter. Maternal mortality was 1.3 per 1,000 births, being an increase of 0.4 compared with the second quarter of 1956. The death rate was 11.4 per 1,000 population; this rate was 0.5 below the rate for the preceding June quarter and was the lowest second-quarter death rate in recent years.

Deaths from the principal epidemic diseases included 97 from influenza, 24 from gastro-enteritis (under 2 years), 8 from measles, and 7 from whooping-cough. No deaths were registered from diphtheria. Deaths from respiratory tuberculosis numbered 147 and from other forms of tuberculosis 45. These numbers were, respectively, 8 below and 6 above the numbers registered in the preceding June quarter. Deaths from malignant neoplasms numbered 1,184, of which 583 were attributed to the digestive system and 146 to the respiratory system.

New Town Birth Rates

Owing to the relatively high proportion of young adults in the twelve new towns in England and Wales, the birth rates there are considerably higher than the rate for the whole country. But the rates for the towns vary between each other, partly in relation to the size of any existing population in the areas where they have been built. If the proportion of immigrants to old inhabitants is low, then the birth rate is lower than in places where it is high. According to the Registrar-General's return for England and Wales for the quarter ending June 30, 1957, a normal annual birth rate for a population composed almost entirely of young married people aged 15-45 would be about 50 per thousand population. The rate for England and Wales as a whole in 1955 was 15. A comparison of the administrative areas containing new towns shows that Peterlee (Co. Durham) has the highest birth rate, 44.4. Next to that is Harlow (Essex) with a rate of 33.1, then Aycliffe (Co. Durham) 32.4, and Stevenage (Herts) 31.9. Except Hatfield (Herts) 18.2, the other new towns have birth rates of about 24.

Poliomyelitis Vaccine in U.S.A. and Britain

Mr. Marion B. Folsom, Secretary of Health, Education, and Welfare in the United States Government, speaking in Washington on October 10, said that there had been an 80% reduction in paralytic poliomyelitis in the U.S.A. over the past two years (*New York Times*, October 11). The fall was from 7,886 cases notified during the first nine months of 1955 to 1,576 cases notified during the same period in 1957. In 1956 the number of paralytic cases was 5,241. This sharp drop was attributed in major part to the Salk vaccine, which first went into licensed production during April, 1955. It is estimated that more than 72 million people in the United States have received one or more doses of the vaccine, out of a total population of 109 million under 40 years of age. Twenty-five million people in the priority groups (those under 20 and expectant mothers) have received three injections, 22 million two injections, and 11 million one injection. Nine million have had no injection of vaccine. Mr. Folsom said that if people would use the vaccine available it would be possible to give poliomyelitis a knock-out blow within the next year.

Speaking at the annual meeting of the Executive Councils Association (England) earlier this week, Mr. Richard Thompson, Parliamentary Secretary to the Minister of Health, said that it was the intention to offer vaccination before next summer to all children under 15 and to expectant mothers. The total number of individuals in this group would approach 13 million, but vaccine for 1½ million of these had already been distributed.

Medical News

Atomic Spill at Windscale.—On Sunday the Atomic Energy Authority announced the suspension of milk distribution from farms in the neighbourhood of its Windscale plant in Cumberland. This was the sequel to overheating of uranium cartridges in a resting reactor three days earlier, and the escape of radioactive iodine into the atmosphere and thus on to the surface of the fields grazed by cows. About 500 farms are in the affected area, which is 200 square miles (518 sq. km.) in extent. This is stated to be only the second time that a full-sized atomic reactor has been involved in an accident of this magnitude—the other was at Chalk River, Canada. Apparently radio-iodine (¹³¹I) is the only radio-isotope to have been detected outside the plant in any quantity, perhaps because of the filters in the chimneys. Milk samples taken last week contained six times the "permissible" concentration of the isotope—"permissible" here relating to a concentration thought safe for a lifetime's milk drinking, not just a few days. However, the ban was thought necessary for the sake of small children. A few employees at Windscale were stated to have been slightly contaminated. On Tuesday Sir WILLIAM PENNEY, F.R.S., was named as chairman of a committee of inquiry into the incident.

"Canadian Journal of Surgery."—The first issue of this new journal published by the Canadian Medical Association has now appeared. "The establishment of a Canadian journal (of surgery)," writes Dr. R. M. JAMES, chairman of the editorial board, "should not be regarded as further evidence of nationalism but as the assumption in yet another field of the obligations that attend our ever increasing size and responsibility." The *Canadian Journal of Surgery* is for original articles, case reports, and book reviews; articles may be in English or French, but each has a summary in the other language. The journal has been founded at the request of the Royal College of Physicians and Surgeons of Canada and other representative surgical bodies in Canada, who feel that the time is ripe for a national journal devoted solely to surgery. Besides Dr. JAMES, formerly professor of surgery at Toronto, its chairman, the editorial board consists of the professors of surgery from the twelve Canadian medical schools. Dr. S. S. B.

GILDER, editor of the *Canadian Medical Association Journal*, is editor. The *Canadian Journal of Surgery* will be published quarterly from 150, St. George Street, Toronto, 5, Canada, at an annual subscription of 10 Canadian dollars.

Purchase of Salk Vaccine.—Negotiations for the purchase of Salk poliomyelitis vaccine from the Connaught Research Laboratories, Toronto, Canada, have been completed, and the first batch of vaccine for testing by the Medical Research Council has arrived in Britain. This was announced by the Ministry of Health last week. Negotiations were still proceeding with an American firm for the purchase of an additional quantity of Salk vaccine in the United States.

Pioneer of Radiology Honoured.—On Wednesday in Paris Dr. RUSSELL J. REYNOLDS was awarded the 1957 Medal of the Centre Antoine Bécère des Relations Internationales en Radiologie Médicale. Dr. Reynolds is the first British doctor to receive the medal, which is in recognition of his "pioneer work in the field of medical radiology." On September 6, 1896,

only nine months after Röntgen had first reported his discovery of x rays, Reynolds, then a boy of 16, took his first x-ray picture with a machine which he had built at home with the help of his father, Dr. John Reynolds. This machine, which we illustrate here by courtesy of the director of the Science Museum, South Kensington (where it may be seen provided notice is given), consisted of a spark coil with the secondary wound in 52 sections and a mercury dipper brake activated by a small electric motor. Seven chromic acid cells provided the current, and the coil gave a 13-inch (33-cm.) spark. Subsequently, Dr. Reynolds introduced a number of improvements in x-ray apparatus, such as adjustable electrode tubes (in 1900). For many years Dr. Reynolds was consulting physician to the radiology and electrotherapy departments of Charing Cross Hospital.

W.H.O. Expert Committees.—Under the chairmanship of Sir ERNEST ROCK CARLING, a W.H.O. expert committee has prepared a training schedule for all categories of public health personnel concerned with the protection of the public against nuclear radiation. The committee's recommendations are being submitted to the W.H.O. executive board in January. Another expert committee, of which Mr. T. C. DENSTON, secretary of the British Pharmacopoeia Commission, was rapporteur, has been at work on a third edition of the *International Pharmacopoeia*. The first edition was published by W.H.O. in 1951, and the second in 1955. One of the difficulties is that the various national pharmacopoeias exhibit differences in their standards, strengths, and nomenclature of drugs.

Memorial to Sir Alexander Fleming.—At Lochfield Farm, Ayrshire, Sir ALEXANDER FLEMING's birthplace, a memorial to him was unveiled on October 12. The memorial is a three-ton block of Cumberland granite bearing the words: "Sir Alexander Fleming, Discoverer of Penicillin, was born here at Lochfield on 6th August, 1881."

Australasian Life Insurance Medical Research Fund.—This year the awards under the Life Insurance Medical Research Fund of Australia and New Zealand have been increased to £35,000, a rise of £10,000. This was announced on October 1 by the chairman of the Life Offices' Association for

Australasia, Mr. W. J. FALCONER, who said the increase was a measure of the growing extent and importance of research there into diseases of the heart and circulation. The Fund was established five years ago to support research in this field. This year's awards, which comprise ten grants-in-aid to research departments and three research fellowships, bring the Fund's total allocations to £135,000.

Postgraduate Travelling Fellowships.—Details of postgraduate travelling fellowships offered by the British Postgraduate Medical Federation and tenable at medical or dental schools, teaching hospitals, or postgraduate institutes of London University are given at p. 51 of the advertisements.

Medical Education in Iran.—A W.H.O. team of medical teachers is visiting Iran this month to discuss medical education and exchange information. Among its members are Mr. H. OSMOND-CLARKE, orthopaedic surgeon to the London Hospital, and Professor R. E. TUNBRIDGE, professor of medicine at Leeds. The team is visiting the medical faculties at Tehran, Tabriz, and Shiraz.

Draft British Standards.—Draft Standards for interchangeable cystoscope fittings (CX(SGC)8688) and for connectors for breathing attachments of anaesthetic apparatus (CX(SGC)8549) have been issued by the British Standards Institution, 2, Park Street, London, W.1. Comments are invited before November 13 and 14, respectively.

Aberdeen University.—Dr. A. W. BRANWOOD, lecturer in pathology at Edinburgh, has been appointed senior lecturer in pathology.

University of St. Andrews.—Dr. R. J. L. DAVIDSON has been appointed to an assistantship in pathology at Queen's College, Dundee.

Simpson Smith Memorial Prize.—Mr. P. P. RICKHAM, paediatric surgeon at Alder Hey Children's Hospital, Liverpool, has won the 1957 Simpson Smith surgical essay prize. The prize is awarded biennially by the Institute of Child Health and consists of a money award of 100 guineas. Mr. Rickham wrote on the treatment of ectopia vesicae and vesico-intestinal fistula.

COMING EVENTS

St. George's Hospital Medical School.—Postgraduate lectures on neurology and psychiatry are cancelled until further notice owing to rebuilding of the School.

Central Mediterranean Forces Surgeons' Club.—Tenth Annual Dinner, October 26, 1957 at Royal College of Surgeons of England, at 7 for 7.45 p.m. Surgeons and anaesthetists wishing to attend should communicate with Mr. HAROLD BURGE, 73, Bathgate Road, London, S.W.19 (telephone Wimbledon 7343).

Middlesex Hospital Variety Concert.—October 29, at the Scala Theatre. Proceeds for cancer research. Details from the hon. secretary, c/o the Medical School, Middlesex Hospital, London, W.1.

National Association for Mental Health.—Annual meeting, 11 a.m., October 30, at the Royal Society of Medicine, Wimpole Street, London, W.1.

Institute of Dermatology.—November 4-25, semi-permanent exhibition on "Sarcoidosis."

British Council for the Welfare of Spastics.—Professor A. A. MONCRIEFF will speak at the annual meeting at 4.30 p.m. on November 13, at B.M.A. House, London, on "Cerebral Palsy To-day."

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Sunday, October 20

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—10.15 a.m. (not 12.30 p.m., as previously stated), seminar for general practitioners by Mr. A. Radcliffe: Common Ear, Nose, and Throat Conditions.

Monday, October 21

● HUNTERIAN SOCIETY.—At Talbot Restaurant, London Wall, E.C.4, 7 for 7.30 p.m., dinner meeting, 8.30 p.m., presidential address by Mr. J. C. Ainsworth-Davis: Vagaries of Haematuria.

Tuesday, October 22

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor W. S. Peart: Some Biochemical Aspects of Hypertension.
DONCASTER MEDICAL SOCIETY.—At Danum Hotel, 7.30 for 7.50 p.m., dinner, Mr. P. H. Beales: Recent Advances in the Surgery of Deafness (illustrated).
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. N. R. Mackay: Radiation Physics (I).
MANCHESTER MEDICAL SOCIETY.—At Arthur Worthington Hall, off Dover Street, 4.15 for 4.45 p.m., university lecture on the history of medicine: The Harvey Tercentenary Film.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Mr. Rodney Smith: Recent Advances in Paediatric Surgery.
ST. MARY'S HOSPITAL MEDICAL SCHOOL (WRIGHT-FLEMING INSTITUTE THEATRE).—5 p.m., Dr. A. M. Joekes: Anuria Following Labour and Abortion.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Mr. K. I. Nissen: Mechanisms of the Carpal Tunnel Syndrome.

Wednesday, October 23

BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—8 p.m., Professor J. R. Squire: Phenylketonuria.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. A. Tickner: Vitamins and Skin Metabolism.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Sir Clement Price Thomas: Carcinoma of the Lung.
● INSTITUTE OF NEUROLOGY.—5.30 p.m., Dr. P. H. Sandifer: Hereditary-familial Degenerative Disorders.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Dr. A. H. Harkness: Non-gonococcal Urethritis.
LONDON COUNTY MEDICAL SOCIETY.—At New End Hospital, Hampstead, N.W., 8.15 p.m., Mr. J. E. Piercy, Dr. Raymond Greene, and Dr. A. T. Richardson: Myasthenia Gravis. A film will be shown.
LONDON UNIVERSITY.—At Senate House, W.C., 5.30 p.m., special university lecture by Dr. A. Hansson (Wiad, Sweden): Interaction of Heredity and Environment in Determining Quantitative Characters.
MANCHESTER MEDICAL SOCIETY: SECTION OF PATHOLOGY.—At Large Anatomy Theatre, Manchester University, 4 for 4.30 p.m., Professor N. F. MacLagan: Tests of Thyroid Function.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. F. V. Flynn: Electrolytes (II).
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Mr. W. E. Tucker: Active Approach to the Treatment of Injuries (illustrated).

Thursday, October 24

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor G. L. Montgomery: Some Problems in the Pathology of Coronary Artery Disease.
COLLEGE OF GENERAL PRACTITIONERS: MIDLAND FACULTY.—At Board Room, Worcester Royal Infirmary, 3 for 3.15 p.m., Mr. John Fry and Mr. T. S. Stewart: T's and A's in Children.
HILL END HOSPITAL MEDICAL SOCIETY.—8.45 p.m., Dr. Macdonald Critchley: Concerning Yes and No.
HONYMAN GILLESPIE LECTURES.—At University New Buildings, Teviot Place, Edinburgh, 5 p.m., Dr. Sheila P. V. Sherlock: Complications of Acute "Virus" Hepatitis.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. S. C. Gold: Connective Tissue Diseases.
INSTITUTE OF PSYCHIATRY.—At Maudsley Hospital, 3 p.m., Dr. W. H. Thorpe, F.R.S.: Drive and Instinct in Animals.
NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, 8.30 p.m., Mr. R. G. Taylor: Studies in American Orthopaedics.

Friday, October 25

● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. F. R. Bettley: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Mr. V. C. Thompson: clinical demonstration.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—(1) 3.30 p.m., clinical discussion for general practitioners by Mr. S. E. Birdsall: Injuries to the Nose. (2) 5.30 p.m., clinical demonstration by Mr. N. Asherson.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Mr. W. J. Lyle: Common Bile Duct.
● ROYAL INSTITUTION.—9 p.m., Mr. M. W. Perrin, B.Sc., F.R.I.C.: Constitution and Aims of the Wellcome Foundation.
ROYAL MEDICAL SOCIETY, EDINBURGH.—8 p.m., Mr. H. A. F. Dudley: Electrolyte Balance.
ROYAL SOCIETY OF HEALTH.—At Great Yarmouth Town Hall, 10.15 a.m., Mr. H. F. Dyson: Post-war Rehousing in Great Yarmouth; Dr. J. W. Beattie: The Development of Geriatrics.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Cooke.—On September 27, 1957, at the Christopher Nursing Home, Wigan, Lancs, to Dorothea (formerly Dalling), M.B., Ch.B., wife of Dr. Peter Cooke, a sister for Stephen.
Hollman.—On October 10, 1957, at University College Hospital, to Dr. Catharine (formerly Large) and Arthur Hollman, a daughter—Barbara Jean.
Lucas.—On September 24, 1957, at Bristol Maternity Hospital, to Mary, wife of Dr. George Lucas, a brother for Angela and Jolyon—Simon George.
O'Brien.—On October 9, 1957, at Wakefield, to Dr. Ailsa and Richard O'Brien, a daughter—Katherine.

Gibson.—To Pat Gibson (formerly Hughes), M.B., B.S., D.A., and Alfred (Hoot) Gibson, B.D.S., by adoption, a son, Richard James, born January 25, 1957.

DEATHS

Auden.—On September 21, 1957, at Umtenweni, Natal, South Africa, Francis Thomas Auden, M.D., aged 88.
Bye.—On September 29, 1957, at Selsey, Sussex, Norman Huthnance Bye, F.R.C.S.Ed.
Davies.—On September 28, 1957, Sidney Trevor Davies, M.R.C.S., L.R.C.P., late of Enfield, Middlesex, Rollesley and Marham, Norfolk, aged 75.
Dodson.—On October 2, 1957, at his home, Leadenham, Lincoln, Charles Sherborne Dodson, M.D.

Any Questions ?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Registration of Change of Sex

Q.—Under what circumstances is it permissible to alter the entry regarding a person's sex on his birth certificate?

A.—The following answer was given in the House of Commons recently (*Hansard*, March 18, 1957, col. 29):

"Dr. D. Johnson asked the Minister of Health the number of cases of change of sex registered under the Births and Deaths Registration Act, 1953, since the inception of the Act.

"Mr. Vosper: My hon. Friend appears to have been misinformed. Corrections authorized to be made in the register by this and earlier Acts relate only to errors made in any particular at the time of the original registration. If there was no such error, no correction can be made by reason of any subsequent changes or alleged changes in the particulars or otherwise."

The statutory requirements for the correction of an error of fact in a register are as follows: "An error of fact or substance in any such register may be corrected by entry in the margin (without any alteration of the original entry) by the officer having the custody of the register, upon payment to him by the person requiring the error to be corrected of a fee of three shillings and ninepence and upon production to him by that person of a statutory declaration setting forth the nature of the error and the true facts of the case made by two qualified informants of the birth or death with reference to which the error has been made, or in default of two qualified informants then by two credible persons having knowledge of the truth of the case."

A doctor who is asked to make a statutory declaration in support of a request to alter an entry in the register must therefore satisfy himself that an error was made at the time of the original registration, for only in such circumstances can the entry be altered.

Endogenous and Menopausal Depression

Q.—What is the prognosis, respectively, in endogenous depression and menopausal depression? What is the place of electroconvulsive therapy in the management of such cases?

A.—The distinction between endogenous and menopausal depressions is a very controversial one, and it is more profitable to answer these related questions as referring to two types of depressive illness differing from one another mainly in terms of the age at first attack.

Depressions first manifesting themselves before the involutional period of life, say, before the ages of 40-45 in women and 50-55 in men, are as a rule of the retarded type. Their average duration is 6 months, and they rarely last longer than 18 months to 2 years. It is often alleged, but without any controlled investigations proving the point, that E.C.T. only alleviates these depressions and that their duration is not affected. Other clinicians claim that early E.C.T. will abort an attack, and, until this claim has been proved invalid, a patient who presents himself early during the illness should be given the benefit of convulsive therapy. Unfortunately, diagnosis of the first attack is often delayed.

Practically all people with depressive illnesses, whatever the age at which they first occurred, sooner or later suffer further attacks, but if E.C.T. has been found effective once it will usually prove equally useful in subsequent illnesses.

Depressions beginning late in life are usually of the agitated variety, as mood and thought content are much influenced by anxiety, fear and dread colouring the depressed

mood. They tend to occur in people of anxious and neurotic make-up. (Depressions in persons of this type may also assume the agitated form even when they first appear before the so-called involutional period.) These agitated depressions often run a prolonged course, but may end in complete recovery after as long as 10 years. There is a good deal of evidence that they respond to E.C.T. with complete recovery more often than do retarded depressions. On the other hand, subsequent attacks, especially after the age of 65-70, may not respond at all well; or the attacks may become increasingly frequent, leaving a residue of mild anxious-depressive and hypochondriacal invalidism. Cerebrovascular disease appears to be more frequent in these patients than in the general elderly population.

Speech Defects in Young Children

Q.—What speech defects in normally intelligent children should be left to cure themselves and which should be corrected by professional speech therapy? A child of 4 years is unable to pronounce "s," for which he says either "sh" or "t." Does he require therapy before starting school?

A.—Phases of stammering and dyslalia are so common in children who are learning to speak that they can be regarded as normal. They should be ignored, for efforts to stop them, particularly in the case of a stammer, are far more likely to lead to their continuation than their cure. It is particularly important that parental anxiety about a child's stammer should be allayed. Substitutions for letters, such as "th" for "s," are very common and usually right themselves. The substitution of "sh" or "t" for "s," as mentioned by the inquirer here, is less common.

If one of these speech defects persists beyond the fourth birthday, it should be treated, and it should be treated before the child starts school, so that he avoids psychological difficulties among his schoolfellows. In short, therefore, phases of difficulty in speaking should be ignored, but persistent defects treated.

Institutional Training and Asthma

Q.—What is the approximate incidence of asthma in children in Britain? In a residential school for blind children, aged 5 to 15, where I have been medical officer for a number of years I have never seen a case. Might this well occur by chance, or has either blindness or institutional training a known negative correlation with asthma?

A.—Roughly the prevalence of active asthma in Britain in children up to the age of 14 years is 1% for boys and 0.5% for girls.

Institutional care may well reduce the prevalence of active asthma, for asthmatic children usually benefit from being sent away to school or admission to hospital. In some countries special homes for asthmatic children have been established for long-term institutional care. Some authorities consider "parentectomy" the most important factor in the resulting freedom from or amelioration of attacks. I know of no published work showing a negative correlation between asthma and blindness.

Oxytocin Infusions in Postmaturity

Q.—Is the use of an oxytocin drip contraindicated under all circumstances in the induction of labour for postmaturity?

A.—The use of an oxytocin drip and postmaturity are both subjects on which it would be unwise to dogmatize. The diagnosis of postmaturity is itself fraught with difficulty and there are no hard-and-fast rules. If a pregnancy has proceeded 7 to 14 days beyond the expected date of confinement, but the case shows no other remarkable features, it may well be justifiable to use an oxytocin drip. It can be less dangerous than allowing further delay in the onset of labour and is certainly safer than giving oxytocin

intramuscularly. If, however, in a similar situation rupture of the membranes has revealed scanty liquor heavily stained with meconium, it is probably unwise to administer oxytocin. Evidence of disproportion also contraindicates this treatment.

Each case must be judged separately in the knowledge that the potential danger of oxytocin is the induction of uterine contractions so violent as to embarrass an already inefficient placenta and thus cause foetal asphyxia. This risk is slight if the concentration of oxytocin in the solution is small, if the rate of drip is kept slow, and if the effect is continually observed by an expert. Closing the tap of the infusion apparatus results in almost instantaneous cessation of the effect of treatment, because any oxytocin remaining in the blood stream is quickly destroyed. Nevertheless, in a case of postmaturity, the margin of safety is narrow and the obstetrician must himself be prepared to stay with the patient constantly, observing the behaviour of the foetal heart after each contraction, and not delegate this responsibility to someone less experienced.

Operative or Post-operative Thrombosis?

Q.—(1) Do venous thrombosis and embolism occur as operative complications of pelvic and abdominal operations (as distinct from post-operative)? A patient who died very shortly after the removal of an ovarian cyst was found at necropsy to have an embolus in the inferior vena cava. (2) Is there any blood investigation which will indicate whether a particular patient is especially liable to venous thrombosis? If so, should such patients receive post-operative prophylactic anticoagulant therapy?

A.—(1) It is not precisely known at what time the post-operative thrombotic process starts, but most people believe that the whole process is nearly always, if not always, post-operative. Some authorities consider, nevertheless, that the process begins by compression damage to the calf veins as the result of the pressure of the operating table on the calf. The inquirer does not state how soon after removal of the ovarian cyst death occurred, but certainly an embolus can grow very rapidly. There is one case on record of pulmonary embolism occurring during the course of lumbar sympathectomy done for thrombo-angiitis obliterans; in that case there was pre-existent thrombus in the vena cava.

(2) A wide variety of minor changes in the physical properties and the chemical constituents of the blood have been described in cases of post-operative thrombosis, but none of these is sufficiently constant or sufficiently notable to serve as an index of liability to thrombosis. Perhaps the circumstances most likely to raise suspicion of the risk of thrombosis is a history of previous thrombosis—puerperal, post-operative, or spontaneous—and in a patient giving such a history post-operative prophylactic anticoagulant therapy would seem to be logical.

Pseudo-cholinesterase and Transaminase Estimations in Liver Disorders

Q.—What is the purpose of the estimation of pseudo-cholinesterase and transaminase following a porto-caval anastomosis for cirrhosis of the liver? What are the normal ranges for these tests and the significance of deviations from normal?

A.—Serum cholinesterase is an enzyme which hydrolyses acetylcholine and many other esters. Because of its non-specificity this enzyme is commonly called serum pseudo-cholinesterase or simply serum esterase. It is a protein manufactured by the liver in parallel with albumin. Normal levels are 0.94 (range 0.58–1.37) units. Low values in cirrhosis represent failure of the liver to manufacture protein and also reflect the nutrition of the patient.¹ Serial determinations are useful in following the progress of a patient with cirrhosis as regards both his liver-cell function and nutrition, although changes in serum albumin levels give equivalent information. Porto-caval anastomosis or any surgical pro-

cedure may temporarily depress liver function in a patient with cirrhosis, and such serial liver function tests are useful in following the course.

Enzymes facilitating the transfer of amino groups from an alpha amino-acid to an alpha keto-acid are called transaminases. Glutamic oxaloacetic transaminase and glutamic pyruvic transaminase are present in high concentration in the liver and increase in the serum when liver cells become necrotic. The normal level for serum glutamic pyruvic acid transaminase is 22.1 (range 5–40) units. The method is of most value in the diagnosis of acute hepatitis in which condition levels rise to 20–500 times normal.² Values in cirrhosis are very variable and the test is not usually used in this condition. It has no particular relation to porto-caval anastomosis.

Aetiology of Kienböck's Disease

Q.—Is Kienböck's disease of the semilunar bone due to trauma, and can an industrial accident cause it? If not, what is its aetiology?

A.—Kienböck's disease is not due to an injury, and it cannot be caused by an industrial accident. The condition is due to avascular necrosis of the carpal semilunar bone, and, though the cause of this necrosis is not known, it certainly does not appear to be traumatic in origin. The most popular suggestion so far is that it is due to a congenital abnormality of the anatomy of the proximal bones of the carpus.

NOTES AND COMMENTS

Do Corpses Sink or Float?—Dr. R. EDGLEY (Australian Migration Mission, Vienna) writes: Further to Mr. Ellul's comment ("Notes and Comments," September 28, p. 776) I would like to add that full expiration before diving is the usual method used by New Guinea and North Australian pearl divers. They first hyperventilate to the point of dizziness, then fully expire and dive. During the war in the Pacific many members of my unit including myself practised this and found that we sank "like a stone" immediately to depths of up to 30 ft. (9.2 m.), that the hyperventilation sustained us for well over 90 seconds (the pearl divers can stay down for alarmingly longer periods), and that return to the surface required a most active jump from the bottom and active upward swimming. The only ill effect was of pressure on the ear-drums. Those pearl divers who are caught at the bottom do not rise until the gases of decomposition form some days later.

STUDIES ON ALDOSTERONE SECRETION IN MAN*

BY

GEORGE W. THORN, M.D., A.M., LL.D., Sc.D.(Hon.)

ERIC J. ROSS, Ph.D., M.B., B.S., B.Sc., M.R.C.P.

JEAN CRABBÉ, M.D.

AND

WALTER VANT HOFF, M.B., B.Chir., M.R.C.P.

From the Peter Bent Brigham Hospital, Boston, Massachusetts, and the Department of Medicine, Harvard Medical School

Interest in the relation of adrenal cortical function to sodium metabolism was stimulated in 1933 by the studies of Loeb, Atchley, Benedict, and Leland, who described the excessive urinary sodium loss in adrenalectomized dogs, and by similar observations of Harrop, Soffer, Ellsworth, and Trescher (1933), who further suggested that one of the functions of the adrenal cortex was to assist the organism to preserve adequate volume and electrolyte composition within the extracellular compartment. Three years later Harrop, Nicholson, and Strauss (1936) reported that adrenal cortical extracts were capable of inducing sodium retention in dogs, and Thorn, Garbutt, Hitchcock, and Hartman (1936) demonstrated similar effects in normal human subjects as well as in patients with Addison's disease.

In 1937 Steiger and Reichstein announced the synthesis of 11-deoxycorticosterone (deoxycortone) acetate. The effectiveness of this substance in correcting the abnormalities of mineral metabolism in patients with Addison's disease was described by Thorn, Howard, and Emerson in 1939. Although synthetic deoxycortone acetate proved very effective as replacement therapy in such patients, there was no indication that this compound was secreted under normal circumstances until the recent findings of Farrell, Rauschkolb, Royce, and Hirschmann (1954), who were able to isolate and identify deoxycortone in the adrenal venous blood of the dog. However, the quantity found in these experiments appeared to be too small to account for any conspicuous biological action.

That the "amorphous fraction" of adrenal extracts contained a substance or substances of high sodium-retaining activity was suggested by Kendall in 1937, and indeed Hartman, Spoor, and Lewis (1939) postulated the existence of an adrenal "sodium factor" different from the life-maintaining fractions of the adrenal cortical extracts available at that time for clinical use, and possessing sodium-retaining activity greater than that of deoxycortone.

*Being an Invited Lecture given on May 20, 1957, in the University of London at St. Mary's Hospital Medical School and in Oslo on May 22 under the auspices of the Malthe Foundation.

In 1937 Thorn and Harrop reported that not only did adrenal extracts, corticosterone and 11-dehydrocorticosterone induce sodium retention and increase potassium excretion in normal human subjects as well as in adrenalectomized dogs and in patients suffering from Addison's disease, but that sex hormones (oestrogens, progesterone, and testosterone), which, as steroids, possess a closely related structure, also decrease the renal excretion of sodium in normal dogs. Of these latter substances only progesterone appeared capable of prolonging the life of bilaterally adrenalectomized dogs (Thorn and Engel, 1938).

With the increasing clinical use of deoxycortone acetate, the occurrence of oedema, hypertension, and cardiac failure was reported during its administration (Ferrebee, Ragan, Atchley, and Loeb, 1939; Thorn and Firor, 1940). These complications were particularly prone to occur since it had become the rule to give patients with Addison's disease a diet rich in sodium chloride and poor in potassium. Early in the use of deoxycortone it became evident that supplementary sodium chloride was contraindicated and that the potassium intake should certainly not be restricted.

In contrast to the picture of excessive weight gain and oedema, another manifestation of deoxycortone overdosage was characterized by hypertension and hypokalaemia leading to episodes of weakness and polyuria. In 1940 Thorn and Firor reported muscular weakness and transient paralysis associated with hypokalaemia in a patient with Addison's disease treated for a short period of time with large quantities of deoxycortone and glucose infusions. This patient improved readily with a diet rich in potassium. These authors pointed out the similarity between the symptomatology observed in this patient with that of patients afflicted with familial periodic paralysis, and they emphasized the usefulness of potassium in both conditions. Kuhlmann, Ragan, Ferrebee, Atchley, and Loeb (1939) were able to induce in normal dogs, by the administration of excessive amounts of deoxycortone acetate, a picture characterized by hypokalaemia, muscular weakness, and a diabetes insipidus-like syndrome. It was readily apparent at this

time, in both man and experimental animals, that supplementary sodium chloride combined with restriction of potassium intake intensified the undesirable side-effects of the salt-retaining steroid hormones, whereas sodium chloride restriction with added potassium salts minimized such effects.

During the succeeding decade many unsuccessful attempts were made to characterize the substance or substances responsible for the "salt-retaining" properties of adrenal cortical secretions. An important piece of indirect evidence was contributed by Greep and Deane in 1947. They reaffirmed the fact that the hypophysectomized animal required minimal sodium chloride supplementation in contrast to the adrenalectomized animal. They also pointed to the persistence of the zona glomerulosa in rats following hypophysectomy, in contrast to the involution and atrophy of the other zones of

FIG. 1.—Formulae of aldosterone.

the adrenal cortex, and suggested that perhaps the "salt-retaining hormone" was secreted by the zona glomerulosa and was less dependent on adrenocorticotrophic hormone (A.C.T.H.) than the cells responsible for the secretion of 17-hydroxycorticosteroids.

In 1950 Deming and Luetscher were able to demonstrate by biological assay the presence of a sodium-retaining factor in the urine of patients with oedema. The potency of the material isolated suggested that it was not one of the known adrenocortical steroids. In 1952 Simpson, Tait, and Bush, employing chromatographic separation, were able to isolate a very potent sodium-retaining factor from adrenal venous blood. This they termed "electrocortin."

The collaboration of the Swiss team of Wettstein, Neher, von Euw, Schneider, and Reichstein with Simpson and Tait finally resulted (Simpson *et al.*, 1954) in the elucidation of the chemical structure of "electrocortin" as the 18-aldehyde of corticosterone (Fig. 1). It was accordingly given the name of "aldosterone."

Very rapidly there followed the isolation of crystalline aldosterone from extracts of the urine of patients with nephrosis (Luetscher, Neher, and Wettstein, 1954) and congestive heart failure (Luetscher, Neher, and Wettstein, 1956) in whom Luetscher and colleagues by bioassay had demonstrated an increased quantity of "sodium-retaining factor." In the meantime the synthesis of aldosterone had been achieved by Schmidlin, Anner, Billeter, and Wettstein (1955). The activity of aldosterone in man was first demonstrated by Mach, Fabre, Duckert, Borth, and Ducommun (1954) in two patients with Addison's disease. There remained only the identification and description of the clinical syndrome ascribed to hypersecretion of aldosterone as a primary factor, "primary hyperaldosteronism," which was reported by Conn (1955).

The studies which we propose to report at this time represent the efforts of our group directed at the investigation of the mechanisms involved in aldosterone secretion. As a preliminary step the methodological aspect of the problem is discussed briefly.

Measurement of Aldosterone in Urine

Aldosterone produced by the adrenal gland may be detected by reliance on its characteristic biological properties, using bioassay techniques such as those standardized by Simpson and Tait (1952), Singer and Venning (1953), or Johnson (1954). It can also be measured chemically after its isolation by means of a physicochemical method such as that proposed by Neher and Wettstein (1955). The results presented and discussed here were obtained by a method which is based upon that of Neher and Wettstein (1955). It consists essentially of acid hydrolysis of a litre aliquot of the total 24-hour urine sample, extraction with chloroform, chromatography on a "florisil" column to remove pigments and other contaminants, progressive isolation of aldosterone by two successive paper chromatographic fractionations (the propyleneglycol-toluene system of Zaffaroni, Burton, and Keutmann (1950) and the Bush (1952) "C" system), and final quantitative estimation by the blue tetrazolium reaction applied to the steroid eluted from the paper (Hernando, Crabbé, Ross, Reddy, Renold, Nelson, and Thorn, 1957).

To date, there is no simple specific and sensitive method available for the measurement of aldosterone in biological fluids. The concentration of aldosterone in urine may be less than one part in one hundred million. Reactions which are sensitive enough to detect aldosterone in microgram amounts are not specific for aldosterone only. It is therefore essential to separate this compound from other steroids which give the same reaction. This necessitates the employment of at least two chromatographic systems. Several tests have been applied to the material isolated from urine by this method to ensure its identity as aldosterone and its freedom from contaminants. Its chromatographic behaviour before and after acetylation and its properties in additional physicochemical tests indicate that this compound is identical with authentic aldosterone. In a few instances contaminants have been found, but the properties of these contaminants fortunately are such that the purity of the material isolated from paper is assured if the ultra-violet absorption and blue tetrazolium measurements agree. To ensure the purity of the material absolutely it is necessary to add a further chromatographic system, such as the E₂B system of Eberlein and Bongiovanni (1955).

The material was also assayed biologically by testing its effect on the urinary sodium/potassium ratio in adrenalecto-

FIG. 2.—Relationship between aldosterone excretion and sodium excretion in the urine of normal subjects on different intakes of sodium. (Based on 201 individual determinations.)

mized rats. Maximum depression of this ratio was obtained with 0.025 to 0.05 μg. per rat (1 μg. is equivalent in this test to 25 to 50 μg. of deoxycortone). The potency of the material isolated from paper is thus consistent with that of d-aldosterone.

With the use of a procedure consisting of as many steps as that currently employed for the determination of aldosterone one can anticipate an appreciable loss of material. Studies designed to test the recovery of aldosterone added to urine and exposed to the foregoing method indicate a recovery rate of 20 to 30%. Most of the loss occurs during the successive steps of paper chromatography, each system being about equally responsible. As the addition of a third chromatographic system (E₂B) will increase this loss it is not used as a routine procedure.

Such large losses obviously affect the reproducibility of results. For example, the aldosterone content of six aliquots from the same urine pool were determined. These six samples were run on six different occasions. The individual quantities of aldosterone isolated were 27, 26, 25, 18, 17, and 12 μg. The employment of radioactive cortisone added to urine as a test of reproducibility and degree of recovery is currently under investigation.

It can be seen from these observations that the method has serious limitations, that the interpretation of results must be tentative, and that the most reliable indication of altered urinary excretion (and, by implication, of adrenocortical secretion) of aldosterone will be derived from serial studies rather than from single isolated determinations. Therefore one is forced at the outset to accept the fact that the measurement of aldosterone, either by biological or by physicochemical methods, is at best an approximation at the present time. Furthermore, without a suitable method for determining the level of aldosterone in blood, the assessment of urinary aldosterone changes in terms of alterations in the secretion of aldosterone by the adrenal gland must be made with reservation.

Urinary Excretion of Aldosterone in Normal Subjects

In a total of 72 urine samples obtained from 17 normal adult subjects, males and females, the mean level of aldosterone excretion was 5.0 μg. in 24 hours (S.D. ± 3.0) on an unrestricted diet. The observations in 16 of these subjects are recorded in Table I, in conjunction with the urinary sodium output on the day aldosterone was measured. In

10% of cases, normal subjects were found to excrete as much as 10 to 15 μg. of aldosterone in 24 hours without any apparent change in diet, electrolyte excretion, or clinical status. No correlation between the level of excretion of

aldosterone and the quantity of sodium excreted in the urine was observed at levels of aldosterone excretion below 8 μg./24 hours. Above that level a correlation was found, as shown in Fig. 2.

A study of diurnal variation in urinary aldosterone excretion in six normal male and six normal female subjects revealed a day-to-night ratio in excess of unity in 10 cases; in one subject the ratio was unity. In only one subject was the ratio less than unity (Fig. 3). The mean value for the day collection (3.9 μg.) was three times as high as that for the night collection (1.9 μg.).

Factors Influencing the Urinary Excretion of Aldosterone

To date, studies by a large group of clinical investigators suggest that the following factors exert an influence, although of varying importance, on the excretion of aldosterone: corticotrophin, fluid balance, sodium balance, and potassium balance.

The observations of our own group on factors influencing the secretion of aldosterone may be summarized as follows:

1. Effect of Corticotrophin

The effect on aldosterone excretion of 25 units of corticotrophin given intravenously over an eight-hour period on

FIG. 3.—Diurnal variation in urinary output of aldosterone observed in normal subjects on an unrestricted diet. "Day" collection, 7 a.m. to 7 p.m. "Night" collection, 7 p.m. to 7 a.m.

two successive days was studied in 21 instances. The pattern of response was very irregular and there was no correspondence between the response of aldosterone and that of 17-hydroxycorticosteroids (see Fig. 4). However, in selected

cases, in which the subjects were maintained on a low-sodium diet, there were indications of a clear-cut rise of aldosterone excretion in association with the administration of corticotrophin. Interpretation of data is made difficult under these circumstances because of the effect of dietary sodium restriction itself on the level of aldosterone secretion. A similar increased response of subjects on a low sodium

intake compared with their response on a normal intake of sodium is to be seen in the papers of Duncan, Liddle, and Bartter (1956) and Muller, Riondel, and Manning (1956).

Patients with long-standing panhypopituitarism may excrete normal or only slightly reduced baseline levels of aldosterone in the urine in contrast with the very low values of 17-hydroxycorticosteroids and 17-ketosteroids found in this disorder. An example of such a case is presented in Table II, in which the urinary aldosterone excretion of 7 µg.

per 24 hours (a normal value) is contrasted with other endocrine parameters. However, when this patient was subjected to a low-sodium diet, weight loss and negative sodium balance occurred without any significant rise in urinary aldosterone levels, in contrast to normal subjects, who show a rather prompt increase under such circumstances.

In the period immediately following hypophysectomy for metastatic breast carcinoma, an increase in urinary aldosterone was observed in two patients (Fig. 5). This rise may be associated with the diabetes insipidus present in both cases.

Finally, a normal subject placed on a low-sodium diet and simultaneously given a large quantity (10 mg.) of 9- α -fluorohydrocortisone daily showed essentially the same increase in aldosterone excretion in conjunction with weight loss as he had previously shown on a low-sodium regimen alone (Fig. 6). This observation suggests that the inhibition of endogenous corticotrophin release (evidenced by a sharp drop in urinary 17-hydroxycorticosteroid excretion) did not prevent the anticipated aldosterone response, although the latter was somewhat decreased in amplitude.

From these observations it would appear that the baseline secretion of aldosterone is not as intimately dependent upon corticotrophin as is that of adrenal hydroxysteroids and ketosteroids, and that a response to exogenous corticotrophin administration is variable in contrast to the consistent stimulation of adrenal secretion of glucocorticoids observed under similar conditions.

Pituitary hormones other than corticotrophin have been administered and their effect on the level of aldosterone excretion has been observed. Beef growth hormone was not found to modify significantly the urinary levels

FIG. 7.—Case M. G. (M.). Urinary aldosterone levels in hypophysectomized man aged 45 during administration of beef growth hormone (Armour, lot D 728076).

FIG. 8.—Case R. A. (M.). Effect of chorionic gonadotrophin administration on urinary steroids in man aged 42 with benign spinal tumour.

of aldosterone in man (Fig. 7). The relative ineffectiveness in man of growth hormone derived from other species is well known, hence the above experiment does not exclude a possible role of human growth hormone in aldosterone secretion in man. An increased excretion of aldosterone has indeed been noted in a pituitary dwarf during the administration of both human and monkey growth hormone (Beck, McGarry, Dyrenfurth, and Venning, 1957). However, studies of growth hormone in animals under conditions in which growth can be demonstrated give no clinical evidence of an excessive secretion of aldosterone.

Chorionic gonadotrophin was likewise devoid of effects on aldosterone excretion in man when administered for a period of four days (Fig. 8).

2. Effect of Changes in Fluid Balance

The effects of pitressin were followed in a patient with diabetes insipidus receiving a daily sodium intake of approximately 100 mEq and an unrestricted fluid intake. An increase in urinary aldosterone output from a mean value of 7 µg. to that of 12 µg. per 24 hours followed the withdrawal

of pitressin. The loss in body weight and increased fluid output that took place as an immediate effect of cessation of pitressin administration were not accompanied by an appreciable increase in sodium excretion.

This increase in aldosterone excretion was thought to be mediated by the deficit of body water which developed under these circumstances. Beck, Dyrenfurth, Giroud, and Venning (1955) have studied the opposite situation and have shown that an expansion of total body water by the forced administration of water during pitressin injections was followed by a fall in aldosterone excretion.

3. Effect of Sodium Restriction

Normal subjects respond to a low-sodium diet with an increase in urinary aldosterone excretion (Fig. 9). Observations in 11 studies carried out on seven healthy male subjects are summarized in Fig. 10. It can be seen that in all instances increased values were observed; however, the variation in response is considerable. The greatest increases were observed in subject J. C. when acetazolamide ("diamox") (500 mg.) was taken on the day before the low-salt diet was instituted. There was no consistent relationship between body-weight loss (regarded as reflecting loss of extracellular fluid), the degree of urinary sodium concentration attained, and the increase in urinary aldosterone excretion. Weight loss and decreased urinary sodium concentration were observed repeatedly before any measurable increase of urinary aldosterone excretion occurred during these studies.

The lack of close correlation between the rapid fall in urinary sodium concentration and the response of urinary

FIG. 9.—Case J. C. (M.). Normal subject aged 28. Effect of dietary restriction of sodium on urinary excretion of aldosterone.

■ = Highest excretion on control diet

FIG. 10.—Effect of dietary restriction on urinary aldosterone levels.

aldosterone excretion is illustrated in Fig. 11. It will be noted that there is a very considerable fall in the urinary excretion of sodium before any rise of aldosterone excretion occurs.

In summary, there appears to be no doubt that aldosterone excretion is increased following sodium restriction. However, the majority of normal subjects will display a fall in urinary sodium concentration before we can observe an appreciable increase in aldosterone excretion. From this it appears that there are factors other than increased aldosterone secretion participating in the response of the kidneys to a decreased dietary intake of sodium.

FIG. 11.—Urinary excretion of sodium and of aldosterone on successive days of a restricted sodium intake (9 mEq per day) in five normal subjects. The points marked (1) represent the first day of sodium restriction, successive points representing succeeding days of the low-sodium diet.

4. Effect of a High Potassium Intake

In normal subjects a moderate and short-term increase in the daily potassium intake in the presence of a normal or low sodium intake did not appear to alter aldosterone excretion significantly (Fig. 12). Small increases in aldosterone excretion have occasionally been observed by other investigators (Luetscher and Curtis, 1955; Bartter, 1956; Laragh and Stoerk, 1957), but in our experience potassium loading is certainly not as uniformly associated with increased excretion of aldosterone as is sodium deprivation.

FIG. 12.—R. A. (M.) Normal subject aged 40. Effect of high potassium intake on urinary excretion of aldosterone.

Studies on Amphenone Inhibition of Aldosterone Excretion

Amphenone B (Fig. 13) exerts an immediate and marked inhibition of the secretion of steroids by the perfused adrenal cortex as shown by *in vitro* studies (Rosenfeld and Bascom, 1956); this inhibition has also been demonstrated in man (Thorn *et al.*, 1956; Hertz *et al.*, 1956; Gallagher *et al.*,

FIG. 13.—Formula of amphenone B (3, 3'-di(*p*-aminophenyl)butane-2,2-dihydrochloride).

1956) (Fig. 14). Failure to recognize the interfering role of urinary metabolites of amphenone on the Zimmermann reaction used for the determination of 17-ketosteroids has resulted in some confusion in reports of the effectiveness of amphenone. Prolonged suppression of 17-hydroxycorticosteroid secretion with amphenone is seen in cases with secreting adrenal tissue which is unresponsive to corticotrophin (as in adrenal carcinoma) or in the presence of maximal corticotrophin stimulation, as during the administration of corticotrophin (Fig. 15). Little or no effect of amphenone on

FIG. 14.—Case S. D. (F.) Effect of administration of amphenone B on blood and urine 17-hydroxycorticosteroids in woman aged 41 with adrenal cortical carcinoma.

FIG. 15.—Case K. H. (M.) Modification of the response to corticotrophin caused by the simultaneous administration of amphenone B in man aged 22 with Cushing's syndrome due to adrenal hyperplasia.

FIG. 17.—Case M. L. Response of urinary excretion of sodium and aldosterone to administration of amphenone in a woman aged 39 with generalized oedema.

the level of 17-hydroxycorticosteroid excretion has been noted in subjects excreting quantities of this steroid within the normal range. Rosenfeld and Bascom (1956) state that the site of block is at the level of the adrenal cell and suggest that this compound interferes with 11, 17, and 21 hydroxylation.

Since it appears that the production of steroids by the adrenal gland is decreased by amphenone because the latter substance exerts an inhibiting effect of steroid synthesis, it might be anticipated that aldosterone secretion would also be affected by this drug. This presumption was supported by the observation that a sodium diuresis often accompanied the administration of amphenone. This sodium diuresis has not been observed in patients with Addison's disease or following bilateral adrenalectomy (Renold *et al.*, 1957).

The disappearance of aldosterone from the urine during amphenone administration is shown in Fig. 16. The fall in urinary aldosterone excretion and the concomitant rise in urinary sodium excretion observed in a patient with oedema and increased urinary aldosterone values is illustrated in Fig. 17. It appeared from these studies that amphenone might be a useful agent to assess the pathogenetic significance of increased urinary aldosterone values in patients exhibiting evidence of excessive sodium retention as in nephrosis, cirrhosis, and congestive cardiac failure. It might be anticipated that patients with excessive fluid retention and high urinary aldosterone levels would respond to amphenone administration with a rise in urinary sodium excretion, if hyperaldosteronism were essential for the genesis or maintenance of the excessive sodium and water retention.

In a patient with late-stage severe heart failure the elevated levels of aldosterone were reduced to normal without a con-

comitant rise in urinary sodium concentration (Fig. 18). These clinical observations suggest that hyperaldosteronism was not the major factor, at the time of study, in perpetuating the marked state of oedema seen in this patient. The failure to observe a rise in urinary sodium concentration despite a fall in aldosterone levels in a patient with cirrhosis and ascites is illustrated in Fig. 19, whereas the response to mercurhydrin is readily apparent. In a second patient with

cirrhosis and ascites an appreciable sodium diuresis accompanied the reduction in aldosterone excretion during amphenone administration. Perhaps in this patient the presumed secondary hyperaldosteronism was pathogenetically important in the excessive accumulation of sodium.

Thus in three patients with "secondary" hyperaldosteronism as evidenced by anasarca and elevated values for aldosterone in the urine, amphenone reduced the aldosterone excretion to normal in all three,

FIG. 19.—Case J. O. B. Influence of amphenone on urinary excretion of aldosterone and sodium in man with cirrhosis of liver and ascites. Sweating was profuse during period of study.

but in only one was a significant sodium diuresis observed. These studies need to be pursued before a final evaluation of the clinical usefulness of amphenone as a diagnostic agent can be established. The results of a study of the effects of amphenone in patients with cardiac and renal oedema might be helpful in depicting those occasional cases of hypertension and cardiac failure that have responded so successfully in the past to total adrenalectomy.

Secondary Hyperaldosteronism? Case Report

An unmarried female nurse aged 39 has been observed over a period of more than 10 years with generalized oedema. All investigations have failed to reveal any under-

TABLE IV.—Effect of Administration of Amphenone on Urinary Excretion of Aldosterone and Sodium in a Woman With Generalized Oedema

Course No.	Dose of Amphenone and Duration of Administration	Period *	Mean Aldosterone Excretion (μ g./24 hr.)	Sodium Excretion † (mEq/24 hr.)
1	6 g./day (5 days)	Control	75	3.4
		Experimental	8.7	13.6
		Control	77	7.1
2	8 g./day (2 days)	Control	108	2.8
		Experimental	9	30.0
		Control	78	3.8
3 ‡	6 g./day (3 days)	Control	75	2.6
		Experimental	9	101.3
		Control	103	13.3

* The control periods before and after the experimental periods are equal in length to the experimental period.
† Sodium intake 9 mEq daily throughout.
‡ Prednisone (100 mg./day) was administered through this course.

lying cardiac, renal, or hepatic disease. The serum protein level was normal. Both pleural fluid and the oedema fluid draining from Southey tubes showed evidence of an elevated protein concentration, since they contained approximately 2.5 g. of protein % without evidence of inflammatory reaction. The intravenous administration of salt-poor albumin first resulted in a rise in serum albumin level and then in an appreciable increase (up to 3.4%) in the protein level in the fluid draining from Southey tubes. Ten days later the protein level returned to a value of 1.9 g.%. It was therefore concluded that a major factor in this patient's incapacitating oedema was a disorder of capillary permeability which permitted an excess of protein to escape from the vascular compartment (Emerson and Armstrong, 1955). For several years all possible means of inducing a sodium diuresis in this patient failed or had been of only transient usefulness.

When methods for measuring aldosterone became available, this patient was found to excrete large amounts of this hormone, the 24-hour urinary values often exceeding 100 μ g. (Table III). Such levels are definitely well above those found in normal subjects maintained on a low sodium intake. In this patient on three separate occasions the administration of amphenone resulted in an immediate and sharp decrease in urinary aldosterone levels and a significant rise in

urinary sodium excretion (Table IV). At no time in her 10-year history did this patient exhibit hypertension, hypokalaemia, alkalosis, or polyuria.

It is probable that secondary hyperaldosteronism existed in this patient as a result of the long-continued oedema and the vigorous therapeutic efforts to relieve the condition. In view of the high levels of aldosterone excretion and also of the sodium diuresis obtained as a result of amphenone administration, it was considered that total adrenalectomy might improve the oedematous condition by decreasing the renal reabsorption of sodium.

In an attempt to study the effect of a sodium load on aldosterone excretion in this patient, a total of 700 mEq of sodium was given orally over a period of five days; the patient retained almost quantitatively the ingested sodium and gained more than 4 kg. in weight. Her urinary sodium excretion failed to increase above 5 mEq a day and aldosterone

FIG. 20.—Case M.L. (F.) Showing absence of response with respect to urinary excretion of sodium and of aldosterone during a sodium load in woman aged 39 with anasarca and secondary hyperaldosteronism.

FIG. 21.—Case M.L. (F.) Showing the sodium diuresis which followed the removal of an adrenocortical adenoma in a patient aged 39 with generalized oedema.

sterone values decreased only slightly (Fig. 20). These studies suggested that the structure responsible for the increased aldosterone output was relatively insensitive to a large and rapid gain in total extracellular sodium and water.

In April, 1956, a left adrenal exploration was carried out by Dr. J. H. Harrison, and a small adenoma weighing 2 g. was found in the adrenal gland. This gland was removed completely. The other side was not explored. Physico-

chemical analysis of the adenoma revealed aldosterone to be present in a concentration of 3 μ g. per g., whereas none was found in the remaining non-adenomatous part of the gland. The removal of this adrenal gland was followed on the day of operation by an immediate and intense sodium loss in the urine which necessitated supportive therapy with sodium chloride and salt-retaining hormone (Fig. 21). The intravenous administration of corticotrophin a week after operation revealed a functioning right adrenal gland as judged by the increase in the urinary excretion of 17-hydroxycorticosteroids and 17-ketosteroids.

Over the subsequent six weeks the sodium balance in the patient did not exhibit any dramatic deficit and her weight decreased by only 3 kg. despite a sodium intake of only 10 mEq. During a period of normal sodium intake (80 mEq a day approximately, for one month) a total of eight determinations of aldosterone averaged 5 μ g. for the 24-hour period (range: 0 to 18 μ g.). On a low sodium intake the mean urinary aldosterone level for nine determinations was almost identical—5 μ g. (range: 0 to 16 μ g.). Subsequently a negative sodium balance was induced by therapeutic means which had been ineffective prior to the adrenalectomy—namely, acetazolamide and prednisone. There ensued a weight loss of 10 kg. in two weeks. The urinary aldosterone excretion was 8 μ g. per 24 hours at that time (range of 12 determinations: 0 to 29 μ g.).

The patient was discharged from hospital on a programme which included a low-sodium diet, prednisone, potassium chloride,

and intermittent administration of acetazolamide. On this regime her weight decreased from 91 kg. to 70 kg. At this weight level, however, she became weak, nauseated, and had muscle cramps, similar to the symptoms of which she had complained in the past when receiving intensive cation exchange resin therapy. These symptoms were believed to be secondary to excessive sodium loss, and she was allowed to increase her sodium intake and regain some weight. She was then readmitted to hospital. Renal function studies were still normal (C_{inulin} =110 ml./min.; C_{PAH} =415

FIG. 22.—Case M.L. (F.) Sodium diuresis following right adrenalectomy in a woman aged 39 with hyperaldosteronism. Left adrenalectomy had been done seven months previously.

FIG. 23.—Case M.L. (F.) Showing the response to sodium loading with respect to the urinary excretion of sodium in a woman aged 39 with generalized oedema, before and after operative removal of the left and right adrenal glands.

ml./min.). During this period she was retaining sodium maximally, excreting less than 1 mEq a day despite a sodium load of up to 130 mEq daily. This almost quantitative retention of sodium was not modified by large doses of prednisone, acetazolamide, or mannitol, nor by the administration of corticotrophin. Amphenone was the only drug which con-

resulted in a prompt sodium diuresis with disappearance of aldosterone from the urine. Furthermore, aldosterone was demonstrable in the tumour and not in the surrounding adrenal tissue. Subsequently the right adrenal gland became the site of increased aldosterone production and the syndrome recurred, with an intractable tendency to accumulate oedema. In this patient secondary hyperaldosteronism was not accompanied by hypertension, hypokalaemia, hypochlor-aemia, or alkalosis, and in this respect the syndrome contrasts markedly with that ascribed to primary hyperaldosteronism.

Hyperaldosteronism and Potassium Deficiency

The classical manifestations of primary hyperaldosteronism as described by Conn (1955) consist of arterial hypertension, polyuria refractory to pitressin, and episodes of muscular weakness associated with hypokalaemia, hypochlor-aemia, and alkalosis, with an alkaline urine and decreased sodium/potassium ratio in saliva, sweat, and stool. Most of the clinical phenomena and the biochemical changes pertaining to this syndrome reflect the intense potassium deficiency induced by excessive aldosterone secretion.

The absence of oedema in primary hyperaldosteronism has not been satisfactorily explained. This is of particular interest in view of the fact that when aldosterone was given to a patient with Addison's disease (Thorn *et al.*, 1955) a rapid retention of sodium chloride and water took place, resulting in a weight gain of over 3 kg. in six days during the administration of aldosterone in doses of 1 mg. a day (Fig. 24). There would appear to be little doubt that clinical experience with aldosterone, when

it becomes readily available, will indicate that oedema is an early complication of excessive administration. Whether or not an increase in endogenous aldosterone secretion in patients with otherwise normal adrenal secretion could facilitate potassium loss without excessive sodium retention remains to be seen. Some of these considerations have been summarized in Fig. 25, in which the sequence of metabolic alterations attendant upon potassium depletion are listed.

It appears essential to distinguish between potassium deficiency as produced by hyperaldosteronism and that encountered more frequently in general medicine and surgery. Under the latter circumstances severe potassium depletion

FIG. 24.—Case W. G. (M.). Metabolic effect of aldosterone in man aged 37 with Addison's disease (0.25 mg. administered intramuscularly every six hours).

sistently induced a sodium diuresis, as it had done before the left adrenalectomy. The sodium diuresis was again associated with the disappearance of aldosterone from the urine. The values of urinary aldosterone, averaging 49 μ g. per 24 hours after admission, fell to a mean of 22 μ g. when salt was given, but rose to a mean of 34 μ g. when prednisone was administered while the high salt intake was maintained.

A right adrenalectomy was performed in November, 1946. Macroscopically the gland appeared normal. Histologically, the cortex was composed chiefly of zona fasciculata, with cells resembling those forming the previously removed adenoma. Following this operation there again occurred an immediate and profound sodium diuresis (as shown in Fig. 22) within four hours of removal of the remaining adrenal tissue. As expected, aldosterone disappeared from the urine and the patient lost weight, and a sodium load revealed no limitation in the renal handling of sodium (Fig. 23). The patient's clinical condition also showed great improvement and she was able to tolerate a diet containing 12 g. of sodium chloride without evidence of sodium retention. When her weight approached 70 kg., however, she again exhibited symptoms suggestive of potassium depletion. It is apparent that the underlying primary factor responsible for her oedema still exists.

It would appear that the continued attempts to reduce salt intake and to induce sodium excretion in this patient by vigorous diuretic therapy had resulted in secondary hyperaldosteronism, in which both adrenal glands should have been involved. The interesting features of this case are the presence of a functioning adenoma and the probability that aldosterone was secreted by this structure only. This is suggested by the fact that the removal of the adenoma

FIG. 25.—Sequence of events consequent upon the long-continued excessive secretion of aldosterone in Conn's syndrome ("primary hyperaldosteronism").

TABLE V.—Protocol of a Woman (Case B.M.), Aged 44, Admitted With Complaints of Three Attacks of Weakness and One Attack of Carpopedal Spasm

Admission to Eastern Maine General Hospital, February, 1957 (Dr. Laura Weed)	
Serum Na	139-147 mEq/l.
K	2.5-3.0 "
Cl	86-98 "
CO ₂	30-41.5 mEq/l.
Ca	11-11.8 mg./100 ml.
P	2.0 mg./100 ml.
N.P.N.	26-34 mg./100 ml.
Blood pressure	150-180/90-110 mm. Hg

When serum K was 2.5 mEq/l. she excreted 40-50 mEq of K daily when on an intake of 70 mEq of K.

Discharged on low-Na diet with supplementary KCl (8 g. day).

Admission to Peter Bent Brigham Hospital, March-April, 1957

Serum Na	134-140 mEq/l.
K	3.0-4.5 "
Cl	97-111 "
CO ₂	16-4-28.9 mEq/l.
Ca	5.3 mEq/l.
P	1.2 mEq/l.
Blood urea	20-38 mg./100 ml.
Arterial pH	7.51
pCO ₂	41 mm. Hg
Urine pH	27 mEq/l.
Urine contained protein on two occasions, with granular and hyaline casts.	
Salivary Na/K ratio	0.37-0.78
Stool Na/K ratio	0.02

Ammonium chloride reduced urine pH from 6.3 to 5.5.

12-hour water deprivation—overnight volume 800 ml., osmolality 737 mOsm/l.

Water load (20 ml./kg.)—67% excreted in four hours.

Creatinine clearance—71 ml./min.

Aldosterone excretion in urine—5 μ g./24 hours (normal sodium intake).

At operation (April 27, 1957) three adrenocortical adenomata were found in left adrenal gland; the gland was excised.

usually occurs in conjunction with large losses of gastrointestinal secretion—for example, vomiting, diarrhoea, draining fistula, intubation of the bowel. Occasionally one encounters the syndrome in elderly patients on the basis of nutritional deficiency or in cardiac patients after the protracted use of mercurial diuretics. The prolonged

administration of large doses of corticosteroids can also induce clinically apparent potassium depletion. Cases of "potassium-losing nephritis" in which the clinical picture is dominated by an inability on the part of the diseased kidney to handle potassium properly are indicated by evidence of pyelonephritis and the presence of an acidosis. However, cases of primary hyperaldosteronism may present serious diagnostic difficulties, particularly when the clinical picture is accompanied by normal values for urinary aldosterone excretion (Chalmers, Fitzgerald, James, and Scarborough, 1956). The protocol of such a case is shown in Table V.

A comparison between the syndrome of "potassium depletion" as seen in medicine and surgery and that of potassium depletion secondary to hyperaldosteronism is summarized in Table VI. Of particular interest is the presence of large quantities of potassium in the urine of patients with hyperaldosteronism coincident with hypokalaemia, whereas the cases of potassium depletion due to most other causes have low urinary potassium levels and an acid urine.

Secondary hyperaldosteronism can usually be differentiated from the primary form by the tendency of these patients to exhibit oedema, a low concentration of sodium in the urine, and no evidence of severe potassium depletion. Because of the difficulty encountered in aldosterone determination by either the chemical or biological methods it was hoped that a low salivary sodium/

TABLE VI.—Comparison of Laboratory Values Found in Experimental Potassium Depletion and Those Found in Conn's Syndrome ("Primary Hyperaldosteronism")

	Experimental Potassium Depletion	Primary Hyperaldosteronism
Na in serum	Normal	Normal or slightly elevated
Na in urine	Reduced	Normal
K in serum	Reduced	Reduced
K in urine	Normal or increased	Increased
Na/K ratio in saliva or sweat	Acid	Reduced
Urine pH		Alkaline

potassium ratio might provide a satisfactory initial screening test which, if positive, would then justify the more prolonged and costly process of measuring aldosterone in the urine. Although it is true that the salivary sodium/potassium ratio tends to be low in both primary and secondary hyperaldosteronism, it does not appear at this time that, in random specimens, there is a close relationship between this ratio and the quantitative value for urinary aldosterone. Studies such as that illustrated in Fig. 26 indicate that, although the salivary sodium/potassium ratio tends to fall as the urinary aldosterone level rises, the correlation at any given point may not be good and the final figure achieved may vary widely for a given urinary aldosterone value.

This work was supported in part by grants from the John A. Hartford Foundation, Incorporated, New York City; the National Institutes of Health, United States Public Health Service, Bethesda, Maryland, and the Eugene Higgins Trust Fund of the Harvard Medical School. We are indebted for gifts of amphenone B to Dr. Roy Hertz, of the National Cancer Institute, Bethesda, Maryland; to Dr. C. J. O'Donovan, of the Upjohn Company, Kalamazoo, Michigan; and to Dr. Robert Gaunt, of Ciba Pharmaceutical Products, Incorporated, Summit, New Jersey. Corticotrophin was kindly supplied by the Upjohn Company. The patients with cirrhosis were studied in conjunction with Dr. W. H. J. Summerskill in Dr. Charles Davidson's department, Thorndike Memorial Laboratories, Boston City

*Collected at 7 a.m. daily

The Hospital Personal Aid Service for the Elderly has published a second detailed account of its work, this report covering the period to December 31, 1956. Established in 1951 by the King Edward's Hospital Fund, the service co-operates with the four Metropolitan Regional Hospital Boards, each of which contributes £500 annually towards the cost, the Fund paying the balance. The service visits, on behalf of hospitals, elderly patients awaiting admission whose medical condition does not involve admission to acute wards. The main objects of the service are to suggest to the hospital the priority of those awaiting admission; to inform the hospital of the home circumstances in support of the suggested priority and as a guide when discharge is considered; to suggest suitable alternatives to admission wherever possible; to ensure that the waiting-list is a "live" one. The service acts only at the request of the hospital staff, who then discuss each case with the general practitioner concerned. Details of the service are obtainable from the secretary, c/o New Cross General Hospital, Avonley Road, London, S.E.14.

FUNCTION OF ALDOSTERONE IN THE METABOLISM OF SODIUM AND WATER IN PREGNANCY

BY

M. G. RINSLER, M.B., B.Chir.

Leverhulme Research Scholar, Royal College of Obstetricians and Gynaecologists

AND

BARBARA RIGBY, M.Sc.

From the Department of Chemical Pathology, King's College Hospital Medical School, London

The recent discovery of aldosterone (Grundy, Simpson, and Tait, 1952) has provided a fresh tool for the study of sodium and water metabolism in pregnancy. Previous observers have recorded an increased renal excretion of aldosterone or sodium-retaining substances in the later months of pregnancy; in pre-eclampsia the excretion was either the same as, or slightly less than, that found in normal pregnancy (Gordon, Chart, Hagedorn, and Shipley, 1954; Martin and Mills, 1956; Venning and Dyrenfurth, 1956; Venning, Primrose, Caligaris, and Dyrenfurth, 1957; Koczorek, Wolff, and Beer, 1957; see Table I).

TABLE I.—Mean Aldosterone Levels in Urine During Pregnancy and Pre-eclamptic Toxaemia

Author	Normal Pregnancy $\mu\text{g./24 Hours}$	Pre-eclamptic Toxaemia $\mu\text{g./24 Hours}$
Gordon <i>et al.</i> (1954)	5.0	13.0
Martin and Mills (1956)	3.6	2.5
Venning <i>et al.</i> (1957)	25.0	14.5
Koczorek <i>et al.</i> (1957)	59.3	40.8

* Calculated on the basis 1 $\mu\text{g.}$ of aldosterone = 30 $\mu\text{g.}$ of deoxycortone in biological assay.

We have studied 38 patients during pregnancy as well as seven normal non-pregnant women. The aldosterone excreted in the urine was estimated at four-weekly intervals from 12 to 16 weeks of pregnancy until term in six normal and three diabetic pregnancies. On one or more occasions similar measurements were made between weeks 28 and 40 of pregnancy on 19 patients suffering from pre-eclamptic toxaemia. Of these patients, 9 had hypertension (greater than 140/90 mm. Hg) and oedema, while 10 had proteinuria in addition. Ten other diabetic pregnant women were investigated during the 28th–36th weeks of pregnancy, and four of these were observed to have hypertension and oedema.

The normal patients were eating unrestricted diets, but those with toxaemia had diets modified only by restriction of table salt.

In five normal pregnant subjects and seven with pre-eclamptic toxaemia the concentrations of sodium and potassium were estimated in 24-hour specimens of urines.

Methods

Urinary excretion of sodium and potassium was determined with an EEL flame photometer, using external standards.

For the estimation of aldosterone in the urine 24-hour specimens were collected without preservative, and extraction was begun within eight hours of completion.

A preliminary extraction at pH 7, four times with 0.25 volumes of chloroform, removed the free cortisone and cortisol which interfere with the identification of aldosterone in the

paper chromatographic system used. After acidification to pH 1 the urine was left at room temperature and extracted four times with 0.25 volumes of chloroform over 48 hours to remove aldosterone as it was released from its conjugates. The combined chloroform extracts of the acidified urine were washed with N/10 sodium carbonate, water, and N/10 acetic acid and then evaporated. The residue was partitioned between benzene and water, and the water-phase re-extracted with chloroform (de Courcy, Bush, Gray, and Lunnon, 1953). After evaporation this residue was applied to a paper chromatogram in a band about 6 cm. wide and run at 37° C. in a benzene-methanol-water (2:1:1) system, using cortisone and cortisol as markers. The area containing the aldosterone between the two markers was eluted and a fraction of the eluate run again as a "spot" in the same system. The chromatogram was developed with methanolic soda and triphenyl-tetrazolium chloride. The quantity of aldosterone thus obtained was estimated by visual comparison of its fluorescence in ultra-violet light with that of cortisol standards. Neher and Wettstein (1955) have observed that aldosterone and cortisol have similar intensities of fluorescence in ultra-violet light.

In recent experiments the aldosterone specimens obtained by chromatography have been eluted, acetylated, and run in a benzene-toluene-methanol-water (10:10:7.5:2.5) system. Their R_f values have corresponded with that of pure aldosterone acetate.

At the time of the earlier experiments pure aldosterone was not available, and, to confirm the identity of the substance measured on the chromatogram, the sodium-retaining activity of most of the samples obtained by paper chromatography was assayed biologically, using a method based on that of Cope and Garcia-Llaurado (1954) and Llaurado (1956).

The test and standard substances were dissolved in 20% ethanol and administered intravenously, the standard at two levels, to groups of 8–12 adrenalectomized rats, each rat weighing 80–90 g. A control group was included in each assay, receiving 20% ethanol only. A salt-and-water load (4 ml. of normal saline) was administered to each animal intraperitoneally at the beginning of the experiment. The urine from each rat was collected for a three-hour period after the bladder had been emptied, and the Na/K ratio of each urine determined by flame-photometry. The reduction of this ratio in the experimental group was compared with that of the control group and expressed as a percentage which provided a measure of the sodium-retaining power of the

Fig. 1.—Aldosterone content of urine in normal and diabetic pregnancies (mean values).

substance administered. The standard used was 9 α -fluorohydrocortisone, which we found to have approximately one-third the potency of aldosterone.

Results

As pregnancy progressed there was an increase in the amount of urinary aldosterone from the non-pregnant level of 2–10 $\mu\text{g./24 hours}$ to a mean of $119.2 \pm 27.3 \mu\text{g./24 hours}$ at 32–40 weeks (Fig. 1), similar to results published by Venning *et al.* (1957) and Koczorek *et al.* (1957). Table II shows that in patients with hypertension and oedema the

(b) Hypertension, + oedema, + proteinuria	10	34.7	± 35.9	0–120	0.01–0.001
Diabetic pregnancy	9	164.9	± 25.3	65–285	0.7
Diabetic pregnancy with hypertension, + oedema	4	38.8	± 2.4	35–45	0.05–0.02

mean excretion of aldosterone ($69.4 \pm 9.2 \mu\text{g./24 hours}$) was significantly lower than that of the normal pregnant subjects. The more severely affected patients with proteinuria in addition to hypertension and oedema excreted even less aldosterone—a mean of $35.0 \pm 11.4 \mu\text{g./24 hours}$.

The diabetic patients without hypertension and oedema had a mean aldosterone output of $164.4 \pm 25.3 \mu\text{g./24 hours}$ between weeks 32 and 40, a value greater than the normal: statistical comparison shows that the difference between the means is not significant. However, five of the nine diabetics during this period excreted aldosterone at rates greater than 150 $\mu\text{g. daily}$, whereas this value was exceeded by only one of the six normal subjects. The diabetic women with hypertension and oedema had rates of aldosterone excretion similar to the other patients with pre-eclampsia—namely, a mean of $38.8 \pm 2.4 \mu\text{g./24 hours}$.

Fig. 2 shows that the Na/K ratio in the patients' urine was related to the aldosterone content in five normal pregnant patients and seven patients with pre-eclamptic toxaemia. Sodium retention, as indicated by a lower Na/K ratio, was greater in the toxaemic than in the normal patients with a similar excretion of aldosterone.

Discussion

There is conflicting opinion regarding the fate of sodium and water which have been shown by balance studies to be retained in considerable quantities during pregnancy (Coons, Coons, and Schiefelbusch, 1934; Hummel, Sternberger, Hunscher, and Macy, 1936; Chesley and Boog, 1943).

Fig. 2.—Excretion of aldosterone in relation to sodium/potassium ratio in the urine of normal and toxaemic patients 32–40 weeks pregnant.

Chesley found an increase in the thiocyanate space in normal pregnancy and that this increase was particularly marked in pre-eclamptic toxæmia. He concluded that much of the sodium retention was the result of expansion of the extracellular fluid (E.C.F.) compartment. The thiocyanate method is based on the assumption that this ion does not penetrate in quantity into the cells before equilibrium takes place in the E.C.F. Should intracellular diffusion occur the volume of distribution will be greater than the actual E.C.F. volume.

Gray and Plentl (1954), using a sodium isotope dilution method, have shown that there is little change in the sodium space and total exchangeable sodium in normal pregnancy, confirming some earlier observations of Lambiotte-Escoffier, Moore, and Taylor (1953). However, they noted a total gain of 500 mEq of sodium in the last six months of pregnancy, which they thought could be accounted for in the products of gestation and the expanded maternal blood volume. The maintenance of a sodium space within the range found in non-pregnant patients indicates that, despite the rise in plasma volume, little change in the E.C.F. volume occurs in normal pregnancy. There is evidence that part of the storage of sodium in pregnancy takes place in the uterus; an increase in the sodium and a decrease in the potassium content per unit dry weight of uterine muscle has been observed (Cort and Cort, 1957; Hawkins and Nixon, 1957).

The absolute gain of sodium and water in the presence of a normal total-exchangeable sodium value and an increased thiocyanate space offers indirect evidence that in normal pregnancy there is an alteration in cell permeability (Chesley and Boog, 1943), associated with an increase in stored maternal intracellular sodium and water in addition to foetal needs. The increased intracellular storage of sodium in the mother, and the foetal requirements, are a drain on the salt content of the maternal E.C.F., which if uncorrected would cause a fall in the E.C.F. and plasma volumes. Bartter, Liddle, Duncan, Barber, and Delea (1956) have demonstrated that a reduction of the E.C.F. volume independent of its tonicity leads to a rise in aldosterone excretion. The rise in aldosterone output observed in normal pregnancy may thus be part of a homeostatic mechanism preserving the volume of the E.C.F. and meeting the loss of sodium from the E.C.F. into the maternal cells and foetal tissues by increased renal reabsorption.

That the E.C.F. is expanded in pre-eclamptic toxæmia is evident on clinical examination. Bartter *et al.* (1956) observed that expansion of the E.C.F. in normal persons produced a fall in the urinary output of aldosterone. The patients in our series of pre-eclamptic toxæmia excreted considerably less aldosterone than the normal patients between weeks 32 and 40 of pregnancy. In our view this fall in the aldosterone excretion is the result of the rise in the E.C.F. volume and the generalized oedema formation.

In the small group of toxæmic patients in whom we measured the urinary sodium and potassium, for a given Na/K ratio the output of aldosterone is less than in the normal group (Fig. 2). Sodium retention is maintained and even increased in pre-eclampsia despite the low aldosterone output. This suggests that a mechanism other than that of aldosterone secretion by the adrenal gland causes sodium retention in pre-eclamptic toxæmia.

A number of the diabetic pregnant women excreted more aldosterone than most of the normal patients. The greater weight of the foetus of the diabetic mother and the increased volume of the amniotic fluid (hydramnios) (Lawrence and Oakley, 1942; Pederson and Jorgenson, 1954) presumably result in an increased demand for sodium and water over and above that of normal pregnancy. The raised output of aldosterone beyond the normal range in these individuals may well be a response to the greater requirement of sodium and water.

It is of interest to consider whether the hypothesis that a redistribution of salt and water in the body may influence the rate of aldosterone excretion can be applied to other con-

ditions. Conn, Louis, Fajans, Streeten, and Johnson (1957) have shown that in familial periodic paralysis, in which increased rates of aldosterone excretion occur during the attacks, there is an associated rise in the intracellular sodium and a fall in potassium in voluntary muscle.

High levels of aldosterone have been observed in the urine of patients suffering from hepatic cirrhosis and ascites (Deming and Luetscher, 1950; Wolff, Koczorek, Jesch, and Buchborn, 1956). In this condition one has to distinguish between the effect of the loss of sodium and water into the ascitic fluid (particularly after repeated paracenteses) and the effect of the fall in plasma albumin and its influence on the E.C.F. volume. Although the E.C.F. volume may be expanded as a result of a fall in plasma albumin and the colloid osmotic pressure of the blood, the new equilibrium of the E.C.F. volume is, we think, maintained by a raised aldosterone output in the face of sodium and water loss into the ascitic fluid. Under these conditions the administration of sodium chloride may produce oedema and a marked increase in ascitic fluid with a fall in aldosterone output (Duncan, Liddle, and Bartter, 1956).

The foregoing conditions illustrate how a redistribution of sodium and water in the body may effect an alteration in aldosterone excretion and add support to the hypothesis that a similar mechanism operates in pregnancy.

Summary

Urinary aldosterone was measured at four-weekly intervals in six normal and three diabetic pregnancies and on one or more occasions between weeks 28 and 40 of pregnancy in 19 patients with pre-eclamptic toxæmia and in 10 other diabetic patients.

A considerable rise was observed in the amounts of aldosterone recovered from the urine of normal pregnant women as pregnancy progressed.

It is suggested that this rise in output is a physiological response by the adrenal cortex to maintain the extracellular fluid volume in the face of loss of sodium and water into the maternal cells and into the products of conception.

A number of diabetic patients were observed to have a considerably greater output of aldosterone from week 28 of pregnancy onwards than that of a normal group. It is thought that this is due to the greater demand for sodium and water by the tissues of the larger foetus and by the increased volume of amniotic fluid.

A gross reduction in the urinary aldosterone was found in pre-eclamptic toxæmia. It is concluded that an agency other than aldosterone is responsible for the further sodium retention and oedema in pre-eclamptic toxæmia.

The effect on aldosterone excretion of a redistribution of sodium and water in the body in certain conditions other than pregnancy is discussed.

Mr. J. H. Peel and Mr. S. G. Clayton, of the department of obstetrics, and Dr. R. D. Lawrence and Dr. W. Oakley, of the diabetic department, have kindly allowed us access to their patients. Professor C. H. Gray has been most generous with laboratory facilities, materials, and advice. Professor Reichstein kindly supplied a small sample of pure aldosterone. We appreciate very much the co-operation of the patients, sisters, midwives, and nurses of King's College Hospital. Miss Marjorie Sandiford has contributed considerable time and skill in the care of the animals; and Miss Mary Pickett and Dr. Peter Dixon provided invaluable laboratory assistance.

M. G. R. would like to thank the President and Committee of the Royal College of Obstetricians and Gynaecologists for the award of a Leverhulme Research Scholarship, and King's College Hospital Medical School for additional financial support.

B. R. thanks the Board of Governors of King's College Hospital for a personal grant from the Diabetic Research Fund.

PANCREATIC ISLET ADENOMATOSIS WITH HYPOGLYCAEMIC EPISODES

BY

HUGH GARLAND, T.D., M.D., F.R.C.P.

Departments of Neurology, General Infirmary at Leeds and Pinderfields Hospital, Wakefield

The clinical manifestations of endogenous ("spontaneous") hypoglycaemia were probably first described by Porges (1910), of Vienna, in a patient with Addison's disease; in 1912 Harvey Cushing described several more examples in patients suffering from pituitary chromophobe adenoma. As a result of the discovery of insulin in 1921 the clinical picture of exogenous hypoglycaemia in the form of "insulin reactions" soon became familiar, and Seale Harris (1924) described five cases in which the patients had experienced similar attacks of hunger, anxiety, weakness, and sweating which were correlated with low blood-sugar levels; in this way he introduced the term "spontaneous" hypoglycaemia, suggesting that this may result from hyperinsulinism produced by overaction of the pancreatic islet cells.

The first example of a pancreatic islet adenoma recorded in the literature was described by Nicholls in 1902, but this was an incidental necropsy finding and the clinical details are not available. The first successful surgical removal of such a tumour was carried out by Roscoe Graham (Howland, Campbell, Maltby, and Robinson, 1929); by 1950 Howard, Moss, and Rhoads were able to analyse the findings in almost 400 cases of islet-cell tumour previously recorded in American medical writings. The rare condition in which there is widespread diffuse adenomatosis of the pancreatic islet cells was first discovered by Lang in 1925, and the relevant literature was reviewed in 1955 by Bickerstaff, Dodge, Gourevitch, and Hearn, who described the first example seen in Great Britain and the seventh in the world. In this the surgically resected body and tail of the pancreas showed very numerous adenomata varying in diameter from 0.2 to 7 mm., together with many hyperplastic islets, though there had been no corresponding visible or palpable abnormality at operation. The

following case report relates to the first example of islet-cell adenomatosis seen in the General Infirmary at Leeds, and appears to be the second example in Great Britain and the eighth in the world.

Case Report

A schoolmistress aged 49 suffered from "attacks" which started in 1949 and occurred about once a week but later became irregular, with free periods of several months, though sometimes there were as many as six in a fortnight. She was of above average intelligence and her previous medical and psychiatric history was non-contributory. It was, however, difficult to elicit an accurate account of her symptoms, but the attacks were apparently all similar in pattern, starting with sudden diplopia in all directions and often associated with tingling round the lips, followed by disturbance of consciousness which varied in severity from a lack of concentration to drowsiness or sleep, though she was probably never in a completely unrousable state and she never had a convulsion; they lasted from 15 minutes to about two hours, and often occurred before lunch or in the evening. During many attacks she continued to walk about but was unsteady and talked nonsense, so that she was often thought to be drunk, and she always had total amnesia for the whole episode except the aura. Soon after the onset a general physician made a diagnosis of hysteria. In 1952 I was consulted and considered (with reserve) that this was "idiopathic" psychomotor epilepsy; at this time the electroencephalogram (E.E.G.) was normal (Fig. 1). In 1953 she was sent to a neurosurgeon, who investigated her condition fully, including air-encephalography, with negative results.

During 1956 the attacks became more frequent, and consequently she was admitted to the neurological department of Pinderfields Hospital, Wakefield. Routine physical examination was repeatedly negative, and during several days of observation she had no attack. A glucose-tolerance test (by the Hagedorn-Jensen method using capillary blood) gave the following results: Fasting blood sugar, 65 mg./100 ml.; blood sugar $\frac{1}{2}$ hour after 50 g. glucose, 75 mg.; at 1 hour, 45 mg.; at $1\frac{1}{2}$ hours, 55 mg.; at 2 hours, 60 mg.; at 3 hours, 65 mg.; at 4 hours, 45 mg.; at 5 hours, 30 mg.; at 6 hours, 35 mg. Urine tests were not recorded.

After this test had been pursued for five hours, consciousness was seriously disturbed, so that she was only just able to swallow glucose, which produced a rapid return to her normal mental state.

The patient was then transferred to the General Infirmary at Leeds, where a second glucose-tolerance test (by a modification of the Folin-Wu method using venous blood) was carried out after 24 hours' starvation; during the fifth hour of the test there was a similar disturbance of consciousness though the blood concentrations were higher (Table I).

A simultaneous E.E.G. by Dr. M. J. Parsonage (during which the patient was very drowsy, with evidence of a cold, clammy sweat) showed a comparatively small amount of alpha rhythm in the parieto-occipital and posterior temporal regions which was frequently interrupted by irregular, diffuse, slow activity of mixed theta and delta frequencies. The record was indicative of a diffuse disturbance of cortical activity compatible with a hypoglycaemic state; there were no precise localizing signs, but at times the slow activity appeared to be maximal in the right temporal region (Fig. 2).

Laparotomy was performed by Mr. A. J. Latchmore on

TABLE I

	Blood Sugar (mg./100 ml.)	Urine
Fasting	60 mg.	No sugar
50 g. glucose orally:		
$\frac{1}{2}$ hour	80 "	
1 hour	60 "	" "
$1\frac{1}{2}$ hours	60 "	
2 "	50 "	" "
3 "	50 "	
4 "	50 "	
5 "	50 "	

July 18, 1956; the pancreas appeared normal both to the naked eye and on palpation, but a hemipancrcreatectomy was performed. Pre-operatively blood-sugar concentrations of 40 and 60 mg. per 100 ml. were recorded and the immediate post-operative value was 230 mg. A further glucose-tolerance test was carried out eight days later and showed (Table II):

	Blood Sugar (mg./100 ml.)	Urine
Fasting	110	No sugar
50 g. glucose orally:		
1 hour	100	
1 1/2 hours	150	
2 hours	150	" "
3 hours	110	" "
4 hours	130	" "
5 hours	120	
5 1/2 hours	110	

At the time of writing the patient has had no attack since operation, and repeated blood-sugar estimations, carried out at different times of the day, have never been below 100 mg. per 100 ml.

Although there was no gross abnormality of the resected portion of the pancreas, multiple small adenomata were

present in stained serial sections cut at approximately 0.5-cm. intervals; they varied in size from 4 mm. in diameter down to about three times the normal diameter of an islet, and the largest ones were visible to the naked eye. Some of these adenomata displayed a papillary pattern, but they were all well circumscribed and there was no attempt at infiltration of the surrounding tissue. No malignant changes were seen (Figs. 3 and 4, for which I am indebted to Dr. F. O'M. Shiell).

The pathological process involved all the pancreatic tissue resected—that is, the tail and about half the body—and there was no evidence of reversion towards normal even in the sections nearest the head. This is an interesting feature, because, in the normal pancreas, islet tissue is found in greater concentration in the body and tail than in the head; thus it would seem likely that similar lesions are present in the remainder of the pancreas left *in situ*, and the prognosis must therefore be guarded.

Comment

In retrospect it is clear that the general physician, the neurosurgeon, and I were misled by the history. Had the patient's emphatic denial of any attack lasting more than a few minutes been rejected and the statement of her friend that the attacks lasted for about an hour been accepted, the diagnosis might well have been established earlier, and, indeed, when the latter account was adopted a diagnosis of endogenous hypoglycaemia was made with some confidence before laboratory investigations were instituted.

It will be noted that a glucose-tolerance test carried out by different methods in two hospitals showed fasting blood-sugar levels

FIG. 1.—E.E.G. Normal appearances. Blood sugar, 90 mg. per 100 ml. at commencement of recording.

FIG. 2.—E.E.G. Abnormal. Generalized slow activity of maximal amplitude in the right anterior temporal region. Blood sugar, 50 mg. per 100 ml. at commencement of recording.

FIG. 3.—A group of islets; the two upper left are approximately normal in diameter, the larger islet in the central field being typical of many seen in the sections (x75).

FIG. 4.—An example of one of the larger islets, which is visible to the naked eye (x65).

HUMAN LIVER METABOLISM

BY

D. B. GRIFFITHS, M.B., B.S., F.R.C.S

Assistant, Surgical Unit, University College Hospital, London

AND

K. R. REES, M.Sc., Ph.D.

Payne Research Fellow, Royal Society,
Department of Morbid Anatomy, University College
Hospital Medical School, London

In the last 20 years much has been learnt about the enzyme patterns and synthetic processes taking place in living tissues. More recently, accurate localization of these processes to certain parts of the cell has been achieved. In carbohydrate metabolism, the enzymes concerned with glycolysis—that is, breakdown of glucose to pyruvic acid—are soluble and are present in the cytoplasm, whereas the enzymes concerned with completing

of 65 and 60 mg. per 100 ml., despite the fact that the latter test was done after 24 hours' starvation. Not only are there many who would regard these figures as within the normal range, and therefore not conforming with Whipple's triad for the diagnosis of organic hyperinsulinism, but there is a further departure from the Whipple dictum in that this patient never seems to have had an attack in the fasting state. According to Whipple (1944), the diagnostic criteria for establishing hyperinsulinism are: (1) a neuro-psychiatric disturbance occurring in the fasting state, (2) blood-sugar levels below 50 mg. per 100 ml., and (3) rapid relief of symptoms following the administration of glucose. It will be noted that in spite of prolonged fasting no blood-sugar level below 50 mg. per 100 ml. was recorded in the General Infirmary at Leeds, and though this level was maintained from the second hour to the end of a prolonged glucose-tolerance test it was not until the fifth hour that symptoms developed.

Despite these anomalies I felt confident that the clinical picture was that of organic hyperinsulinism, and it was agreed with the surgeon in advance that in the event of the pancreas appearing normal at laparotomy a hemipancrcreatectomy would be carried out. It would seem that failure to remove part of the pancreas in patients who have appropriate symptoms but in whom no pancreatic abnormality is found may well be the explanation for the apparent rarity of islet-cell adenomatosis.

Attention has already been drawn to the probability that this patient still has adenomatosis of the remaining half of the pancreas, and in the event of a return of symptoms consideration would have to be given to further surgical intervention, though this will not be undertaken without a careful trial of the only valuable medical treatment available for organic hyperinsulinism—namely, a high-carbohydrate diet.

It is interesting that both the neurosurgeon and I took the view that this patient was suffering from temporal lobe seizures, and there would seem to be little doubt that her attacks did result from disturbance of function in one or both temporal lobes, though the duration of the episodes was much longer than that usually seen in temporal lobe epilepsy. It is therefore interesting that the E.E.G. showed an abnormality in the right temporal region, and attention has already been drawn by Moorhouse (1956) to the importance of disturbed temporal lobe function in hypoglycaemic states. Though most references in the literature describe symmetrical E.E.G. patterns in hypoglycaemic states, a similar asymmetry was recorded by Bickerstaff *et al.* (1955).

Summary

A case of pancreatic islet adenomatosis is described, being probably the second in Great Britain and the eighth in the world.

The history, which extended over seven years, consisted of recurrent episodes of disturbed consciousness with amnesia and automatism, reminiscent of the symptoms of temporal lobe dysfunction.

Attacks did not occur in the fasting state, and the fasting blood-sugar levels were never below 60 mg. per 100 ml.

When a diagnosis of organic hyperinsulinism is established a hemipancrcreatectomy should be carried out if the pancreas appears to be normal at operation.

the oxidation of pyruvic acid to carbon dioxide and water (tricarboxylic acid cycle) are insoluble and are localized on the mitochondria. This latter enzyme system is also the pathway for the oxidation of fatty acids and amino-acids (see Diagram). These oxidations are responsible for energy production (the process of oxidative phosphorylation), the majority of this energy being produced by the mitochondria. Claude has called the mitochondria "the energy dynamos of the cell." The mitochondria are also the site of a number of syntheses, such as the synthesis of fats and nucleic acids.

Much of this information has been obtained from investigations carried out on the liver of experimental animals, notably the rat. In this species a great deal is known about the levels of activity of these enzymic processes, and changes resulting from experimental liver damage. In man, however, there are many gaps in our knowledge of these matters, mainly because samples of liver as required for enzyme studies have to be removed either during life or immediately after death. Waterlow

(1953) has explored some aspects of this problem, using 4-mg. samples of liver obtained by needle biopsy, but the technical difficulties with such small amounts of material are great, and so far only preliminary results are available. We felt that normal levels of enzyme activity could be better established with larger quantities of liver, and our material has therefore been obtained during operations on the upper abdomen, a method that provides specimens weighing about 1 g.

Methods

Tissue Preparations.—Approximately 1 g. of liver was excised at surgical operation, usually from the anterior margin or upper surface of the right lobe, and placed in ice-cold 0.25 M sucrose solution. A small slice was removed for histological examination. The capsule was then dissected off the remainder and the liver was homogenized in 0.25 M sucrose under the standard conditions recommended by Schneider (1948) to give a homogenate of approximately 15% w/v. In certain cases mitochondria were also isolated from the liver homogenates by the method of Schneider (1948).

Respiratory Measurements.—The measurements of respiration were carried out in the standard Warburg apparatus, using the following medium, final concentrations of the reagents being given. The reagents were prepared and purified by the methods employed by Christie, Judah, and Rees (1953).

Adenylic acid (A.M.P.)	0.001 M
MgSO ₄	0.0067 M
KCl	0.025 M
Sodium orthophosphate buffer, pH 7.4	0.0133 M
Cytochrome c	0.0002 M
Substrate	0.01 M

The tissue suspension was added in 0.25 M sucrose (0.5 ml.) and the volume was made up to 3 ml. with water; the gas phase was air and the temperature 38° C. As a routine, homogenates were prepared from liver biopsy material and the endogenous respiration determined along with the oxidation of L-malate and of succinate as substrates. The N content of the tissue preparation was determined by a microKjeldahl method.

Incorporation of ³²P into Liver Phosphatides and Ribonucleic Acids (R.N.A.).—The method employed was based

on that described by Kennedy (1953). The tissue suspension was added to the following medium, final concentrations being given.

A.M.P.	0.001 M
MgSO ₄	0.0067 M
KCl	0.025 M
Inorganic phosphate	0.0033 M
L-Glutamate	0.01 M
Cytochrome c	0.0002 M
Glycerol	0.0066 M
Trihydroxymethylaminomethane (tris) buffer, pH 7.4	0.016 M
and 0.2 ml. inorganic phosphate labelled with ³² P (1 ml. ≡ 6 μ mols inorganic phosphate ≡ 50 μc)	

1 ml. of the tissue suspension was added and the volume made up to 3 ml. with water, the mixture was incubated for 40 minutes, the gas phase was air, and the temperature 38° C. At the end of the experiment the phospholipid and R.N.A. fractions were separated by fractionation. The phospholipids were estimated by the method of Kennedy (1953), radioactivity being determined in films of zero thickness on metal planchettes, using an end-window counter. The R.N.A. fraction was determined, using the method of Davidson, Frazer, and Hutchison (1951).

Results

Homogenates and mitochondrial suspensions prepared from human liver oxidized added intermediates of the tricarboxylic acid cycle and L-glutamate. The level of these oxidations was considerably lower than that found in the rat (Table I). In the rat liver about 25–30% of the tissue nitrogen is localized in the mitochondria, but we have found

TABLE I.—Oxidation of Some Tricarboxylic Acid Cycle Intermediates by Human and Rat Liver

Preparation	μl. Oxygen/mg. Nitrogen/Hour			
	Human		Rat	
	Homogenate	Mitochondria	Homogenate	Mitochondria
Substrate:				
L-Malate	32	76	117	760

that in the human liver only about 15% of the tissue nitrogen is in the mitochondria. Both homogenates and mitochondrial preparations carried out oxidative phosphorylation, and the P/O ratios—that is, the efficiencies—obtained were of the same order as encountered in liver preparations from the rat.

Table II shows the levels of endogenous respiration and oxidation rates of L-malate and succinate by liver homogenates. The cases have been divided into normal and abnormal on the bases of histological examination of the liver sections and also on clinical details. The types of anaesthetic and duration of the anaesthesia used at the operation were noted, and in some cases the level of blood sugar was estimated at the time of removal of the liver sample.

The investigations of the synthesis of phosphatides and R.N.A. showed that human liver homogenates incorporated ³²P into both the phosphatide and R.N.A. fractions of the homogenates, and the rate of incorporation was of the same order as that found in rat preparations (Table III). Four

Systems as described under methods. The same ³²P concentration was added in each case and experiment carried out under identical conditions.

normal and five abnormal livers were studied and the results are given in Table IV. It can be seen that two livers from cases of obstructive jaundice showed reduced phosphatide synthesis. However, these liver preparations contained bile, which is known to inhibit *in vitro* liver oxidations. Further experiments showed that adding human bile *in vitro* to a normal human liver homogenate inhibits ³²P incorporation into the homogenate phosphatide.

Discussion

Our results show that in the human liver, as in other animal tissues, the tricarboxylic acid cycle enzymes are contained in the mitochondrial fraction of the cell. The low aerobic activity of human liver homogenates, as compared with rat preparations, is due to two factors. In the first place the mitochondrial population of the human liver per unit weight is lower than that of the rat; and, secondly, the rate of oxidation of human liver mitochondria is considerably lower than that of the rat. Also it was found that the addition of soluble coenzymes to the human liver homogenates and mitochondrial preparations did not accelerate the rate of oxidation of tricarboxylic acid intermediates. However, it appears that these lower levels of oxidation and their resultant energy-production are not necessarily limiting factors for the synthesis of complex molecules, as the

rate of synthesis of phosphatides, an intermediate in fat synthesis and R.N.A. synthesis, is of the same order as is found in rat preparations. Animal experiments have shown that agents with a toxic action upon the liver parenchyma produce alterations in metabolism. For example, administration of carbon tetrachloride causes impaired mitochondrial function (Christie and Judah, 1953), thioacetamide or azo-dyes given over a long period lead to a fall in the mitochondrial population and reduced mitochondrial activity (Grant and Rees, 1957). Do similar changes occur in human beings, for instance, as a result of the use of anaesthetics? And what effect have pathological conditions found in man upon the metabolism of the liver cell?

We have found that the type of anaesthetic used in this series of operations, and the length of anaesthesia within the established range, had no effect upon the metabolic reactions which we have studied. However, livers showing fatty change on histological examination display a marked reduction in the oxidation rates in the homogenate preparations, and preliminary studies on liver slices confirm this low oxidative metabolism of fatty liver. In this connexion it is of interest that livers of children suffering from kwashiorkor showed decreased levels of succinoxidase and cholinesterase (Waterlow, 1953). Of three livers from patients with obstructive jaundice which were investigated by us, two showed marked reduction of phosphatide synthesis. But R.N.A. synthesis was not reduced in any of the three livers, and the respiratory rate fell within the normal range in another instance. The reduced phosphatide synthesis seen in obstructive jaundice could be an artifact, since the livers in question contained appreciable amounts of bile in the bile ducts, which would become mixed with the liver parenchyma during homogenization. However, adding bile in suitable amounts to normal liver homogenate led to reduction both of phosphatide and of R.N.A. synthesis. It now remains for us to check these results by the use of liver slices obtained from both normal cases and cases of obstructive jaundice. We are, however, convinced that this type of investigation promises much valuable information about the function of the normal and pathological human liver cell.

Summary

An attempt has been made to find out more about what goes on in human liver cells in health and disease. Methods giving valuable insight into cell metabolism in animals are shown to be applicable to pieces of liver removed at operation in humans. Oxidations concerned in the final stages of breakdown of sugars and the incorporation of phosphorus (in isotope form) into phosphatides and nucleic acids can be followed in man if experimental techniques are slightly modified. Our results suggest that the oxidative and synthetic activity of liver cells may be seriously disturbed when there is obstructive jaundice, liver fibrosis, fatty degeneration, or

infiltration of the organ by carcinoma or leukaemia. Such functional disturbances quite likely initiate the gross structural changes in the liver. Anaesthesia used during biopsy does not modify liver cell metabolism.

We wish to acknowledge the help and encouragement of Professor Sir Roy Cameron, Mr. D. R. Davies, and Professor R. S. Pilcher in the preparation of this paper, and to thank all the surgeons of University College Hospital who provided the material.

MEGALOBlastic ANAEMIA AND VITAMIN-B₁₂ DEFICIENCY AFTER ANTICONVULSANT THERAPY

REPORT OF TWO CASES

BY

PATRICK KIDD, M.B.

Consultant Pathologist, Royal Infirmary, Worcester

AND

DAVID L. MOLLIN,* M.B., B.Sc.

Lecturer in Pathology, Postgraduate Medical School of
London, W.12

In 1952 Mannheim and his colleagues described leucopenia and megaloblastic anaemia in an epileptic patient receiving treatment with hydantoin. Macrocytosis and hypersegmented polymorphs were present in the blood films of other patients, but only scanty haematological details were given. Badenoch (1954) reported detailed studies in two epileptic patients who developed a megaloblastic anaemia while being treated with phenobarbitone and phenytoin sodium ("epanutin") and suggested that the megaloblastic anaemia might be due to the anticonvulsant drug. Since then megaloblastic anaemia has been reported in 21 other patients receiving phenytoin sodium and/or primidone ("mysoline") (Hawkins and Meynell, 1954; Chalmers and Boheimer, 1954; Rhind and Varadi, 1954; Webster, 1954; Berlyne *et al.*, 1955; Fuld, 1955; Ryan and Forshaw, 1955; Vaishnava, 1955; Girdwood and Lenman, 1956; Girdwood, 1956; Christenson *et al.*, 1957; Gydell, 1957; Newman and Sumner, 1957) and in one non-epileptic patient receiving large doses of quinalbarbitone sodium and amylobarbitone sodium (Hobson *et al.*, 1956).

The cause of the megaloblastic anaemia in these patients is uncertain. Most patients have responded only to treatment with folic acid, but there has rarely been evidence of intestinal malabsorption. Although some patients have taken an inadequate diet (Gydell, 1957; Newman and Sumner, 1957), in most the diet has been adequate. It has therefore been suggested that the megaloblastic anaemia is due to interference with the tissue metabolism of folic acid. In none of the patients hitherto reported has there been definite evidence of vitamin-B₁₂ deficiency.

*In receipt of a grant from the Medical Research Council.

The purpose of this paper is to give details of two epileptic patients who developed a megaloblastic anaemia while being treated with anticonvulsant drugs. In both there was evidence of vitamin-B₁₂ deficiency due to dietary inadequacy.

Case 1

A 41-year-old woman had been treated for epilepsy since childhood. She had received phenobarbitone, 2 gr. (0.13 g.) daily, for many years, and for the last two years she had received, in addition, phenytoin sodium, 100 mg. daily. She lived with her mother in poor circumstances, subsisting on a meagre diet which at times consisted of little more than bread, buns, and boiled sweets. Two months before admission she was found by her family doctor to be suffering from bleeding gums, purpuric blotching of the skin, and swollen ankles. He diagnosed scurvy and treated her with 200 mg. of ascorbic acid daily for six weeks. The bleeding stopped and the purpura rapidly disappeared, but she became progressively more anaemic, and was admitted to hospital on August 25, 1955.

On examination she was found to be of low intelligence and retarded in speech and behaviour. The only abnormal physical signs were gross pallor and severe gingivitis. Chest x-ray examination revealed no abnormality.

Investigations.—Red cells, 1,100,000 per c.mm.; Hb, 4.5 g. per 100 ml.; packed cell volume, 13%; mean cell volume, 118 cubic microns; leucocytes, 1,700 per c.mm., of which 1,122 were polymorphs. Stained films showed macrocytosis, anisocytosis, and poikilocytosis. Sternal marrow films showed severe megaloblastic haemopoiesis. The vitamin-B₁₂ concentration of two samples of serum taken before treatment, measured with the Euglena assay, was 50 and 40 µg. per ml. respectively (normal range 100 to 900 µg. per ml., Mollin and Ross, 1954). The low serum concentration was not due to a growth inhibitor, for similar values were obtained at various dilutions. Furthermore, when vitamin B₁₂ was added to the serum and the serum was re-assayed, 83 to 94% of the added vitamin B₁₂ was recovered. The serum iron was 90 µg. per 100 ml. Direct Coombs test was negative.

The serum protein was 6.3 g. % (albumin 3.55 g., globulin 2.75 g.); serum bilirubin 0.7 mg. per 100 ml.; thymol turbidity 1 unit; colloidal gold 0; alkaline phosphatase 4.5 King-Armstrong units per 100 ml.

Quinine test meal (with histamine) showed free HCl to be present. The fat-balance study had to be abandoned because the patient was uncooperative, but the amount of faecal fat was within normal limits, being 18% of dried stool.

The radioactivity of the plasma after an oral dose of 1 µg. of ⁵⁷Co vitamin B₁₂ (specific activity 5.0 mc. per mg.) was maximal at eight hours, when 1.5% of the administered dose was present in the plasma (normal range 1 to 2%, Booth and Mollin, 1956). This indicated that the patient was able to absorb vitamin B₁₂ normally.

Treatment.—On August 30 she was given an intramuscular injection of 100 µg. of vitamin B₁₂. Three days later her serum iron was unchanged, being 97 µg. per 100 ml., and the marrow obtained by sternal puncture was still grossly megaloblastic. The haemoglobin concentration was now 3.6 g. per 100 ml.; red cells were 1,020,000 per c.mm., and the reticulocyte count was 4.8%. She was then given 10 mg. of folic acid three times daily; five days later the reticulocytes had reached a peak of 36%. The serum iron had fallen to 28 µg. per 100 ml. By September 21 the red cells were 2,400,000 per c.mm.; the haemoglobin concentration was 7.8 g. per 100 ml.; packed cell volume was 29.6%; and the mean cell haemoglobin concentration was 29%. Folic acid was reduced to 10 mg. twice daily, and a proprietary preparation of colloidal ferric hydroxide ("neoferrum") 8 ml. twice a day, and ascorbic acid (50 mg. daily) were also given. On October 21 the red cells were 4,600,000 per c.mm.; the haemoglobin concentration was 13.3 g. per

100 ml., and the packed cell volume 44%. Treatment with phenytoin sodium, 100 mg. daily, and phenobarbitone, 1 gr. (65 mg.) three times a day, had been continued throughout. The patient continues to take 10 mg. of folic acid daily, and there has been no sign of haematological relapse to date.

Comment.—This patient appeared to be suffering from deficiency of both vitamin B₁₂ and folic acid, for although her serum vitamin-B₁₂ concentration was as low as that found in patients with untreated vitamin-B₁₂ deficiency she failed to respond to treatment with vitamin B₁₂ alone. Her sternal marrow was grossly megaloblastic three days after an injection of 100 µg. of vitamin B₁₂, whereas in patients with uncomplicated vitamin-B₁₂ deficiency erythropoiesis would be proceeding on essential normoblastic lines by this time. Her serum iron was also unchanged three days after the injection. Houghton and Doan (1941) and Hawkins (1955) have emphasized that a fall in the serum iron is an early and valuable sign of response to treatment in patients with megaloblastic anaemia. Her anaemia responded completely when folic acid was given, in spite of the fact that treatment with phenytoin sodium was continued.

Case 2

A feeble-minded female epileptic aged 34 was admitted to hospital on June 9, 1956, in *extremis* and died with acute pulmonary oedema two hours later. On admission the red cell count was 650,000 per c.mm. and the haemoglobin 2.7 g. per 100 ml. The blood film was typical of severe megaloblastic anaemia, and sternal marrow aspirated before death was grossly megaloblastic.

The patient had been receiving phenobarbitone, 1½ gr. (0.1 g.) daily, for many years. In May, 1955, phenytoin sodium, 100 mg. daily, was started and given in addition to phenobarbitone, and from October, 1955, primidone, 250 mg. daily, later increased to 500 mg. daily, was also given. About two months before admission the dose of phenytoin sodium had been reduced to 30 mg. daily.

Two months before admission she had undergone an emergency hysterectomy for intractable menorrhagia of one month's duration. Before a transfusion of 4 pints (2.3 litres) of blood the haemoglobin concentration was 5.9 g. per 100 ml. At this time, although she appeared well nourished, great difficulty was found in persuading her to eat whilst in hospital, and she had taken a grossly inadequate diet before admission. Her mother stated that she had had very little to eat since her discharge.

Post-mortem Examination.—Necropsy was performed 11 hours after death, little being found other than acute pulmonary oedema and the usual stigmata of gross anaemia. No focal lesion was found in the brain. The marrow in the ribs, sternum, and lumbar vertebrae was pinkish grey in colour and grossly hyperplastic on histological examination. The gastric mucosa was of normal thickness and structure. The serum vitamin-B₁₂ concentration of a sample of right auricular blood taken at necropsy was 40 µg. per ml.

Comment.—This patient was also suffering from vitamin-B₁₂ deficiency, for her serum vitamin-B₁₂ concentration was very low. The fact that her serum was obtained from blood taken after death does not invalidate this result, for our experience has been that the serum vitamin-B₁₂ concentration is never subnormal in the 24 hours after death unless the subject suffered from vitamin-B₁₂ deficiency (Mollin and Ross, unpublished observations). The fact that the gastric mucosa was normal excludes the possibility of Addisonian pernicious anaemia, but intestinal malabsorption syndrome was not excluded. Nevertheless, it seems probable that her condition was similar to that found in the first patient.

Discussion

Both these patients had serum vitamin-B₁₂ concentrations as low as those seen in severe Addisonian pernicious anaemia. As neither of them was suffering from this condition, and as there was no evidence of intestinal malabsorp-

tion of vitamin B₁₂ or of fat in the one patient in whom detailed studies were made, it is probable that the deficiency of vitamin B₁₂ was due to inadequate diet. It is unlikely that these low serum levels were due to the anticonvulsant drugs, for while it is possible that these drugs might interfere with the metabolism of vitamin B₁₂ it is difficult to see how this could deplete the serum of its vitamin.

The previously published reports suggest that the megaloblastic anaemia found in patients receiving anticonvulsant drugs is due to interference with the metabolism of folic acid in the tissues. In at least one of the patients described above (Case 1) there was evidence of deranged folic acid metabolism, for the anaemia did not respond until folic acid was also given. However, the dietary deficiency of vitamin B₁₂ may have helped to precipitate the megaloblastic anaemia in both patients.

Vitamin-B₁₂ deficiency does not appear to be common in the patients so far described with this type of megaloblastic anaemia.

Apart from the patient described by Newman and Sumner (1957), few if any of the patients were taking a diet grossly deficient in vitamin B₁₂ and there has been little direct evidence of vitamin-B₁₂ deficiency. The serum vitamin-B₁₂ concentration was within the normal range in the nine patients in whom it was measured and was also normal in four others whose sera we have recently assayed. Although some patients were reported to have responded to treatment with vitamin B₁₂ the responses have been slow, and the anticonvulsant drugs were also stopped or changed before or at the same time as treatment with vitamin B₁₂ was started.

One of our two patients had also suffered from deficiency of ascorbic acid, and it is possible that the intractable menorrhagia in the other was due to this deficiency. Ascorbic acid deficiency was also reported by Gydell (1957) in two of his three patients, and one of the two patients described by Newman and Sumner (1957) may well have suffered from this condition. Gydell (1957) suggests that ascorbic acid deficiency may be more common in this type of megaloblastic anaemia than has been suspected. He points out, for instance, that both patients described by Badenoch (1954) and one of the patients described by Fuld and Moorhouse (1956) suffered from oral lesions, and that Kimball (1939) found evidence of ascorbic acid deficiency in patients who developed these lesions on phenytoin sodium. Furthermore, the ascorbic acid saturation test in the patient described by Chalmers and Boheimer (1954) was abnormal, although there were no other signs of ascorbic acid deficiency.

It is known that a scorbutic diet may produce a megaloblastic anaemia in animals (May *et al.*, 1950) and that a megaloblastic anaemia may be found in scurvy (Brown, 1955), so it is possible that ascorbic acid deficiency may also be a precipitating factor in some of the patients with megaloblastic anaemia associated with anticonvulsant therapy. It is unlikely that it is ever the sole or principal cause of the anaemia in these patients, for treatment with ascorbic acid did not relieve the anaemia in our own patients or in those described by Gydell (1957). The megaloblastic anaemia associated with scurvy alone responds rapidly to treatment with vitamin C (Brown, 1955; Booth and Mollin, 1956, unpublished observations).

There was a clear-cut history of dietary deficiency of vitamin C in all the patients mentioned above who gave a definite history of bleeding, but not in the patients with oral lesions or in the patients described by Chalmers and Boheimer (1954). It is therefore possible that the administration of anticonvulsants may itself tend to precipitate deficiency of ascorbic acid.

Summary

Two epileptic patients, one of whom was treated with phenytoin sodium, the other with phenytoin sodium and primidone, developed megaloblastic anaemia.

The serum vitamin-B₁₂ concentrations of both patients were very low, but neither suffered from Addisonian pernicious anaemia. Both had been taking a very inadequate diet, and one had recently suffered from scurvy.

Vitamin-B₁₂ deficiency was not the sole cause of the megaloblastic anaemia in the one patient in whom serial observations were made.

We wish to thank Dr. J. E. Bradley for the ⁵⁶Co; Dr. E. Lester Smith, F.R.S., of the Research Division of Glaxo Laboratories, for the labelled vitamin B₁₂; Dr. J. O. Terry for permission to investigate Case 1; Dr. G. E. R. Bibbings and Dr. J. W. B. Parsons for much helpful information about the two patients; Miss Barbara Anderson for help with the radioactive measurements, and Mrs. Helen Berriman for the microbiological assays.

KNOCK-KNEE IN CHILDREN

BY

A. J. M. MORLEY, M.B., D.C.H.

From the Institute of Orthopaedics and the Royal National Orthopaedic Hospital, London

To learn more of the natural history of knock-knee over 1,000 examinations were made on unselected normal children from infant welfare clinics and from a school in North-west London. It was considered that a greater understanding of the natural history would simplify the management of children with knock-knee and avoid unnecessary treatment. The methods used were simple, and were applicable in any clinic.

Two groups of children were studied. Those with any defect or disease which might affect their lower limbs—for example, spastics—were excluded.

Material

From Three Infant Welfare Clinics.—Any child who was old enough to walk unaided was seen, and all children were invited to reattend in six months for remeasurement. Studies were made of 451 children aged 1 to 4 years inclusive. Of these, 245 were seen once, 146 on two occasions, and 60 on three occasions, making a total of 717 examinations. Thirty-nine examinations were also made on children aged 5 years and over. The results of two or three examinations on the same child have been used, provided that the child was in a different age group on each occasion. Return visits appear to have been made by a representative sample of the children, as the incidence of knock-knee found at the first examinations is similar to that of the whole series.

Likewise, the proportion of children immunized and receiving vitamin supplements is similar at the first examination and in the complete series.

From an L.C.C. Junior Modern and Infant School.—318 children, aged 5 to 11 years inclusive, were examined. All children in certain classes were seen, provided that their parents had given written permission for examination. These children were not re-examined, and no history was available, as the parents were not present.

History and Examination

In infant welfare clinics, where the child's mother was usually present, the following history was obtained: birth weight; age at which the child first walked unaided; details of diet, including the duration of breast-feeding and whether the child had vitamin supplements; illness as judged by the number of days the child had spent in bed since it started to walk; any habitual sleeping or sitting posture noticed by the mother; whether the mother had ever noticed anything wrong with the child's legs, feet, or back; if she had, details including any treatment received were noted.

In both the infant welfare clinics and the school the following facts were recorded.

Age in Months.

Weight.—Children in school wore vest and pants only, as did the majority of children in infant welfare clinics. If they were weighed naked or in any other clothes the weight was adjusted accordingly. The actual weights were used in calculations on children under 5 years old, but not enough children were seen for this to be satisfactory in the school age groups. For this reason the indices of Sutcliffe and Canham (1950) were used when calculating average heights and weights of children aged 5 years and over. (These indices are corrected for age and sex, and have a standard deviation of 15. The indices range from 65 to 135, with 100 representing the mean. Children in this series are rather heavier, after allowing for weight of vest and pants, and taller than Sutcliffe and Canham's subjects. However, it is reasonable to use these indices to compare different groups within this series.)

Height.—This was measured with the children standing barefoot against a vertical tape or rule. The actual heights were used in calculations on children under 5 years, and the indices of Sutcliffe and Canham for older children.

Knock-knee.—This was measured as the child lay or sat with the length of its legs supported on a couch. The legs were held with the patellae facing vertically upwards, the feet dorsiflexed to a right angle, and the inner surfaces of the knees just touching; the distance between the medial malleoli was then measured. In clinical work the amount of knock-knee recorded is usually less than this, as some pressure is applied to approximate the ankles. Four grades of knock-knee were used: Intermalleolar distance of less than 1 in. (2.5 cm.); 1 in. (2.5 cm.) but less than 2 in. (5 cm.); 2 in. (5 cm.) but less than 3 in. (7.5 cm.); and 3 in. (7.5 cm.) and over.

FIG. 1.—Method of grading footprints (see text).

Postural Deformities of the Feet.—Many children appear to have flat feet. In infants this is normal; the flat appearance, as is well known, is due to a fat pad which obliterates the arch. Some children show a flatness which persists, and sometimes, with or without this pes planus, there is an eversion of the foot—pes valgus. This might be associated with the deformity of the knees and even be a causative or aggravating factor. These abnormalities of the foot are difficult to measure exactly, and the valgus element in particular cannot be accurately assessed. Footprints were taken by smearing the feet with petroleum jelly and then letting the child walk over photographic paper. This gave a measure of the flatness of the arch but did not indicate how much of it was due to eversion of the foot. The footprints were measured as in Fig. 1. A line (A) was drawn along the medial border of the foot and a perpendicular (B) drawn from this line through the highest point of the arch. The ratio of the height of the arch (x) to the width of the foot (y) along this line was used to grade the footprint into one of four groups:

If x was less than $\frac{1}{4}$ y the footprint was graded as F1
 " " $\frac{1}{4}$ up to $\frac{1}{2}$ of y " " " " F2
 " " $\frac{1}{2}$ " " " " " " " " F3
 " " $\frac{1}{2}$ y or more " " " " " " F4

Where, upon measurement, the right and left footprints fell into more than one of the above grades, that grade representing the grosser degree of flatfoot was used.

Valgus Feet.—Eversion of the feet was assessed by watching the child walk and stand. Valgus feet were recorded as such only if the valgus was pronounced enough to be visible when the child was observed from behind. The grades used were "moderate" and "severe." Minor amounts of valgus were ignored.

Results

The incidence of knock-knee at different ages is shown in Fig. 2. Children under 5 years of age were placed in half-yearly age groups. Schoolchildren were divided into three age groups: 5 and 6 years; 7, 8, and 9 years; and those of 10 and 11 years. The incidence of knock-knee increases until 3 to 3½ years of age; it then declines. Between 3 and 3½ years of age only 26% of children had less than 1 in. (2.5 cm.) of knock-knee, 52% had between 1 and 2 in. (2.5 and 5 cm.), while 22% had a knock-knee of 2 in. (5 cm.) or more.

There was no sex difference in the incidence of knock-knee in children under 5 years of age. In schoolchildren, although the incidence of knock-knee of 3 in. (7.5 cm.) or more was the same in both sexes, lesser amounts of knock-knee were more common amongst the girls.

Where the knock-knee angle remains constant the intermalleolar distance must increase as the leg grows. The length of the tibia is about 7 in. (17.5 cm.) at 3 years and

FIG. 2.—Incidence of knock-knee at different ages. Black areas indicate knock-knee of over 3 in. (7.5 cm.).

about 10 in. (25 cm.) at 7 years. Thus a knock-knee of 2 in. (5 cm.) at 3 years will have become 3 in. (7.5 cm.) at 7 years if the angle remains constant (Fig. 3). Consequently, if the angle between the legs is used to measure knock-knee instead of the intermalleolar distance, the incidence of knock-knee at different ages will show a much more dramatic peak at 3 to 4 years. The curves in Fig. 4 were obtained by using the average length of the tibia at different ages to convert the intermalleolar distances into degrees of genu valgum.

At 3 years of age 22% of children were found to have a knock-knee of 2 in. (5 cm.) or more (which corresponds to about 16 degrees), but by 7 years of age only 1 or 2% of children had knock-knee of 3 in. (7.5 cm.) or 16 degrees. Lesser amounts of knock-knee show a similar trend.

There were 7 girls and 21 boys with bow-legs. Except in children under 2 years old, the distance between the knees was so small—usually less than $\frac{1}{4}$ in. (1.3 cm.), and always less than 1 in. (2.5 cm.)—that it is not likely to be important clinically.

	4	135	116.3	3	135	124.4

* One observation not obtained.

Relationship Between Knock-knee and Body Weight.—The weight curves of the girls are related to different amounts of knock-knee in Fig. 5. The differences between the weights on the upper and lower curves were statistically significant. The mean weight of children with knock-knee is greater than the mean weight of children without knock-knee (Tables I and II). This was true in both sexes and for all ages, except in the youngest group of girls, where

FIG. 6.—Incidence of valgus ankles. Cross-hatching indicates moderate valgus; black areas indicate severe valgus.

there are only two observations in the 1-2 in. (2.5-5 cm.) knock-knee grade.

Relationship Between Knock-knee and Height.—There is a tendency for children with more than 2 in. (5 cm.) of knock-knee to be taller than those of the same age with less than 1 in. (2.5 cm.) of knock-knee. However, amongst a group of heavy children those with knock-knee are not taller than the rest. It is known that heavy children are above average in height, and there is probably no other relationship between height and amount of knock-knee than that due to the increased weight.

Valgus Feet.—The incidence of valgus feet was alike in each knock-knee grade, and no sex difference was found. Valgus feet became less frequent with increasing age (Fig. 6).

Flatfoot.—The footprints showed that the incidence of flatfoot decreased as the age increased. Among children under 18 months, 97% were graded as F1. By 10 or 11 years only 4% of children remained in this grade (Fig. 7). No association was found between knock-knee and flatfoot. The incidence of flatfoot was similar in each knock-knee grade. No constant relationship was found between body weight and flatfoot.

FIG. 7.—Incidence of flatfoot in different age groups.

When comparing the birth weights of children in different knock-knee grades it was found that the mean birth weight was slightly higher in those with increased amounts of knock-knee. There does not seem to be any association between the age at which the child started to walk and the development of knock-knee. No relationship was found between the duration of breast-feeding and the development of knock-knee. The percentage of children taking vitamin supplements was similar for each grade of knock-knee. The number of days spent in bed through illness showed no relationship to the development of knock-knee.

Mothers were usually extremely vague about habitual sleeping or sitting postures. Many children sleep in a prone-kneeling position when young, and this did not seem to be especially common in those children who had knock-knees. Other information about posture was too unreliable or too scanty to be useful.

Roughly 1% of children seen in these infant welfare clinics had been advised to wear wedged shoes at some time. About 4% had been taught foot and leg exercises (this figure is high because a physiotherapist was attached to one of the clinics). An additional 2% had attended hospital solely for observation. Only one child was seen who had worn night splints for knock-knees. He was aged 59 months and had 4 in. (10 cm.) of knock-knee. In the past he had worn night splints for six months and had been given exercises at hospital for a similar period. Neither of these treatments had been effective, and he was still under hospital observation.

Conclusions

Knock-knee is commonest among children aged 3 to 3½ years. At this age 22% of children were found to have a knock-knee of 2 in. (5 cm.) or more. Only 1 to 2% of children aged 7 years and over have an equivalent amount of knock-knee.

The mean weight of children with knock-knee is greater than the mean weight of comparable children without knock-knee.

The development of knock-knee is not associated with any of the following factors: valgus feet; flatfoot; age at which the child started to walk; duration of breast feeding; quantity of vitamin supplements taken during the first 18 months; illness as judged by the number of days spent in bed.

Knock-knee is very common among toddlers, but fortunately it usually improves without treatment. Apart from operative procedures, no effective treatment for knock-knee is known.

Knock-knee in children under 7 years of age can probably be safely ignored unless it is excessive or unless an underlying cause, such as epiphyseal damage from a fracture or renal rickets, is present.

An underlying cause for knock-knee should be sought if: (1) the knock-knee is excessive—over 3½ in. (9 cm.); (2) the knock-knee is of unequal amount in the two legs; (3) the child is short for its age: this might rarely be due to an epiphyseal dysplasia or to an endocrine disorder; (4) there is a family history of severe knock-knee or other bony deformity; this could be due to a metabolic disorder such as Fanconi's syndrome.

Toddlers' knock-knee can be allowed to join the growing group of developmental deviations which seldom need treatment, such as the infant's tight foreskin (Gairdner, 1949) and the baby's umbilical hernia (Woods, 1953).

I thank Mr. H. J. Seddon, of the Institute of Orthopaedics, for suggesting this investigation and for his continual interest and guidance. I am grateful to Mr. J. I. P. James, of the Institute of

Orthopaedics, for much helpful advice. I am indebted to Dr. J. A. Scott, Principal School Medical Officer, London County Council, to Dr. John Brown, Education Officer, and to the Education Committee of the London County Council, for permission to attend the school; also to Dr. D. H. Geffen, Medical Officer of Health, Metropolitan Borough of St. Pancras, for permission to attend the infant welfare clinics. I am grateful to the headmistress of the school, the clinic medical officers, and the health visitors, who have been most generous with their assistance. I also thank Dr. J. Knowelden, of the London School of Hygiene and Tropical Medicine, who has advised me on statistical problems, and the photographic department of the Institute of Orthopaedics, who developed the many footprints.

ENCEPHALOPATHY DURING SALICYLATE TREATMENT OF ACUTE RHEUMATISM

BY

MICHAEL HONEY, M.B., M.R.C.P.

Research Assistant, Department of Cardiology, University College Hospital, London

Salicylates are still widely used in the treatment of acute rheumatism, often in toxic doses. Some patients have an idiosyncrasy to salicylates and develop anaphylactic or allergic symptoms which are sometimes fatal. Other well-known toxic effects (Gross and Greenberg, 1948; Goodman and Gilman, 1956) include "salicylism" (tinnitus and deafness, nausea and vomiting, sweating and vasodilatation, etc.), haemorrhages due to hypoprothrombinaemia, capillary damage, or thrombocytopenia (Rappoport *et al.*, 1945; Troll and Menten, 1945), and respiratory alkalosis associated with low pCO₂, high pH, and later an elevated bicarbonate level in the plasma (Guest *et al.*, 1945; Rappoport and Guest, 1945; Boyle *et al.*, 1947; Farber *et al.*, 1949; Reid *et al.*, 1950; Singer, 1954).

Salicylates may also produce cerebral excitation (Gross and Greenberg, 1948; Goodman and Gilman, 1956), with delirium, hallucinations, disorientation, restlessness, excitability, and irritability; later there may be depression leading to coma with respiratory failure and cardiovascular collapse, sometimes with terminal asphyxial convulsions. Ryder *et al.* (1945) describe a fatal case with symptoms partly attributable to a severe respiratory alkalosis, in which necropsy revealed a toxic encephalopathy with nerve-cell degeneration and haemorrhages.

The case reported here was treated with orthodox doses of sodium salicylate and developed an encephalopathy, from which the patient nearly died.

Case Report

A labourer aged 20 was admitted to hospital on February 25, 1954, under Dr. Kenneth Harris. He had had scarlet fever and rheumatic fever at the age of 12. He had not been feeling well for a fortnight, and for the past week had had pain, swelling, and stiffness of both knees and ankles. He was febrile (temperature 101.4° F.: 38.6° C.), and his pulse was dicrotic (100 a minute). He was flushed and looked ill. Both knees and ankles were swollen and

extremely tender, and there was a small effusion in the right knee-joint; movements of these joints and of the hips were limited by pain. The heart was moderately enlarged, with a thrusting impulse 11 cm. from the midline in the left fifth intercostal space. At the apex there was a loud systolic murmur and thrill, faint third heart sound, and soft, short, variable mid-diastolic murmur; a moderately accentuated pulmonary second sound was heard, but no basal murmur. The other systems were normal. The urine contained no sugar or albumin.

Blood count: Hb, 84% (Haldane); white cells, 10,600 per c.mm. (normal differential); E.S.R., 54 mm. in one hour. Throat swab: no *Streptococcus haemolyticus* grown. Anti-streptolysin O titre, 500 units per ml. Chest radiograph showed moderate cardiac enlargement. E.C.G.: P-R interval 0.24 second; left axis deviation. A diagnosis was made of recurrent acute rheumatism with carditis in a case of chronic rheumatic heart disease with mitral incompetence.

Treatment was started on admission with sodium salicylate (10 g. a day) without bicarbonate. The fever and arthritis subsided in 48 hours. On March 3 the plasma salicylate level was 26.5 mg. per 100 ml. Next day the fever recurred (temperature 100.2° F.: 37.9° C.) and he complained of precordial pain. A widespread pericardial friction rub was heard. The E.S.R. was 58 mm. in one hour. On March 5 the dose of sodium salicylate was increased to 12 g. a day; the chest pain, fever, and pericardial friction rub rapidly disappeared. On the 10th the plasma salicylate level was 26 mg. per 100 ml. On March 14 his respirations were noticed to be very deep. Next day his condition was unchanged on awakening; hyperpnoea was still present. At 10.45 a.m., almost immediately after an uneventful venepuncture, he groaned and became unconscious, with extensor spasm of arms, legs, and back. At this time, pulse and heart sounds were undetectable, respirations had ceased, and he became cyanosed. The pulse returned abruptly after approximately one minute. He was given intravenous nikethamide, and oxygen by B.L.B. mask. He started to breathe again, irregularly at first, and then very deeply and noisily.

At this stage his limbs were flaccid and he had very weak reflexes and absent plantar responses. He then started to have frequent tonic extensor spasms of all four limbs, accompanied by trismus and opisthotonos; between the spasms there was general muscular flaccidity. They continued for over an hour.

Intravenous calcium gluconate (10 ml. 10%) and mephene-sin (1 g.) were without effect, as was 7 ml. of intramuscular paraldehyde. Anaesthesia was then induced by Dr. R. Molloy with thiopentone (0.5 g.) and gallamine triethiodide (8 mg.), and the tonic spasms ceased immediately. Controlled respiration was maintained by the anaesthetist. Lumbar puncture was performed; the C.S.F. pressure was more than 300 mm.; the fluid was clear and colourless, and the chemical and cytological findings were normal. The temperature was 100.2° F. (37.9° C.). At 12.30 p.m. the plasma salicylate level was 50 mg. per 100 ml., plasma CO₂ content 18.1 mEq/l., plasma chloride 111 mEq/l., prothrombin concentration 31%. The E.C.G. was normal (P-R interval, 0.18 second).

He gradually recovered consciousness and had no further spasms. An intravenous drip was started and 750 ml. of 5% sodium bicarbonate solution and 570 ml. of M/6 sodium lactate were administered. On March 16 he was conscious and alert, and hyperpnoea was less marked. Sodium bicarbonate was given freely by mouth. The plasma salicylate was 23.5 mg. per 100 ml., the plasma CO₂ content 27 mEq/l., the plasma chloride 105 mEq/l., the prothrombin concentration 51%. Clinical examination revealed no abnormality in the central nervous system. A lumbar puncture on March 19 showed the C.S.F. to be under normal pressure.

The patient was subsequently treated with corticotrophin, and ultimately, after a prolonged course with recurrent fever, chest pain, pericardial effusion, and erythema marginatum, all evidence of rheumatic activity disappeared. Cortico-

trophin therapy was supplemented with small doses of calcium aspirin; the plasma salicylate never rose above 11 mg. per 100 ml. and there were no ill effects.

Discussion

Central nervous symptoms occurring in the course of acute rheumatism treated by salicylates may be due to the disease or to the treatment, and in many of the reported cases it is difficult to be certain which was responsible. Cerebral manifestations of acute rheumatism at the present time appear to be exceedingly rare, and standard textbooks scarcely mention them, but it seems that they are usually associated with rheumatic hyperpyrexia. Southey *et al.* (1982), writing shortly after the introduction of salicylates, which were given to only a few of their cases, discuss in detail the features of hyperpyrexial acute rheumatism. Delirium was almost always present and sometimes preceded the onset of hyperpyrexia. Among other nervous symptoms noted were restlessness, insomnia, coma, tonic spasms, risus sardonicus, convulsions, etc.; but these occurred in relatively few cases, and clearly were not essential or even common features of this complication of acute rheumatism. Cruickshank (1951) reported a case of acute rheumatism in which the rectal temperature rose to 110° F. (43.3° C.), and the sequence of events included rhythmic twitching of the limbs, generalized clonic movements, intermittent tonic spasms with arching of the back, and coma with flaccid limbs and areflexia between spasms; the patient recovered but was left with temporary cerebellar signs. This patient had been treated with 16 g. of sodium salicylate daily (with alkali) for three days, and on the fourth morning complained of buzzing in the ears and a black cloud in front of the eyes. It is at least possible that the encephalopathy was due to sodium salicylate.

Though our patient had some features—namely, coma, and tonic extensor spasms with opisthotonos—in common with the descriptions quoted, he had no hyperpyrexia (temperature 100.2° F.: 37.9° C.), and the episode of encephalopathy was short-lived. After recovery from the general anaesthetic, about six hours after the onset of the encephalopathy, he had no further spasms or any other evidence of central nervous excitation. Though cardiac arrest continued for approximately one minute, the clinical picture was not that of a Stokes-Adams attack.

It seems almost certain, therefore, that the episode was one of salicylate poisoning. This is supported by the fact that it was preceded by marked hyperpnoea, and that recovery was associated with a fall in the plasma salicylate level from 50 to 23.5 mg. per 100 ml.

It seems likely that the nervous symptoms and signs in this case were due to a direct cerebral and spinal excitation. The alkalosis was only moderate (plasma CO₂ content 18.1 mEq/l.), though unfortunately no pH measurements were made. Petechial haemorrhages have been observed in the brains of fatal cases of salicylate poisoning; these may be due to a direct action on the capillary endothelium or the hypoprothrombinaemia. In this case the "prothrombin" concentration (by the one-stage method) was reduced to only 31%, and the rapid clinical recovery is perhaps against a haemorrhagic cause. The raised C.S.F. pressure suggests that cerebral oedema may have been present.

Large doses of salicylates are commonly recommended in the treatment of acute rheumatism, and plasma salicylate levels of 35 mg. per 100 ml. or more are advocated (Coburn, 1943; Taran and Jacobs, 1945). Illingworth and his colleagues (Illingworth *et al.*, 1954; Holt *et al.*, 1954) aimed at serum salicylate levels between 30 and 40 mg. per 100 ml.; though this appears to be effective, these authors express uncertainty whether such high dosage is essential. Unless it is shown that cortisone or corticotrophin alone produce better results, it is likely that salicylates will continue to be used for the treatment of acute rheumatism and that large doses will be given. Holt (1954) and Reid (1948) have discussed some of the difficulties involved in maintaining

AN EVALUATION OF THE MICROSPECTROGRAPHIC DIAGNOSIS OF APLASTIC ANAEMIA

BY

K. W. KEOHANE, B.Sc.

AND

W. K. METCALF, M.B., B.S.

Department of Anatomy, University of Bristol

Our attention has recently been drawn to a paper by Kobayashi and Watanabe (1955) describing differences in the spectroscopic absorption curves of the haemoglobin in individual erythrocytes of leukaemia and aplastic anaemia. They suggest that their technique may be of some help in the differential diagnosis of these two conditions. We have in this laboratory some experience of cytospectrophotometry and its attendant errors, and we consider that the absorption curves published by them show enough inaccuracies to invalidate their conclusions. As the medical treatment of these two conditions may be diametrically opposite, we felt that it was essential to publish, as soon as possible, preliminary results confirming our doubts about the value of this method of diagnosis.

Absorption Curves of Red Cells

Fig. 1 shows the absorption curves of normal red cells redrawn from the paper by Kobayashi and Watanabe. A close examination of these curves reveals considerable inaccuracies. We have regularly plotted absorption spectra (4,000–7,000 Å) from small areas of individual red cells, both normal and abnormal, from various mammalian species (man, rat, guinea-pig, camel), and have always obtained curves having their maxima at identical wavelengths (4,150 Å, 5,420 Å, and 5,750 Å) (Keohane and Metcalf, 1956). These agree with the figures obtained by us and by many others for solutions of haemoglobin (Sidwell *et al.*, 1938; Jope, 1949). The differences in the chemistry of haemoglobins of different species are differences in the globin part of the molecule, and do not affect the visible absorption spectrum, which is entirely due to the haem radical.

Many early workers in this field found it difficult to obtain the 4,150 Å (Soret) absorption with intact erythrocytes (Adams, 1938; Keilin and Hartree, 1941), and others obtained inaccurate maxima for the 5,420 Å and 5,750 Å absorption (Cordier and Coudier, 1950). These errors have been shown to be due to scatter in the apparatus (Jope, 1949; Keohane and Metcalf, 1956). Elimination of this scatter corrects the error and improves the consistency of the curves. As the wavelengths of the absorption maxima of haemoglobin are constant it can be assumed that the peaks demonstrated above 4,500 Å in Fig. 1 are simply fluctuations due to experimental error and give a measure of the accuracy of the method. Other workers have failed to demonstrate the α and β (5,420 and 5,750 Å) absorption of intracellular haemoglobin (Jope, 1949; Metcalf, 1951). This is not surprising, as the percentage absorption of light at this wavelength is of the same order as the accuracy of photometric photometry (~10%). We have adopted a photometric technique in order to be able to obtain the α and β absorption maxima consistently and accurately in individual cells (Keohane and Metcalf, 1956).

The type II curve of Kobayashi and Watanabe (Fig. 2) shows decreased absorption in the Soret region but considerable absorption in the 4,500–5,000 Å region, a wavelength band in which haemoglobin should have no absorption. This spurious absorption is easily produced by using

steady blood levels, and it appears to be inevitable that in some patients the plasma salicylate level will rise dangerously; weekly estimations are no guarantee that this will not occur.

Previous reports state, and experience with this case confirms, that marked hyperpnoea should be taken as a warning of impending dangerous toxic reactions; it should be an indication for a reduction in dose. The plasma level is not an absolute guide, as it is evident that the toxic level varies greatly from patient to patient. Graham and Parker (1948) have found that severe drowsiness and excitement commonly appear at levels of 35 to 55 mg. per 100 ml. Intravenous salicylate administration to patients with carbon dioxide retention and respiratory acidosis has been shown (Wégria *et al.*, 1955) to reduce the arterial pCO₂, and has been suggested as a possible method of treatment of such cases: the use of salicylate-induced hyperpnoea in this way would seem to be dangerous, as the blood levels which may be required or involuntarily achieved to produce a therapeutic effect differ little from those which in some subjects are dangerously toxic.

In treatment of established salicylate encephalopathy, general anaesthesia, with the use of a relaxant and controlled respiration, may be necessary, and was effective in the above case in arresting the tonic spasms; elimination of salicylate in the urine may be encouraged by the administration of intravenous sodium bicarbonate. Bicarbonate was formerly recommended to combat the supposed acidosis, but its main action is to promote renal excretion of salicylate (Parker, 1948; Reid, 1948). It may, however, cause a further rise in pH (Rapoport and Guest, 1945); but, theoretically, inhalation of high CO₂ gas mixtures might be expected to correct the metabolic disturbance. A high rate of urine formation should be maintained by an adequate fluid intake (either intravenous or oral).

Summary

A case of acute rheumatism, complicated by encephalopathy attributed to sodium salicylate therapy in ordinary dosage, and associated with a plasma salicylate level of 50 mg. per 100 ml., is described.

Hyperpnoea should be taken as a warning sign of impending dangerous toxic effects of salicylate therapy.

Encephalopathy occurring in these circumstances can be treated successfully by general anaesthesia, with the use of a relaxant and controlled respiration, intravenous administration of sodium bicarbonate, and the maintenance of a high fluid intake.

a mountant which mismatches the refractive index of the cell, with consequent loss of light by refraction. Decreased absorption at 4,150 Å is frequently due to focusing errors, as even apochromatic objectives show appreciable change of focus with wavelength in the violet part of the spectrum.

Assuming that the same apparatus has been used to produce Figs. 1 and 3, Type 3 curves cannot be true absorption curves.

FIG. 2.—Absorption curves of single R.B.C. (Type II). Ordinate: Optical density. Abscissa: Wavelength in $m\mu$. (After Kobayashi and Watanabe.)

the apparatus. Experiments which we have performed (unpublished), with a view to discovering the limitations of refracting microscopes in microspectrophotometry, show that spurious "curves," with absence of peaks and changes in absorption intensities, can be obtained by varying the condenser aperture and the wavelength at which the microscope is focused. As a result of these findings the earlier work of one of us (W. K. M.) was not extended.

FIG. 3.—Absorption curves of single R.B.C. (Type III). Ordinate: Optical density. Abscissa: Wavelength in $m\mu$. (After Kobayashi and Watanabe.)

The Soret absorption band of individual red cells can be demonstrated very simply by illuminating the microscope with monochromatic light derived from a mercury arc with filters or from a monochromator (Huggins, 1865; Wilkins and De Carvalho, 1953). The intense absorption of the haemoglobin in the cells in the violet region can be clearly seen. This absorption falls away very rapidly in the blue and green. We have examined smears of red blood cells in this way from a wide variety of haematological diseases (including myeloid leukaemia and aplastic anaemia), and in no case was the Soret band absent, although the absorption is somewhat diminished in hypochromic anaemia owing to the well-recognized diminution in the intracellular haemoglobin concentration in this disease.

This simple experiment is sufficient to show that the Soret band is present in these haematological diseases, and a more formal microspectrophotographic analysis will be published in due course.

Summary

Accurate absorption measurements have shown that intracellular and extracellular haemoglobin have identical absorption maxima at all wavelengths in the visible spectrum. Observations of erythrocytes in monochromatic violet light confirm the presence in them of the Soret absorption band in a number of haematological disorders, including aplastic anaemia.

The differences in absorption between "leukaemic" and "aplastic" red cells described by Kobayashi and Watanabe are, we believe, due to experimental errors in their technique.

The Department of Scientific and Industrial Research is to replace the present Fuel Research Station at Greenwich by a new research station at Stevenage. Work has already begun on the new station, the estimated cost being about £750,000. The station should be completed early in 1959. Among the work to be transferred to Stevenage is that on atmospheric pollution and its prevention. It is hoped to provide a fuller scientific service in this field for the Ministry of Housing and Local Government, to assist it in making the administrative decisions necessary under the Clean Air Act regulations.

CLINICAL ASSESSMENT OF HAEMOGLOBIN CONCENTRATION

BY

Some assessment of the patient with regard to the presence or absence of anaemia forms part of every general clinical examination. This may be done by inspection of the conjunctivae, palm creases, oral mucosae, and nail-beds, for the normal pink coloration. Generally a very rough assessment is made into "normal" and "pale," and, if the latter is found, the haemoglobin is more accurately determined. If the patient is thought not to be anaemic it may be thought unnecessary to pursue the evaluation of the haemoglobin by a more accurate method.

The purpose of the present investigation was to determine with what accuracy a haemoglobin percentage could be predicted by clinical examination alone. The investigation was also designed to determine whether inspection of the conjunctivae was more or less accurate than inspection of the palm creases, and whether an overall opinion, which took into account the appearance of the patient as well as the colour of the conjunctivae and palms, was more or less accurate than any individual form of assessment.

Material and Method

Two hundred consecutive new patients attending an outpatient clinic for blood diseases were used for the investigation. The selection for this clinic was made almost entirely by the general practitioners who refer the patients, and only a few patients were referred by other clinicians in the hospital.

The patients were seen independently by two of us (A. S. D. and S. G. M.). An initial assessment of facial colour was

recorded as either normal or pale. The conjunctivae were inspected before the palm creases in the first 100 consecutive patients (C₁ series), and vice versa for the second 100 patients (P₁ series). An estimate of the haemoglobin level in multiples of 5% was recorded in each instance. The palm creases were inspected with the hand held at heart level, and the skin of the palm stretched so that the creases were opened. A final assessment was then made, taking into account the two recorded figures and the skin colour, and a percentage again recorded. These results were compared with the figure obtained by estimation of the haemoglobin concentration in an EEL photoelectric colorimeter, calibrated so that 100% was equal to 14.8 g. of haemoglobin per 100 ml. The accuracy of the colorimeter was checked regularly, using a standard sample of blood of known haemoglobin concentration provided by Messrs. Keeler, Ltd. In most instances capillary blood from a finger-prick was used, but occasionally heparinized venous blood when venepuncture was required for some other reason.

Results

For the purpose of expressing results it was decided that 80% should be taken as a critical figure. This figure was chosen because it was thought that an estimate below 80% would usually be checked by more detailed blood examination and any discrepancy between the estimate and the true figure thus be corrected. If the estimate was below 80% and the true figure above 80%, the error was not important, as it would soon be detected. On the other hand, if the estimate was above 80% and the true figure below it, then the error was serious for obvious reasons.

If there were no errors in the conjunctival (C) or in the palm-crease (P) estimates, the relationship between C, P, and the "true" value (T) would be C=T and P=T. The results in each series, however, show that the coefficients of C and P in the regression equations of T on C and of T on P are significantly different from 1. At the lower end of the scale the conjunctival and palm-crease values underestimate the true value—for example, clinical estimation =40%; true value=47%—and at the upper end the clinical assessment overestimates on the true value—for example, clinical estimation=100%; true value=91%. The regression equation determines mean values of T for given values of C or P, but by the use of the standard error of estimate it is possible to calculate, for a given value of C or P, the probability that an individual patient will have a value of T equal to or less than 80%, as shown in Table I (A. S. D.'s results). Thus, if the conjunctival estimate of an individual patient in the C₁ series is C=50%, there is a probability of 0.99 that T is equal to or less than 80%. This means that on the average 99 patients in every 100 will have a true value of haemoglobin less than or equal to

TABLE I.—Probability of a Haemoglobin Estimate within the Range 30–110% being Equal to or Less than a "True" Value of 80%. Estimates were made after Inspection of the Conjunctivae (C) and Palm Crease (P). The Regression Equation for each Series is also Given (see text)

C₁ Series = 100 patients in whom conjunctival estimate was made before palm-crease estimate. P₁ Series = 100 patients in whom palm-crease estimate was made before conjunctival estimate. C = Conjunctival estimate of Hb%. P = Palm estimate of Hb%. A = Final assessment of Hb%. T = "True" value of Hb%.

80%. In the same series, for an assessment of 60% there would be on the average 95% of patients with a true value of haemoglobin less than or equal to 80%. At the other end of the scale, if $C=110\%$ there would be on the average only 4 to 5% of patients with a true haemoglobin less than or equal to 80%. The results in Table I which occur beneath the heavy line drawn at 80% indicate the liability to serious error in each series of estimations.

In this paper only the results of one observer (A. S. D.) have been given. We have felt justified in this, as the differences between the results of S. G. M. and A. S. D. were surprisingly small, and the conclusions which we draw from this investigation are as true for the results of the one as for the other. The results of S. G. M. have therefore been omitted in order to simplify the paper.

Table II shows the correlation between skin colour and true haemoglobin percentage. The results illustrate the fallibility of the skin as an index of haemoglobin concentra-

TABLE II.—Distribution of Observations According to Skin Colour and "True" Haemoglobin Percentage

	Skin Normal	Skin Pale	Total
True Hb > 80%	72	34	106
" Hb < 80%	28	66	94
Total	100	100	200

tion. Twenty-eight per cent. of patients with a normal skin colour had haemoglobin values less than 80%, while 34% of patients with pale faces had, in fact, a haemoglobin of 80% or more.

Discussion

It is valuable to know the limitations of the clinical and laboratory techniques used in everyday medical practice. Much has been written about the errors of laboratory methods, but less about the errors of clinical examination, largely because of the difficulties in equating a clinical sign with a suitable laboratory procedure. The present investigation has been concerned with the clinical assessment of haemoglobin concentration, and this is fortunately one of the few aspects of clinical examination which can readily be compared by a laboratory method.

There is an unpredictable personal factor in the determination of many physical signs. In the present investigation it was surprising to find so close an agreement between the results obtained by two observers independently. One of us tended to estimate slightly higher than the other at certain times, but there was no statistical difference between the regression coefficients in any of the series.

The most accurate clinical assessment of haemoglobin percentage was made by inspection of the conjunctivae in the series of 100 patients in whom the conjunctivae were inspected before the palmar creases (C_1 series). The final assessment in this series, which took into account the palmar creases and facial colour as well as the conjunctivae, was almost identical with the conjunctival assessment alone, so that it would appear that inspection of the palmar creases and skin colour has nothing to add to the accuracy of conjunctival inspection. In an occasional patient chronic conjunctivitis has led to an erroneously high haemoglobin assessment being made, and this assessment has been corrected by inspection of the palmar creases. Conversely, interpretation of the palmar creases was difficult in many patients. The palm crease was found not infrequently to have a brown pigmentation, which made estimation of the haemoglobin unreliable. This was particularly common amongst housewives, possibly as a consequence of the use of washing soda and detergents. Thickening and hardening of the skin of the palm from manual work also produced a similar problem.

Wintrobe (1950) has stated, and Silverman (1954) has confirmed, that a colourless palm crease is indicative of a haemoglobin of under 50%. We have also found this to be

true. At levels between 55 and 75% we found that the palm creases often had lost the normal bright red colour and were instead a brownish red.

The results which we have obtained, and which are set out in Table I, show the liability to "serious error" as previously defined and the degree of accuracy of estimates from 30 to 80%. Serious errors were fewer with conjunctival estimates than with palm-crease estimates in both the C_1 and P_1 series. It can be seen from Table I that for conjunctival estimates of 90% haemoglobin on the average 29-36% of patients had, in fact, a true haemoglobin value equal to or less than 80%—that is, the liability to serious error was 29-36%. The figures for estimates of 100% and 110% haemoglobin in the same series were 12-15% and 4-5% respectively. Compared with these results the estimates for the lower haemoglobin estimations were much more favourable. With the same series as before, for an estimated haemoglobin value of 60% there were, on the average, 94-95% of patients with a true haemoglobin value equal to or less than 80%. Corresponding figures for estimates of 50% and 40% haemoglobin were 98-99% and 99% respectively.

It is concluded from these results that the clinical assessment of anaemia is a reasonably accurate procedure when estimates of haemoglobin are of 60% or below, but that it is unreliable when the haemoglobin is estimated as above 60%, and a more accurate method of haemoglobin evaluation is then required for the diagnosis of anaemia.

Summary

An investigation was carried out on 200 out-patients attending a haematological clinic to determine the value of a clinical assessment of haemoglobin concentration.

Estimations of haemoglobin were made independently by two observers after inspection of the conjunctivae and palmar creases. The facial colour was also recorded as normal or pale. A final assessment was made, utilizing these three results. The figures recorded by the two observers showed close agreement.

The estimates were compared with readings obtained by measuring haemoglobin concentration in a photo-electric colorimeter, and showed that the liability to error was small with clinical estimates of haemoglobin at 50% or less, that at 60% the error was appreciable, and that above 60% estimates were so often erroneous that they could not be relied upon in the diagnosis of anaemia.

It was also concluded that, with few exceptions, conjunctival inspection gave a more reliable estimate of haemoglobin than inspection of the palmar creases.

We wish to thank Professor L. J. Davis for permission to publish this paper and for his helpful criticism. Part of the expenses for this work was borne by the Rankin Fund of the University of Glasgow.

Wintrobe, M. M. (1950). In *Principles of Internal Medicine*, edited by T. R. Harrison. Blakiston Company, New York and Toronto.

The quality of the milk analysed during the second quarter of 1957 is discussed in the latest report of the Birmingham city analyst. The average composition of the milk submitted for analysis—8.79% solids-not-fat, and 3.48% fat, a total of 12.27% solids—was stated as being exceptionally high for the time of year, and an improvement on the two previous years. Of the samples analysed 88 did not conform to the required standards: 16 were deficient in solids-not-fat, 69 in fat, and 3 in both constituents. The preponderance of samples low in fat content over those deficient in non-fatty solids was thought to be connected with the change from winter stall-feeding to spring pasturing.

Medical Memorandum

Marasmus Resulting from Gastro-intestinal Allergy

Allergy to cow's milk has been held accountable for a multitude of gastro-intestinal symptoms in infants. Vomiting, colic, diarrhoea, melaena, and constipation have all been reported in various patients (Collins-Williams, 1956). In most of these cases, however, the infants do well in that they gain weight in spite of their symptoms (Nelson, 1954). The following case of gastro-intestinal allergy to cow's milk is thus particularly interesting in that the symptoms were so severe that the presenting picture was one of marasmus.

CASE REPORT

An 8-weeks-old white male infant was admitted to hospital on November 20, 1956, because of protracted vomiting, dehydration, and failure to thrive. The mother's pregnancy, her second, was uneventful, as was the delivery. The infant, whose birth weight was 7 lb. 2 oz. (3,230 g.), did well during his first week of life and was discharged at 1 week of age, having recovered his birth weight. He was fed "Baker's modified milk" (skimmed cow's milk with coconut oil, destearinated beef fat, and vitamins A, C, D, and B).

When 2½ weeks old the infant developed intermittent vomiting, which gradually increased in severity and frequency. On arrival in England from the U.S.A. he was put on a proprietary milk in varying concentration, without effect. Vomiting was occasionally projectile but never bile-stained, and occurred any time from one minute to half an hour after the feed. At the time of admission to hospital he had been vomiting after every feed. There had apparently been neither diarrhoea nor constipation.

Hay-fever was noted on the maternal side of the family. Otherwise the family history was non-contributory.

On examination he was a severely malnourished, dehydrated, but active infant weighing 5 lb. 10 oz. (2,550 g.)—that is, 1 lb. 6 oz. (682 g.) less than birth weight. The anterior fontanelle was depressed. Skin elasticity was diminished. The head circumference was 13 in. (33 cm.), the chest circumference 12½ in. (31.7 cm.). There was no neck stiffness. Fundi were normal. Eyes, ears, nose, throat, chest, abdomen, and extremities were otherwise normal. The liver and spleen were not enlarged on physical examination. No pyloric tumour was palpated, nor were peristaltic waves seen.

Laboratory Investigations.—Hb, 12.2 g./100 ml.; R.B.C., 4,900,000; W.B.C., 7,700 (37% polymorphonuclear leucocytes, 61% lymphocytes, 2% eosinophils). Urine negative; repeated urines were negative for reducing substances. Nose and throat culture revealed normal flora. Blood culture yielded no growth. Blood urea nitrogen, 16 mg. per 100 ml. Blood sodium, 139 mEq/l. Blood potassium, 4.5 mEq/l. Spinal fluid: clear, under normal pressure; sterile; no cells seen; protein, 25 mg. per 100 ml.; sugar, 117 mg. per 100 ml. (slightly high in our laboratory); Pandy test negative; culture sterile. Subdural taps yielded no fluid on either side. Stools: repeated cultures for enteric pathogens were negative; ova and parasites were not seen; tryptic activity of stool positive 1:300. Chest x-ray films were within normal limits.

In hospital the child was fed initially on an evaporated milk formula which he took eagerly but vomited almost immediately. X-ray and fluoroscopic examination of the upper gastro-intestinal tract showed no abnormality of the oesophagus or stomach, the barium passing readily through the pylorus to the duodenum.

Because of the child's severe debility and dehydration, plus an apparent inability to retain feeds, a small blood transfusion was given followed by maintenance on intra-

venous water, glucose, and electrolytes. That evening another feed of evaporated milk was offered and taken, but again vomited. This time, however, in addition to vomiting the child also developed a watery diarrhoea. Repeated routine stool cultures were negative for enteric pathogens.* The child was maintained on intravenous fluids and starved for the next 96 hours until the diarrhoea subsided. Then oral feeds of glucose water were offered and retained without diarrhoea. Parenteral fluids were discontinued. The child was then offered "mullsoy" (a hypo-allergenic soya food). This was taken and well tolerated with neither vomiting nor diarrhoea. In the course of the next two weeks the concentration was gradually increased. The infant did well and gained weight. Strained solid foods were offered, one at a time, and well tolerated. By December 18 (the 28th hospital day) his weight had increased to 8 lb. 2 oz. (3,685 g.), and he was taking lamb, rice cereal, apple sauce, iron drops, and vitamin drops, in addition to mullsoy. He was then discharged, and the mother was instructed to adhere precisely to the above diet.

The infant continued to do well and gain weight. After he had been at home one month he was offered a bottle of evaporated milk formula (one part milk to two parts water). This was promptly vomited. He was therefore maintained on mullsoy, which he continued to tolerate, and on which he returned to the U.S.A. The mother has since written to say that her local physician again tried to substitute cow's milk, and that the symptoms of vomiting once again recurred, necessitating a return to mullsoy. The infant was 5 months old at that time, weighed 12 lb. (5,443 g.), was otherwise completely well, and had no other allergic manifestations.

COMMENT

The diagnosis of milk allergy is substantiated in this case by the appearance of vomiting with the use of cow's milk, the inability to demonstrate other causes for the vomiting, the disappearance of the symptoms with the elimination of the allergen, and the reappearance of the symptoms on two separate occasions following the reintroduction of cow's milk. These criteria are, after all, the basic ones for the establishment of the diagnosis. A family history of allergy, present in this case, is a useful but not essential adjunct in making the diagnosis. Eosinophils in the stools are a helpful indication of gastro-intestinal allergy as described by Rosenblum and Rosenblum (1952). Unfortunately this test was not carried out in this case, nor was it really needed to establish the diagnosis.

The reported frequency of allergy to cow's milk varies widely, owing, of course, to the different criteria for diagnosis. Clein (1951) states that roughly 7% of children have some degree of allergy to cow's milk. Collins-Williams (1956) places the total incidence at only 0.3%. In either case, however, various gastro-intestinal symptoms are important, and are frequently the only manifestation. Usually the symptoms are mild. Only rarely, as in the case described above, is the infant severely debilitated and marasmic.

Appreciation is expressed to Colonel Kenneth E. Pletcher, Commander of the 7505th U.S.A.F. Hospital, for his kindness in granting permission to submit this case report for publication.

PHILIP WARREN, M.D.,

Captain, U.S.A.F. (M.C.), 7505th U.S.A.F. Hospital,
Burdorpe, Swindon, Wiltshire.

*A superimposed gastro-enteritis cannot be ruled out by the laboratory studies that were conducted. Indeed, it is unlikely that the diarrhoea was an allergic manifestation, since it was never a part of the symptom-complex before admission nor did it recur subsequently.

Reviews

PLASTIC SURGERY

The Principles and Art of Plastic Surgery. By Sir Harold Gillies, C.B.E., F.R.C.S., and D. Ralph Millard, jun., M.D. Chapter on Anaesthesia by Ivan Magill, C.V.O., F.F.A.R.C.S. Foreword by Jerome Pierce Webster, M.D. Volumes I and II. (Vol. I—pp. 317+xxi; illustrated. Vol. II—pp. 320-652; illustrated. £12 10s. per set.) London: Butterworth and Co. Ltd. 1957.

It could have been expected that this work based on Gillies's lifetime of surgical and artistic experience would be something out of the ordinary. It might have been expected that it would fail to conform to any standardized pattern either in content or in presentation. These things would have been but a reflection of the character of the senior author and of the energy and the freshness of approach of his younger collaborator. What was not obvious was that this break with tradition (both on the part of the authors and of the publishers) would result in something which bids fair to become a masterpiece. Here in two volumes is an accurate and an informative history of the development of the specialty of plastic surgery written by the man who perhaps most of all has been responsible for its evolution from war to peace and through peace back to war. There are, of course, many who have contributed to the emergence of this type of surgery, and to them generous acknowledgment is made. Perhaps one of the most fitting of these consists in a chapter written by Magill, who led that band of anaesthetists whose increasing technical skill has pushed surgical boundaries ever farther afield. It is very fitting that such a book as this should contain so graceful an acknowledgment of the debt that surgeons everywhere owe to their anaesthetist colleagues.

The surgical part of the book opens with chapters on technical details which are fascinating as much to the experienced surgeon as to the student. From then onwards we are shown the application of the principles of repair surgery applied at a superlative level to almost every imaginable lesion of the body surface. The facility with which the result is achieved may well prove a deception to the beginner, but this is so whenever one sees the expert at work. The second volume continues through most of the congenital and acquired defects of the face and facial skeleton. Cosmetic procedures are discussed and described, so that all in all the book presents a cross-section of present-day reparative surgery. There may possibly be those who will find the presentation too far removed from the routine. Indeed it is—hardly a page without an illustration; some pages without a word, and few illustrations with a caption. After all, if an illustration cannot be self-explanatory either by itself or with its adjacent text it need not be there. The text itself is devoid of much of the jargon which has become inseparable from textbooks and its place is often taken by colloquialism. There is no massive bibliography, which is very often an indication of intense secretarial activity and of paucity of authoritative opinion.

Here is the expression of the skill and the personality of a surgeon as interpreted by himself and his enthusiastic co-author. Here is a plastic surgery in its "art and in its principles," and indeed it is a monument to its producers.

R. MOWLEM.

MAMMALIAN LIFE

The Life of Mammals. By J. Z. Young, M.A., F.R.S. (Pp. 820+xv; illustrated. 84s.) Oxford: Clarendon Press. London: Oxford University Press. 1957.

In these days, when most comprehensive works are the product of a team, or, more accurately, a collection of authors, it is refreshing to find that it is still possible for one person to produce a scholarly and interesting treatment of a broad subject. Starting from the viewpoint that the mammal is the

example *par excellence* of a homoeostatic mechanism in living organisms, Professor Young has produced an elementary treatise which yet succeeds in taking the reader right up to the boundaries of present-day knowledge in anatomy, physiology, histology, and embryology. All are aspects of structure and function within a single unity; the common feature which unites them is the fact that they are all concerned in achieving a dynamic stability of the organism in its changing environment—a stability which transcends the individual, since over the course of time it affects the race, the species, and its evolutionary history. The treatment of the subject is based on tissue and organ systems from the rabbit or man, but the author does not hesitate to quote examples from other mammals, and even from invertebrates where they best serve to illustrate his point. The reader will expect to find the nervous and endocrine systems treated at some length; almost a third of the book is concerned with these mechanisms for transmitting and dealing with biological information. Mammalian embryology is presented in a separate section against a background of comparative vertebrate embryology as an exercise in the analysis of mechanisms of development.

This is a book to be read—not a reference book—and this may account for, though it does not entirely excuse, its somewhat inadequate index and its sectionalized but useful bibliography of recent literature. It is unfortunately a heavy and expensive tome, but the medical student (of all ages) can be strongly recommended to buy it for the broad insight it will give him into the structure and workings of the organism which concerns him most.

J. E. HARRIS.

PAYMENT FOR MEDICAL CARE BY INSURANCE

Voluntary Health Insurance in Two Cities: A Survey of Subscriber-Households. By Odin W. Anderson, Ph.D., and the staff of the National Opinion Research Center, University of Chicago. (Pp. 145+xiii. 40s.) Cambridge, Mass.: Harvard University Press. London: Oxford University Press. 1957.

The United States is much concerned about the rising costs of medical care and of hospitals. The medical profession and many others resist stoutly any proposal to follow the British example, which they brush off with the contemptuous title of "socialized medicine." Instead they are pushing voluntary prepayment schemes in the hope that by this means the hospitals can be kept solvent and the present system of medical care can continue. The survey presented in this book is the first analysis that has been made of the extent to which those covered by voluntary insurance are helped to pay their hospital and other medical bills and the extent to which the insured are satisfied. The two cities were Birmingham, Alabama, and Boston, Massachusetts. The procedure was to question at their homes 2,893 persons covered by the Birmingham Blue Cross/Blue Shield Organization; 3,844 by the Massachusetts Hospital Service and the Massachusetts Medical Service, which sponsor a joint prepayment scheme; and 976 in the group insurance of Aetna of Boston, presumably a commercial insurance company. The Blue Cross covers hospital charges, and the Blue Shield charges made to the patient by the medical staff of hospitals.

It is pointed out that classical insurance against death, fire, or accident is against things which are not increased as a result of insurance, but that applications for medical care may be. The complexities of the system are revealed by the many detailed tables in the book. The percentages of the total gross charges incurred for all forms of medical and dental care met by insurance benefits varied from 3 to 41, with a general average between 20 and 31. However, the majority of the insured are completely satisfied with their coverage, though over 20% said that they would like additional cover, mainly a contribution towards the bills of doctors consulted in their "offices." But between a quarter and a half of those who wanted this extension were unwilling to pay any extra premium for it. There are many

exclusions in the standard contract, such as diagnostic outpatient services; payment for illnesses developing before the waiting period has expired; and the exhaustion of benefit after a specified number of days of hospital care or because the doctor's bills exceed the amount specified in the contract. In order to provide a benefit of 80% of the charges for hospital care the premiums would need to be raised by 14% in Birmingham, by 19% in Boston, and by 9% for those insured by Aetna. To cover 80% of the bills for surgery the premium increases needed would be: Birmingham, 61%; Boston, 15%; and Aetna, 24%. The book does not, however, give precise figures of what the premiums actually are, nor their proportions to the mean income of the families. In the different groups the gross bills to be met per family during the survey year varied from \$76 to \$92 for hospital charges, surgeons' bills, and obstetrics, but for the complete range of medical care, including family doctor, drugs, and dentistry, it was from \$220 to \$262 for the year. This is before the receipt of benefits under the insurance scheme. Abuse of the scheme is not regarded as serious, but it is doubtful whether all downright forms of abuse can ever be entirely eliminated.

This book will be read with profit by all who are interested in the various ways of paying for medical care, especially by those who think that a change to prepayment voluntary insurance would be preferable to the present British system.

ALLEN DALEY.

THE LEUKAEMIAS

The Leukemias: Etiology, Pathophysiology, and Treatment. Edited by John W. Rebuck, Frank H. Bethell, and Raymond W. Monto. (Pp. 711; illustrated. \$13.) New York: Academic Press Inc. London: Academic Books Ltd. 1957.

This book is the record of a symposium which was held at the Henry Ford Hospital, Detroit, in March, 1956, with an attendance of some 450. It is more readable than most reports of symposia, as it consists of a series of grouped short papers with abstracts of the comments on them. The chief heads of discussion were the structure of the leukaemic cell, the aetiology and transmission of leukaemia, the radiation biology of leucocytes, the classification of leukaemia and the lymphomas, the physiology of the leucocytes, and the biochemical aspects of leukaemia and their therapeutic applications. The book gives an excellent picture of the present position of research on the leukaemias. Special points which might be picked out are, first, the recent evidence that leukaemia may be transmissible by a virus in mammals as well as in birds. This is probably of less practical importance than the discovery that leukaemia can be induced by ionizing radiations, in mice and men, and that x-radiation offers one of the most promising tools for the investigation of leukaemia. This is still news, and Jacob Furth makes the point that the full story cannot be told until the final mortality statistics are available of this present generation which has been exposed to radiation in diagnosis, in treatment, and in war. Finally, it is noteworthy that half the book is devoted to biochemical studies of leukaemia and chemotherapy. Indeed, one of the impressions one had at the conference itself was that it was largely an audience of chemists. Neoplasia depends on the synthesis of nucleic acids and proteins, and it is here that the chemist hopes to find weak points in the armour of the leukaemic cell. The book is beautifully though expensively produced, and the editors are to be congratulated on the speed and skill with which they have completed their task.

L. J. WITTS.

VIRUS RESEARCH

Advances in Virus Research. Edited by Kenneth M. Smith and Max A. Lauffer. Volume IV. (Pp. 339+ix; illustrated. \$8.) London: Academic Books Ltd. 1957.

This is the fourth volume of an annual review on advances in virus research. The first essay, by C. H. Andrewes, entitled "Factors in Virus Evolution," emphasizes the part played

by transmission of virus disease and antigenic variations as factors in virus evolution. Virus evolution is brought closer to the field of general biology. Another general article, that of A. Kleczkowski on "Effect of Non-ionising Radiation on Viruses," gives a comprehensive review of the effect of these radiations on plant, bacterial, and animal viruses. It describes clearly the physics of the subject. Two articles deal with bacterial viruses. The first, by A. D. Hershey, "Bacteriophages as Genetic and Biochemical Systems," is a masterly account of this difficult field, and ways are suggested of remedying the defects in our knowledge. Many virologists may find the phage model helpful in their own spheres. The second article, by L. J. Tolmach, on "Attachment and Penetration of Cells by Viruses," deals solely with bacterial viruses but gives a very full account of this phenomenon. Plant virology is allotted three articles. N. W. Pirie gives an up-to-date survey on "The Anatomy of Tobacco Mosaic Virus," while B. Kassanis in his "Effects of Changing Temperature on Plant Virus Diseases" deals mainly with the effect of incubation period, symptoms, and heat therapy. "Mechanical Transmission of Plant Viruses," by C. E. Yarwood, reviews methods of inoculation and the effects on them of environment, host and donor plants, and various chemicals. A. Isaacs in his essay gives a concise and lucid account of measuring infectivity titres and total number of virus particles in a preparation; the relation between viable and total particle counts and the significance of filaments and incomplete virus are discussed. Finally K. E. Jensen's essay on "Serological Relation among Influenza Viruses" describes the antigens involved and the changes undergone by the dominant antigens in the last 25 years; the importance of these changes to vaccination is emphasized. This volume contains something of value for workers in all fields of virology.

P. S. GARDNER.

GREAT DOCTORS

Six Great Doctors: Harvey, Pasteur, Lister, Pavlov, Ross, Fleming. By J. G. Crowther. (Pp. 207. 10s. 6d.) London: Hamish Hamilton. 1957.

The title of this book almost challenges the reader. Which six doctors would you choose as exemplars? Would you select the six here written about—Harvey, Pasteur, Lister, Pavlov, Ronald Ross, and Alexander Fleming—or, if not, what changes would you make? Pasteur, of course, was not a doctor but a chemist, yet it is true to say (as is stated on the cover of the book) that he contributed more to medicine than any other man during the past hundred years. Surely that entitles him in the eyes of the world to an honorary and honourable medical degree in every university in the world. On the whole we think the chosen six would get most votes in a referendum. These short biographies, each about 30 pages in length, are obviously intended primarily for the general public, but they contain so much interesting matter and are so well written that they should find many readers among the medical and nursing professions. The little volume is of a handy size and would make an excellent bedside book for the weary doctor. We found only one misprint.

ZACHARY COPE.

Many books have been written for the instruction and guidance of the expectant mother, but few for the prospective father. In *Husbands, Wives and Pregnancy* (Darwen Finlayson, 54, Bloomsbury Street, London, W.C.1; 112 pages; 7s. 6d.) W. H. Genné provides a useful handbook for expectant and nursing fathers. He describes the early symptoms and signs of pregnancy, its hygiene and dangers, the comparative merits of hospital and domiciliary confinement, the mechanism of labour, and the postnatal care of wife and child; he also advises on the responsibilities of parenthood. A note on natural childbirth and some suggestions for further reading conclude this very practical guide for those who, either as "enthusiastic volunteers or reluctant conscripts," have joined the brigade of expectant fathers.

SATURDAY OCTOBER 26 1957

EXPERIMENTAL MUTATIONS IN PLANTS

The word mutation came into biological literature through its use by de Vries, of Amsterdam, about 60 years ago for abrupt inherited changes in an organism. He had observed such changes in the evening primrose and used the behaviour of this plant as the basis of a theory of evolution by mutation. Subsequent research has shown that the evening primrose is a curious kind of hybrid and that the mutations observed by de Vries were due to new combinations of genes rather than to changes in the genes themselves. The term mutation is now normally restricted to the latter phenomenon. The most characteristic feature of gene mutation is that the change is permanent, or in other words that the gene is inherited indefinitely in the changed form. A second feature is that mutations are usually of rare occurrence, the normal characteristic of genes being their great stability.

An outstanding development in the study of gene mutation was the discovery by Muller in 1927 that treatment with x rays much increased the frequency of mutation. It was subsequently found that mutations are induced by all types of ionizing radiations and also by ultra-violet light. With ionizing radiations such as x rays, the frequency of occurrence of mutations was linearly proportional to the dose in roentgen units and independent of other variables such as the wavelength of the radiation and the intensity of the dose (that is, the time of irradiation). Since roentgen units are measures of ionizations per given volume, it was suggested that mutation resulted from a single ionization event in the neighbourhood of the gene. Up to the time of the 1939-45 war hypotheses were favoured which attempted to explain mutation in such purely physical terms, although it was realized that the natural mutation rate of genes

was considerably greater than could be accounted for by natural sources of suitable radiation, such as radioactive materials and cosmic rays.

An important development in the study of mutation occurred during the war, when Charlotte Auerbach and J. M. Robson¹ at Edinburgh discovered that mustard-gas will cause mutation. It is now known that many substances can do so. They range from inorganic to complex organic compounds, and so their mechanism of action must be diverse. Purely physical theories of mutation suffered further setbacks with the discovery that the mutagenic effects of ionizing radiations were much influenced by the chemical environment, such as the oxygen concentration; at the time of treatment. Also it was found that irradiating the culture medium prior to inoculating with fungal or bacterial cells caused mutations. It is not surprising therefore that hypotheses are now favoured which attempt to explain mutation primarily in terms of the liberation of organic peroxides or other active substances in the neighbourhood of the gene.

There have been several outstanding recent developments in the study of mutation. M. Demerec^{2,3} and co-workers at the Carnegie Institution of Washington, New York, have made some remarkable discoveries with *Escherichia coli*. They have found that particular mutagens, whether chemical or physical, cause different mutation rates in specific genes over a wide range of frequencies. Thus, gene A was found to be particularly sensitive to manganous chloride, gene B to ultra-violet light, gene C to x rays, and so on. Indeed, some genes were found to be stable to some mutagens, or even to all the mutagens tested, although their capacity to mutate was evident, since they were observed to do so spontaneously. These findings were unexpected because it is known that the types of mutations caused by one mutagen are essentially similar to those caused by another. Demerec infers that at least the majority of these induced mutations arise through indirect action of the chemical or physical agent. The mutagen is thought to induce specific physiological changes in the treated cells, and these in turn to cause mutation of certain of the genes.

S. Benzer⁴ at Purdue University, Indiana, and G. Streisinger and N. C. Franklin⁵ at the California Institute of Technology have studied mutation in bacteriophages of *E. coli* and have obtained detailed information about the structure of particular genes. It appears that, just as in higher organisms genes are linearly arranged on the chromosomes, so in phage (and apparently in other organisms also) the gene itself is composed of linearly arranged units. Mutation of a particular gene results whenever a change occurs in any of its component units. Thus, if the

B.C.G. VACCINATION IN THE U.S.A.

The prevention of tuberculosis by B.C.G. vaccination is now an accepted public health measure in almost every country in the world. A striking exception is the United States of America, where B.C.G. has so far not been used on a national scale. This is surprising, for as long ago as 1949 the American Trudeau Society advocated the vaccination of contacts and others at special risk from tuberculosis; and the value of B.C.G. in such circumstances is also accepted by the United States Public Health Service. Medical opinion about B.C.G. may become more favourable in the U.S.A. now that a medical advisory committee has examined the validity of the objections raised to vaccination there.¹ Some of these objections are of long standing, and, although formerly advanced in other countries as well as the U.S.A., are now less seldom heard elsewhere. The committee, for example, examines and accepts the view that the safety of B.C.G. is undoubted. As to the efficacy of the vaccine, the committee's report discusses in some detail the early findings² of the Medical Research Council's clinical trial of tuberculosis vaccines at present being undertaken in this country, and conclude that the results "can leave no doubt in the mind of an unbiased observer that B.C.G. afforded a substantial protection against tuberculous disease." The contribution made to the prevention of tuberculosis by vaccination would in all likelihood more than compensate for the loss of the tuberculin test as a diagnostic measure.

Two less familiar objections to B.C.G. vaccination which have been heard only in recent years are also discussed by the committee. The first is that instead of vaccination chemotherapeutic drugs might be given to tuberculin-negative reactors as a precautionary measure. It is pointed out, however, that chemoprophylaxis is inferior to vaccination in that it does not raise immunity of itself, suppresses tubercle bacilli only during the period that the drug is being taken, is so far experimental, and requires continued co-operation from the patient for many years. For these reasons it seems unlikely that chemoprophylaxis could in the foreseeable future take the place of vaccination. The second recent objection to vaccination in the U.S.A.—that morbidity from tuberculosis is now so low that vaccination schemes are unnecessary—is one which is likely to be increasingly discussed in all countries as the mortality and incidence of tuberculosis

normal gene is represented by ABC . . . XYZ, one mutant might have b instead of B, another mutant of the same gene pqr instead of PQR, and so on. Some of the mutants are thought to be deletions of parts of the hereditary material, rather than substitutions.

Important contributions to the study of mutation have also been made with higher plants. In particular, Barbara McClintock, also working at the Carnegie Institution of Washington, New York, by a combined cytological and genetical study of maize, has revealed the existence of a mechanism for the biological control of the mutation rate of genes. That such biological control must exist has been known for some time, for mutation rate is known to be influenced by the genetic constitution of the organism, and in general to be adapted to the needs of the species. Thus mutation rates appear to be adapted to the generation time of the species, being lower per given time interval in long-lived organisms than in short. McClintock^{6,7} finds evidence that certain structures in the chromosomes, to which she gives the name "controlling elements," influence profoundly the rate of mutation of numerous genes. The best known of these controlling elements, "Dotted," can cause one of the genes for anthocyanin pigmentation to mutate with high frequency. There is reason to believe that the controlling elements are situated in specialized parts of the chromosomes which are composed of heterochromatin. Hitherto heterochromatin has usually been regarded as genetically inert, and its biological function has not been understood.

From these recent studies, which are probably of wide application, it is evident that mutation is not a simple process. The great stability of the hereditary material, manifest from Demerec's discovery of mutagen-stable genes, has probably been achieved through specific adaptations in cellular organization, such as McClintock's controlling elements, which protect the genes to greater or lesser degree from chemical and physical mutagens. In view of this complexity, it is not surprising that the use of mutagenic agents in plant breeding must be on a largely empirical basis at present. (It is for the same reason that the magnitude of the mutagenic effects of atomic radiations on man is still largely unpredictable.) S. Shapiro⁸ describes an experiment which is being conducted in the U.S.A. for the induction of mutations in plants by continual irradiation during growth by means of a cobalt-60 source. Although most mutations are harmful to the species, a small proportion may be desirable, and these can be selected by the plant breeder. The method has only recently been adopted, but shows promise of providing a valuable new source of hereditary variability in plants.

decline. However, 100,000 new cases of tuberculosis were notified in the United States in 1954. Tuberculosis thus remains a serious threat to health in America, and it seems likely that B.C.G. could make an effective contribution to its elimination. If mass vaccination schemes are to be introduced in at least some areas of the United States, there would remain the problem of the most suitable age to give the vaccine. In the clinical trial of B.C.G. at present being undertaken by the United States Public Health Service, most of the cases of tuberculosis have so far occurred in participants who were tuberculin-positive on entry to the trial and were thus ineligible for vaccination.³ In such circumstances vaccination at an earlier age would appear to be indicated. Similarly, a relatively high incidence of tuberculosis in children aged 14 years was observed in the M.R.C. investigation in Britain. Doubts about the duration of protection conferred by B.C.G. suggested that in Britain vaccination should be given at the age of 13 years, the usual age for general vaccination at the present time. M. I. Griffiths and W. Gaisford⁴ have, however, suggested vaccination at 10 years. This view is supported by a recent review of the question by T. M. Pollock,⁵ who concludes that the morbidity arising from infection sustained before 13 years in England and Wales is sufficiently high to warrant general vaccination at the earlier age. In the light of the variation in opinion about the most suitable age for vaccination in this country, any decisions made about the application of B.C.G. in America will be followed with especial interest here.

PROBLEMS OF ACNE

While acne vulgaris in adolescence may be regarded as a normal expression of the physiological developmental changes of puberty, it may get out of hand and be a source of distress, sometimes seriously disrupting the lives of young people. Though knowledge has steadily increased, much still remains obscure, and treatment, which should be essentially individual, can too easily become empirical, stereotyped, and ill-proportioned.

Certain facts are self-evident, such as the influence of heredity, of climate, and of diet. That hormonal influences are fundamental is clear from the age incidence of the disease and from study of the pubertal castrated subject and other experimental work. Matrimony is often a curative influence. The importance of the androgen-oestrogen balance has been recognized for some time; latterly it has become apparent that progesterone and the pituitary, with its gonadotropic hormones, must play a significant part. Comedo formation without accompanying seborrhoea may occur with corticotrophin therapy, and recently a "sebaceous-gland-stimulating hormone" has been isolated from the pituitary which does not provoke follicular hyperkera-

toxis or comedo formation. Probably there are independent effects on gland and follicle, though the changes are related and to some extent react one upon the other. Follicular keratosis and plugging in cases of deficiency disease, chronic lupus erythematosus, pityriasis rubra pilaris, and other follicular keratotic affections are not associated with acne. And acne cannot be wholly explained by infection of stagnant secretion behind a gland orifice blocked by a comedo. Why certain limited sites are affected in the acne process is not known. It is interesting that the skin of the axilla in the adult male is not provoked to clinical or histological change by strong hormonal influence consequent upon local implantation of androgenic or oestrogenic substances.¹ Though K. A. Baird claims² nearly 100% cure from the use of gonadotropic hormones, combined with anti-infective measures, endocrine therapy has been unfruitful in the hands of most dermatologists, even in heavy dosage. The artificial, often industrial, forms of acne may arise on any site of contact and are rather different in character. In cases of oil acne there is a much more intense cellular infiltration rather like the early stages of acne cheloid. G. W. Hambrick³ has shown that certain chlornaphthalenes stimulate keratinization and comedo formation while causing atrophy of sebaceous glands.

There is so much more in the aetiology of acne than hormonal influences that each serious case merits individual consideration. Local infection of the upper respiratory tract, indiscretions in diet, and hot and humid or greasy environmental conditions may call for attention. Emotional factors, however, in the adolescent are less easy to unravel, and they may sometimes play the most important part in aetiology. Infection of the skin is of importance, as in most seborrhoeic ills, but it is rather a change in the soil than in the organisms that is responsible, for the infective agents are normal residents of the skin surface and not transient or virulent visitors. In a large proportion of all types of acne, chemotherapeutic and antibiotic measures internally or locally produce notable but temporary amelioration. Some authorities give small doses of antibiotics over long periods to control acne, but the practice would seem open to serious objection. Others apply a blunderbuss local treatment with hormones and chemotherapeutic agents, sulphur, and resorcin. While extreme heat and humidity may aggravate acne, moderate exposure, sunlight, fresh air, and sea-bathing are beneficial. Most patients improve in the summer, so that ultra-violet-light therapy is sometimes favoured; the effects of it are due partly to exfoliation of the skin, with consequent removal of blackheads and drainage of glands, and partly to anti-infective influences. But this treatment too is apt to be of only temporary benefit, as are fractional doses of x-radiation, which reduce the activity of the glands and diminish the state of seborrhoea. Dermabrasion,⁴ the removal of the surface skin by rotating wire brushes, or stone or metal cylinders, is

practised in many centres. At first used for treatment of the scarring resulting from acne, it is now sometimes employed in the active stage, even when there are cystic abscesses.

Acne is not a specific disease due to any single cause. The understanding and co-operation of the patient are necessary for success, and no single regimen will serve all. Occasionally dangerous measures may be justified if used with care, but usually simple measures will serve if the approach has been on broad lines. Hereditary and naevoid features in the more severe examples of acne may defeat persistent treatment.

ACCIDENT AT WINDSCALE

The recent accident at the Windscale plant of the Atomic Energy Authority resulted in the distribution of radioactive fission products of uranium-235 over the surrounding Cumberland countryside. The principal contaminant was radioactive iodine. The melting and boiling points of iodine are low, 114° C. and 183° C. respectively, compared with those of other possible constituents such as radiostrontium (725° C. and 1,150° C.), and this probably accounts for the fact that the filters in the reactor chimney were unable to retain the iodine in gaseous form, whereas they were effective in stopping the solid particles of the other fission products. The uptake of the radioiodine by contaminated vegetation and pasture depends for the most part on the concentration of iodine in the soil, and is nearly independent of the form of vegetation. The amount of iodine in green foodstuffs ranges from 2 µg. per kilo to several hundred times that level. Radioiodine falling on the soil is incorporated in the greenstuff eaten by grazing animals. Iodine in inorganic form is quickly and completely absorbed by the small intestine at an exponential rate depending on the activity of the thyroid gland of the animal concerned. This iodide is removed from the blood stream by the thyroid at the rate of 2.5% per hour, by the muscle tissues at the rate of 1.5% per hour, and is excreted by the kidneys at the rate of 6% per hour.¹ Thyroglobulin, the thyroid storage protein, removes the iodide from the blood, which in addition to the ingested iodine from the food contains "break-down" iodide from the tissues and circulating "hormonal" iodine formed in the course of metabolism.

One of the consequences of the accident at Windscale, as we reported last week (p. 951), was a suspension of milk distribution from farms over a large area round the plant. The reason for this was that cows grazing the contaminated fields were giving milk containing six times the permissible concentration of radioiodine. The levels of iodine in cow's milk have been reported, but an average value is 3-7 µg./100 ml. This can be increased many times by the addition of iodine to the foodstuffs given, but the danger at Windscale would appear to result from the substitution by radioiodine of some of the iodine ordinarily present, rather than by a greatly

increased concentration of iodine in the milk. It has been reported that when iodine is added to the cow's diet the percentage recovered in the milk is low, and remains of the same magnitude irrespective of the concentration or form of intake.²

A cow in milk requires on an average 600 µg. of iodine daily, of which a small proportion would ordinarily be radioactive. This small proportion would be diluted still further by the existing iodine in the animal's body, and hence the milk derived from the animal would contain very little radioiodine. Whatever was present would be found almost entirely in the skimmed milk fraction and not in the fat portion of the milk.

The iodine requirements of an adult range from 60 to 120 µg. of iodine daily, and for a growing child from 30 to 50 µg. per day. On a normal diet the adult obtains iodine from fish, green vegetables, cereals, milk, meat, and root vegetables, but in practice vegetables and milk supply the greatest part. Growing children consume a greater proportion of milk in relation to other foods than adults, and therefore they would be in greater potential danger. It is for this reason that the milk supplies from the Windscale area have been so stringently examined.

The possible hazards to health depend mainly on four factors—the type and energy of the radiations emitted, the half-life of the radioiodine, its distribution in the tissues, and the rate at which it is excreted by normal persons. Radioiodine has a half-life of only 8.1 days, so that 100 units of activity will decay to 50 in eight days and to 25 in 16 days. The radiations emitted are fairly low-energy β and γ-rays, and these are thought to be less harmful when absorbed by ingestion than would be the case if the ingested substance was an α-ray emitter. Ingested radioiodine is absorbed selectively by the thyroid, but when thyroid activity is normal radioiodine will be "diluted" by inactive iodine from uncontaminated sources of food and by the iodine already present in the tissues. A dose comparable to the maximum dose likely to be received from the milk at Windscale, given experimentally, was excreted in the faeces (2%) and in the urine (65%) in two days in a normal individual.¹ The action taken by the authorities at Windscale is clearly designed to eliminate any possible danger to persons in the vicinity of the plant, including children who drink relatively large quantities of milk and persons with disease of the thyroid gland. Radioiodine is by no means the most dangerous isotope which could have been encountered after an accident in a reactor. Had strontium-90 been distributed in a comparable manner, the problem would have been enormously aggravated.

No exact figures about the amount of contamination at Windscale have yet been given, but doses of radioiodine of the order of 1,000 to 5,000 times the maximum amount likely to be consumed by drinking milk from cows in the contaminated area are given in hospitals for the diagnosis and treatment of diseases of the thyroid gland: it has been estimated that in order to ingest 1 ounce (28 grammes) of pure or carrier-free radioiodine from the Windscale milk it would be necessary to drink 800 million million pints of it.

EPIPHYSIAL BONE GROWTH

The growth of bone presents many interesting problems. These may puzzle the endocrinologist concerned with over-all body growth and maturity¹⁻³ or the orthopaedic surgeon concerned with a particular bone. For the surgeon, particularly, the need for a dependable clinical method of producing local acceleration or retardation of epiphysal growth makes the advancement of knowledge in this field a matter of importance. The general subject has recently been reviewed by H. A. Sissons,⁴ who has outlined developments particularly in the histology of endochondral ossification, and discussed the many factors—genetic, dietary, endocrine, vascular, and physical—known to affect the growth of bone. Most clinical abnormalities of epiphysal bone growth can be explained in terms of influences such as these, though several important conditions still elude adequate explanation; they include the retardation of epiphysal growth accompanying prolonged immobilization^{5,6} and the growth abnormality responsible for scoliosis.

The effects of compression forces on the growing epiphysal cartilage plate are of great interest,^{7,8} for compression is the method used at present to retard epiphysal growth in patients.⁹ The usual operative technique consists in the insertion of a number of steel staples across the edge of the epiphysal cartilage plate, thus rigidly uniting the epiphysis and diaphysis. Under these conditions the growth activity of the plate leads to its compression, and thus to cessation of growth. Reasonably precise prediction of the shortening to be expected in any particular case is possible,¹⁰ this depending on the growth rate of the epiphysis and the relative skeletal maturity, or "skeletal age," of the patient. An informative account of the structural changes in compressed epiphysal plates has recently appeared.¹¹

Animal experiments¹² have shown that pressures of 40–45 lb. per sq. in. (2.8–3.2 kg. per sq. cm.)—far outside the limits of physiologically sustained forces—must be applied to retard epiphysal bone growth measurably, and that much greater forces are required to bring about complete cessation of growth. This explains the observation that strong staples are required to arrest epiphysal growth, for weaker ones are broken by the expanding forces of the insufficiently compressed epiphysal plate. Epiphysal stapling is used clinically to correct the in-

equality in length of leg that occasionally follows such conditions as poliomyelitis, bone and joint tuberculosis, or osteomyelitis. A preferable way of equalizing the lengths of the legs would be to stimulate growth in the abnormal limb instead of retarding growth in the normal one, and such a method has long been sought. The various procedures investigated all seem to depend on vascular factors for any effects they show, but these are not great. Clinical attempts to stimulate growth of bone by sympathectomy^{13,14} have had only minor and transitory effects. However, J. Trueta¹⁵ has described the effect of interfering with the circulation at the growing end of a bone by blocking the medullary cavity of the shaft, and he finds that this results in increased growth. He makes a comparison between his experimental results and the occasional occurrence of bony overgrowth in association with osteomyelitis, overgrowth being found only when the shaft is involved and when a mass of new bone has obstructed the major blood vessels there. But similar experimental studies by other investigators,¹⁶ as well as other types of experimental approach,^{17,18} indicate that here too the ultimate increase in length that can be obtained is small. Epiphysal stimulation as a practical measure, still much to be desired, is an objective as yet unattained.

SCIENTIFIC EXHIBITION, 1958

The Annual Meeting of the B.M.A. is to be held in Birmingham next year from July 14 to 18, and those who wish to exhibit at the scientific exhibition should apply for a stand as soon as possible. The closing date for applications is December 31. Competition for space is likely to be all the keener now that the exhibition has become such a useful and popular reinforcement of the scientific sessions. It was noticeable at Newcastle this year that many visitors to the scientific exhibition—which is quite distinct from the exhibition of pharmaceutical products, books, and medical appliances—returned several times to study a display which they found informative or to talk over matters of common interest with the demonstrators. The scientific exhibition offers the same facilities to the individual general practitioner or medical officer of health as it does to the large research department or great clinical teaching school; and, even though accommodation is limited, the modest exhibit, if it has a useful story to tell, will not be squeezed out by more imposing neighbours.

An innovation at the Annual Meeting at Newcastle this year was the award of certificates of merit to the exhibits judged to be "of the highest excellence of presentation" and "of the highest scientific merit and originality." These awards will be made at future meetings, and, by encouraging exhibitors to further efforts, should make a tour of the exhibition even more rewarding for the ordinary visitor. Forms of application for space at the exhibition are obtainable from the Secretary of the B.M.A.

TESTING BLOOD COMPATIBILITY

SYMPOSIUM AT SHEFFIELD

[FROM A SPECIAL CORRESPONDENT]

Under the aegis of the Regional Hospital Board a symposium on "Compatibility Tests for Hospital Use" was held at Sheffield on October 17. The organizer was the director of the Regional Transfusion Centre, Dr. C. C. BOWLEY. Welcoming the many pathologists who attended, Dr. W. A. RAMSAY, the Board's senior administrative medical officer, expressed his grave concern at the increasing use now being made of blood. "I don't quite know what we are going to do about it," he said: "it's a very thorny problem as to whether blood should be available every time it is demanded by a clinician, and it is indeed a problem which will have to be settled."

Detection of Agglutination

Dr. A. E. MOURANT took the chair for the morning session. Dr. F. STRATTON (Manchester) opened by discussing the mechanism of agglutination. Sensitization and agglutination were two different processes; while the former would occur in any medium, agglutination depended very much on the physico-chemical conditions. To facilitate its recognition the cells should be in close juxtaposition and their movement limited. The sandwich technique, as well as the albumin replacement and layering techniques, were examples of manipulations of the physico-chemical conditions for this purpose. Some agglutinin-agglutinin reactions occurred in saline solutions, others needed serum or albumin suspensions; most took place in tubes though some better on slides, and at least one needed the intervention of complement before the sensitization could occur. Tube-centrifuge methods with albumin replacement or layering he thought probably the most generally effective—except for the detection of Kell antibodies. Agglutination must always be detected microscopically, the cells being examined moving as well as at rest, so as to distinguish true agglutination from rouleaux formation and from plaques due to excessive centrifugation; it also helped to identify some rare reactions, notably with Le^a and the A₂ agglutinin.

Dr. P. L. MOLLISON (M.R.C. Blood Transfusion Research Unit) discussed the survival of erythrocytes transfused into a recipient with an incompatible antibody. The classical anti-ABO and anti-Rh or anti-Kell antibodies destroyed transfused cells rapidly so that their half-life was measured in minutes. But some antibodies destroyed less than half the transfused cells at this fast rate, the surviving cells having a half-life of ten days or more; such antibodies were anti-P, anti-Le^b, and α_1 acting on A₁B cells. Homozygous cells were usually destroyed more quickly than heterozygous. Antibodies which did not cause agglutination above 31° C. were never responsible for haemolytic reactions. Some antibodies when coated on red cells reacted with the anti-(non-gamma-globulin) component of the anti-globulin reagent, so that this should always be present in Coombs reagent.

Dr. J. WALLACE (Glasgow) discussed the difficulties he had encountered in cross-matching 60,000 bottles for 20,000 recipients. Technical difficulties, usually slight, occurred in 4%. Serious errors leading to an incompatible transfusion were usually due to errors of labelling or of identification. Rapid ABO and Rh testing had an error of about 0.25%—mostly false positives. His standard procedure for cross-matching was the anti-globulin test, albumin being used only for "dangerous" recipients. Antibodies which had disappeared after several years' careful avoidance of a stimulating injection were a great potential danger. His general opinion could be summarized in the vulgar expression, "It's not the clot in the bottle you fear, but the clot outside."

Dr. G. H. TOVEY (Bristol) described his method for minimizing labelling mistakes. He uses a set of three racks which clip together in positions indicated by coloured markers; different tests are done in tubes of different sizes, and the three racks are incubated at 4°, 20°, and 37° C. For

urgent cases he advised a tube-centrifuge method; the cell-serum mixture was spun at 3,000 r.p.m. for 1 min., then shaken vigorously, incubated at 37° C. for 15 min., and spun again for 3 min. at 1,000 r.p.m. The deposit of cells was taken up and dropped on saline on a slide, rocked, and examined microscopically; only true agglutination persisted. It was as well to stamp on the laboratory protocols the time at which the tubes were put into and taken out of the incubator.

Methods in Emergency

In the afternoon, with Dr. E. K. BLACKBURN in the chair, Dr. K. L. G. GOLDSMITH (Westminster) discussed his emergency methods. He pointed out that most emergencies could be avoided by exchange of information. It was important that clinicians should be well informed on the problems of blood selection as well as about haemodynamics, and essential to have written confirmation of telephoned requests. As for technique, control serum and cells should always be available, and for ABO-grouping tube methods were excellent. For cross-matching anti-globulin methods were to be preferred. In emergency, all tests should be set up in duplicate and the second set read at leisure.

Dr. G. DISCOMBE (Central Middlesex) analysed the facilities available in a selected sample of provincial hospitals, mostly non-teaching. Among hospitals with fewer than 400 beds about a quarter had a laboratory staff so small that frequent night calls would seriously interfere with the normal running of the laboratory, and in another quarter interference would probably be appreciable. Laboratory space was equally scarce, a quarter having less than 200 sq. ft. (18.6 sq. m.) per 100 beds, and a half less than 300 sq. ft. (27.9 sq. m.). In one hospital with over 1,000 beds, all haematology, including for transfusion, had to be done on a 6-ft. (1.8-m.) bench in a corridor. Medical staffing was equally varied—from 1 doctor to 60 beds to 1 to 600; in most London hospitals the proportion was about 1 to 120. The number of technicians varied from 1 to 9 per 200 beds, and from 1 to 13 per doctor. After reviewing these facts, he suggested that very simple, rapid, and consistent techniques might prove better for staff and patients than would the more elaborate ones, even though the former would miss some antibodies. He suggested the Richardson Jones tube-centrifuge procedure as a possibility.

Dr. P. KIDD (Worcester) stated that technical errors were rarely the cause of trouble; in his experience administrative or clerical errors accounted for 6 out of 7 cases. The really dangerous reactions were those in the ABO, Rh, Kell, and Duffy systems, others were seldom important. He had compared the effect of reducing the incubation time in the anti-globulin, albumin replacement, and albumin layering techniques; sensitization seemed almost complete after 15 min. and was appreciable in 4–6 min. He thought that with 8–15 min. incubation the anti-globulin test was excellent, and the albumin replacement or layering techniques, using centrifugation to deposit the cells, quite satisfactory. For Rh the Murray slide method was quite rapid, especially if the serum were mixed with the albumin, and Stratton's sandwich procedure was also convenient. Löw's papain method was very useful for detecting any Rh antibodies.

Dr. W. WEINER (Birmingham) summarized these papers, and pointed out that, since nearly all antibodies caused some cell destruction, a strong case could be made out for the most perfect serological procedures possible.

General Conclusions

After tea an open forum was held, with Dr. BOWLEY in the chair, and continued for over an hour and a half. It was generally agreed that one could not rely on patients' statements or on request forms to decide whether the recipient was a "dangerous" recipient or not (previous illegitimacies, abortions, unconscious patient, and so on), so that the simplification of technique for those "free from danger" might endanger some patients.

K., and Miltner, L. J., *ibid.*, 1937, 19, 909.

Dr. DOROTHY PARKIN (M.R.C. Blood Group Reference Laboratory) pointed out that the incompatibilities in the ABO system were the most dangerous, and should therefore receive the greatest care in clinical laboratories; instead, familiarity seemed to breed contempt. For emergency work, when the serologist might be a tyro, he needed control cells and serum, and he must know where to find them in the middle of the night. Too often these simple precautions were omitted, and some wretched houseman would be found scouring the darkened laboratory looking for reagents which he had only the haziest idea how to use.

The general conclusion of the symposium was that good administration would avoid most of these faults and minimize clerical errors; if these were overcome the technical problems were not particularly difficult.

HARVEIAN ORATION

DR. HUNTER ON HARVEY'S CONTEMPORARIES

Dr. DONALD HUNTER, for the St. Luke's Day Harveian Commemoration Oration of the Royal College of Physicians of London on October 18, took as his subject "Harvey and his Contemporaries."

As everybody knew, he said, Harvey was born in the middle of the reign of Elizabeth I, served James I and Charles I as personal physician, found himself on the losing side in the Great Rebellion, and died at 79 years of age, exactly 300 years ago. The Tercentenary Congress held in the summer had been a Festival of Discovery, a symposium in the form of a review of the many notable advances which had made of the last forty years a rich harvest-time in cardiovascular physiology. Harvey's great achievement was his study of flow in vessels, and it was therefore appropriate that he should have been commemorated by a symposium on the conquests of the cardiac catheter; of the application of the advances in instrument technology to the basic phenomena outlined by his work.

In the circumstances it was perhaps appropriate to paint a picture of where the biological and allied sciences stood in Harvey's day. Everyone knew of him because of his *De Motu Cordis*, but he had also gathered extensive data on insects, which he valued and which were destroyed by the enemies of Charles I as a deliberate act of war. In his *De Generatione Animalium* he applied his method of observation and experiment to establishing that all life proceeded from previous life and not from spontaneous generation.

Rediscovery of Galen

Born in Folkestone, Harvey must as a boy of 10 have shared in the excitement of the defeat of the Armada, although of his early years very little was known. Prior to his birth, however, other events of an equally epoch-making nature had occurred. In 1453 Constantinople had fallen and the flight of the Byzantine scholars to Italy carried to that country the original texts of Greek learning. Within a few years Thomas Linacre arrived in Padua to study, and his faithful and accurate Latin translations of the rediscovered original texts of Galen made it clear to physicians that men had for centuries relied upon garbled and second-hand versions of their favourite author. In the next generation John Caius also went to Padua. To-day they paid homage to those two scholar-physicians for the work they did in helping to provide a corporate cultural background for the development of science and medicine in the seventeenth century. Caius died five years before Harvey was born, so that he came under his posthumous influence at Cambridge.

The seventeenth century witnessed many discoveries in mathematics and astrophysics. Following the work of Copernicus in 1543 on the revolution of the planets around the sun, Galileo invented the telescope in 1609, Kepler stated the laws governing planetary motion in 1618, and Newton the law of gravitation in 1682. Logarithms were

invented by Napier in 1614, Descartes founded analytic geometry in 1637, while Torricelli invented the barometer in 1643 and Hooke a compound microscope in 1665.

Dormancy of Biology

Compared with that astonishing rate of progress most branches of biology remained dormant. As to botany nobody thought of it in terms of function. If a herb could be classified, cultivated, and its medical performance assessed the Renaissance botanists were well satisfied; their knowledge of plant anatomy stood virtually where Theophrastus had left it 2,000 years earlier. More than one generation passed after Harvey had demonstrated the circulation of the blood before John Ray made experiments on the movement of sap in trees, and it was not until 100 years after the publication of *De Motu Cordis* that Stephen Hales demonstrated at Teddington that root pressure, transpiration, and capillary pressure all played a part in the upward movement of the sap. As to plant respiration, like Harvey, he was handicapped by ignorance of the composition of the atmosphere. It was not until thirteen years after the death of Hales that John Priestley discovered oxygen. The general attitude of most, in Harvey's day, was an uncritical acceptance of previous writings, and Harvey commented on it, "The method of investigating truth commonly pursued at this time is to be held erroneous and almost foolish, in which so many inquire what others have said and omit to ask whether the things themselves be actually so or not."

Harvey's attitude to chemistry was far too scornful, but he had an intense dislike of alchemists and their nonsensical claims. Nevertheless there was a great body of practical knowledge of empirical chemistry, mining, dyeing, smelting, and tanning. A contemporary of Harvey, Johann Rudolph Glauber, a German, was a great practical chemist; he made copper sulphate, zinc chloride, and hydrochloric acid, and noted the use and value of the tar produced from the destructive distillation of wood. His *Miraculum Mundi* showed keen observation and practical ability, yet his writings were full of stupid superstitions and there was never a more complete alchemist. He expressly declined to sell or publish his supreme secret, the Alkahest or Universal Solvent.

In spite of the serenity of Shakespeare, the lusty *joie de vivre* of Rubens and Frans Hals, the spirit of the seventeenth century was sombre. Europe was dominated by famine, plague, and war, while a superstitious populace still regarded comets with awe as harbingers of impending evils and ills, and believed in witchcraft. In 1634 three of the Pendle Forest witches from Lancashire were brought to London and examined by Harvey, who, with great courage, reported that he could find on them none of the recognized stigmata.

White Dolomite and Silicosis

A notable contemporary of Harvey, and the two were friends, was Inigo Jones, the first of our great Renaissance architects, surveyor-general of the Royal buildings, to whom we owed the dignified simplicity of the Queen's House at Greenwich and the Banqueting Hall in Whitehall. What a pity that that great hall with its ceiling painted by Rubens, and from a window of which a King of England stepped out on to a scaffold and execution, could be used for nothing better than a military museum. Inigo Jones introduced brick and stone to London architecture and exploited the use of the beautiful white dolomite from Portland Bill, and thereby, in conjunction with Sir Christopher Wren, who also exploited it, saved many from dying of silicosis, for the dolomite did not produce the sharp silicon dust as did sandstone.

To read Harvey's works was to be conscious of companionship with a man of dynamic personality and a great lover of truth. Across three centuries of time William Harvey, the immortal founder of modern physiology and modern medicine, exhorted them to search and study out the secrets of Nature by way of experiment, and for the honour of the profession to continue in mutual love and affection.

APPROVED NAMES

On June 29, 1957 (p. 1528), we printed the last supplement (dated May, 1957) to the consolidated list of "approved names" selected by the British Pharmacopoeia Commission. Below is the latest, dated October, 1957. We have added a brief note on the main use of each drug. Communications relating to "approved names" should be addressed to the secretary, British Pharmacopoeia Commission, General Medical Council Office, 44, Hallam Street, London, W.1.

Approved Name	Chemical and Other Names	Notes
Acetpromazine	2-Acetyl-10-(3-dimethylamino-propyl)phenothiazine	Tranquillizer
Bialamicol	"Notensil" is the maleate 3:3'-Diallyl-5:5'-bisdiethylaminomethyl-4:4'-dihydroxydiphenyl	Anti-amoebic compound
Buphenine	"Camofom" is the hydrochloride 1- <i>p</i> -Hydroxyphenyl-2-(1-methyl-3-phenylpropylamino)propanol	Vasodilator
Captodiamine	"Perdilatal" is the hydrochloride <i>p</i> -Butylthiodiphenylmethyl 2-dimethylaminoethyl sulphide	Sedative
Cyclomethycaine	"Covatin" is the hydrochloride 3-(2-Methylpiperidino)propyl <i>p</i> -cyclohexyloxybenzoate	Local analgesic
Dequalinium chloride	"Surfactin" is the sulphate Decamethylenbis-(4-aminoquinolinium chloride)	Bactericide
Dicyclomine	"Dequadin" 2-Diethylaminoethyl dicyclohexyl-1-carboxylate	Antispasmodic
Diloxanide	"Wyovin" is the hydrochloride <i>N</i> -Dichloroacetyl- <i>p</i> -hydroxy- <i>N</i> -methylaniline	Anti-amoebic compound
Edrophonium chloride	"Entamide" Ethyl- <i>m</i> -hydroxyphenyldimethylammonium chloride	Cholinergic agent
Hedaquinium chloride	"Tensilon" Hexadecamethylenbis-(2-isoquinolinium chloride)	Antifungal agent
Hydroxydione sodium succinate	"Teoquil" Sodium 21-hydroxypregnane-3:20-dione succinate	Local analgesic
Liothyronine	"Viadril" (-)-Tri-iodothyronine	Metabolic stimulant
Mecamylamine	"Tertroxin" is the sodium derivative 3-Methylaminoisocamphane	Oral hypotensive agent
Melphalan	"Inversine" is the hydrochloride; "mevasine" is the hydrochloride <i>p</i> -Di-(2-chloroethyl)amino- <i>L</i> -phenylalanine	Chemotherapy of malignant disease
Methotrimeprazine penthiolate	"Meprofen" 10-(3-Dimethylamino-2-methylpropyl)-2-methoxyphenothiazine	Tranquillizer
Phenoxybenzamine	2-(<i>N</i> -Benzyl-2-chloroethylamino)-1-phenoxypropane	Adrenergic blocking agent
Pipenzolate	"Dibenzyl" is the hydrochloride; "dibenzyl" is the hydrochloride <i>N</i> -Ethyl-3-piperidyl benzilate	Anticholinergic agent
Thiopropazate	"Piptal" is the methobromide 1-(2-Acetoxyethyl)-4-[3-(2-chloro-10-phenothiazinyl)propyl]-piperazine	Tranquillizer
Trimeprazine	10-(3-Dimethylamino-2-methylpropyl)phenothiazine	"

Reports of Societies

ROYAL SOCIETY OF TROPICAL MEDICINE BRIGADIER BOYD ON DYSENTERY

For his presidential address to the Royal Society of Tropical Medicine and Hygiene on October 17 Brigadier J. S. K. Boyd, F.R.S., chose as his title, "Dysentery: Some Personal Experiences and Observations." Among Europeans in the tropics, he said, bacillary dysentery was more important than amoebic dysentery. But, since bacillary dysentery rarely became chronic and was easily cured by modern drugs, it had recently received less attention than amoebic dysentery, which, unless very thoroughly treated, tended to persist as a subacute or chronic condition. Nevertheless, bacteria could become resistant to sulphonamides and antibiotics, and the emergence of resistant strains of dysentery bacilli might jeopardize the present satisfactory therapeutic position.

In the first world war bacillary and amoebic dysentery had accounted for 22-64% of admissions to medical units in Salonika, Egypt, and Mesopotamia. Among 120,000 casualties from Gallipoli between August and October, 1915, a high proportion had been caused by dysentery, and it was claimed that 65% of the dysenteric infections had been caused by amoebae. But Wenyon and O'Connor had found that only 6.5% of 246 convalescents evacuated from Gallipoli were carriers of *Entamoeba histolytica* cysts, compared with 4.5% of 11,037 others with no history of dysentery. From this it was concluded that the incidence of amoebic dysentery among the casualties at Gallipoli had been overestimated. Amoebic infection accounted for a considerable proportion of the steady admissions of dysenteric patients all the year round, but bacillary dysentery occurred in epidemic waves mainly in late summer and autumn and to a less extent in spring, and was everywhere the predominant type of the infection. Between the two world wars the work of Manifold had led to the greater appreciation of the importance of bacillary dysentery as a cause of ill-health in the British Army in India.

Brigadier Boyd recalled how in 1929 when inagglutinable Flexner dysentery bacilli presented an unsolved problem he had one morning found two types of colony on a plate on which a culture of one of the inagglutinable types had been made. One of the colonies was smooth like the parent strain and composed of inagglutinable bacteria, whereas the other, which was semi-rough, was highly agglutinable; it became clear that this strain had undergone degradation and was producing two different types of bacteria. Those with smooth colonies possessed a specific surface antigen which rendered them inagglutinable by the antisera of known strains. The second type, which produced rough colonies, had lost this surface antigen and as a result an underlying group antigen had been exposed. Its components were common to other members of the Flexner series, so that it had become agglutinable by their antisera. Three new types of organisms had been identified by their surface antigen, and the few which remained, each with a specific antigen but lacking the common group antigen, had been classified as a separate species.

In the Middle East during the second world war a type of bacillary dysentery slow in onset and progress but quite unamenable to treatment had been recognized as a cause of mortality. Most of the more serious cases were caused by Shiga's bacillus, but a few Flexner infections also ran a very protracted course and had been difficult to cure. Antitoxin and bacteriophage had been ineffective as therapeutic or prophylactic agents. The situation had been completely and dramatically altered by the introduction of sulphaguanidine.

Motoring News

AFTERTHOUGHTS ON THE MOTOR SHOW

Once again many thousands of people have journeyed to Earls Court to see the new cars and to see what the manufacturers have been working on during the last 12 months. The outcome has, however, been somewhat disappointing, for the tendency has been towards one of progressive improvement rather than of great new developments. British car manufacturers have been content simply to improve their existing models rather than introduce more original designs. This is a sensible policy to pursue for a while, but the time may now have come for advanced ideas to be incorporated in new cars. The Motor Show this year has seen the start of some of these advanced ideas on the more expensive cars; in successive years the new designs, accessories, or whatever they may be are gradually incorporated on the cheaper mass-produced models at lower prices.

Perhaps the greatest innovation to be seen at Earl's Court this year has been fully automatic transmission on cars for the family motorist. This form of transmission usually consists of a clutch, torque converter, and a series of gears.

The converter consists of a series of oil-immersed paddles which effect a fluid drive to the gears, which are similar to those in a normal gearbox. The whole unit is operated by a "brain" which reacts to the load or gradient and can be controlled by the driver's selector lever, which provides for low- or high-gear drive, reverse, neutral, and park. Automatic transmissions usually increase the consumption of fuel because they absorb more engine power than the normal system and they are heavier. There is no question about their efficiency, however, for they are very reliable and considerably reduce the driver's fatigue on long journeys.

This form of luxury motoring is now available on many of the medium-sized cars as well as the large ones. For the man who has a small car there are also pleasures in store, for the two-pedal system is being incorporated on many of these, and it will not be long before the clutch, as it is known at present, will cease to exist. The two-pedal system is merely a term for a gearbox layout with no foot-operated clutch. There is a switch on the gear lever which the driver presses as he changes gear; this puts the automatic clutch system to work, so eliminating footwork by the driver. This arrangement is admirable for all family cars because it is neither expensive nor complicated, does not affect fuel consumption, protects the transmission against rough usage, and can be fitted to even the smallest car.

Another of the great improvements offered in the mechanical sphere this year is the disk brake. The idea is not entirely new, for it has been incorporated on some of the faster sports models during the past year. Though it is being constantly tested and improved by the large brake companies, it is now being fitted to many of the heavier sports saloons. Disk brakes offer many advantages over conventional types such as freedom from fade, no failure when flooded with water, less squealing, and easy replacement of lining pads. Finally, turning to less technical things, we shall see 1958 models in brighter colours; de luxe versions of popular models will appear in two-tone hues, and seasonal changes will be made in existing ranges.

IAIN GELLATLY.

Correspondence

Blood Transfusion in Obstetric Haemorrhage

SIR.—The constructive suggestion of Mr. W. G. MacGregor and Dr. A. D. Tovey (*Journal*, October 12, p. 855) that the blood volume should be estimated in cases of accidental obstetric haemorrhage, so that patients do not suffer from under- or over-transfusion, is welcome.

Failure to replace blood in correct quantity may lead to kidneys already affected by the toxæmia being deprived of oxygen. Anuria may be avoided sometimes by adequate transfusion. Yet "adequate" transfusion, especially when it rises to the order of 13,200 ml. of blood and 800 ml. of concentrated plasma—the contents of 35 "pint" bottles—as was given in Case 5 quoted, carries its own dangers, as is well known. Some obstetric surgeons fear the risks of anuria inherent in giving transfusions, as a result of which appreciable numbers of cells that may be rather old and prone to lysis are placed into a patient.

One way of avoiding such massive transfusions is by carrying out early caesarean section where indicated. The situations in which such interference is advisable have been admirably summarized in Mr. J. Chassar Moir's latest edition of *Munro Kerr's Operative Obstetrics*.¹ It is pointed out that the degree of shock and the duration of uterine apoplexy (his italics) predispose to anuria and afibrinogenæmia. The uterus, therefore, should be emptied if not active within 8 hours.

If the case considered in the introduction to Mr. MacGregor and Dr. Tovey's paper is examined further in this light, we can see that not merely failure to transfuse adequately but failure to carry out caesarean section possibly

contributed to the patient's death. The authors are right to point out that blood pressure estimations were misleading. We should often be better off without the sphygmomanometer, relying more on pulse rate variations and the general condition of the patient, as well perhaps on blood volume estimations. Blood volume estimations with Evans blue are not in themselves entirely devoid of risk. If the uterus in this particular case had been emptied after 8 hours the patient would have been delivered 12 hours quicker. These hours are precious. In accidental ante-partum haemorrhage where bleeding continues, the placenta is a dangerous element that should be removed rapidly. The uterus is seldom dangerous, and usually should be preserved. Of course the caesarean operation must be through the lower segment, which is seldom the seat of marked uterine apoplexy.

Caesarean section does not preclude blood transfusion, nor does blood transfusion preclude section. Yet, admittedly, during the section transfusion can be very difficult because of venous spasm. Accordingly two or even three "drips" should be set up, if possible, before the operation is started. The uterus should not be packed where there is a gross clotting defect, as an empty uterus bleeds less easily than one where the maternal sinuses are unable to close properly. Drains should be inserted to prevent the collection of blood retro- or intraperitoneally, for shock results from such blood. The operation should be performed fairly rapidly. With these precautions caesarean section can still be of use to the mother in the most severe cases where the general condition is not improving and labour not advancing. The work of O'Donel Browne² should not so easily be discounted, for indications for the operation do still exist, occasionally, even in the most severe cases where the foetus has perished.—I am, etc.,

London, W.1.

Testosterone in Dwarfism

SIR.—You are to be congratulated on your timely leading article on testosterone therapy in dwarfism (*Journal*, October 12, p. 870). Not only does it review the value of hormones in the treatment of disturbed growth, but it also describes very clearly the importance of assessing skeletal maturation when evaluating the physical status of a child.

I would like, however, to question the validity of one of your conclusions. You write: "Secondly, in about half the children the skeletal age . . . advanced more rapidly than the height-age. . . . Thirdly, while the stimulating effect of testosterone on growth did not continue in the year after therapy was stopped, the apparent effect on skeletal maturation continued. There is therefore a delay in the epiphyseal development to a degree which is recognizable by radiography." Surely on your own premises the last sentence should read, "There is, therefore, an acceleration of epiphyseal development . . ." It might be pertinent to add that a disturbance in the predetermined balance between growth and skeletal maturation is not confined to "diseases affecting growth, such as coeliac disease," but occurs in every illness which causes lines of increased density to appear in the radiograph of the metaphysis, and possibly also in others where no such lines are visible.¹⁻³ My own experience⁴ supports the conclusion of Follis and Park⁵ that these lines are due to a dissociation between chondroplasia and osteogenesis, terms which are given to the histological processes underlying growth and skeletal maturation, and these authors have observed such a dissociation as a "result of illnesses of a most temporary and relatively mild nature."⁴—I am, etc.,

Hospital Confinement

SIR.—Dr. J. H. S. Geggie (*Journal*, October 12, p. 883) is in error in assuming that women in this country are clamouring for hospital admission for their confinements. In a preliminary sample of 42 cases, where mothers who have had at least one child born in hospital and at least one born at home have been asked which they preferred, 34—i.e., 81%—stated that they preferred to have their babies at home. This confirms one's general experience, even though it appears that our consultants are not aware of the fact.

Dr. Geggie's table, in which he correlates certain improvements in health indices with the increase in hospital confinements since the year 1940, reaches a new low in pseudo-scientific confusion. Very much else has changed since 1940 besides an increase in births in hospital.—I am, etc.,

I. GORDON.

Ilford, Essex.

SIR.—Dr. J. H. S. Geggie (*Journal*, October 12, p. 883) is hardly justified in implying that the improvements in certain vital statistics in Canada are necessarily related to the increase in the proportion of confinements that take place in hospital. His presentation of "some statistics" is likely to be misleading. The corresponding vital statistics for England and Wales are very similar, and are as follows:

Year	Maternal Mortality (Rate per 1,000 Total Births)	Stillbirths (Rate per 1,000 Total Births)	Neonatal Mortality (Rate per 1,000 Live Births)	Infant Mortality (Rate per 1,000 Live Births)
1940	2.24	37.2	28.6	57
1945	1.47	27.6	24.2	46
1950	0.86	23.0	18.5	30
1955	0.54	23.2	17.2	25

Changes of this kind have occurred in all developed countries, and are no doubt due to a number of factors, but it would appear to be difficult to establish in the case of any of them that the improvements are dependent upon whether the place of confinement has substantially changed. The figures given above show some interesting differences in comparison with those of Dr. Geggie, but I am anxious to point out only the more general aspects of Dr. Geggie's letter, and it is probable that the reasons for the differences referred to would in any case prove difficult to elucidate.

Consider the cases of Holland and Sweden. The best figures to use for this purpose are no doubt those of the maternal mortality rate, stillbirth rate, and mortality in the first week of life. I am not able at the moment to obtain the first two figures for these countries, but in place of the last the neonatal mortality is at least somewhat relevant. Holland and Sweden both had a neonatal mortality rate of 13 per 1,000 live births in the year 1956, and these two countries are in this respect well in advance of all others, except New Zealand. The point is that in Sweden almost all confinements are institutional, and in Holland the position is largely the reverse, for there the majority are domiciliary. These things are chiefly dependent, surely, on the standards of work of the doctors and midwives concerned. If these workers are determined to apply sound principles, in adapting these to the circumstances of their cases, in the antenatal period and during delivery and the puerperium, then the best results will be obtained.—I am, etc.,

Reading.

E. C. H. HUDDY.

Caudal Analgesia

SIR.—Dr. M. B. Comerford states (*Journal*, September 28, p. 763) that those familiar with extradural analgesia find the sacral hiatus difficult or impossible to locate in 25% of patients. This is far from my own experience, based on some 20,000 inductions during the last 19 years. It has proved possible to introduce the needle correctly to lie within the sacrum in over 99% of all cases. I employ an ordinary lumbar puncture needle, using the technique I described in *Orthopaedic Medicine*.¹ The simple expedient of pressing quite hard on the cornua with the left thumb

keeps the point of the needle down towards the floor of the hiatus.

No sepsis or death has resulted from these out-patient inductions. The patient rests on the couch for 15 to 30 minutes and then walks out. There have been two patients who have developed an aseptic meningism, each recovering within a week, and one case of hypersensitivity to procaine. Twenty minutes after the extrathecal injection of 0.25 g. procaine the patient became unconscious for two hours and had to be given artificial respiration. There were no ill-effects afterwards.—I am, etc.,

London, S.E.1.

Asian Influenza

SIR.—The incidence of pneumonia as a complication of influenza is increasing, and it is now possible to make some observations on the aetiology and treatment of this complication. During the first wave of influenza in late August and early September, all R.A.F. recruits who contracted the disease at a recruit training establishment were x-rayed, and 19 cases of pneumonia were discovered out of a total of 391 cases of influenza. Radiographic appearances in these cases were typical of segmental aspiration pneumonia,¹⁻³ which is frequently encountered in R.A.F. personnel secondary to upper respiratory tract infections. This low complication rate was thought to be due to the fact that the incidence of upper respiratory tract infections with excess secretion was low amongst recruits at that time of year. As the incidence of upper respiratory infections increases, however, during the winter months the incidence of segmental aspiration pneumonia complicating influenza can be expected to rise, and preliminary observations in the Royal Air Force show that this is already happening.

The subsequent course of a segmental aspiration pneumonia we believe depends upon the type and virulence of the organism or organisms aspirated with the upper respiratory secretions. During past winters the majority of cases of pneumonia have been relatively benign, but serious complications may occur this winter due to aspiration of *Staphylococcus aureus* or *Haemophilus influenzae*. The presence of these organisms in the respiratory tract is apparently enhanced in quite a remarkable way by an attack of influenza. We have not as yet noticed any increase in the incidence of the *Haemophilus influenzae* in sputum or throat swab cultures, but the dangers of the organism have been stressed recently,⁴ and perusal of the literature written after the 1918-19 influenza epidemic shows how frequently the *Haemophilus influenzae* was found in fatal cases at that time.

A number of cases of staphylococcal pneumonia have, however, been encountered. All have initially presented as typical cases, clinically and radiologically, of segmental aspiration pneumonia, but, because routine sputum tests are carried out on all patients on admission to hospital, they have rapidly been diagnosed as cases of staphylococcal pneumonia. It has thus been possible to isolate such cases within a short period and remove them from a ward containing other cases of pneumonia and influenza, where they must have constituted a potential threat to the other patients. It would seem that, in the majority of cases, staphylococcal pneumonias in the early stages do not differ in any significant way from other cases of pneumonia complicating influenza and that there is a strong case for carrying out bacteriological examination of sputum in all cases of pneumonia on admission to hospital.

Most staphylococci encountered will probably still be penicillin-sensitive and the antibiotic of choice when a patient is admitted with pneumonia should still be penicillin. If the patient deteriorates before the result of sputum culture is available, it might be as well to assume that he has a staphylococcal pneumonia and give penicillin plus erythromycin. If a positive culture for *Staphylococcus aureus* is then reported and the organism is sensitive to penicillin, the erythromycin can be stopped and heavy doses of penicillin

given. If, on the other hand, the organism is penicillin-resistant a change can be made to an appropriately sensitive antibiotic, or, if it is decided or necessary to continue with erythromycin, it is suggested that novobiocin be added to delay the emergence of erythromycin-resistant strains.*

The treatment of segmental aspiration pneumonia is, in our view, only complete when the segment or segments involved have fully re-expanded. Cases of staphylococcal pneumonia show severe segmental collapse, and it is likely that bronchiectatic changes will rapidly occur in the affected areas.⁷ It is not enough, therefore, to save the patient's life with antibiotics. Physiotherapy should be given as early as possible in the form of breathing exercises, posturing, and percussion to minimize bronchial damage by removing secretions and allowing the re-expansion of the collapsed areas.—I am, etc.,

Wirral, Cheshire.

SIR,—In your timely leading article on pulmonary complications of influenza (*Journal*, October 12, p. 872) you write: "Fortunately the virulence of the Asian strain appears to be fairly low, and has not apparently been enhanced during its journey from the East"; you also "hope that it will remain mild" and mention that "the possibility of a change for the worse cannot be ruled out."

The Registrar-General of Scotland reports 90 deaths from influenza in the 17 principal towns of Scotland during the week ending October 12. Our experience of the influenza (presumably "Asian") prevalent here is, if assessment is by the incidence of respiratory involvement and the severity of ensuing debility, that it is not of a mild type. One of us saw this influenza in Singapore a few months ago and found it to be mild (as it affected Europeans) with complications rare.

We suggest that enhancement of the "Asian" strain of virus has in fact taken place since it left Singapore, that the change for the worse has already occurred, and that to label this influenza as mild is wrong if not, indeed, dangerous.—We are, etc.,

A. F. MCINNES.
J. B. ROSS.

Edinburgh, 9.

SIR,—We enjoyed reading Dr. E. C. Atkinson's able summary (*Journal*, October 5, p. 821) of his experiences of the present epidemic in Sheffield. In our district of Ipswich the virus struck in force in the week beginning September 9, and the epidemic reached its peak in the week September 23–29. Up until the time of writing we have seen 194 new cases. We know, however, that many at risk have been ill but did not seek professional advice.

Like Dr. Atkinson, we have noticed different varieties, and agree with his classification, and also his comments on the comparative rarity of the disease in the elderly. One wonders if they have met this before, as suggested in your leading article (*Journal*, October 12, p. 872). We have experienced only four cases of pneumonia; two in chronic bronchitis, aged 77 and 79 years; one in a healthy adult of 46 years; and one in a child of 13 years. Many more had rales at one or other base persisting for one to two days (unlike Dr. Atkinson's series). A relatively common complaint has been of earache, principally in children in the early stages of the disease, but examination has revealed no abnormality, except in one case when a concomitant otitis media was found.

Our most unexpected finding has been of recurrent attacks, occurring soon after the initial illness. Out of the 194 seen, 7 so far have had second episodes with at

least 4–15 days' apparent fitness between the attacks. The patients concerned have often been back at work or school. In 5 of the cases we witnessed both febrile episodes, and were interested to note the repetition of the same symptomatology and physical signs. In the other 2 the symptoms described appear to have been typical of influenza, whilst we witnessed the second attack owing to parental anxiety. We feel that these are genuine cases of reinfection and presume that the initial invasion of the virus has produced, in these cases, little if any antibody response by the time reinfection has occurred. Time alone will tell whether this is going to become more noticeable as the epidemic grows older.—We are, etc.,

Ipswich.

RONALD HORN.
P. K. WILSON.

SIR,—Your leading article on the pulmonary complications of influenza (*Journal*, October 12, p. 872), which was both timely and informative, omitted any reference to the particular problem presented by patients on long-term adrenal steroid therapy. Already during the present epidemic we have had referred to us two patients with rheumatoid arthritis receiving steroids, in whom a critical condition developed because of delay in diagnosing and treating their pulmonary infection and failure to maintain or increase their steroid dosage.

We would therefore like to emphasize the fact that patients receiving steroids are particularly susceptible to all known infections,^{1,2} which can be very difficult to detect because of the masking of clinical symptoms and signs by such steroid therapy.³ It is because of this that antibiotics should be given at the slightest hint of infection and in much larger doses than normally used.⁴ Further, and this appears to us to be not as widely known as it should be, steroid therapy should not be stopped when these patients have an acute infection. In fact, larger doses are generally required during their period of stress, as a state of relative hypo-adrenalism may develop^{5,6} which in the event of circulatory failure supervening necessitates, as you indicate in your article, intravenous hydrocortisone.

Finally, we feel that the position with patients on long-term steroid therapy is comparable to that of diabetics on insulin, and that they should be fully informed of the nature of their treatment, carry a card giving details of that treatment,⁷ and be warned to report to their doctor if feeling at all unwell.—We are, etc.,

London, W.C.1.

SIR,—In common with most general practitioners, I have been seeing a large number of influenza cases in the past few weeks. I have been struck with a symptom common to most that I have not seen described hitherto. I find many patients complaining of severe pain in the scalp on the second day when the toxæmia seems at its height. This pain is often associated with an epicritic hyperaesthesia of the scalp in the distribution of the frontal branches of the fifth nerve.

I would be interested to know if this is a common finding.—I am, etc.,

London, N.W.3.

A. H. MENDOZA.

SIR,—Although we may regret the encroachment of the Ministry of Health and medical officers of health on clinical medicine we should recognize that on the whole this has been beneficial to the health of the public, and I for one welcome the advice given by these agencies to the public concerning

the present epidemic of influenza. This advice has allayed much of the panic that was arising and so has helped me by reducing the large number who have sought my advice, and has facilitated my treating of others by telephoned advice, notices in my surgery waiting-rooms, etc. Thus my visits have been kept within normal limits for the time of year, and I have been able to give adequate attention to those patients who have appeared to need a visit.

I understand some doctors have been visiting up to 50 patients a day. This, to my mind, ensures that those who really need a little time spent on them cannot receive it, and also that the doctor will be so exhausted that his work will suffer and he may well become ill himself. Had those doctors made use of the advice of the Ministry and of the local M.O.H., and passed it on, modified according to circumstances, to their patients, they might have saved themselves from exhaustion and been in better condition to treat those patients who really needed attention.—I am, etc.,

Brighton, 6.

R. S. SAXTON.

SIR,—Dr. Agnes Wilkinson (*Journal*, October 12, p. 881) insinuates that I dispute the necessity for patients to request their doctor's attention for influenza (*Journal*, September 28, p. 763). I did not say anything of the kind. The only purpose of my short letter was to stop the unnecessary frightening publicity in the lay press. On the contrary, I advise all my patients to stay at least three days in bed under strict medical supervision. The few cases of relapse (without any "panic") have mostly occurred in patients who did not go to bed at all or for an insufficient time.—I am, etc.,

Nottingham.

G. FIELDING.

Cancer Research

SIR,—Dr. E. Gallop (*Journal*, October 5, p. 824) is indulging in that well-known parlour game armchair planning of research, but he suspects that no "established research organization will take the suggestion seriously." For this we may be thankful, because his suggested experiments with a "large number of mice" would, if carried out, exemplify some of the mistakes he has castigated in his first paragraph.

But I would like to protest particularly against this first paragraph, with its statement that laboratory animals—mice and rats are most commonly used for cancer research—"are often wild creatures who have to submit to captivity, with all its abnormalities and gross disturbance of their normal sexual instincts." These animals have been bred in the laboratory for countless generations, and show no remnant of the wild creature's shyness of man; their cage is their home, and, when removed, they normally seek to return to its security, where there is food and water *ad lib*. Their sexual life is necessarily governed by the quantitative needs of carrying on their strain and race, and is therefore regulated by man, but it is no more grossly disturbed than our own. Much effort in recent years has been devoted to the care and management of laboratory animals so as to reduce and eliminate the stresses that bad husbandry may be supposed to provoke, for a "stressed" laboratory animal is a bad laboratory animal. The success of this effort is seen in the excellent health records of all good colonies—far better than that of wild, or improperly maintained captive, populations.

Lastly, that care should be taken in extrapolating animal results to man is well understood by most experimenters. It is not a question of animals and man resembling each other in their entirety, but of certain reactions in animals—and for that matter in micro-organisms and other systems—being comparable with certain reactions in man—an entirely different proposition. There is no fallacy here.—I am, etc.,

London, N.W.3.

W. LANE-PETTER.

SIR,—Your correspondent Dr. E. Gallop (*Journal*, October 5, p. 824) seems to imply that chimney sweeps' cancers are the only examples of chemically induced cancers

in man. There is no doubt, however, about the occurrence of chemically induced industrial cancers of the skin and bladder. It is true that conditions of stress may modify the incidence of chemically induced cancers in animals and that a small incidence of tumours has been observed in sites treated with what had been believed to be an inert substance. Both influences are in fact provided for in a well-designed animal experiment.

There are very good reasons for supposing that the fundamental features of carcinogenesis are the same in animals and man. The demonstration of such features by animal experiments is a valid procedure; such experiments have yielded important general concepts such as that of co-carcinogenesis. I feel that the limitation of animal experiments which Dr. Gallop has in mind refers to experiments from which it is hoped to infer that, because a substance is carcinogenic in one or more species of animal, it will be so in man. Such inferences are not, of course, valid. The induction of cancer in animals by the smoke or tar of tobacco does not permit a conclusion that the correlation between smoking and lung cancer in man derives from a causal relationship. All that such experiments can show is that a causal relationship is biologically possible. This, surely, is something worth noting, although such experiments *prove* nothing about the human problem.—I am, etc.,

Radlett, Herts.

HAROLD B. HEWITT.

Cancellous Strip Grafting

SIR,—In your annotation (*Journal*, September 28, p. 759) on cancellous strip grafting it seems to be implied that the technique works in the manner of a by-pass graft. You refer to refreshing the cortex above and below the level of the fracture and applying the strips of cancellous bone to the bared surfaces, as if to infer that, stabilization being achieved by union of the graft to each fragment, union subsequently occurs at the fracture site.

Three questions arise: (1) Is it an essential part of the technique that one aims to achieve union of the cancellous bone to raw surfaces of the fragments and awaits bone union at the fracture as a sequel of this? (2) If this is so, is there any real difference between "old-fashioned" onlay cortical grafting and a by-pass cancellous graft other than the material used? (3) How was it that Phemister¹ achieved excellent results using chiefly cortical bone? Phemister did not consider that removal of bone from the fragments was an essential part of the technique. His description of his first successful case—an infected mandibular fracture—makes no mention of refreshing the cortex except for separation of the periosteum on one side. In his general account of the technique he states: "The bone is exposed, and the periosteum is reflected only from the site to which the transplanted bone is to be applied. The remaining periosteum and callus hold the fragment end together. If the denuded surface is level *no bone is removed*" (my italics). It is also clear from examination of the x-rays published by Phemister that union at the fracture site is not a sequel of a successful by-pass but occurs synchronously with incorporation of the graft.

What does happen at the fracture site when delayed union becomes progressive union merely because a graft is laid down about the fracture? (Phemister said he had no opportunity for microscopic examination of the callus during the period of transformation into bone.) Mr. John Charnley, in speaking to Wilson's paper at the British Orthopaedic Association meeting to which you refer, described the technique as one of the great advances in surgery. Would it not be true to say that the "advance" in this instance is that we may be on the threshold of discovering why the mere presence of compact or cancellous bone about the fracture influences the physiology of the fracture site?—I am, etc.,

Lincoln.

Avoidance of Multiple Death Duties

SIR,—In these days, when air travel by whole families is becoming increasingly popular, the question of safeguarding one's property against multiple death duties in the event of disaster is one of serious import. A method of so doing which I think is an improvement on that suggested by your medico-legal correspondent (*Journal*, October 12, p. 888), is for the testator to provide that beneficiaries shall not succeed unless they survive him or her for, say, one month, and make alternative dispositions of property to take effect should any beneficiary not acquire a vested interest through failure to survive for the specified period. In this way, should the testator die and a beneficiary, not being killed outright, survive for the specified period, there would be a reasonable chance of recovery and therefore succession in accordance with the terms of the will. On the other hand, should the beneficiary be killed at the same time or survive a disaster but die before the specified period, he or she would not succeed and therefore no vested interest would be acquired, so that no death duty in respect of that bequest would be payable out of the beneficiary's estate. By this simple precaution payment of multiple death duties will often be avoided.—I am, etc.,

London, N.21.

S. CHAPLIN.

Tabulating Data

SIR,—We are very grateful for the special effort and kindness of the *B.M.J.* in publishing our recent article (*Journal*, September 14, p. 619), with its difficult typesetting problems, and we would like you to know that we have received many appreciative letters concerning possible uses for the method and also some suggestions for simplification. We would like to reply through your columns and say that Dr. B. Lennox's method (*Journal*, September 28, p. 466) is an alternative to ours where percentages are not of interest, although we doubt whether a triangular chart is very much less cumbersome than a square one on the same diagonal. Where only inter-relationships are required, a chart can be prepared in which the percentage figures are replaced by symbols showing the statistical significance of the pair of factors in each cell. Of course the arithmetical work has to be done first, and there is no saving except in clarity of presentation of conclusions. We have been using charts of this type for some years reproduced on transparent paper so that they can be compared with similar studies by superposition. For example, in obstetrics the chart for primigravidae can be compared very profitably with the chart for multiparae; the chart for 1952 can be compared with the chart for 1956 and the value of modified treatment reliably assessed. On the other hand, the numerical chart has uses which should not be overlooked. In planning investigations or changes in routine treatment, knowledge of the numbers and percentages of patients likely to be involved enables reliable estimates to be made of the work and cost involved, and of the time for which the investigation must run if statistically valuable conclusions are to be reached.—We are, etc.,

London, W.C.1.

M. N. BAINBRIDGE.

Clinic for Psycho-sexual Disorders

SIR,—May I through the courtesy of your correspondence columns draw the attention of Dr. Clifford Allen (*Journal*, September 21, p. 715) and others interested to the clinics for psycho-sexual disorders which are held at the North Kensington Marriage Welfare Centre?

These clinics were started for women as early as 1934 under the guidance of the late Dr. Joan Malleon and were extended for men in 1953. Four sessions are now held every week by men and women consultants. Fees are from 30s. according to income, but those unable to pay are never refused. Appointments are booked in the usual way; further details can be obtained from the Secretary, North Kensington Marriage Welfare Centre, 12, Telford Road, London, W.10.—I am, etc.,

London, W.10.

JEAN W. D. PASMORE,
Chairman of Medical Committee,
North Kensington Marriage Welfare Centre.

Radiation Pneumonitis

SIR,—Dr. William M. Ross (*Journal*, September 21, p. 708) wisely emphasized this complication of palliative radiotherapy. It may be thought to be pleurisy and bronchitis arising soon after the completion of treatment. I have found that treatment with prednisolone 5 mg. four times a day is dramatic in cases following radiotherapy for carcinoma of the breast when there was no previously existing lesion in the lungs. I add tetracycline or other appropriate antibiotics, as indicated by sputum culture, to the prednisolone in cases following irradiation of bronchial carcinoma. The rapid cessation of dyspnoea and improved sense of well-being justifies the cost of the drug. I have been using this treatment for some long time and find the fatal unexplained pneumonias occurring soon after treatment, previously not uncommon, are now rare.—I am, etc.,

London, W.1.

ANTHONY GREEN.

Motor Complications of Herpes Zoster

SIR,—With regard to Dr. D. Kendall's article on motor complications of herpes zoster (*Journal*, September 14, p. 616) and with particular reference to his paragraph on Bell's palsy, the following case may be of interest.

A married woman of 77 was admitted to the geriatric unit of the West Middlesex Hospital under the care of Dr. Warren. She gave a fortnight's history of severe pain in the left pre-auricular area, and on the morning of admission had developed weakness of her left arm and leg. Examination showed that she had a severe torticollis, with her chin deviated to the right, and left facial weakness of infranuclear type and a spastic left hemiparesis. No local cause for her pain was discovered and there was no sensory impairment. The cerebrospinal fluid contained 116 mg.% of protein but no increase of cells. She made a good functional recovery from her left hemiparesis and at the time of discharge after eleven weeks' treatment her facial palsy had greatly improved.

It was thought that a double lesion was responsible for this syndrome, but the question is now raised whether it could have been due to a herpes zoster infection without skin manifestations.—I am, etc.,

Isleworth, Middlesex.

C. H. TOWNER.

Toxic Effects of Meprobamate

SIR,—In view of recent correspondence on the toxic effects of meprobamate from Dr. David L. Miller (*Journal*, August 3, p. 300), Dr. Helen Wagstaff (*Journal*, August 17, p. 414), and Dr. A. Gordon Beckett (*Journal*, September 28, p. 763) the following similar case may be of interest.

A woman, aged 49, was given a single dose of 400 mg. meprobamate ("equanil") to alleviate her anxiety concerning bright erythematous rash, involving mainly the trunk and to a lesser extent the limbs but not the face. At the same time she had a severe rigor which was followed by the development of pyrexia—101° F. (38.3° C.). Two hours later there was diarrhoea, vomiting, and extreme general malaise. The patient was admitted to hospital and found to have a white blood count of 22,800 (polymorphs 96%, eosinophils 1%, leucocytes 3%). Treatment was started at 50 mg. orally three times a day, and within 24 hours the temperature had settled, the white cell count had returned to 10,350 per c.mm., and the rash had started to fade, but several small vesicular eruptions had appeared over the sternum. Within 48 hours symptoms and signs had disappeared. There was no history of ever having taken this drug before or any similar type of preparation.

This case appears to correspond in general with previously described cases, but the rigor, pyrexia, vomiting, diarrhoea, and leucocytosis in addition to the typical rash are interesting features.—I am, etc.,

Bebington, Cheshire.

P. L. ROBINSON.

Obituary

ARTHUR J. CLEVELAND, O.B.E., M.D., F.R.C.P.
Dr. Arthur J. Cleveland, consultant physician to the Norfolk and Norwich Hospital, died at Norwich on October 8. He was 85 years of age.

Arthur John Cleveland was born at Brighton on September 17, 1872, the son of Mr. Henry Cleveland, solicitor of the Government of Bombay. Educated at Clifton College, he afterwards entered Guy's Hospital, qualifying M.R.C.S., L.R.C.P. in 1897. In the following year he obtained the London M.B., proceeding to the M.D. in 1899. He was elected M.R.C.P. in 1900 and admitted a Fellow in 1921. While at Guy's Hospital he held the post of medical registrar and tutor. He settled at Norwich in 1902, and two years later joined the medical staff of the Norfolk and Norwich Hospital as an electrotherapist. The following year he was appointed assistant physician and in 1919 full physician. In his earlier days at the hospital he helped to develop the x-ray department. Dr. Cleveland was at one time physician to the Jenny Lind Hospital, and during the first world war he worked at the Thorpe Military Hospital, his services there being rewarded by his appointment as O.B.E. in 1919. He was also neurological specialist to the Ministry of Pensions. When he retired from the active staff of the Norfolk and Norwich Hospital in 1937 he was appointed consultant physician. For 10 years he was a director of the Norwich Union Insurance Societies.

Dr. Cleveland gave notable service to the Norfolk and Norwich Hospital and to the hospital services in Norfolk generally, both as a medical man and an administrator. From the time of his appointment as a physician he gave of his best to his patients and was the instigator of many improvements designed to bring the hospital services into line with modern medical thought. For many years he was a member of the board of management and in 1938 was elected chairman. Normally this appointment was held for one year, but in those uneasy days it was felt that Dr. Cleveland's exceptional ability as an administrator warranted extending the appointment, and he did in fact give yeoman service for five years. During the early years of the second world war much improvisation was required. The hospital was partially evacuated more than once, and in 1942 suffered severe damage by enemy action. Dr. Cleveland's exceptional administrative capability enabled the work to be carried on with a minimum of disturbance. In November, 1942, he was elected lord mayor of Norwich, although he was not a member of the city council. Though then a man of 70, Dr. Cleveland was an energetic lord mayor and did magnificent work for the war-battered city. Both at the hospital and in the city he set a fine example of leadership in a time of exceptional strain and responsibility. With the advent of the National Health Service in 1948 Dr. Cleveland continued his work for the hospital as a member of the new group management committee. In that year he wrote and published *A History of the Norfolk and Norwich Hospital from 1900 to the End of 1946*, thus carrying on an earlier history by Sir Peter Eade which told the story of the hospital from 1770 to 1900. A member of the British Medical Association for 55 years, he was president of the Norfolk Branch in 1922-3. Dr. Cleveland, who married the elder daughter of the late Mr. Edward Jackson, was left a widower in 1955. He leaves a son and a daughter.—J. M. R. T.

A. D. WILLIAMSON, M.B., F.R.C.S.Ed., D.O.M.S.
Mr. A. D. Williamson, for many years ophthalmic surgeon at the General Hospital, Singapore, and lecturer in ophthalmology in the University of Malaya, died on August 18. He was 52 years of age.

Alexander Dewar Williamson was born in 1905 and was educated at Glasgow High School and at Glasgow University,

where he graduated M.B., Ch.B. in 1927. Three years later he obtained the D.O.M.S. of the English Royal Colleges, and in 1932 he was elected F.R.C.S.Ed. After graduation he held the appointments of house-surgeon and house-physician at Glasgow Western Infirmary. In 1928 he became senior house-surgeon at Glasgow Eye Infirmary, where subsequently he was McCann research scholar for some years and clinical assistant. In 1935 Williamson was appointed ophthalmic surgeon to the General Hospital, Singapore, and lecturer in ophthalmology in the King Edward VII College of Medicine (now a constituent college of the University of Malaya). He established the school of ophthalmology in Singapore in very difficult circumstances and in its early days conducted the department single-handed. For a year after the Japanese occupation of Singapore during the second world war he carried on his work more or less as usual, but was eventually interned. After the liberation he took only a short leave of absence before returning to the work he had begun ten years before.

After the war the decision of the university authorities to increase the number of medical students made teaching an essential part of the work of Williamson's department, and he cheerfully and energetically undertook the extra work. With all the claims on his time in other directions, Williamson was first and foremost an ophthalmologist. An authority on trachoma, he collaborated with Dr. P. C. Leong in a fruitful investigation of keratomalacia in newborn infants. As a result of their work, vitamin A was added to all tinned and dried milks sold in Malaya, and this proved completely effective as a preventive. In 1949 the Army Council appointed him honorary consultant to the Army in Singapore; he was also consultant to the Singapore Association for the Blind and a member of its executive committee. He retired in April of this year, leaving his department completely staffed by his former students. Mr. Williamson is survived by his wife, formerly Dr. Catherine McL. Buchanan, who is also an ophthalmologist.

JOHN WALKER, M.C., L.R.C.P.&S.Ed.

Dr. John Walker, who was in general practice at Hastings for nearly 40 years, died at the Royal East Sussex Hospital on September 13. He was 64 years of age.

John Walker was born at Blantyre, Lanarkshire, on July 10, 1893, and was educated at Uddingston Grammar School. He studied medicine at St. Mungo's College, Glasgow, taking the Scottish triple qualification in 1915. After holding the appointment of resident physician at the Ruchill Fever Hospital, he entered the Army and saw service overseas as a captain in the R.A.M.C. during the first world war. He was awarded the Military Cross in 1918 for conspicuous gallantry and devotion to duty, and was also mentioned in dispatches. Soon after the end of the war he settled at Hastings, and was engaged in the work of his practice there until three days before his death. Gay in manner, he was much loved by his patients. His special interest was obstetrics. He was chairman of the Hastings Division of the British Medical Association in 1934-5. A good golfer, he was a past captain of the Hastings Downs club, and he had held several high offices as a freemason. During the second world war his personal example was an inspiration to all civil defence workers, for he showed great courage in helping to rescue the injured during the air raids on Hastings.

BERNARD GRELLIER, M.C., M.R.C.S., D.M.R.E. L.D.S.

Dr. Bernard Grellier, who was for many years a radio-logist at the Royal East Sussex Hospital, Hastings, died on September 10 at the age of 60.

Bernard Grellier was born at Ipswich on October 17, 1896, and was educated at Epsom College. He then studied dentistry at the Royal Dental Hospital, qualifying by taking the L.D.S. of the Royal College of Surgeons of

England in 1910. Later he enrolled as a medical student at Charing Cross Hospital and took the London Conjoint diploma in 1913. After qualifying in medicine he held the appointment of house-surgeon and casualty officer at Charing Cross Hospital and then for a time was assistant dental surgeon to the Royal Dental Hospital and dental surgeon to the City of London Police Hospital. During the first world war he served as a captain in the R.A.M.C. in France and India, and was awarded the Military Cross in 1916. He again served in the R.A.M.C. in the second world war. In 1922 he obtained the Cambridge D.M.R.E., and three years later was appointed radiologist at the Royal East Sussex Hospital, where, a year later, he was joined by his twin brother, the late Dr. Norman Grellier. The two brothers together were in charge of the hospital's x-ray department until the death of Dr. Norman Grellier in 1949, after which Dr. Bernard Grellier carried on alone at the hospital until 1952. He was chairman of the Hastings Division of the British Medical Association in 1951-2. He and his brother, who were the kindest of men, were identical twins, and had much in common, including an interest in model engineering. Together they did much good work in Hastings in an unobtrusive way. In 1936 they were injured in a serious flying accident, but soon started work again. Dr. Bernard Grellier was unmarried, and the sympathy of all who knew him is extended to his mother, now in her 105th year, in her loss.

A. W. M. BATTERSBY, L.R.C.P.&S.Ed., D.P.H.

Dr. A. W. M. Battersby, medical officer of health to the Uttoxeter urban and rural district councils, died at the City Hospital, Derby, on September 23. He was 54 years of age.

Alexander Watson Muir Battersby was born at Glasgow on May 3, 1903, and was educated at Glasgow Academy. He studied medicine at St. Mungo's College, Glasgow, where his father, Professor James Battersby, F.R.C.S., was dean, and took the Scottish triple qualification in 1927. He then held the appointments of house-surgeon and house-physician at the Glasgow Royal Infirmary, resident medical officer at Robroyston Sanatorium, and resident physician-superintendent at Lightburn Fever Hospital, Shettleston. He obtained the Glasgow D.P.H. in 1934, and shortly before the outbreak of the second world war in 1939 was appointed assistant medical officer of health for Shropshire. Two years ago he became medical officer of health to the Uttoxeter urban and rural district councils. He was taken ill while at work and died a few days later. He leaves a widow and twin son and daughter.

G. IDWAL GRIFFITHS, M.R.C.S., L.R.C.P., D.P.H.

The death occurred at Bangor, North Wales, on September 24, the day after his 65th birthday, and after a long and painful illness, of Dr. G. Idwal Griffiths. He was one of Bangor's oldest medical practitioners.

Griffith Idwal Griffiths was born at Bangor in 1892 and was educated at the Priors School there, at the School of Pharmacy, Liverpool, and at the University College of North Wales. He first qualified as a pharmaceutical chemist, and during the first world war he served as a pharmacist with the R.N.V.R. with the rank of sub-lieutenant. After the war he turned to the study of medicine at Liverpool University, taking the London Conjoint diploma in 1921. In the following year he obtained the Liverpool D.P.H. After holding the appointments of senior casualty officer at Liverpool Royal Infirmary and pathologist and cardiologist to the Ministry of Pensions at Liverpool, "Dr. Idwal," as he became affectionately known to his patients, built up a large and successful practice at Bangor, which he had to give up through failing health two years ago. He contributed much to the work of the city council, the port health authorities, and the St. John Ambulance Brigade, which he served for over 30 years as a lecturer, examiner,

divisional surgeon, and corps surgeon. In 1938 he was made an honorary member for Caernarvonshire and in 1942 an honorary life member of the Priory of Wales. He was chairman of the former Caernarvon and Anglesey Division of the British Medical Association from 1948 to 1950. Dr. Griffiths, who was unmarried, is survived by three brothers.

T. W. P. LEIGHTON, O.B.E., M.B., Ch.B.

Dr. T. W. P. Leighton died suddenly on October 2 at his home at Stinchcombe, Gloucestershire, at the age of 79.

Thomas William Parkinson Leighton was born on November 18, 1877, and was educated at Ushaw College, Durham, and at the Victoria University of Manchester, where he graduated M.B., Ch.B. in 1904. He practised for 34 years in the Withnell district of Lancashire, where he was medical officer to the urban district council. Having served in the first world war with distinction, he was appointed O.B.E. in 1920 for his services while a prisoner of war in Germany. A sincerely religious man, he was choirmaster and organist at St. Dominic's Catholic church at Dursley, in Gloucestershire. He enjoyed music, gardening, and sport, and was captain of the Withnell cricket club for many years. When he retired from general practice in 1938 he moved from Lancashire to Gloucestershire, but on the outbreak of the second world war he resumed professional life and acted as locumtenent for general practitioners in the neighbourhood. He also served on the Gloucester medical recruiting board and subsequently became the permanent chairman, an appointment he held until his death. He died in the beautiful garden he had made and loved.

Medico-Legal

INFLUENZA DEATH

An inquest was held in Nottingham on October 21 on Mrs. G. Selby, a 32-year-old married woman, who died of pneumonia following Asian influenza.¹ The coroner, Mr. A. Rothera, concluded that her death had not been aggravated or caused by the inability of the doctor to call and examine her when asked by telephone at 3.30 a.m.

The husband, Mr. K. R. Selby, said that his wife developed a cough on October 13, but she felt better after a doctor prescribed medicine the next day. On October 15 she went to bed feeling worse, and at 3.30 a.m. on October 16 her temperature was 104.5° F. (40.2° C.). He telephoned their doctor, Dr. K. S. Macdonald-Smith, who recommended aspirins, keeping the patient in bed, and sponging her to try to reduce the temperature. At 12.30 p.m. on the same day the doctor called and sent the patient to hospital, where she died the next day.

In his evidence Dr. Macdonald-Smith said that Mrs. Selby had caught a form of pneumonia which swamped the body's defences. Asked whether hospital treatment at 4.30 a.m. would have given better results, the doctor said that at 12.30 p.m. on that day there were only scattered signs of moisture in both lungs. At 3.30 a.m. he would not have found those signs. He was able to detect the pneumonia, but it was not sufficient for him to say it was as dangerous as it turned out to be.

The pathologist's evidence was that hospital treatment at 3.30 a.m. would not have been likely to achieve any different results.

The coroner said that doctors were receiving heavy demands during the epidemic and there were limits to what they could do. Dr. Macdonald-Smith correctly diagnosed the complaint and properly advised treatment, and there was nothing to indicate that he had erred. A verdict of death from pneumonia was recorded.

¹ *Yorkshire Post*, October 22, 1957.

DOCTOR SUES DOCTOR

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On October 10, 1957,¹ the Sheriff Principal of Lanarkshire dismissed an appeal by Dr. David McNeill, of 103, Randolph Road, Glasgow, against a decision of Sheriff-substitute A. G. Walker. Dr. McNeill had practised for 19 years at 479, Vincent Street, Glasgow, and for the last two years Dr. Herbert McCluskey had also used the premises for his own practice. There was an arrangement by which each looked after the other's practice during holidays. In January, 1955, Dr. McCluskey took an appointment as a ship surgeon, and after January 24 did not attend his patients any more. With the consent of the executive council for Glasgow Dr. McNeill agreed to deputize for him until May 31, 1955, when his National Health Service responsibility to his patients came to an end. There were about 600 patients on Dr. McCluskey's list, and during the four months that Dr. McNeill was acting as deputy the fees for them, amounting to some £200, were paid to Dr. McCluskey in full.

Dr. McNeill claimed from Dr. McCluskey £119 for services rendered to his patients during that period, estimating the value of the services at what the Sheriff Principal called the modest figure of £7 per week. The defence was that Dr. McNeill had agreed to deputize during the period without payment.

In his judgment the Sheriff Principal said he had no doubt that Dr. McNeill entered into a contract to act as Dr. McCluskey's deputy without payment, and treated his probationary period at sea as if he were on holiday as a ship surgeon. He therefore refused the appeal with costs.

¹ *Glasgow Herald*, October 11, 1957.

Vital Statistics

Influenza

Deaths from influenza in the great towns in the week ending October 12 were as follows, with the figures for the previous week in parentheses: England and Wales 591 (442), Scotland 90 (75), Northern Ireland 19 (5), and Eire 2 (1). The disease is reported to be waning in the north of England but to be widespread in other parts of Great Britain. Towns with 10 or more deaths from influenza were as follows: Sunderland 16, Leeds 11, Sheffield 12, Bolton 14, Liverpool 33, Manchester 19, Salford 14, Leicester 15, Nottingham 10, Birmingham 33, Stoke on Trent 35, Walsall 10, Wolverhampton 15, London 48, Brighton 10, Cardiff 11, Edinburgh 10, Glasgow 44, Belfast 19.

The accompanying graph shows numbers of deaths in the 160 great towns of England and Wales from early September to the latest date for which figures are available.

The regional distributions of deaths from various causes in England and Wales were as follows in the week ending October 12:

	All Causes	Influenza	Pneumonia	Bronchitis
Northern	394	43	52	22
E. and W. Riding	773	50	69	44
North-western	1,264	142	137	113
North Midland	460	53	39	31
Midland	759	113	58	63
Eastern	327	16	31	15
London and S.E. (including Greater London)	2,110	119	157	136
Southern	225	16	11	9
South-western	344	22	16	14
Wales	185	23	11	23

The following table shows the age distribution of deaths from influenza in the 160 great towns of England and Wales:

Week Ending	0-	1-	15-	25-	45-	65+
Sept. 14	1	9	3	4	14	16
" 21	2	18	8	17	39	37
" 28	3	25	22	47	102	83
Oct. 5	2	36	28	57	159	160
" 12	4	36	32	58	213	248

According to W.H.O. reports the epidemic has reached northern Europe and is increasing in the eastern part of the continent. The height of the epidemic seems to have been reached in West Germany, Belgium, Holland, Italy, and Greece. A recurrence of the disease in Japan seems to be of only limited importance. In other Asian countries it has disappeared or occurred only as sporadic outbreaks.

Week Ending October 12

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 336, whooping-cough 317, diphtheria 1, measles 1,217, acute pneumonia 2,275, acute poliomyelitis 94, dysentery 210, paratyphoid fever 5, typhoid fever 5.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1948-56 (influenza, 1952-6) are shown thus - - - - -, the figures for 1957 thus ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

Compared with the previous week, the largest variations in the notifications of infectious diseases in England and Wales during the week ending October 5 were increases of 513 for acute pneumonia, from 1,367 to 1,880; 347 for measles, from 981 to 1,328; 60 for dysentery, from 202 to 262; and a fall of 181 for whooping-cough, from 564 to 383.

The largest rises in the notifications of measles were 93 in Norfolk, from 33 to 126, and 70 in Lancashire, from 123 to 193. The number of cases of whooping-cough was the smallest since this disease was made notifiable in 1940: the largest fall during the week was 33 in Surrey, from 41 to 8. The notifications of scarlet fever numbered 305, the same number as in the preceding week, and no variations of any size were reported in the local trends. 3 cases of diphtheria were notified, being 2 more than in the preceding week; 2 of these cases were notified in Birmingham C.B. The largest rises in the incidence of acute pneumonia were 119 in Lancashire, from 279 to 398, and 62 in Essex, from 23 to 85.

Four of the six cases of typhoid fever were notified in Warrington R.D., Lancashire.

The notifications of acute poliomyelitis numbered 116, and the number of cases of paralytic poliomyelitis was the same as in the preceding week, the non-paralytic cases being 8 fewer. The largest returns were Lancashire 10 (Ormskirk U.D. 4, Skelmersdale U.D. 2), Devonshire 9 (Seaton U.D. 4, Plymouth C.B. 2, St. Thomas R.D. 2), and London 7.

The centres with the greatest prevalence of dysentery were Yorkshire West Riding 48 (Leeds C.B. 13), Lancashire 36 (Liverpool C.B. 15), Cheshire 33 (Chester C.B. 16, Stockport C.B. 15), Durham 22, and London 22.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending October 5 (No. 40) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1957					1956

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
§ Includes puerperal pyrexia.

Medical News

Royal Society of Medicine.—The Royal Society of Medicine celebrated the jubilee of the granting of its second Royal Charter by a dinner at the Dorchester Hotel on October 16. The president, Sir CLEMENT PRICE THOMAS, was in the chair, and among the many distinguished guests were Lord NUFFIELD, Lord ADRIAN, O.M., and Sir HENRY DALE, O.M. The Master of the Rolls, Lord EVERSHER, who proposed the health of the Society, in the course of a gently humorous speech said that the 50 years of the Society's existence under its present name had been 50 years of very great and notable achievement, and like all achievement it had not been gained without effort and serious struggle. Now it was their wish for the Society that it might go forward on its road to the future with all possible good fortune. Sir CLEMENT PRICE THOMAS, responding to the toast, referred to the steady progress which the Society had made. Its library, he said, was now a national asset. During his period of office and his trips abroad he had been impressed—and he hoped their foreign guests would not mind him saying so—by the high standing of British medicine. That, he thought, rested largely upon the individual service to the community which their profession afforded. Any voluntary institution depended for its success on individual service to one's fellows, and he hoped and trusted that in the evolution of the National Health Service that sense of service would be preserved. The Society had decided that efforts should be made to increase international contacts, and it was hoped that they would have affiliations in the United States and Dominions and probably in other countries. The president then presented the honorary fellowship of the Society to Lord NUFFIELD, who said it had given him the greatest pleasure to have done what he had been able to do. After the presentation to Lord Nuffield, specially bound copies of the recently published book *Sidelights on the History of Medicine*, edited by Sir ZACHARY COPE, were presented to Dr. JULIA M. B. KUTSCHBACH, editor of the Society's *Proceedings*, and to Sir ZACHARY COPE. The president said the gifts were in recognition of the work for the Society which those two members had done. Mr. TERENCE CAWTHORNE then proposed the health of the guests, and in reply Mr. DEREK WALKER-SMITH, Minister of Health, spoke feelingly of Lord Nuffield as a great humanist and great citizen as well as a great industrialist and benefactor; he had earned the future gratitude of millions yet unborn. Lord DOVERCOURT also replied.

Travelling Grant for G.P.s.—The English-speaking Union invites applications from general practitioners (preferably in their thirties, but not over 50) for a Ford-English-Speaking Union travel grant to visit the United States for 70 days within the period March to June, 1958. The purpose of the grant is to enable an "opinion-forming person" who would not normally have an opportunity of visiting the United States to get to know the traditions, customs, and manner of thinking of that country, with a view to fostering international understanding. Further details are obtainable from the secretary, The English-Speaking Union of the Commonwealth, Dartmouth House, 37, Charles Street, Berkeley Square, London, W.1. The closing date for applications is December 31.

"Journal of Mental Deficiency Research."—The first issue of this new journal, which will appear half-yearly to begin with, contains contributions on the genetics of anencephaly, improvement of performance in imbeciles, the leucocytes in mongolism, mental deficiency problems in the United States, and phenylketonuria. It is edited by Dr. B. W. RICHARDS, with an editorial board of eight under the chairmanship of Professor L. S. PENROSE, F.R.S. Publication has been made possible by financial assistance from the National Society for Mentally Handicapped Children. It is stated that articles on all aspects of mental deficiency will be included, "but there will be a medical bias, and a high proportion of avail-

able space will be allotted to papers reporting the results of original research." The annual subscription is 15s. (single copies 7s. 6d. or \$1.50 each). Subscriptions should be sent to the publishing manager, Mr. A. HIGHFIELD, 10, Shendon Way, Sevenoaks, Kent; editorial matter or inquiries to Dr. B. W. RICHARDS, St. Lawrence's Hospital, Caterham, Surrey.

Department of Anaesthesia at Charing Cross.—Sir ROBERT MACINTOSH, Nuffield professor of anaesthetics at Oxford, opened a new department of anaesthesia at Charing Cross Hospital Medical School on October 8. The new department is under the direction of Dr. H. K. ASHWORTH, senior anaesthetist at the hospital.

"Microscopium."—At a reception held by the Anglo-Netherlands Society in London on October 16, presentation copies of an English edition of *Microscopium* were handed to representatives of medical and scientific institutions by Sir NEVILLE BUTLER, formerly British ambassador to the Netherlands. *Microscopium* is an illustrated account of the development of the microscope and its uses from 1656, the date of Pierre Borel's original monograph on microscopy, to the present day. The author, Dr. MARIA ROOSEBOOM, who attended the reception, is director of the national museum of the history of the natural sciences, Leyden, and the first publication of *Microscopium* was as No. 95 in the museum's *Transactions*. The scientific bodies to which the special library volumes were presented included the Royal College of Surgeons of England, the Royal College of Physicians of London, the Royal Society of Medicine, the Royal Society of Tropical Medicine and Hygiene, the Institute of Basic Medical Sciences, the Society of General Microbiology, the Wright-Fleming Institute, and the Harveian Society of London. In addition each guest at the reception received a copy. The sponsors of the English translation, which has been distributed privately, are Messrs. Pfizer Ltd.

Press and 'Flu.'—The Leeds Local Medical Committee, after a unanimous vote at its meeting on October 1, sent the following resolution to the Press Council: "The Leeds Local Medical Committee, representing the general medical practitioners of Leeds, take the strongest possible exception to the manner in which the present influenza epidemic has been highlighted by the local evening press by their persistence of sensational reporting of deaths from influenza, which are quite out of all proportion to the cases involved and about which the general public are quite unable to form their own judgment as to the statistical significance and insignificance of these deaths. A great deal of unnecessary anxiety has been engendered among the general public and an unnecessary additional burden has been imposed on an already overburdened profession." Copies of the committee's complaint were sent to the *Yorkshire Evening News* and the *Yorkshire Evening Post*. In a leader published the day after the complaint to the Press Council the *Yorkshire Evening Post* replied: "We reported the news as it developed—the good and the bad. When official reassurance was forthcoming, we gave prominence to such news." Earlier, in response to criticism of the local press by the executive council's chairman, Dr. J. E. RUSBY, the *Post* said: "In the matter of this influenza epidemic the press as a whole has admirably fulfilled the function of informing the public, which is part of its daily duty."

Moxon Medal.—At a ceremony at the Royal College of Physicians of London on St. Luke's Day this year's Moxon medal was presented to Sir JOHN PARKINSON, the eminent cardiologist. The citation records that Sir John's "keen perception of what would be of help to the patient has always guided his researches into the diagnosis of heart disease, in order to bring it within the compass of practical therapy."

Sir Henry Tidy, 80.—On Sunday Sir HENRY LETHEBY TIDY will be 80. Consulting physician to the Royal Military Hospital, Millbank, and to St. Thomas's Hospital, and a former Censor of the Royal College of Physicians, Sir Henry is also familiar to generations of medical students as author

of a successful textbook, *Synopsis of Medicine*. Friends, colleagues, and students alike will wish to join us in congratulating him.

Liverpool Medical Institution.—Dr. MARGARET E. THOMAS was installed as president at the inaugural meeting of the Institution's 121st session on October 10. Professor BRYAN MCFARLAND, the retiring president, said it was an historic occasion, for Dr. Thomas was the first woman to be elected president since the Institution was founded in 1837. Dr. Thomas gave her inaugural address on "The Artist's Contribution to Medicine," in which she made particular reference to the work of Leonardo da Vinci and the Dutch School and referred to the local artist George Stubbs.

World Federation for Mental Health.—1960 has been designated "World Mental Health Year" by the Federation. Activities planned for that year include: (a) the training of groups to undertake co-ordinated surveys of the occurrence and causes of all types of mental and emotional ill-health; (b) the study of causes which may be preventable through education or community action; (c) increased efforts to study the development of good "positive" health and human relations whatever the interpretation of these may be in different cultures; (d) stimulation of activities within countries all over the world.

Royal Society of Health.—Dr. J. A. SCOTT, Medical Officer of Health, London County Council, has been installed as chairman of council for the year 1957-8.

COMING EVENTS

Maudsley Lecture.—Royal Medico-Psychological Association's Maudsley Lecture will be given by Sir WILFRID LE GROS CLARK, F.R.S., on November 14 at 2 p.m. His subject will be "Sensory Experience and Brain Structure."

Frederick Price Lecture.—Sir RUSSELL BRAIN will deliver the Frederick Price Lecture on November 14 at 5 p.m. at the Royal College of Physicians, 9, Queen Street, Edinburgh, 2. His subject will be "Neurology: Past, Present, and Future."

Specialist Conference on Psychiatry, Glasgow, October 28 to November 1, arranged by the Postgraduate Medical Education Committee of Glasgow University and the Royal Faculty of Physicians and Surgeons, 242, St. Vincent Street, Glasgow, C.2.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, October 28

INSTITUTE OF CARDIOLOGY.—9.30 a.m., Sir John Parkinson: Palpitation.
MANCHESTER MEDICAL SOCIETY: SECTION OF GENERAL PRACTICE.—At Large Anatomy Theatre Manchester University, 8.30 for 9 p.m., Dr. R. W. Fairbrother: Recent Developments in the Antibiotic Field.
MANCHESTER MEDICAL SOCIETY: SECTION OF ODONTOLOGY.—At Lecture Room, Dental Hospital, 4.30 for 5 p.m., Presidential Address by Mr. F. Taylor Monks: Conservative Surgery in the Treatment of Adamantinomas.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. A. G. Leatham: Art of Auscultation.

Tuesday, October 29

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. J. P. Shillingford: Study of the Circulation by Dye Dilution Curves.
FOUNTAIN HOSPITAL.—5 for 5.30 p.m., paper by Dr. D. H. Stott: Some Recent Work on the Causation of Mental Defect; film by Mr. James Robertson: Maternal Deprivation in Young Children.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. N. R. Mackay: Radiation Physics (2).
MANCHESTER REGIONAL DERMATOLOGICAL ASSOCIATION.—At Clinical Sciences Building, York Place, 8.30 p.m., in conjunction with North-west England Faculty of College of General Practitioners. Lecture for general practitioners, Dr. B. Portnoy: Bacterial and Viral Diseases of the Skin; Dr. P. Meirink: Acne and Seborrhoea.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Sir Robert Macintosh: Anaesthetics Behind the Iron Curtain.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Dr. J. D. W. Pearce: Depressive States.
ST. MARY'S HOSPITAL MEDICAL SCHOOL (WRIGHT-FLEMING INSTITUTE THEATRE).—5 p.m., Mr. W. J. H. M. Beattie: The Acute Abdomen and the Gynaecologist.
WEST END HOSPITAL FOR NEUROLOGY AND NEURORADIOLOGY.—5.30 p.m., Dr. G. A. D. Gordon: Demonstration of Neuroradiology.

Wednesday, October 30

ABORTION LAW REFORM ASSOCIATION.—At Lancaster Room, Caxton Hall, 6.30 p.m., annual general meeting, 7.15 p.m., public meeting, Mrs. Lena Jeger, M.P.: Family Planning in China.
BRITISH ASSOCIATION OF SPORT AND MEDICINE.—At University College Hospital Medical School, 5.30 p.m., Dr. I. J. MacQueen: Influence of Somatotype on Selection and Training for Sport and Athletics.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Diagnosis of Furunculosis Infection.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Professor J. W. Crofton: Methods of Clinical Research in Chest Disease.
● INSTITUTE OF NEUROLOGY.—5.30 p.m., Dr. Helen E. Dimsdale: Generalized Infections.
● INSTITUTE OF OBSTETRICS AND GYNAECOLGY.—4.30 p.m., Mr. D. H. MacLeod: Problem of Endometriosis.
● INSTITUTE OF ORTHOPAEDICS.—8 p.m., Professor Jose Valls (Buenos Aires): Aspiration Biopsy of the Spine.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. D. I. Williams: Malformations of the External Genitalia.
LIBRARY ASSOCIATION (MEDICAL SECTION).—At Chaucer House, Malet Place, London, W.C., 6.30 p.m.: Dr. J. G. Thwaites, Mr. W. J. Bishop, and Mr. W. R. Maidment: How Far Should the Public Library Provide Medical Literature?
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. J. D. N. Nabarro: Diabetes and Carbohydrate Metabolism (II).
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Professor T. H. Davey: Domestic Animals and Human Disease.

Thursday, October 31

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, W.C., 5.30 p.m., Dr. Rosemary Biggs: Haemophilia and Christmas Disease.
CHADWICK TRUST.—At Usher Institute, Warrender Park Road, Edinburgh, 5 p.m., Professor I. H. F. Brotherton: William Pulteney Alison, Scottish Pioneer of Social Medicine.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. G. C. Wells: Pigmentation.
INSTITUTE OF PSYCHIATRY.—At Maudsley Hospital, 3 p.m., Dr. W. H. Thorpe, F.R.S.: Drive and Instinct in Animals.
LIBRARY ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Old Library, R.M.A. House, 8.30 p.m., Professor Dorothy S. Russell: Changing Scene from the Pathologist's Angle.
LONDON UNIVERSITY.—At Royal Society of Medicine, 5 p.m., Semon Lecture by Mr. F. C. W. Capps: Abductor Paralysis, Theory and Practice Since Semon.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Robert Jones Lecture by Professor J. S. Barr: Arthroplasty of the Hip.
ROYAL SOCIETY OF HEALTH.—At Caxton Hall, Westminster, S.W., 2.30 p.m., Conference on Health Education in Relation to Smoking and Lung Cancer. Papers by Mr. R. W. Raven, Professor Andrew Semple, and Dr. John Burton.

Friday, November 1

COLLEGE OF GENERAL PRACTITIONERS: MIDLAND FACULTY.—At Board Room, Worcester Royal Infirmary, 3 for 3.15 p.m., Dr. I. E. Phelps: Certification—Family Doctors and the Ministry.
● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. A. Porter: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. K. F. W. Hinson: clinical demonstration.
PLYMOUTH MEDICAL SOCIETY.—At Freedom Fields, 8.30 p.m., Dr. Alice M. Stewart: Recent Developments in Social Medicine.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Professor Henry Barcroft: Sympathetic Control of Limb Blood Vessels.
● ROYAL INSTITUTION.—9 p.m., Sir Hugh Beaver, M.Inst.C.E., M.I.Chem.E., M.E.T.C.: Clean Air—What We Know and What We Do Not Know.
ROYAL MEDICAL SOCIETY, EDINBURGH.—8 p.m., dissertation by Mr. C. V. Ruckley: Alcohol.
ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—At Royal Faculty of Physicians and Surgeons of Glasgow, 8.30 p.m., symposium on paediatric surgery. Mr. J. F. R. Bentley: Surgical Help for Some Infants with Respiratory Symptoms; Mr. N. J. Blockley: Recent Advances in Paediatric Orthopaedics; Mr. J. L. Morton: Vomiting in the Newborn.

Saturday, November 2

ASSOCIATION OF CLINICAL BIOCHEMISTS: SOUTHERN REGION.—At Royal Free Hospital, W.C., 2.15 p.m., annual general meeting, followed by scientific papers.

Sunday, November 3

MANCHESTER UNIVERSITY: FACULTY OF MEDICINE.—At Theatre 1, Clinical Sciences Building, York Place, 11 a.m., in conjunction with North-west England Faculty of College of General Practitioners. Lecture-demonstration for general practitioners. Mr. R. L. Holt and Mr. A. Jolleys: The Acute Abdomen.
UNIVERSITY COLLEGE HOSPITAL.—10.15 a.m., lecture-demonstration for general practitioners by Professor C. E. Dent: Renal Stones, Their Aetiology, Symptoms, and Prevention.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Beven.—On October 16, 1957, at Queen Charlotte's Hospital, London, W., to Suzanne (formerly Hassan), wife of Geoffrey Beven, M.D., a daughter.—Rosemary Margaret.
Hardman.—On September 18, 1957, at the Sandford Nursing Home, Llandudno, to Brenda, wife of Dr. Gordon Hardman, a son.
Ollerenshaw.—On October 16, 1957, to Joan (formerly Weatherill), wife of Dr. Guy Ollerenshaw, of Skipton, Yorks, a son.

DEATHS

Griffiths.—On September 24, 1957, at Bangor, North Wales, Griffith Idwal Griffiths, M.R.C.S., L.R.C.P., D.P.H., aged 65.
Kellough.—On September 29, 1957, at his home, 31, Ladbroke Road, London, W., Thorold McDiarmid Kellough, M.D.
Lavery.—On September 29, 1957, at King George Hospital, Ilford, Essex, James Aloysius Lavery, L.R.C.P.S., L.R.F.P.S., D.P.H.
Ray.—On September 29, 1957, in London, Charlotte Ray, M.R.C.S., L.R.C.P., of 28, Cholmeley Lodge, Highgate, London, N.
Roy.—On September 9, 1957, at Blackpool, Lancs, James Lumsair Davie Roy, M.B., Ch.B., D.P.H., late of Sudan, aged 53.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Peripheral Circulatory Failure in Peritonitis

Q.—In toxic myocarditis due to a fulminating peritonitis, what measures should be adopted to prevent peripheral circulatory failure until the peritonitis can be brought under control?

A.—There seems to be no value in any measures directed specifically to prevent peripheral circulatory failure in peritonitis. Peripheral circulatory failure is best prevented, and most effectively reversed, by correction of the patient's fluid and electrolyte state and relief of his abdominal distension. Suitable intravenous administration of half-strength saline together with potassium, if the potassium level is low, and the institution of gastro-intestinal suction, usually improve the peripheral circulation even before antibiotics have begun to bring the infected organism under control. The peripheral circulatory failure is an effect not so much of toxins as of fluid and electrolyte depletion.

Angular Stomatitis

Q.—A young woman developed fissures at the angles of her mouth during a recent pregnancy. These have persisted despite treatment with vitamin preparations and an ointment containing neomycin and hydrocortisone. Her teeth are healthy. What is the aetiology and treatment of the condition?

A.—Fissures at the angle of the mouth (angular stomatitis) are often evidence of nutritional deficiency, especially in pregnancy. They may be associated with an iron deficiency anaemia and achlorhydria or lack of one of the components of the vitamin-B complex, notably riboflavin. Sometimes the aetiology is obscure and there is no valid explanation for their presence. A full blood count and test meal should be included in the investigation. Although in the case described vitamin preparations have not proved helpful, it is possible that their potency has not been sufficient. It is suggested that tablets of aneurin, co. fort. of the National Formulary (two tablets thrice a day) might be helpful. These tablets consist of aneurin (5 mg.), riboflavin (2 mg.), nicotinamide (20 mg.), and pyridoxine (2 mg.).

Invalids at High Altitude

Q.—In what conditions is (a) a holiday and (b) residence at a high altitude (5,000–10,000 ft.—1,524–3,048 m.) contra-indicated? Would, for instance, a holiday at a winter sports resort at over 6,000 ft. (1,830 m.) be harmful to a patient with emphysema and bronchitis and coronary disease?

A.—Apart from such general benefit as is to be derived from convalescence in a pleasant environment and climate, the only specific benefit of a holiday or residence at high altitude is derived from the beneficial effect which it usually has upon chronic bronchitis. This is derived in part from the avoidance of contact with inhaled allergens, a factor which, although it is most obvious when an asthmatic factor is clinically evident, is also probably of some importance in many cases of chronic bronchitis; and in part from the lessened liability to intercurrent respiratory infections. Most chronic bronchitics, however, would have to be careful about the sudden changes of temperature to which they might be exposed at high altitudes.

The possible ill-effects arise from the lowered barometric pressure leading to lowered oxygen tension at altitudes. At 6,000 ft. (1,830 m.) the barometric pressure is reduced from the normal 760 to approximately 600 mm. Hg, with a corresponding reduction of oxygen tension in the inspired air.

In health, a reduction of this degree is without clinically evident effect. In a patient with emphysema and bronchitis and coronary disease, the effect would depend upon which of these disabilities was predominant. If the emphysema, which is characterized by a reduction in the diffusing capacity of the lung, was predominant, the effect of altitude would be expected to be deleterious; if, on the other hand, the bronchitis was the principal feature, the beneficial effect on this element in the disability might predominate. The coronary artery disease would also need to be taken into consideration, since the lowered arterial oxygen which would be expected at this altitude if the patient was severely emphysematous would undoubtedly be undesirable in a patient with severe coronary artery disease. Another factor to be considered in a patient with coronary disease is the physical effort involved in the journey to a high altitude resort. On the whole, residence at a high altitude would be desirable in the case described only if the bronchitis was clearly the predominant feature.

Masturbation in Young Girl

Q.—What advice should I give to a mother who tells me that her daughter, aged 5 years, masturbates herself to sleep every night and, if she is bored, does it also during the day? She started the habit when she was 2 years old.

A.—This question is a difficult one. The odds are that the problem is the result of determined efforts on the part of the mother to stop the girl handling the genital area. In the first place the parents should be brought to realize that the habit is harmless and that efforts to stop it will do nothing but make it continue. It should be ignored. During the day the only alternative to ignoring it completely is to distract the girl by giving her some new occupation—without making it obvious to her that one is trying to stop the masturbation. Secondly, any obvious source of insecurity in the home should be removed, in particular excessive strictness—or lack of discipline—constant nagging and reprimands, or favouritism towards a sibling. If there is undue jealousy, every effort should be made to let the girl feel loved and important.

It sometimes helps to apply a local analgesic ointment to the genital area. This might be done when the child is put to bed if other measures fail.

Unusual Reaction to Injection of Liver Extract

Q.—A case of herpes ophthalmicus was treated in its early stage by intramuscular injection of liver extract. After two hours the patient developed the following symptoms: slight rigor; maniacal tendency with a desire to strangle her cat, attack her husband, etc.; headache and muscle weakness. Is there any record of such effects following liver injections, or could there have been a direct connexion between the disease itself and the cerebral crisis?

A.—Rigor, headache, and muscular weakness are not unusual accompaniments of allergic reactions to injections of liver extract, which are of course quite common and which is one of the reasons why cyanocobalamin has replaced liver extract (or ought to have replaced it) in therapeutics. The aggressive psychological symptoms recorded are very unusual manifestations of an allergic reaction, but must nevertheless be ascribed to the same mechanism. It is difficult to trace any connexion between the disease and the unusual cerebral crisis. It is very doubtful whether injections of liver extract or of cyanocobalamin are of any value in herpes ophthalmicus.

Occupational Raynaud's Phenomenon

Q.—Is a man with Raynaud's phenomenon due to his occupation eligible for a disability allowance? The condition is not a prescribed disease, nor can his employers be accused of neglect.

A.—If the man is unfit for work he may be eligible for sickness benefit, but a claim for the special benefits of the Industrial Injuries Acts would not normally be expected to

succeed. Industrial injuries benefit is paid only for disability resulting from an industrial accident or one of the prescribed industrial diseases. It has been held that Raynaud's phenomenon caused by a continuous process cannot be regarded as the result of an "accident." Nor is the condition prescribed as an occupational disease. The question whether it should be so prescribed was examined by the Industrial Injuries Advisory Council in a report published in 1954, but by a majority the council recommended against its prescription.^{1,2}

Prognosis and Treatment after Bilateral Torsion of the Testicle

Q.—Three years ago a young man suffered torsion of the left testicle which subsequently atrophied; six months ago the same happened to his right testicle, so that he now has bilateral testicular atrophy. Secondary sexual characters are at present normal, and attraction to the opposite sex is experienced. Is replacement therapy indicated, and what is the prognosis regarding potency and fertility?

A.—This is an unusual sequence of events, and it is possible after such torsion for all the elements in the testes to atrophy so that the patient becomes eunuchoid. It is also possible for the more sensitive seminiferous tubules to atrophy but the interstitial cells to remain functional. In these circumstances the secondary sexual characters, libido, and potency would remain normal, but the patient would be sterile. This appears to be the case in the patient described.

Replacement therapy for such a condition is not called for, and fertility cannot be restored. If, on the other hand, the interstitial cells have atrophied, replacement therapy with testosterone "linguets" under the tongue, 25 mg. twice daily, or oral methyltestosterone, 25 mg. twice daily, is of immediate benefit in restoring libido, potency, and secondary sexual characteristics.

Rhinophyma

Q.—What can plastic surgery offer for a progressive rhinophyma in a man of 45?

A.—Very mild cases of rhinophyma can sometimes be helped by wire-brush abrasion. By this method the thickened skin can be planed down. More marked cases are better treated by deliberate excision, either of lobulated aggregations around the nostril, leaving enough nostril tissue to reshape the nose, or by excision of the affected skin to full thickness and its replacement by free graft or flap as may be appropriate.

Chemical Contraception and Foetal Abnormality

Q.—In pregnancies which result despite the use of chemical contraceptives is there any evidence that the chemical can so damage the fertilized ovum as to result in a mentally defective or malformed child?

A.—I think it quite fair to say that there is no evidence of any kind that pregnancies which have occurred despite the use of chemical contraceptives have resulted in any excess of congenital abnormalities in the offspring, such as might have happened had a damaged sperm fertilized the ovum. The chemical itself cannot directly affect the fertilized ovum; it could only cause damage by some injurious effect on surviving sperms.

NOTES AND COMMENTS

Effect of Adoption on Fertility.—Dr. J. K. PATERSON (Huntingdon) writes: May I add a note to your expert's answer on this subject ("Any Questions?" September 21, p. 719). The most comprehensive attempt to answer this question that I have found quotes 8% (of 202 cases) as reporting conception following adoption. This gross figure is corrected by the authors by the exclusion of cases in which there were (a) no uterus, (b) no Fallopian tubes, or (c) no spermatozoa, to give a figure of 15.7%, which

they regard as being insignificant. I feel that, where evidence of non-production of male germ cells is accepted as a cause for exclusion from this series, lack of evidence of production of female germ cells should likewise disqualify: if cases of persistent non-ovulation are thus excluded, the post-adoptive conception rate is 17.4%, and I would question whether this is not in fact statistically significant. I have attempted to gain figures from adoption societies and from the General Register Office, so far without success, and I would be most grateful for details of cases of post-adoptive conception known to your readers.

REFERENCE

- ¹ Hanson, F. M., and Rock, J., *Amer. J. Obstet. Gynec.*, 1950, 59, 311.

Anaesthesia in Hepatic Disease.—Dr. D. ZUCK (Enfield, Middlesex) writes: I was surprised to see that your expert in answer to a question on anaesthesia in hepatic disease ("Any Questions?" September 28, p. 776) advises the use of "relaxants such as suxamethonium" without any qualifications. One of the outstanding features of liver disease from the anaesthetist's point of view is impaired production of pseudocholinesterase, with consequent sensitivity of the patient to suxamethonium; conversely there is resistance to the effects of the curarizing drugs. Reference may be made to a review of the problems of anaesthesia for the jaundiced patient in the symposium on jaundice published in the *British Journal of Clinical Practice*, 1957, 11, 365.

OUR EXPERT replies: In my answer to this question I suggested that the anaesthetic be administered by a real expert conversant with modern methods, and assumed therefore that such a drug as suxamethonium would be used only in appropriate dosage. Small doses of suxamethonium seem to be well tolerated in the usual patient with jaundice needing an operation. In point of fact, depression of serum cholinesterase is a feature of advanced cirrhosis with malnutrition. It is little changed in obstructive jaundice. Patients with advanced hepatocellular disease should not be having a laparotomy for the diagnosis of jaundice. Further details of this problem can be found in the paper by Foldes *et al.*¹

Prophylactic Gargling.—Dr. W. HARGRAVE-WILSON (London, W.1) writes: In answer to this question ("Any Questions?" September 28, p. 775) your expert states: "I doubt whether gargling is, in any ordinary circumstances, likely to do harm." I have found several patients suffering from cervical spondylosis in whom the hyperextension of their neck associated with gargling has been found to bring on or aggravate their symptoms. It was quite some time before I got on to this, and, unless one bears the possibility in mind, one can easily be baffled by the patients' failure to respond to treatment.

Correction.—In our medico-legal article, "Who Died First?" (*Journal*, October 12, p. 888), the third line of the second paragraph should have read Buckinghamshire, not Buckingham, Lancashire.

Collected Articles from the "British Medical Journal"

SOME EFFECTS OF ADRENAL CORTICAL STEROIDS ON INTERMEDIARY METABOLISM*

BY

GEORGE W. THORN, M.D., A.M., LL.D., Sc.D.(Hon.)

Hersey Professor of the Theory and Practice of Physic, Harvard Medical School; Physician-in-Chief, Peter Bent Brigham Hospital

ALBERT E. RENOLD, M.D.

AND

ALBERT I. WINEGRAD, M.D.

Research Fellow in Medicine, Harvard Medical School; Assistant in Medicine, Peter Bent Brigham Hospital; Post-doctoral Fellow of the United States Public Health Service

The importance of the adrenal gland to the total economy of the individual was indicated by the classic description of Thomas Addison in 1855 and the subsequent experiments of Brown-Séquard (1856). It was not until 1903, however, that Bierry and Malloizel first described hypoglycaemia in adrenalectomized dogs. Porges in 1909 independently described a similar phenomenon in patients with Addison's disease, and in the following year first observed the occurrence of low levels of liver and muscle glycogen a few hours after adrenalectomizing fasted dogs. These observations were confirmed by Schwartz (1910) and Kahn and Starkenstein (1911).

Following the discovery of insulin, Maranon (1925) reported that patients with adrenal insufficiency exhibited marked sensitivity to administered insulin, and Cori and Cori (1927), extending the original observations of Porges, Schwartz, and Kahn and Starkenstein, showed that adrenalectomized rats fasted for 24 hours had practically no liver glycogen.

During this early period Britton and Silvette (1932) championed the theory that the "prepotent" function of the adrenal cortex was concerned with the regulation of carbohydrate metabolism. In summarizing their observations these investigators noted: "The effects of adrenalectomy on carbohydrate metabolism are profound in character and appear to be primarily responsible for the death of the animal. Blood glucose and liver glycogen . . . show marked reduction from the normal levels. There are also associated decreases in muscle glycogen and increases in blood lactate. The glycogen of the heart is not reduced. . . . Completely adrenalectomized animals show a markedly reduced ability to store liver glycogen. Normal animals who were injected with glucose stored eight to ten times as much glycogen as operated animals."

Controversies necessarily arose as different species of animals were used by different investigators and since the importance of the sodium and potassium content of

the diet was not appreciated. In addition, the early preparations of adrenal extract showed wide and unpredictable variations in potency, so that standardization of dosage, permitting comparison by different investigators, was practically impossible.

In 1934 Hartman and Brownell observed that adrenalectomy significantly modified the severity of pancreatic diabetes in the cat, and that the diabetic syndrome was exacerbated by the administration of adrenal extract. Subsequently, in an extensive carefully controlled series of experiments, Long and Lukens (1934-5) established the effect of adrenalectomy on pancreatic diabetes.

In 1936 Evans demonstrated that fasted adrenalectomized animals excreted 25% less nitrogen than normal controls. The excellent paper by Long, Katzin, and Fry (1940) summarized the situation as of that time. In short, they noted that adrenalectomized mice and rats maintained on sodium salts retained practically normal carbohydrate levels when fed; however, when fasted, the levels declined more rapidly than in normal animals. Fasted adrenalectomized animals also excreted less urine nitrogen. The administration of cortical extract to either fasted-normal or adrenalectomized mice and rats was followed by large increases in liver glycogen and slight hyperglycaemia. The muscle glycogen was not affected. At the same time there was a significant increase in nitrogen excretion, suggesting that increased protein catabolism was the source of this newly formed carbohydrate. Moreover, they noted that in partially pancreatectomized rats adrenalectomy and maintenance on sodium salts was associated with decreased glucosuria; that the administration of adrenal extract and of certain crystalline steroids then available exacerbated the glucosuria; and that the ability to produce increased glucosuria was not shared to an equal degree by the crystalline steroids then obtainable.

About this same time naturally occurring 11- and 11, 17-oxygenated steroids, in addition to synthetic 11-desoxycorticosterone (deoxycortone), became available in amounts which, though small, were sufficient for clinical trial. An attempt therefore was undertaken to extend the experimental studies to man.

Studies in Addison's Disease

In 1940 Thorn, Koepf, Lewis, and Olsen reported that the severe reactive hypoglycaemia observed in patients with Addison's disease after an intravenous infusion of glucose was not affected by the administration of deoxycortone acetate (30 mg.), but was abolished by the administration of an equivalent quantity of 17-hydroxy, 11-dehydrocorticosterone (compound E of Kendall, cortisone). Not only was the hypoglycaemia corrected by cortisone but a *delayed glucose disappearance curve and accompanying glucosuria* were noted (Fig. 1). Corticosterone (compound B of

FIG. 1.—Intravenous glucose-tolerance tests in a woman (E.L.) aged 51 with Addison's disease. (From Thorn, Koepf, Lewis, and Olsen, 1940.)

Kendall) at the dose level of 85 mg. was also found to be effective in this regard. Comparison with adrenal cortical extract indicated that the most potent commercial extract then available contained less than 1 mg. of cortisone equivalent per millilitre.

That the increased fasting blood glucose level observed with corticosterone and cortisone was perhaps "diabetic" in nature was suggested by the observed fall in the fasting respiratory quotient (R.Q.) at the height of the blood glucose elevation induced by these substances (Fig. 2). The limitations set to the interpretation of overall R.Q. values are appreciated, but the remarkable changes noted in this well-trained patient maintained on a carefully controlled diet and metabolic regimen merit consideration. Furthermore, the lowering of the non-protein R.Q. was associated with an increase in basal nitrogen excretion and a rise in basal metabolic rate. These observations suggested at that early date that the 11- and 11,17-oxysteroids enhance gluconeogenesis and increase utilization of non-carbohydrate

FIG. 2.—Fasting respiratory quotients and blood glucose levels in a woman (E.L.) aged 51 with Addison's disease. (From Thorn et al., 1940.)

sources of energy. Studies such as this presaged the "diabetogenic" potential of these steroids when employed clinically in large doses.

The susceptibility of patients with Addison's disease to fasting hypoglycaemia may be due in appreciable measure to the increased effectiveness of endogenous insulin in these patients and may explain some of their psychological difficulties. The changes observed over a period of years in a patient with Addison's disease who developed complicating diabetes mellitus between the years 1939 and 1942 support this concept (Fig. 3 and Table I) (Thorn and Clinton, 1943).

FIG. 3.—Intravenous glucose-tolerance tests in Addison's disease (patient J.H.H.), 0.5 g. of glucose per kg. of body weight. (From Thorn and Clinton, 1943.)

TABLE I.—Observations in a Patient With Addison's Disease Who Developed Diabetes Mellitus

1. Marked psychological improvement.
2. Fasting hyperglycaemia, minimal ketonuria.
3. Marked insulin sensitivity despite hyperglycaemia.
4. Acute, transient hypokalaemia with paralysis after insulin and glucose.
5. Modest increase in nitrogen excretion following insulin withdrawal.
6. Persistently abnormal E.E.G. despite hyperglycaemia.
7. Marked hyperglycaemia and ketonuria after cortisone.

In conjunction with a slowly increasing fasting blood glucose level this patient lost his negativistic and almost catatonic attitude and became a warm, outgoing person. Until his diabetic state became flagrant there was also appreciable improvement in his overall activity, suggesting that major clinical manifestations of adrenal cortical deficiency were not limited to specific hormone depletion, but were in part due to the unopposed action of persistent hormonal secretions such as insulin. In this patient the elevation of blood glucose levels to higher-than-normal values did not in itself result in a correction of the abnormal electroencephalographic changes, thereby suggesting that glucocorticoid activity is more important than the absolute blood glucose level in restoring this indicator of brain metabolism to normal in patients with severe adrenocortical hypofunction. This observation confirms earlier studies of Engel and Margolin (1942) and Hoffman, Lewis, and Thorn (1942), who were unable to correct the abnormal electroencephalographic changes of patients with Addison's disease by the intravenous infusion of glucose.

At that time, calculation of the "caloric distribution" in the basal state served to emphasize some of the more subtle changes in metabolism which occurred in this patient as compared with an untreated Addisonian patient and a normal subject (Thorn and Clinton, 1943). Although the interpretation of these calculations is highly questionable, they do emphasize alterations of intermediary metabolism, and it was of interest to note an approximately normal "caloric distribution" under fasting conditions in this Addisonian-diabetic patient as compared with a patient with uncomplicated Addison's disease. The normal caloric distribution was, however, attained at the expense of a fasting blood glucose level of 280 mg. Following the administration of a single dose of cortisone, the untreated, uncomplicated

Addisonian patient attained a normal caloric distribution, whereas the normal subject, and particularly patient J. H. H., with Addison's disease and diabetes, increased greatly the proportion of fat being utilized according to the then accepted interpretation of the data.

These early studies on patients with Addison's disease, and in particular the unique opportunity afforded by the spontaneous development of diabetes mellitus in a patient with Addison's disease, confirmed in man the importance of specific adrenal steroids in the regulation of intermediary metabolism.

Steroid Structure and Biological Activity

An attempt has been made to assign comparative values to the more generally available adrenal steroids in terms of their effectiveness in regulating intermediary metabolism in man. In general the criterion for this action is based upon the effectiveness of a specific hormone to restore to normal in patients with Addison's disease treated with deoxycortone those major abnormalities which persist despite this form of therapy. Some of these abnormalities are listed in Table II.

TABLE II.—Persisting Defects Observed in D.C.A.-treated Patients With Addison's Disease

1. Fasting hypoglycaemia and hypersensitivity to insulin.
2. No prompt diuresis following water load.
3. Abnormal E.E.G. and E.C.G.
4. Persistent personality changes.
5. Pigmentation.
6. Frequent eosinophilia.
7. Febrile response to intravenous glucose.
8. Poor resistance to stress in any form.

FIG. 5.

The synthetic steroid deoxycortone possesses little or no carbohydrate-regulating activity. The clinical improvement in patients with Addison's disease in whom this substance is the sole therapeutic agent can be largely accounted for by the restoration of electrolyte balance and of normal circulatory status with an attendant increase in appetite and overall activity. However, with continued deoxycortone therapy and without sodium chloride restriction or potassium supplementation, intermediary metabolism may be adversely affected (Kuhlmann, Ragan, Ferrebee, Atchley, and Loeb, 1939). Presumably such an untoward effect is brought about, in major part at least, by potassium deficiency. Clinically, one may observe hypertension and cardiac enlargement, impaired neuromuscular function, and persistent abnormalities in the electroencephalogram and electrocardiogram, diminished gastric secretion, and changes in renal tubular function (polyuria resistant to "pitressin").

The quantity of aldosterone commercially available has not permitted extensive clinical observations, but it would appear that this naturally occurring mineralocorticoid is more active than deoxycortone with respect to its carbohydrate-regulating capacity. Certainly its "eosinopenic" effect is easily demonstrated, and represents a deviation from the usual close correlation between eosinopenic and carbohydrate-regulating activities observed in the case of the more active glucocorticoids (Thorn, Sheppard, Morse, Reddy, Beigelman, and Renold, 1955). Aldosterone is oxygenated in both carbon 11 and carbon 18. The biological effect of the oxidation of carbon 18 appears to result mainly in an enhanced electrolyte-regulating activity, whereas the addition of an oxygen atom in position 11 is probably the structural change responsible for its increased glucocorticoid activity.

The well-defined glucocorticoid activity of corticosterone and 11-dehydrocorticosterone is in keeping with the latter hypothesis and demonstrates that the addition of an oxygen atom in position 11 is essential for significant carbohydrate-regulating activity. The associated and rather marked sodium-retaining activity of these substances has limited their use as the sole form of therapy in Addison's disease.

FIG. 4.—Comparative effects of hydrocortisone and delta-hydrocortisone (prednisolone) in a man (R.A.) aged 40. (From Thorn, Renold, Morse, Goldfien, and Reddy, 1955.)

In contrast to the importance of the oxygen atom in position 11, an oxygen atom in position 17 alone confers a much lesser degree of carbohydrate-regulating activity. Thus 11-deoxy, 17-hydroxycorticosterone is a relatively inactive steroid. However, the addition of an oxygen atom in position 17 in compounds already oxidized in position 11 results in marked enhancement of glucocorticoid activity. Thus cortisone and hydrocortisone derive their physiological and pharmacological importance from their glucocorticoid potency and are the most active naturally occurring corticosteroids.

One of the most intriguing recent developments in this area of steroid-structure relationships has been the synthesis of derivatives possessing biological activity many times greater than that of the naturally occurring secretory products of the adrenal cortex. Among these fluorocortisone (9 α -fluorohydrocortisone) and the delta-1 derivatives of cortisone and hydrocortisone (prednisone and prednisolone) have been extensively investigated (Fried and Sabo, 1955; Thorn, Renold, Morse, Goldfien, and Reddy, 1955). The glucocorticoid activity observed with prednisone is approximately four times that of cortisone with a relative decrease in sodium-retaining activity, thus making this preparation especially useful in situations in which "anti-inflammatory" activity without appreciable sodium retention is desired. The steroid fluorocortisone is highly potent, being approximately twenty times as active as its parent substance hydrocortisone with regard to glucocorticoid action. In this instance, however, there is a still greater increase in sodium-retaining activity, thereby diminishing the therapeutic usefulness of the compound. Interestingly enough, delta-1 fluorohydrocortisone does not appear to differ appreciably in its activity in man from the carbohydrate- and electrolyte-regulating activity of the parent compound, fluorohydrocortisone. It has recently been reported that the introduction of a hydroxyl group in position 16 obliterates the sodium-retaining effect of the 9 α -fluoro substitution (Bernstein, Lenhard, Allen, Heller, Littell, Stolar, Feldman, and Blank, 1956).

Undoubtedly some modification will take place in the order in which these substances are classified as additional evidence becomes available regarding their anti-inflammatory action, the efficacy with which they suppress corticotrophin stimulation, and their effect on other body functions such as the gastro-intestinal tract. It is interesting to note that until fluorohydrocortisone was synthesized an increase in glucocorticoid activity was almost invariably associated with reduced mineralocorticoid activity. The mechanism of the spectacular potentiation of glucocorticoid activity by apparently small structural changes is, of course, as unknown as the precise mode of action of these hormones. It appears

FIG. 6.—Synthesis of total carbohydrate by liver slices from treated and untreated adrenalectomized rats (incubated in Krebs-Ringer phosphate buffer). (From Koepf *et al.*, 1941.)

likely that their increased effectiveness cannot be entirely explained on the basis of a delayed rate of conjugation, degradation, or inactivation.

Some Specific Glucocorticoid Effects

Studies in Vitro

In 1941 Koepf, Horn, Gemmill, and Thorn showed in rat liver slices that prior administration of adrenal cortical extract to adrenalectomized animals led to increased synthesis of carbohydrate from pyruvate and lactate (Fig. 6). This finding was then interpreted as suggesting increased hepatic gluconeogenesis as a result of adrenal cortical extract action. Similarly it has been shown since with C-14-labelled compounds that adrenalectomy restores to normal the excessive synthesis of glucose from pyruvate by liver slices from diabetic rats (Renold, Teng, Nesbitt, and Hastings, 1953) and that the administration of cortisone to adrenalectomized diabetic animals promptly results in marked acceleration of glucose synthesis from pyruvate (Ashmore, Hastings, Nesbitt, and Renold, 1956), as illustrated in Fig. 7. Renold and Hastings (1953) demonstrated

FIG. 7.—Synthesis of glucose from pyruvate by liver slices from diabetic adrenalectomized rats sacrificed 0 to 48 hours after cortisone administration. (From Ashmore *et al.*, 1956.)

increased glucose production but normal glucose utilization by liver slices from normal rats pretreated with large doses of cortisone for several days (Fig. 8).

Whereas the observations made on isolated liver which have just been reviewed are all compatible with increased hepatic gluconeogenesis as a major glucocorticoid effect, further effects on lipid and protein metabolism have also been established. Brady, Lukens, and Gurin (1951) observed that pretreatment with cortisone greatly reduced the incorporation of labelled acetate into fatty acids by liver slices. Furthermore, the impaired lipogenesis observed in liver tissue of diabetic animals was restored toward normal by adrenalectomy. Kline (1949) reported that adrenalectomy decreased the release of amino-nitrogen by isolated rat diaphragm and that prior treatment of the animal with adrenal cortical extract restored the rate of nitrogen release to normal.

In leucocytes, cortisone and hydrocortisone decrease lactic acid production (Martin, McKinney, and Green, 1955) and corticotrophin has been shown to increase the glycogen content of these cells (Robineaux, Bazin, Delbarre, and Delaunay, 1951). In mammary gland tissue of the rat before parturition or after weaning, incubation with cortical hormones has been reported to decrease lipogenesis and to prevent the lipogenic effect of insulin when both were added to the incubation medium (Balmain, Folley, Glascock, and McNaught, 1954). The adrenal steroids have a less specific effect on brain tissue. Although a decrease in Q_{O_2} has been shown, this appears to correlate with the anaesthetic action of these steroids rather than their carbohydrate-regulating capacity (Gordan, 1956). Cortisone as well

FIG. 8.—Uptake and production of glucose by liver slices from untreated and cortisone-treated rats (incubated in Hastings buffer K=110 mEq/l., with glucose 20 mM/l. and pyruvate 40 mM/l. as substrates). (From Renold and Hastings, 1953.)

as deoxycortone decreases the respiration of adrenal slices (Sourkes and Heneage, 1952), whereas corticotrophin is known to increase the respiration of this tissue (Reiss, Brummel, Halkerton, Badrick, and Fenwick, 1953). Some of these glucocorticoid effects resulting from studies *in vitro* have been summarized in Table III.

TABLE III.—Some Effects of Glucocorticoids on Tissues

1. Increased glycogen deposition (liver, leucocytes).
2. Increased glucose output (liver).
3. Increased glucose synthesis from pyruvate (liver).
4. Increased release of amino-acids (muscle, liver).
5. Decreased lipogenesis (liver, mammary gland, carcass).
6. Decreased oxygen uptake (brain).

Studies in Experimental Animals

Long *et al.* (1940) showed that the administration of adrenal cortical extract or crystalline glucocorticoid preparations to fasted normal or adrenalectomized rats was followed by a large increase in liver glycogen with an associated increase in nitrogen excretion. In the same year Lewis, Kuhlman, Delbue, Koepf, and Thorn (1940) demonstrated that cortisone increased greatly the renal excretion of glucose and nitrogen in adrenalectomized, phlorizinized rats (Fig. 9). In contrast to an initial glucose to nitrogen ratio of 2.5 in the untreated adrenalectomized group (a ratio which did not change appreciably during the 48-hour period

FIG. 9.—Urinary glucose and nitrogen excretion in phlorizin-treated normal, adrenalectomized, and cortisone-treated adrenalectomized rats, in the fasting state. (From Lewis *et al.*, 1940.)

of phlorizinization), the hormone-treated animals displayed a higher initial ratio—that is, 2.8—and a progressive increase to a level of 3.3 during the experimental period. Furthermore, when a lactate load was administered to phlorizinized normal, adrenalectomized, and cortisone-treated rats, urinary glucose excretion accounted for 71% of the administered lactate in the normal group, for 80% in the hormone-treated group, and for only 26% in the untreated adrenalectomized-phlorizinized group (Fig. 10). In a similar type of experiment, adrenal cortical extract restored the capacity of phlorizinized-adrenalectomized rats to form glucose from alanine.

Direct demonstration of increased hepatic gluconeogenesis in intact animals had to await the development of adequate isotopic labelling techniques. In 1952 Welt, Stetten, Ingle, and Morley, employing a continuous intravenous infusion of carbon-14-labelled glucose in anaesthetized rats, demonstrated a sevenfold increase over normal in the rate of gluconeogenesis in rats pretreated with large doses of cortisone. The rate of glucose oxidation, on the other hand, was not greatly affected by pretreatment with the hormone. The experiments of these investigators also indicated a relatively low specific activity of liver glycogen in the presence of a high liver

FIG. 10.—Urinary glucose excretion in phlorizin-treated normal, adrenalectomized, and cortisone-treated adrenalectomized rats, after administration of lactate. (From Lewis *et al.*, 1940.)

glycogen content, suggesting that under these circumstances a preponderance of the glycogen originated from non-isotopic—that is, non-glucose—precursors.

It also has been established that adrenalectomy decreases, and that administration of adrenal extracts increases, the amino-acid concentration in the serum of hepatectomized animals (Ingle, Prestrud, and Nezamis, 1948; Bondy, 1949), thus establishing that the effect of glucocorticoids is not limited to increasing hepatic gluconeogenesis. Indeed, it is entirely possible that the as yet unknown primary site of glucocorticoid action will be found in the extrahepatic tissues. Studies of this type emphasize the fact that adrenal cortical action and, more generally, hormonal action are conditioned by the chemical configuration of the hormone molecule on the one hand and by the specific nature of the responsive tissue on the other hand. This is further illustrated by the strikingly different response of the two organs known to be sites of significant gluconeogenesis—that is, liver and kidney. As shown in Fig. 11 the liver of fasting adrenalectomized rats responds to cortisone administration with a marked deposition of glycogen, whereas the kidney fails to do so (Froesch, Ashmore, and Renold, 1957).

FIG. 11.—Glycogen deposition in liver and kidney of adrenalectomized rats following subcutaneous administration of cortisone (20 mg. initially, then 10 mg. four-hourly for two doses, and 5 mg. four-hourly for two doses). (From Froesch *et al.*, 1957.)

Studies in Man

As has been previously pointed out, early studies in patients with Addison's disease suggested that in man, as in experimental animals, glucocorticoids affect the ability of the organism to produce glucose from non-glucose sources. Although isotopic techniques have not as yet been applied to the study of glucocorticoid effects in man, rather direct evidence for the gluconeogenic effect of glucocorticoids in the intact human organism has been obtained recently from observations in two subjects with renal glucosuria on the one hand (Froesch, Winegrad, Renold, and Thorn, 1957), and in diabetic patients receiving constant infusions of fructose on the other hand (Felber, Winegrad, Renold, and Thorn, unpublished observations).

By taking advantage of the spontaneous occurrence of renal glucosuria in two patients admitted to the metabolic ward, the effects of hydrocortisone infused intravenously could be studied over a period of eight hours subsequent to a 16-hour fast. The measurements made included blood glucose as well as urinary glucose excretion; in addition inulin clearance was measured throughout and tubular glucose load and reabsorption could be calculated. The results of one of these studies are shown in Fig. 12. Blood and urine glucose was measured enzymatically. Within two hours of the beginning of intravenous hydrocortisone administration urinary glucose excretion increased, and by the end of the experimental period it reached 34 mg. a minute, a sixfold increase over base-line levels. This represents a very considerable glucose loss of approximately 1.5 g. an hour. Despite this considerably increased loss of glucose in the urine in this fasting individual, blood glucose rose by approximately 20 mg. per 100 ml. Since it may be safely assumed that, in a fasting individual given hydrocortisone, liver glycogen is increasing and not decreasing, the most reasonable conclusion which these observations allow is that of increased hepatic gluconeogenesis of the order of magnitude of at least 1.5 g. an hour as a result of hydrocortisone administration.

FIG. 12.—Effect of hydrocortisone on blood glucose and renal glucose clearance in a fasting patient (a man (F.N.) aged 22, weight 73 kg., height 168 cm.) with renal glucosuria: II. (From Froesch, Winegrad, Renold, and Thorn, 1957.)

per 100 ml., then remained constant. Blood glucose steadily declined from levels around 170 to levels around 130 mg. per 100 ml. Since this patient's blood glucose behaved similarly if the overnight fast was prolonged by eight hours, this observation was interpreted as suggesting that most of the fructose administered (approximately 200 g.) had been deposited as liver glycogen or metabolized by pathways other than the production of glucose—for example, produc-

Continuous infusions of fructose have also been used in order to further analyse the activity of hepatic gluconeogenesis. It is well recognized that fructose is metabolized mainly in the liver and its major pathway of metabolism involves the splitting of fructose-1-phosphate into two three-carbon fragments. The hepatic production of glucose from fructose then involves the resynthesis of six-carbon compounds from three-carbon fragments (Fig. 13). Since fructose is metabolized by liver at a very nearly constant rate under almost all conditions tested, the fraction of fructose which is metabolized to glucose is likely to parallel its gluconeogenic activity at that time. Measurement of the conversion of fructose to glucose is therefore likely to provide an estimation of hepatic gluconeogenic activity.

Patient B. B., a 67-year-old woman with mild diabetes mellitus and not receiving insulin, was given a prolonged infusion of fructose with a constant infusion pump for a period of eight hours at the rate of 0.5 g./kg./hour (Fig. 14). Blood fructose rapidly increased to levels around 50 mg.

tion of pyruvate and lactate. When the procedure was repeated, together with the concurrent administration of hydrocortisone at the rate of 25 mg. an hour from the third hour onwards, blood fructose levels were not affected but blood glucose rose sharply, beginning two hours after initiation of hydrocortisone administration. The maximum level reached was 280 mg. per 100 ml. Whereas urinary glucose excretion during the last four hours of fructose

FIG. 13.—Major pathways of hexose metabolism in liver.

FIG. 14.—Changes in blood glucose levels in a woman (B.B.) aged 67 with diabetes mellitus during the continuous intravenous infusion of fructose (0.5 g./kg./hr. for 8 hours). (From Felber, Winegrad, Renold, and Thorn, unpublished observations.)

infusion averaged less than 50 mg. an hour on the control day, it averaged 5 g. an hour on the day of hydrocortisone administration.

The strikingly increased blood glucose levels and urinary glucose excretion during the hydrocortisone-fructose infusion periods is again interpreted as strong evidence in favour of accelerated hepatic synthesis of glucose from intermediary metabolites as a result of glucocorticoid action in man.

Cushing's Syndrome and Diabetes Mellitus

The metabolic abnormalities in patients with Cushing's syndrome provide the opportunity to compare a disorder associated with primary glucocorticoid excess with one associated with primary insulin deficiency (diabetes mellitus). The incidence of abnormalities of carbohydrate metabolism in 36 patients with Cushing's syndrome is summarized in Table IV. The following criteria have been observed: an elevated fasting blood glucose was considered to be one above 110 mg. per 100 ml., using the Somogyi-Nelson method. An abnormal glucose-tolerance test represented the failure to observe a return to normal glucose levels within 60–90 minutes after the intravenous administration of

TABLE IV.—Abnormalities of Carbohydrate Metabolism Occurring in 36 Patients with Cushing's Syndrome

	Patients	%
Abnormal glucose-tolerance curve	29	81
Glucosuria	14	38
Fasting hyperglycaemia	12	33
Overt diabetes mellitus	10	28

a glucose load of 0.5 g. per kg. body weight administered over a period of 30 minutes. Glucosuria was considered positive when present constantly or on more than one occasion. Overt diabetes was diagnosed in the presence of persistently elevated fasting blood glucose levels and glucosuria, usually requiring insulin therapy.

TABLE V.—Steroid Diabetes Mellitus Versus Classical Diabetes Mellitus

1. Depletion of body protein out of proportion to other symptoms of deranged intermediary metabolism.
2. Relative insulin resistance.
3. No tendency to severe ketoacidosis.
4. Evidence suggestive of maintained peripheral utilization of glucose (i.e., normal changes in serum PO_4 , blood lactate, and pyruvate during glucose-tolerance test).
5. Exaggerated fructose conversion to glucose, even when glucose-tolerance test normal.

"Glucocorticoid diabetes" has several characteristics which differentiate it from non-steroid diabetes mellitus (Table V). In the first place, one is impressed by the marked overall protein depletion exhibited by patients with Cushing's syndrome. This may be true even in cases where the diabetes is relatively mild or non-existent. Osteoporosis, thinning of the skin with striae, "bruiseability," and loss of muscle mass are much more striking in this disorder than one ordinarily sees even in long-standing, severe, and poorly treated classical diabetes mellitus. These observations, of course, suggest that steroid diabetes inherently reflects excessive glucose formation from endogenous protein sources with consequent severe depletion of the supporting body tissues. Secondly, the hyperglycaemia and glucosuria of Cushing's syndrome may be relatively resistant to insulin therapy, although this is not uniformly true. Thirdly, when glucose-tolerance tests are carried out in conjunction with the measurement of indices of peripheral glucose utilization, such as changes in serum inorganic phosphate, serum potassium, or blood pyruvate and lactate, it is commonly observed that these indices show a normal response to the glucose load even in the presence of an abnormal glucose profile. Indeed, it has been suggested that blood pyruvate and lactate levels are elevated in the fasting state in patients with hyperadrenocorticism and respond by an abnormally brisk increase to the administration of a glucose load (Frawley, 1955; Henneman and Bunker, 1957).

The most likely interpretation of these findings is that of persistent adequate peripheral glucose utilization—that is, of normal, or perhaps better than normal, insulin secretion, albeit frequently inadequate to achieve completely normal blood glucose levels in the presence of excessive gluconeogenic activity. Fig. 15 finally illustrates that in certain patients with Cushing's syndrome increased gluconeogenesis may be detected in the presence of a normal intravenous glucose-tolerance test by means of the blood glucose response to an acute intravenous fructose load. After the intravenous administration of 0.5 g. of fructose per kg. over 10 minutes this patient's blood glucose increased by 24 mg. per 100 ml., whereas metabolically normal individuals rarely show any significant blood glucose rise under these conditions.

The intimate dependence of the hyperglycaemia of Cushing's syndrome on steroidogenesis can be well demonstrated by temporarily blocking the secretion of glucocorticoids by amphenone administration. This can be achieved

quite readily in patients with adrenal cortical carcinoma (Thorn, Renold, Goldfien, Nelson, Reddy, and Hertz, 1956; Hertz, Renold, Reddy, Pittman, Graff, and Thorn, 1956), as illustrated in Fig. 16. In patient S. D. the administration of amphenone resulted in a sudden decrease in plasma and urine steroid levels and concomitantly in a dramatic improvement of her diabetic state. Fasting blood glucose levels approached normal values, glucosuria markedly decreased, and insulin could be withheld. The severity of the diabetic state was restored to pre-amphenone levels within hours of amphenone withdrawal.

Studies with amphenone, as well as the comparison of the glucosuric effect of corticotrophin with that of known quantities of cortisone or hydrocortisone, give no support to the concept that patients with Cushing's syndrome and diabetes secrete a glucocorticoid of much greater potency than the major known glucocorticoids.

Preliminary Studies of Insulin Reserve in Man

The availability of corticotrophin and adrenal steroids has provided the clinical investigator with an important means of stressing the insulin-secreting mechanism in normal individuals as well as in patients with potentially decreased insulin reserve. Fajans and Conn (1954) have reported that

FIG. 15.—Intravenous glucose- and fructose-tolerance tests in a woman (F.B.) with Cushing's syndrome (glucose: 0.5 g./kg./30 minutes; fructose: 0.5 g./kg./10 minutes).

FIG. 16.—17-Hydroxycorticoids in urine and plasma during amphenone Rx in a woman (S.D.) aged 41 with adrenal cortical carcinoma. (From Thorn, Renold, Goldfien, Nelson, Reddy, and Hertz, 1956.)

glucose-tolerance tests carried out shortly after the administration of glucocorticoids may unmask a group of potential diabetic patients, as yet compensated but perhaps approaching decompensation. We have explored the possibility that the glucosuric response to a standard glucocorticoid stress might be applicable to the evaluation of insulin reserve in a manner sufficiently practical to be suitable for large-scale application. These studies were begun when a purified glucose-oxidase preparation became available, thus providing for the first time an adequate and specific method for the determination of small amounts of glucose in urine. With this procedure the influence of non-specific reducing substances, which may greatly exceed the normal quantity of glucose present in the urine, can be readily eliminated.

Careful studies in well over 100 normal subjects have shown that the 24-hour glucose excretion of normal adults averages 115 mg. and rarely exceeds 200 mg. daily, despite rather wide variation in the dietary carbohydrate intake. With steroid administration (dosage selected for standard test: 50 mg. daily of prednisone) there occurs almost invariably an immediate increase in true glucose excretion on the first day. This may amount to between 200 mg. and 10 g. a day. With continued steroid administration in the non-diabetic subject, the glucose level returns to normal

by the second or third day (Fig. 17), whereas the diabetic patient is unable to compensate for the added metabolic stress and continues to excrete increasing quantities of glucose throughout the period of steroid therapy (Fig. 18). It would seem reasonable to assume, therefore, that increased insulin secretion contributes to the metabolic readjustment leading to a compensation of the initial glucosuria in subjects with normal islet-cell reserve. Preliminary results in a group of students, with and without diabetic family history, suggest that standardized intensive steroid administration for two or more days, combined with measurement of the urinary excretion of true glucose, may unmask latent diabetes, which otherwise escapes detection, and may further provide some measure of the functional reserve of the pancreatic islets in as yet well-compensated states.

Conclusion

The adrenal cortex influences to a major degree the metabolism of carbohydrate, protein, and fat by the mammalian organism. These effects are mediated by adrenal cortical steroids which have, in common with other biologically active steroids secreted by the adrenal cortex, a 21-carbon chain, the unsaturation in ring A, and oxygen substitutions in position 3, 20, and 21. In addition, the most specific structural requirements relating to intermediary metabolic activity of naturally occurring corticoids appear to be the oxygen substitutions in positions 11 and 17. According to our present knowledge, the main carrier of this activity in man is hydrocortisone (cortisol).

The effects of adrenal cortical steroids on intermediary metabolism have been studied in isolated tissues, in intact experimental animals, and in man. In man these studies have included observations made after the administration of exogenous steroids as well as the analysis of

the syndrome resulting from excess or absence of endogenous glucocorticoids—that is, Cushing's syndrome and Addison's disease. Increased hepatic gluconeogenesis is the most readily demonstrated metabolic effect of these steroids, and has been established in isolated liver as well as in the intact animal and human organism. The time lapse between the administration of the hormones and the first appearance of evidence suggesting increased gluconeogenesis is approximately one to three hours, and is the same in the intact human organism and in tissues isolated from treated animals. In experimental animals, corticosteroids also inhibit the synthesis of long-chain fatty acids by liver and, to a less degree, by adipose tissue. In addition a direct effect upon the catabolism of body protein can be demonstrated in the liverless organism. The occurrence of marked protein depletion in patients with Cushing's syndrome at a time when glucose tolerance is still normal or affected only to a minor degree suggests that the latter effect is independent of the effect on hepatic gluconeogenesis and that it may be closer to the primary site of corticosteroid action.

Although our understanding of the effects of adrenal-cortical steroids on intermediary metabolism has been improved we are as yet unable to assign discrete meta-

bolic sites to any of these effects, let alone suggest a primary site of corticosteroid action which could account for all their known metabolic effects.

THE DIAGNOSIS OF ADRENAL CORTICAL DYSFUNCTION

BY

J. D. N. NABARRO, M.D., F.R.C.P.

AUDREY MOXHAM

AND

G. WALKER, M.B., M.R.C.P.

Institute of Clinical Research, the Middlesex Hospital,
London, W.1

Although the history and clinical findings are important in the diagnosis of endocrine disorders, confirmatory biochemical tests are necessary in many cases. If possible, these biochemical tests should give direct evidence of the gland's activity by measuring the hormone levels in the blood or, where applicable, excretion in the urine. When this cannot be done it is necessary to rely on indirect evidence, usually metabolic changes resulting from altered hormone production.

In the case of the adrenal cortex, assessment is complicated by the multiplicity of hormones produced. Three require particular consideration: hydrocortisone, aldosterone, and the adrenal androgens. Of these the most important is hydrocortisone. Although sometimes referred to as the glucocorticoid hormone because it increases gluconeogenesis, it has other more important actions affecting the blood pressure, renal function, and homeostasis of the extracellular fluid (Mendelsohn and Pearson, 1955).

It is unfortunate that the only direct measurement of adrenal cortical hormones commonly undertaken is the urinary excretion of 17-ketosteroids. These are for the most part metabolites of adrenal androgens, which are among the less important of the adrenal cortical hormones. Furthermore, 17-ketosteroid excretion may be reduced in any chronic serious illness without impairment of the essential activities of the adrenal cortex. Measurement of aldosterone excretion in blood and urine is possible, but only as a complex research procedure, and there is little likelihood of its becoming practicable for routine study of patients. A number of methods for estimation of hydrocortisone and its metabolites in the blood or urine have been described during the last 10 years. The blood methods and the earlier urinary ones are complex and undertaken in only a few centres.

In recent years two comparatively simple methods for measuring urinary glucocorticoid excretion have been described. The first is the Reddy-Jenkins-Thorn (1952) procedure in which the steroids are extracted with butanol and after purification measured colorimetrically by the Porter-Silber reaction. The second is the Norymberski method (Norymberski *et al.*, 1953), in which the steroids to be measured are converted to 17-ketosteroids by oxidation with sodium bismuthate. The 17-ketosteroids already present and those formed by this oxidation are extracted, purified, and measured by the Zimmerman colour reaction that is routinely used for this purpose. The increase of 17-ketosteroids following oxidation—the urinary 17-ketogenic steroids—are an index of glucocorticoid excretion. A comparison of these two methods has been reported elsewhere (Moxham and Nabarro, 1956). Norymberski (Appleby *et al.*, 1955) subsequently described a modification of his original

procedure, in which the pre-existing 17-ketosteroids in the urine are first destroyed so that all 17-ketosteroids present after oxidation are derived from hydrocortisone and its metabolites. They are referred to as the total 17-hydroxycorticosteroids. Studies have been made of the value of urinary total 17-hydroxycorticosteroid estimations in patients suspected of having dysfunction of the adrenal cortex. The method used is a modification of the original, and is very similar to that already used in hospital laboratories for estimations of the urinary 17-ketosteroids (Medical Research Council, 1951). The method is described in the Appendix to this paper.

Results

The urinary total 17-hydroxycorticosteroids (total 17-OHCS) have been estimated (by this method) in a number of adults with normal adrenal cortical function, and the results were:

	No.	Mg. 17-OHCS per 24 hours	
		Mean	Range
Men	41	14.9	7.3-23.6 (S.D. 4.4)
Women	57	11.0	4.6-17.8 (S.D. 3.5)

Total 17-OHCS estimations have been made on 100 urine collections from 22 adrenalectomized patients receiving oral cortisone acetate up to 150 mg. a day, or 9 α -fluorohydrocortisone 0.5 mg. daily. The results are shown in Fig. 1. The correlation coefficient between steroid dose and steroid excretion is 0.94. The relationship between them is given by the equation:

$$\text{Cortisone acetate dose} = 2.88 \times \text{total 17-OHCS} - 3.0.$$

Steroid excretion is approximately 36% of the daily dose of cortisone acetate.

FIG. 1.—17-OHCS excretion of adrenalectomized patients receiving oral cortisone acetate. At each dose level the range and mean excretions are shown, and also the calculated regression line.

Diagnosis of Adrenal Cortical Dysfunction

The main syndromes of adrenal cortical dysfunction are:

1. Chronic adrenal cortical insufficiency: (a) Primary—Addison's disease; (b) secondary—in panhypopituitarism.
2. Adrenal cortical overactivity due to tumour, hyperplasia, or simple hyperfunction: (a) Cushing's syndrome—

secretion of excess glucocorticoids; (b) syndromes of excess androgen secretion; (c) hyperaldosteronaemia; (d) iatrogenic hyperfunction from injected corticotrophin.

3. Dysfunction due to failure of normal hormone synthesis—congenital adrenal cortical hyperplasia.

Measurement of urinary glucocorticoid excretion may be of considerable value in the diagnosis of a number of these syndromes.

Diagnosis of Chronic Adrenal Insufficiency

Cases of Addison's disease vary in severity. In some the adrenal cortex is almost entirely destroyed or atrophic, whereas in others there is a significant remnant, able, if continuously stimulated by endogenous corticotrophin, to maintain an adequate steroid output. There is, however, no adrenal cortical reserve, and no response to injected corticotrophin can be demonstrated.

In the severe cases the diagnosis can usually be made on clinical grounds, and may be confirmed by biochemical tests. The plasma sodium will be low, the plasma potassium and blood urea raised, and despite the hyponatraemia a random urine specimen will contain 20 mEq./l. or more of sodium. If these abnormalities are found it is dangerous to delay treatment for further investigation, although later a confirmatory corticotrophin test may be made to differentiate a salt-losing renal lesion from Addison's disease.

In the mild or incomplete case the diagnosis is more difficult. The plasma electrolytes and blood urea are unaltered, the urinary excretion of 17-ketosteroids is low, but this may be a non-specific effect, and the urinary glucocorticoid excretion is usually in the lower part of the normal range. A number of tests have been suggested based on the secondary metabolic changes resulting from deficiency of adrenal cortical hormones. The simplest is the water-load test, with and without cortisone (Soffer and Gabrilove, 1952). Delayed water excretion has been noted in many conditions, but it is seldom improved by cortisone except when caused by primary or secondary adrenal cortical insufficiency. There may, however, be some improvement in cases of steatorrhoea and hepatic fibrosis, and patients with mild Addison's disease are occasionally able to excrete a water load normally (Fig. 2). The Cutler salt-deprivation test, although safe in a mild case, is dangerous in more severe adrenal cortical insufficiency, and may give false positive results in chronic

FIG. 2.—Water-load excretion tests. 20 ml. per kg. body weight of water given between 6 and 6.15 a.m.; urine collections made at 7, 8, 9, and 10 a.m. Shaded area represents excretion without cortisone; clear area, the increase on a subsequent occasion when the test was preceded by 100 mg. of cortisone acetate given by mouth at 2 a.m.

renal disease. The Robinson-Power-Kepler test is known to give false positive results in many conditions, and its use can no longer be recommended. These indirect tests have been superseded by the corticotrophin tests of adrenal cortical reserve. In a severe case they may be applied after cortisone therapy has started, and steroid administration can be continued during the test. In the incomplete case absence of any reserve capable of responding to additional corticotrophin is the essential feature of the condition.

In the original corticotrophin test (Thorn *et al.*, 1948) indirect indices of adrenal response—the absolute eosinophil count and urinary uric-acid:creatinine ratio—were measured. Subsequently, Thorn (Thorn *et al.*, 1951) pointed out that it was essential to have direct evidence before making the diagnosis of Addison's disease, and suggested estimating urinary 17-ketosteroids. A diagnostic test using corticotrophin gel has been described (Nabarro, 1954). Daily intramuscular injections of 100–120 units of gel were given for up to three consecutive days. Significant reduction of the

absolute eosinophil count or the urinary sodium:potassium ratio was found to be satisfactory evidence of an adrenal response. In the absence of this evidence the urinary 17-ketosteroids were estimated and Addison's disease was diagnosed only if 17-ketosteroid excretion was unchanged by stimulation. The smallest increase in a patient with normal adrenal glands was 4 mg. per 24 hours. Tests have since been carried out in 22 more patients

FIG. 3.—Comparison of the increase of total 17-hydroxycorticosteroids and 17-ketosteroids in 22 patients with normal adrenal glands given corticotrophin gel 100 units daily for three days.

with normal adrenal glands and the increase of urinary glucocorticoid excretion (measured as total 17-OHCS by the method described) compared with that of the 17-ketosteroids. The results are shown in Fig. 3, the maximum total 17-OHCS excretion was from 38 to 225 mg. per 24 hours, whereas that of 17-ketosteroids was 5 to 63 mg. The method for estimating the 17-OHCS is as sensitive as that for the 17-ketosteroids, and therefore the test becomes much more delicate if the urinary total 17-OHCS can be measured. The results in four patients are shown in Fig. 4; one is a typical normal response, and one that of a patient with Addison's disease. The last two patients were suspected of having Addison's disease, and it will be noted that the increase of urinary 17-ketosteroids was very small, but the increase of total 17-OHCS was unequivocal.

The corticotrophin test is of limited value in the diagnosis of secondary adrenal cortical insufficiency. The control levels of 17-ketosteroids and total 17-OHCS excretion are usually below normal, but the adrenal cortex has responded to corticotrophin in the nine cases we have studied. The response may be delayed and smaller than normal, depending on the duration of the pituitary failure.

Diagnosis of Cushing's Syndrome

The essential features of Cushing's syndrome result from increase of circulating hydrocortisone. For confirmation of the diagnosis it is desirable to be able to demonstrate a raised plasma hydrocortisone concentration or an increase

of the urinary excretion of hydrocortisone and its metabolites. In the past many indirect tests have been performed on patients suspected of having this condition; these included glucose and glucose-insulin tolerance tests, urinary 17-ketosteroid estimations, plasma electrolyte concentrations,

FIG. 4.—Response of steroid excretion to corticotrophin gel. A, Normal response; B, Addison's disease; C and D, Patients suspected of having Addison's disease.

and absolute eosinophil counts. In practice the results of these investigations are often equivocal, and a convenient method of urinary glucocorticoid estimation would be helpful in some of the more difficult cases.

The following results have been obtained in cases of Cushing's syndrome:

Case	Adrenal Pathology	Total 17-Hydroxy-corticosteroids mg./day	17-Ketosteroids mg./day
1 (F)	..	73	51
2 (F)	..	29	8
3 (M)	..	58	40
4 (M)	..	38	18
5 (M)	..	38	15
6 (M)	..	68	17
7 (F)	..	24	15
8 (F)	..	25	16
9 (F)	..	25	13
10 (F)	..	25	37
11 (F)	..	36	16
12 (F)	..	27	18
13 (F)	..	60	20
14 (F)	..	49	15
15 (F)	..	18	12

It will be noted that the 17-ketosteroid excretion was often normal. The total 17-OHCS varied widely, but with a single exception were raised. In most cases the figure shown is the mean of several determinations; in the last case only one urine collection was available. When the condition is due to hyperplasia there may be considerable variation due to spontaneous fluctuation in severity. If the clinical condition suggests Cushing's syndrome, but the first urine steroid estimation fails to confirm the diagnosis, further specimens should be studied. It must be pointed out that the total 17-OHCS include certain steroids not derived from hydrocortisone; normally these are present in only small amount, but they may be greatly increased in cases of adrenal cortical carcinoma and congenital adrenal hyperplasia (Appleby and Norymberski, 1955).

Virilizing Adrenal Cortical Carcinoma

Steroid excretion has been studied in three cases of adrenal cortical carcinoma with evidence of hormone production but not of Cushing's syndrome. The steroid excretions were:

Case	Total 17-Hydroxy-corticosteroids (mg./24 hrs.)	17-Ketosteroids (mg./24 hrs.)	17-Ketogenic steroids (mg./24 hrs.)	17-Hydroxy-corticoids* (mg./24 hrs.)
A (M)	63	100	21	13
B (M)	136	122	79	50
C (F)	130	62	103	48

* Reddy-Jenkins-Thorn method.

In these cases it appears likely that the high level of total 17-OHCS is due to abnormal steroid compounds, but the results did not give rise to any problems of diagnosis.

Iatrogenic Cushing's Syndrome

Although corticotrophin is now seldom used for the treatment of allergic, rheumatic, or haematological disorders, West (1956) has pointed out the importance of confirming from time to time that the preparations used are active and that the patients' adrenals are responding. He has shown that much more information is obtained from estimation of urinary glucocorticoid metabolites than 17-ketosteroids.

When patients are treated with cortisone or prednisone the adrenal glands are suppressed and it may be considered advisable to stimulate them periodically with corticotrophin. If this is done, evidence of an adrenal response should be sought, and an increased excretion of urinary total 17-OHCS has proved a convenient index (Fig. 5).

FIG. 5.—Response to corticotrophin Z. Patients with rheumatoid arthritis on steroid therapy for five months, receiving prednisone 20 mg. daily during the test.

Discussion

For many years clinicians have had to be satisfied with figures for urinary 17-ketosteroid excretion as the only direct measurement of adrenal cortical activity undertaken by hospital laboratories. The 17-ketosteroids are a poor indication of adrenal cortical activity: in men they are not derived exclusively from the adrenal cortex; for the most part they are metabolites of the least important of the adrenal hormones, and they are reduced in any serious illness.

Simple methods for the estimation of hydrocortisone metabolites in the urine are now available. Corticotrophin tests for the diagnosis of Addison's disease are more sensitive if figures for the excretion of glucocorticoids during the period of stimulation are available. The diagnosis of Cushing's syndrome can often be made on clinical grounds. In some patients, however, it may be suspected and many investigations performed without any definite result. A simple method for estimating urinary glucocorticoids would be valuable and probably make it unnecessary to perform the numerous time-consuming investigations at present undertaken in these cases.

Increased excretion of urinary total 17-OHCS is not always the result of increased hydrocortisone secretion by the adrenal cortex. Steroids with a 17.20 diol, or 21-deoxyketol type of side chain, give rise to 17-ketosteroids in this procedure (Appleby and Norymberski, 1955). Normally they are present in only small amount, but in adrenal cortical carcinoma and congenital adrenal hyperplasia they may be greatly increased. The high urinary total 17-OHCS excretion does not then reflect an increase of hydrocortisone production, but the clinical condition is usually clear and does not suggest Cushing's syndrome.

Summary

Some of the problems in the laboratory diagnosis of chronic adrenal insufficiency and Cushing's syndrome are discussed. A major difficulty has been the lack of any convenient method for estimating hydrocortisone and its metabolites in the urine.

A method based on the Norymberski procedure for measuring total 17-hydroxycorticosteroids is described. The steroid outputs of normal subjects were 7.6 to 23.6 mg. per 24 hours in men, and 4.6 to 17.8 mg. per 24 hours in women. In 100 estimations on urines from adrenalectomized patients the steroid output showed good correlation with the dose of cortisone acetate.

The effect of injections of corticotrophin gel on total urinary 17-hydroxycorticosteroid excretion was compared with that on the 17-ketosteroids. It is concluded that corticotrophin tests for adrenal cortical insufficiency are more sensitive if total 17-hydroxycorticosteroids are estimated.

The total 17-hydroxycorticosteroids were measured in 15 cases of Cushing's syndrome and three of virilizing adrenal cortical carcinoma. Estimation of the total urinary 17-hydroxycorticosteroids was of diagnostic value in Cushing's syndrome and should make it unnecessary to undertake numerous time-consuming investigations in patients suspected of having this condition.

APPENDIX

Method for Estimation of Urinary Total 17-Hydroxycorticosteroids (Total 17-OHCS)

A 24-hour urine collection is made without preservative; if the total volume is less than two litres, it is made up to two litres with distilled water.

20 ml. of urine is placed in a 50-ml. ground-glass stoppered test-tube and 100 mg. sodium borohydride added. Excess frothing may be stopped by adding a few drops of ether. The tube is allowed to stand overnight at room temperature, and next morning 20 ml. glacial acetic acid (A.R.) and 4.5 g. sodium bismuthate (A.R.) are added in that order. The tube is stoppered and shaken in the dark for 30 minutes in a Kahn shaker. The stopper is removed and the tube is centrifuged at 2,000 r.p.m. for five minutes; the supernatant is poured into another tube and again centrifuged. 25 ml. of the fluid is then pipetted into a 250-ml. round-bottomed flask and the following added in order: 15 drops freshly prepared 5% solution sodium metabisulphite, 25 ml. distilled water, 7.5 ml. conc. hydrochloric acid (A.R.), 25 ml. benzene (A.R.), and a few chips of porous pot. The contents of the flask are boiled under reflux for 30 minutes and then cooled. The aqueous layer is removed in a separating funnel and shaken with two further 25-ml. amounts of benzene. The three lots of benzene are pooled, washed twice with 15 ml. of normal sodium hydroxide, once with 15 ml. N/2 hydrochloric acid, and three times with 15 ml. distilled water, using a 100-ml. stoppered separating funnel shaken by hand. The washed benzene extract is transferred to a 100-ml. round-bottomed flask, evaporated to dryness under reduced pressure in a water bath, and placed in a desiccator for 12

hours. The residue is dissolved in 1 ml. ethanol (R.R. quality, Distillers Co. Ltd.), and 0.2 ml. (representing 2.5 ml. of urine) taken for the Zimmerman reaction, which is performed by the M.R.C. method (1951) using the colour correction recommended. Results are expressed as mg. dehydroepiandrosterone per 24 hours.

If the diluted urine contains more than 0.5% reducing substance, this must be removed at the beginning. 25 ml. of urine is placed in an incubator at 37° C. with about 0.75 g. baker's yeast. The concentration of reducing substance will be less than 0.5% after 6 to 24 hours; the urine is then centrifuged and an aliquot of 20 ml. taken for the estimation.

We wish to thank our colleagues at the Middlesex and other hospitals for urine specimens from cases of Cushing's syndrome. We are indebted to the Clinical Research Committee of the Middlesex Hospital for the provision of laboratory facilities and for a personal research grant to J. D. N. N. The charts were prepared by Mr. V. K. Asta.

MATERNAL AGE AND FOETAL OXYGENATION

BY

ELIZABETH P. N. TURNBULL, M.D.

Obstetric Medicine Research Unit (Medical Research Council), Midwifery Department, University of Aberdeen

AND

DUGALD BAIRD, M.D., B.Sc., F.R.C.O.G., D.P.H.

Professor, Midwifery Department, University of Aberdeen

In previous papers (Walker and Turnbull, 1953; Walker, 1954) it was shown that the margin of safety in the supply of oxygen to the foetus gradually diminishes in the later weeks of pregnancy, and especially when pregnancy is prolonged beyond the expected date of delivery. These findings have recently been confirmed by MacKay (1957). It was also shown (Walker and Turnbull, 1953; Turnbull and Walker, 1956) that the oxygen supply to the foetus may be reduced if pregnancy is complicated by pre-eclampsia or threatened abortion.

The purpose of the present investigation was to determine whether, in primigravidae, the margin of safety in foetal oxygenation decreases with age; this might be a factor in the well-known fact that the stillbirth rate rises with age, especially in primiparae.

Before the results of the investigation were available the staff of the Aberdeen Maternity Hospital agreed to adopt a new policy of treatment based upon the assumption that foetal oxygenation is, in fact, frequently reduced to dangerous levels in elderly primigravidae who do not go into labour before the end of the 41st week. The procedure and its results are briefly discussed.

Methods

One hundred primigravidae were studied. In all, pregnancy was clinically normal. Spontaneous delivery occurred in 73 cases, caesarean section was performed in 8, and "low" forceps delivery in 19. There were no stillbirths or neonatal deaths in the series. Spinal analgesia was used for caesarean section and pudendal block for low forceps delivery. Most spontaneous deliveries were conducted without gaseous analgesia, but in a few cases "gas and air" was given from a Minnitt machine.

Immediately after delivery a segment of umbilical cord was clamped at both ends, and samples of arterial and venous blood were withdrawn anaerobically. The oxygen content of the blood was measured by the method of Van Slyke and Neill (1924), employing the modified procedure of Orcutt and Waters (1937) in the cases where the mother had been given nitrous oxide.

The haemoglobin concentration of the blood was estimated in an M.R.C. grey-wedge photometer (100% = 14.8 g.). All oxygen and haemoglobin measurements were performed at least in duplicate.

Results

The results have been divided into three groups according to the age of the women: (1) up to 24 years, (2) 25-29 years, and (3) 30 years and over.

Fig. 1 shows the average oxygen saturation in the umbilical vein from the 38th week onwards in the three age groups. The percentage saturation is highest in those under

FIG. 1.—Average oxygen saturation of blood in the umbilical vein at various stages of pregnancy, by maternal age.

25 and lowest in those over 30. In each age group the percentage saturation falls at a similar rate as the pregnancy is prolonged beyond 39 weeks, so that the lines on the graph are almost parallel. The oxygen levels for arterial blood show similar trends, the average difference in arterio-venous saturation being about 27%.

It is clear that the saturation tends to decrease with age and gestation time. The two effects can be estimated simultaneously as follows: Regression of O_2 saturation on age and gestation is

$$O_2 = 212.0 - 0.76A - 3.62G$$

where A is age last birthday and G is the n th gestation week. Standard errors of regression coefficients are $S.E.b_A = 0.205$, $S.E.b_G = 0.765$. The data for individual patients in any given age group and gestation period varied widely around the means shown in Fig. 1. The analysis of variance (Table I) shows that the effects of age and gestation are statistically highly significant.

In the course of the statistical analysis such factors as the length of labour, both first and second stages, and the weight of the baby were taken into consideration, but none of these was found to have an influence upon the oxygen saturation levels.

TABLE I.—Analysis of Variance

	d.f.	C.S.O. $_2$	Mean Sq.	F.	Significance
Attributable to gestation	1	1,736.59	1,736.59	16.03	Highly significant
Extra attributable to age	1	1,492.95	1,492.95	13.79	"
Attributable to age and gestation	2	3,229.54	1,614.77	14.91	"
Unaccountable	97	10,503.37	108.28		
Total	99	13,732.91	138.72		

Discussion

These findings confirm our suspicion that the margin of safety in foetal oxygenation is diminished in the older primigravida. They also show that placental efficiency, judged by the oxygen saturation of the umbilical venous blood, declines after the 38th and 39th weeks of pregnancy. In primigravidae of 30 years or more the oxygen saturation of venous blood is on an average little more than 30% at the end of the 42nd week of pregnancy. Since the average oxygen saturation of blood in the umbilical arteries is about 27% less than in the vein it would not be surprising if the foetus of the elderly primigravida sometimes showed clinical evidence of distress, such as the passage of meconium or irregularity of the heart-beat.

In primigravidae booked for hospital confinement the incidence of "unexplained" perinatal deaths in mature infants (birth weight $5\frac{1}{2}$ lb. (2.5 kg.) or over) in the years 1938-52 increased steadily from 2.3 per 1,000 in the age group 15-19 to 19.0 in those aged 35 or more; a similar, though less marked, rise occurred in multiparae (Baird, Walker, and Thomson, 1954). At necropsy the appearances characteristic of anoxia were found in 70% of the "unexplained" deaths (Walker, 1954). In about 40% of all "unexplained" deaths the pregnancy had lasted 42 weeks or more, compared with 20% of all pregnancies, so that both age and gestation time influence their occurrence. Deaths from birth trauma and the stress of labour also increase steadily with the mother's age, and again in about 40% of them the pregnancy has reached the 42nd week or more. These findings suggested the possibility that in many cases the baby of an elderly primigravida undelivered at or soon after term had little reserve of oxygen at the onset of labour; if dystocia then occurred the reserve would be further diminished.

In this clinic, induction of labour in the 42nd week began to be practised in occasional "normal" cases from 1948

TABLE II.—Caesarean Section Rates in Primigravidae, 1938-56, All Aberdeen (Percentages)

Age:	15-19	20-24	25-29	30-34	35+	Total	No. of Cases	Caesarean Sections
1938-42	—	0.6	1.2	1.6	4.0	1.1	4,878	55
1943-5	0.5	0.3	1.6	1.7	6.0	1.4	2,996	41
1946-7	—	0.6	1.5	2.6	8.3	1.6	3,004	49
1948-50	0.3	1.0	3.0	5.3	20.9	2.7	3,325	91
1951-2	—	1.4	2.0	7.5	28.6	2.8	1,863	53
1953-4	2.3	2.2	5.5	11.5	28.8	4.7	2,014	94
1955-6	0.8	2.2	5.6	10.1	33.3	4.1	2,112	87

onwards. During the years 1953-6 it was adopted as a routine procedure in primigravidae aged 25 years or more. It was hoped in this way to anticipate and thus avoid some of the "unexplained" intrauterine deaths occurring before the onset of labour, and to start labour while the baby's oxygen supply was still good and thus decrease the incidence of foetal distress during labour and the need for caesarean section. Induction was not practised routinely in primigravidae under 25 years of age, partly because of the large numbers involved and partly because at that age the incidence of both "unexplained" and traumatic deaths is relatively low. Table II gives the incidence of caesarean section by age in primigravidae since 1938 for the City of Aberdeen. It shows that a rise in the caesarean section

rate began in the years 1943-5 in the age group 35+ and gradually spread to the younger age groups.

Fig. 2 shows that the great increase in the caesarean section rate in the years 1948-52 was accompanied by some decrease in the perinatal mortality, but in women over 35, where the caesarean section rate rose from 8 to 28%, the fall in perinatal mortality was relatively slight. The policy of routine induction of labour in the years 1953-6 led not to the hoped-for decrease in the caesarean section rate but to a slight increase; it was, however, accompanied by such a

FIG. 2.—Perinatal mortality rates (stillbirths plus first-week deaths per 1,000 births and stillbirths) in Aberdeen Maternity Hospital booked primigravidae, by age, in 1938-47, 1948-52, and 1953-6.

FIG. 3.—Comparison of stillbirth rates in primiparae, by age, in Scotland and in the City of Aberdeen.

striking fall in the perinatal mortality in women aged 30 or more that the age gradient disappeared.

Between the periods 1948-52 and 1953-6 the caesarean section rate in primigravidae rose from 2.7 to 4.3%. In the latter period only a few more caesarean sections were done for dystocia but many more for foetal distress in women over 25, since routine rupture of the membranes often revealed that the liquor was already heavily stained with meconium—a valuable sign of foetal distress. Induction of labour, therefore, made delivery by caesarean section possible in those cases where formerly intrauterine death occurred before the onset of labour or suddenly and unexpectedly early in labour. The fact that the perinatal mortality has fallen more in the years 1953-6 than in 1948-52 suggests that the policy of induction plus caesarean section in the last four years has proved more effective than that of increased use of caesarean section alone in the years 1948-52.

The data in Fig. 2 are for perinatal mortality in Aberdeen Maternity Hospital booked primiparae. Fig. 3 compares the

trends with age of stillbirth rates in primiparae in Scotland, 1948-52 and 1953-5, and in the City of Aberdeen as a whole, 1948-52 and 1953-6. During the earlier period the Aberdeen rates were less than those for Scotland, and in both there is a rise with increasing age after the age group 20-24. In the later period the Scottish figures still show a rise with age, but the Aberdeen rates are considerably modified; in the city there is no rise with age, at least up to the age group 30-34. The relatively high rate in Aberdeen primiparae aged 35 and over is based on three deaths only, and may be due to chance. These statistics suggest that if the policy of routine induction in the Aberdeen Maternity Hospital since 1953 were adopted more widely many deaths from anoxia and birth trauma could be prevented.

These findings are of particular importance to primigravidae in the upper social classes, who tend to be older than the average; consequently the foetus is more exposed to the risks of anoxia and dystocia. Table III shows that the

TABLE III.—Stillbirth Rate in Primiparae by Social Class: Scotland, 1953-5, and Aberdeen City, 1953-6

Social Class:	I and II	III	IV and V	All Classes
Scotland	19.8	25.0	29.3	25.6
Aberdeen	11.2	15.4	24.6	16.8
Aberdeen as a percentage of Scotland	57	62	84	66

stillbirth rate in primiparae in Aberdeen is considerably lower than that of Scotland as a whole, 16.8 compared to 25.6. It is also evident that the difference between the rates is greatest in social classes I and II (professional, managerial, and generally well-to-do classes) and least in classes IV and V (semi-skilled and unskilled working classes). The relatively very low rate in the upper social groups in Aberdeen is thought to be attributable, at least in part, to the policy of routine induction applied to elderly primiparae. The of routine induction applied to elderly primiparae in the lower social classes, who are mostly young, and in whom deaths due to anoxia and birth trauma are relatively infrequent; in these classes, prevention by obstetrical intervention is much less easy, since about 70% of the perinatal deaths are due to other causes, particularly prematurity, accidental haemorrhage, and certain types of foetal malformation.

Conclusion

It is well to point out that although the results of a policy of routine induction in primigravidae aged 25 and over have been gratifying, the method is essentially inefficient. Even in prolonged pregnancy in elderly primigravidae the oxygen levels in foetal blood vary widely and in many instances are compatible with safety. Routine induction therefore means that many unnecessary operations are undertaken to prevent relatively few deaths. More lives could be saved by routine induction at term, but the proportion of unnecessary operations would then be greatly increased. Again, induction is not entirely free from danger, since infection may be introduced, and, rarely, a foetal blood vessel may be punctured (Mitchell, Anderson, and Russell, 1957). In our hands, however, the gains appear greatly to have outweighed the risks.

There is, at present, no alternative to a policy of routine induction if lives are to be saved. It is not enough to await the spontaneous onset of labour and postpone intervention until signs of foetal distress supervene: before the new policy was introduced about 40% of "unexplained" (anoxic) deaths took place suddenly before the onset of labour, and even when labour was being very carefully supervised foetal death sometimes occurred suddenly with a few or no warning signs. A very high standard of antenatal and intranatal care of the usual type is therefore of limited value in preventing these deaths.

What is needed is a practical method of predicting the onset of foetal distress or of lethal lack of oxygen in the individual case. It would then be possible to differentiate

those cases where induction or immediate caesarean section is indicated from those in which pregnancy may be allowed to proceed with safety.

Summary

The oxygen content of venous and arterial blood from the umbilical vessels was determined after 100 first deliveries. Pregnancy in all the primigravidae had been clinically normal. The average oxygen saturation became less as maternal age and the length of gestation increased, and was sometimes dangerously low, especially in primiparae aged 30 or more delivered after the 41st week of pregnancy.

It is suggested that the relatively high rate of perinatal mortality in elderly primiparae—often clinically unexplained and accompanied by post-mortem evidence of foetal asphyxia—is due in part to inadequate foetal oxygenation after term.

Since 1953, in Aberdeen, labour has been induced routinely by rupture of the membranes in primigravidae aged 25 or more who are undelivered before the end of the 41st week, and caesarean section has been used more frequently if there are signs of foetal distress, especially meconium in the liquor amnii. Apparently as a result, the excess perinatal mortality in elderly primigravidae has been eliminated. Possible limitations and hazards of the procedure are discussed.

We wish to thank Mr. W. Z. Billewicz for undertaking the statistical analysis.

RESPIRATORY AND CARDIAC ARREST DURING ANAESTHESIA IN CHILDREN

BY

ERNEST H. RAINER, F.R.C.S.Ed.

Ear, Nose, and Throat Surgeon, Dartford, Orpington, and Sidcup Groups

AND

JOHN BULLOUGH, M.B., F.F.A.R.C.S., D.A.

Anaesthetist, Dartford Group

Outside the realms of cardiac surgery, cardiac arrest often occurs unexpectedly, sometimes during quite minor operations. During recent years an ever-increasing number of publications have appeared in this country and in America suggesting both increased awareness and increased incidence of the condition. In the United Kingdom nearly three million operations are performed annually with an average anaesthetic death rate of 600 (Milstein, 1956).

Stephenson *et al.* (1953) pointed out that cardiac arrest is by no means rare in children. Out of 212 fatalities, 20% were found to have occurred in children under 10, the highest incidence of any age group reviewed.

Following the occurrence of two deaths on the table in 1951 and 1952, a method of resuscitation was developed by one of us (E.H.R.) which has been employed successfully on eight occasions without a

single failure. We believe it saved the lives of at least five of these children. In the other three instances there is some doubt whether the heart had definitely stopped beating after cessation of respiration, but, as is stressed later, the method can be applied so easily and quickly that we would not wait for confirmatory evidence before resorting to it.

The literature on cardiac arrest has been amply reviewed in recent years (Palomera, 1952; Stephenson *et al.*, 1953; Johnson and Kirby, 1954; Lewis and Stanley-Brown, 1955; Milstein, 1956). Survival rates generally were low (from 10 to 28%). A notable exception was the 66% survival rate reported by Lahey (1953). Prompt action, a prearranged plan, and readily available equipment are considered to have been the reasons for this good survival rate.

Diagnosis and Treatment

Cardiac arrest is presumed to have occurred if it is impossible to feel the peripheral pulses (carotid, radial) or the apex beat. In addition there will be no respiratory movements, no operative bleeding, ashen-grey pallor, dilating pupils. (Looking for capillary refill and recording blood pressure are probably a waste of time.) We agree that a diagnosis can be made with certainty only by electrocardiogram or by opening the chest and inspecting the heart directly.

Resuscitation in cardiac arrest requires restoration of heart action and pulmonary ventilation within a very short time. After three to four minutes permanent damage will occur to the vital brain centres. Thus an effective cerebral circulation must be instituted in this time by artificial means, and maintained until a spontaneous heart-beat returns.

We claim that in young children it is possible in most—if not all—cases to restore heart and lung action by a single, simple, and effective manœuvre which can, if necessary, be carried out single-handed. Of our eight cases only two can be described as "poor risk" cases. The patients' ages varied from 8 weeks to 13 years. In all cases respiratory failure preceded cardiac arrest.

One of us (J.B.) had personal experience of only one of these cases, which occurred after this paper had been prepared. The other seven cases occurred at four different hospitals, each with a different anaesthetist.

Five cases are described in some detail. Of the other three cases, unfortunately, no adequate data were kept, though in none of them could a pulse be felt before resuscitation began. All our cases were preceded by respiratory arrest due to one or more of the following factors: prolonged hypoxia or anoxia; hypercapnoea; overdosage of anaesthetic agents—for example, thiopentone, cyclopropane; and possibly vagal stimulation.

There is no doubt that some degree of anoxia was present in every case, either as part of a general oxygen lack or owing to an inadequate airway. In one case inhalation of a small quantity of blood appears to have been a factor. It was not always possible to be quite certain of the exact stimulus or agent responsible. Most accidents occurred during induction of anaesthesia or at the end of operation.

Description of Method

As soon as it appears reasonably certain that cardiac arrest has occurred (the signs of which have already been described), no time-wasting manœuvres for confirmation of diagnosis are employed. It is then possible to start effective resuscitation in a matter of seconds, as follows:

1. Any blankets, towels, instruments, or other impediments close to the patient having been quickly discarded, the table is lowered to approximately 10 degrees Trendelenburg by the anaesthetist, while the surgeon positions himself at the patient's right side.
2. A nurse is instructed to check the time and call out each minute (as suggested by Bailey, 1941, 1947).

3. Having made sure that the airway is clear, the anaesthetist rhythmically inflates the lungs with 100% oxygen. Unless an endotracheal tube is already in position or can be inserted immediately, no time is wasted over intubation at this stage. The lungs can be adequately ventilated through a face-piece and reservoir bag connected to a Boyle's machine.
4. Meanwhile the surgeon places his right forearm under the patient's knees and his left forearm behind his neck.
5. The patient's bent knees are raised and the hips fully flexed, forcing the thighs against the upper abdomen and chest, the spine being flexed at the same time (Fig. 1, A).
6. When full flexion is reached, the surgeon compresses the patient's chest with the bent knees, using some of his own weight judiciously to add to the pressure (Fig. 1, B).
7. He then lowers the patient's legs, fully extending them on the operating table (Fig. 1, C). At this point the anaesthetist inflates the lungs.

FIG. 1.—A, Patient's bent knees are raised and hips flexed so as to bring thighs in contact with upper abdomen and chest. B, Surgeon uses some of his own weight to press patient's thighs and knees against his chest and upper abdomen. C, Patient's legs are lowered and fully extended on the operating table. (At this stage the lungs should, if possible, be inflated with oxygen.) If an anaesthetic machine is not at hand, an assistant standing at the head of the table should here extend the patient's arms above his head as in Silvester's manœuvre.

FIG. 2.—Above: Spirometric tracing of patient aged 10 years and weighing 5 st. 1 lb. (32.2 kg.). Spontaneous breathing at A. Arrow=given injection of suxamethonium. Spontaneous respirations ceased at B. Our resuscitative manœuvre applied at C (N.B., omitting lung inflation). Arm-raising added at D. Vertical divisions represent minutes, horizontal divisions 100 ml. Spontaneous respirations=average 300 ml. Our manœuvre=average 200 ml. With added arm-raising=average 350-400 ml. Below: Spirometric tracing of patient aged 11 years and weighing 5 st. 11 lb. (36.7 kg.). Spontaneous respirations at A. Given 75 mg. of suxamethonium (arrow). Respiratory paralysis at B. Flexion-extension manœuvre applied at C. Added arm-raising started at D. Spontaneous respirations=average 250-300 ml. Our manœuvre=average 250 ml. With added arm-raising=average 350-400 ml.

The manœuvre is repeated 12 to 15 times a minute, which appears to be the optimum rate. If there is no response after one to one and a half minutes, the chest must be opened and the heart massaged (always provided the airway is satisfactory).

Even if the manœuvre is not successful in restoring the heart-beat within that time, both surgeon and anaesthetist have been doing something active to the child (and, as we believe, maintained a cerebral circulation) while the theatre nurse prepares for thoracotomy.

In one of our cases the above manœuvre was continued for one and a half minutes before a heart-beat could once more be felt.

O-4

An effective method of resuscitation should fulfil the following criteria; it must be simple to apply; it must not be too fatiguing for the operator; it must be effective in providing adequate ventilation, and at the same time have an effect on the circulation sufficient to maintain a cerebral blood flow so as to prevent cell damage. To this we might add that it must be successful every time. In our experience to date it has been so.

(N.B.—One of our patients—Case 5—twice became apnoeic in the ward in spite of a good airway being present. Artificial respiration by the above method was carried out by the nurse in charge and was rapidly successful both times.)

The following five cases out of a total of eight illustrate the successful use of the method.

Case 1

A healthy boy aged 5½ was admitted for adenoidectomy. Premedication: "Omnopon" 1/9 gr. (7 mg.), and scopolamine, 1/450 gr. (0.14 mg.). Anaesthesia was induced with nitrous oxide, oxygen, and cyclopropane followed by ether. During the course of induction laryngospasm developed. The anaesthetic was stopped and the lungs were inflated with 100% oxygen without effect. After about 30 seconds no pulse could be felt, the patient was white, and the pupils were dilated. The surgeon was called to the anaesthetic room and agreed that cardiac arrest had occurred. Immediate resuscitation by our method was begun—that is, about one minute after cardiac arrest had been diagnosed by the anaesthetist. After one minute's resuscitation the patient's pulse could once more be felt. It was weak and rapid. Soon after, feeble spontaneous respiration began and the pulse progressively improved. The patient recovered consciousness about five minutes later. The operation was abandoned and the patient was returned to his ward, where he fell asleep. When seen about five hours later he was fully conscious and there was no sign of cerebral irritation. Three days later he developed chicken-pox and was discharged home. Adenoidectomy was performed without mishap a year later.

Comment.—In this case cardiac arrest was probably due to a combination of anoxia and cyclopropane sensitization.

Case 2

A healthy girl aged 7 was admitted for tonsillo-adenoidectomy. Premedication: pentobarbitone sodium, 2 gr. (0.13 g.), and atropine, 1/100 gr. (0.65 mg.). Induction: nitrous oxide, oxygen, ether. Patient struggled during induction. She was taken into the theatre and a Boyle-Davis gag was inserted. While adenoidectomy was being performed the patient started to "gag." The anaesthetist proceeded to give an intravenous injection of thiopentone (about 0.25 g.): apnoea followed. Meanwhile the adenoid bed was packed with gauze and resumption of respirations awaited, before proceeding with tonsillectomy. No respirations had begun after half a minute, when the anaesthetist

reported that the pulse was impalpable. The surgeon quickly inserted a Magill endotracheal tube and removed the mouth gag. Cardiac arrest was suspected and the patient's head was lowered and towels and sandbags were discarded. Within one and a half minutes following respiratory arrest, resuscitation by our method was under way (between 30 and 40 seconds after cardiac arrest was thought to have occurred). After one to one and a half minutes of resuscitation a feeble pulse could be felt and spontaneous respiration quickly returned while the pulse increased in volume. The operation was completed and there were no sequelae.

Comment.—In this case cardiac arrest was probably due to a combination of anoxia and thiopentone.

Case 3

A healthy girl aged 4 was taken to the theatre because of bleeding following tonsillectomy. She was anaesthetized by nitrous oxide and oxygen followed by ether about one hour after the original operation. Although she was placed in the head-down position, it appears that some blood reached the larynx and produced laryngeal spasm. The blood was removed by suction, and oxygen was inflated from the anaesthetic machine by face-mask while the head was lowered still further. Quick release pressure on the chest was also tried but proved to be ineffective. After about one minute the pulse became impalpable. Immediate application of our method resulted in speedy return of both pulse and respiration after about nine or ten manœuvres (40–50 seconds). Subsequently the bleeding-point in the tonsil bed was secured, no further anaesthetic being required.

Apart from some rise in temperature for three days after operation, convalescence was uneventful.

Comment.—It appears that a combination of hypoxia and laryngeal spasm due to blood on the cords was responsible.

Case 4

A boy aged 8 weeks with polycystic disease of the lungs had been in respiratory difficulties since birth. He had areas of collapse and consolidation and was too weak to cough up his secretions. Respiration was "grunting" in character. He had received various antibiotics. He had been in an oxygen tent for two weeks, which was keeping him alive, as when he was taken out he became grey and limp in a few minutes. Bronchoscopy and removal of secretions by suction was proposed. Atropine, 1/150 gr. (0.43 mg.), was given, and a "polymask" with a high flow of oxygen was attached for transportation to the theatre; this actually improved his colour.

Induction was attempted with cyclopropane and oxygen, but this resulted in almost immediate apnoea several times, so "open ether" with added oxygen was given for 15 minutes, when breathing was regular and rhythmical. The larynx was sprayed once with 4% lignocaine. A suckling bronchoscope was passed without difficulty; oxygen was insufflated down the bronchoscope. Some secretions were removed from the bronchial tree by suction. After three minutes the baby started to strain weakly on the bronchoscope and cyanosis began to appear, the colour previously having been pink. The surgeon was informed; a finger was kept on the pulse. A minute later the pulse disappeared and the colour became grey. It was not possible to inflate the lungs satisfactorily via the bronchoscope, which was removed, a face-mask was applied, and the lungs were rhythmically inflated by bag-pressure. There was no immediate response to this, so the legs were intermittently flexed on to the abdomen and chest in time with the lung inflation. Half a minute later the pulse and colour returned; thus preparations for cardiac massage were left. Spontaneous breathing soon returned, and the child's general condition over the next few days was actually improved. There were no signs of cerebral irritation in spite of perhaps two minutes' circulatory arrest. (Cardiac massage in this case would have been technically difficult.)

Comment.—Cardiac arrest in this case was obviously due to several factors: prolonged hypoxia caused by pulmonary disease, further restriction of available lung surface during bronchoscopy, presence of secretions in bronchi, and possibly sensitization of myocardium following earlier use of cyclopropane.

Case 5

A previously healthy 12-months-old boy had been admitted three weeks earlier suffering from laryngo-tracheo-bronchitis. An emergency tracheotomy was performed the same night and the child seemed to make a good recovery on antibiotic treatment and steam inhalations. However, blocking of the tracheotomy tube by sticky secretions once or twice gave trouble on the first day and subsequently.

During the third week further respiratory difficulties seemed to indicate the presence of sticky bronchial secretions, which could not be removed by suction through the tracheostoma. It was therefore decided to perform a bronchoscopy.

Premedication was by atropine, 1/100 gr. (0.65 mg.). Before induction the child was noted to have marked dyspnoea, a poor colour, chest retraction, and a tracheal tug.

Induction of anaesthesia was by nitrous oxide and oxygen (50%) via a tracheotomy tube, with a small quantity of trichlorethylene added. As this proved to be insufficient for anaesthesia, the same mixture was given from another machine simultaneously by face-mask. The child lost consciousness gradually, and colour and respiration seemed to improve. He was then given 0.05 g. of thiopentone intravenously in order to produce sufficient relaxation; 100% oxygen was then given for 60 seconds. Apnoea lasted for 45–60 seconds, and was then replaced by even shallow respiration. A bronchoscope was introduced into the larynx, while the tracheotomy tube was removed. It was impossible to pass the instrument through the cords without using unjustifiable force. A further 0.025 g. of thiopentone was given with no effect on the cords, which remained closed. At that point the child seemed to "collapse," lost colour, and stopped breathing altogether. 100% oxygen was rapidly and forcefully given via a face-mask, while the surgeon attempted to reintroduce the tracheotomy tube (which proved to be very difficult). Colour seemed to return, but was rapidly lost again and the child completely failed to respond to oxygen (very little entered the chest, as there was scarcely any airway present).

Up to that point a strong apex beat could be felt. The colour now became ashen grey, the pupils were diverging and dilating, and a pulse could no longer be felt. Immediate resuscitation by our method was begun, while a knife for thoracotomy was brought. After 30–40 seconds the patient's colour changed from that of pre-mortem cyanosis to light cyanosis and the pulse could again be felt. After a further two minutes the anaesthetist managed to introduce a gum-elastic catheter via the cords, so that effective synchronous inflation with 100% oxygen could be given. The combined manœuvre was kept up for a total of 10 minutes before the child made any attempt to breathe. Spontaneous respirations, however, were intermittent (Cheyne-Stokes) for the next 45 minutes.

A No. 18 bivalve tracheotomy tube with inner tube eventually established an adequate airway, and the bronchi were sucked out through this.

The child subsequently twice stopped breathing after return to the ward without any obvious cause and was resuscitated as described.

Eventual recovery, though slow, was complete and there were no neurological sequelae.

Comment.—The use of thiopentone (even though the dosage was small), and the long-continued respiratory obstruction, producing hypoxia and hypercapnoea, possibly also reflex vagal stimulation during attempted bronchoscopy, were the factors involved in leading to cardiac arrest in this case. We believe that cardiac massage would have been of no avail, as the airway was inadequate during the critical first few minutes.

Analysis of Method

It is thought that resuscitation is effected as follows, the ventilatory and circulatory mechanisms being dealt with separately.

Pulmonary Ventilation.—(1) *First Expiratory Phase:* When the thighs are pressed against the abdomen the diaphragm is forced upwards, initiating pulmonary emptying; then as the chest is compressed this part of expiration is completed by external pressure. (2) *First Inspiratory Phase:* First, on release of pressure by the thighs, the chest re-expands by its own elastic recoil (Proctor *et al.*, 1950; Proctor, 1952). Next, on release of pressure from the abdomen the diaphragm descends, and this phase is completed as the body is fully extended. The next two phases occur if an anaesthetist has access to an anaesthetic apparatus (this is the usual intermittent positive-pressure pulmonary ventilation). (3) *Second Inspiratory Phase:* The anaesthetist inflates the lungs by positive pressure from a bag and mask, at the end of the first inspiratory phase described above (2). (4) *Second Expiratory Phase:* On release of the positive pressure in (3) the chest and the lungs recoil to the resting position, emptying the lungs. This phase then leads on to (1) above.

Circulation.—The following is an explanation of how an artificial circulation sufficient to resuscitate the patient is thought to occur. (1) Raising the legs causes venous blood to gravitate towards the abdomen. (2) Flexing the knees and hips squeezes venous blood out of the legs into the abdomen. (3) Pressure of the thighs on the abdomen forces blood from the abdomen into the chest, where it reaches the heart. (4) Pressure of the thighs on the chest squeezes blood out of the chest into the periphery, the brain receiving some blood especially, being lower than the heart. (5) When the chest re-expands on release of external pressure a negative intrathoracic pressure will initiate entry of blood into the chest, which will be continued in (1) above. This supposed artificial circulation depends, of course, on the heart valves and venous valvular system preventing blood merely moving back and forth.

As a preliminary check on its effectiveness the method was substituted for short periods in patients otherwise ventilated by intermittent bag-pressure. These patients had received an anaesthetic involving endotracheal intubation, conditions for which were supplied by the use of the muscle relaxant suxamethonium, which causes total muscular paralysis for a short time. The method was then substituted for bag-pressure, the patient being connected to a spirometer (in some cases) to obtain a tracing, instead of to an anaesthetic apparatus. (It was a proviso in these cases that no additional risk should attach to the procedure.)

It was found that the method itself—that is, without positive pressure—could maintain satisfactory pulmonary ventilation with a tidal exchange greater than by Schafer's method, there being no circulatory disturbance as judged by colour, pulse rate, and blood pressure.

It was further found that by adding arm-raising (as in Silvester's method) and thus making a two-phase into a four-phase manœuvre, tidal exchange could be almost doubled, but bag-inflation (with oxygen from a Boyle machine) proved as effective and would normally be used in the operating theatre.

Discussion

The effects on the circulation of methods of artificial respiration do not always appear to have received the attention that they deserve. However, Pollock (1942), and Thompson *et al.* (1946) and Thompson and Rockey (1947) have shown that mechanical inflation and deflation of lungs produce "actual movement of blood column" and that "blood can be circulated over the entire body without the benefit of any heart action whatever." They also found that positive plus negative pressures (push-pull) were more efficient than only positive pressures plus release or negative plus release.

Similar conclusions were reached by Sadove *et al.* (1951). Moreover, Hill (1900) had found evidence that the brain could be kept alive by a mere trickle of blood. On the other hand, Pask (1948) considered that it was unlikely that artificial respiration could do anything worth while for the patient whose circulation had completely stopped and whose heart made no expulsive beats at all. In his opinion complete failure of the circulation for more than two or three minutes made recovery by any means impossible. Volpitto (1942) had reached similar conclusions.

Thompson's animal experiments with the use of tracer substances (radioactive sodium, oxygen, etc.) fit in with our own experience, as judged by results—namely, that prompt and efficient artificial respiration in the manner described by us can and does restore heart action (in children at any rate, whose supple bodies lend themselves more easily to such manœuvres). We also agree with Thompson's findings that mere positive inflation of lungs plus release is not enough, and that it is essential to deflate the lungs actively as well in order to produce an effect on the circulation. The same conclusions were reached by Sadove *et al.* (1951), who investigated several methods of artificial respiration on curarized human volunteers. They found that push-pull methods were at least twice as efficient as Schafer's method.

Careful studies of ventilatory volumes and airflow patterns as well as measurements of circulatory effects were carried out by Gordon *et al.* (1951). In their opinion arterial oxygen saturation appeared to offer more convincing proof of the efficiency of resuscitative measures than mere measurements of pulmonary ventilation.

Spirometric tracings obtained during performance of our method of artificial respiration on paralysed subjects showed that slightly better tidal volumes could be obtained than by the use of Schafer's method. (Incidentally, by adding arm-raising, as in Silvester's method—thus making it a push-pull manœuvre—tidal volumes were doubled (see Fig. 2).)

Cordier (1943) lays down the following principles underlying all methods of artificial respiration: They must (1) give sufficient pulmonary ventilation (as near as possible to normal subjects at rest); (2) stimulate heart and circulation to help respiratory exchange and transport of oxygen to the tissues; (3) be harmless in themselves and rapid in obtaining results. All these precepts are apparently fulfilled in the method described by us, and in addition it is thought that an artificial circulation sufficient to prevent cerebral damage is produced.

Until the advent of relaxants in anaesthesia, experiments on human subjects (volunteers) were difficult to perform and widely varying results were obtained (see Table taken from Cordier, 1943). Anaesthetized subjects who have been rendered apnoeic by the use of muscle relaxants correspond most closely to those in whom accidental cardiac arrest occurs (Sadove *et al.*, 1951).

Of the vast number of methods of artificial respiration advocated from time to time (Fisher, 1944, lists over 70), at most half a dozen are now being taught to first-aid teams. The one described by Byrd in about 1870 is still in use as an excellent method of resuscitation in asphyxia neonatorum. In carrying it out the obstetrician holds the supine infant in the crooks of his arms, and by compressing his whole body like a concertina and then stretching it he actively deflates the child's lungs (and incidentally at the same time stimulates his circulation) before allowing the elastic recoil of the chest wall to take in air. It will be seen that our method is very similar in its conception and thus not really new.

In conclusion we want to say that there is both theoretical and practical evidence to support our belief that artificial respiration carried out in the manner described by us is a life-saver, and that it should be tried without any delay when unexpected respiratory failure in a child is followed by cardiac arrest and carried out for 1½ minutes before proceeding to thoracotomy, as there is a very good chance that the latter may prove unnecessary. Ideally, the time to start using it is before the heart has actually stopped beating.

Widely Varying Results Achieved in Ventilation Studies Prior to the Advent of Muscle Relaxants. (After Cordier, 1943.)

Experimental Conditions	Author	Lung Ventilation in c.cm.	
		Schafer's Method	Silvester's Method
1. Subjects having voluntarily suspended their breathing	"Suspended Animation" Committee (1903)	366	458
	Schafer (1904)	520	178
	Burton-Ostiz (1922)	504 (average)	—
	Ploman (1906)	500-600	1,200-2,000
	Hamburger (1909)	616	454
	Liljestrand <i>et al.</i> (1913)	500	540
2. Subjects in apnoea	Eve (1932)	1,000	—
	Killick and Eve (1933)	350-550	200
3. Non-rigid cadaver	Liljestrand <i>et al.</i> (1913)	170	190
	Héderer (1934)	100-150	250-280
	Bruns (1927)	40-50	200
4. Apnoeic patients in moderately deep anaesthesia	Bruns and Thiel (1930)	20	200
	Waters and Bennett (1936)	2 females, 180 (average)	214 (average)
		2 males, 662 (average)	933 (average)

We furthermore believe that this method may have wider applications beyond those of the operating theatre—for instance, in coal-gas poisoning, drowning, electric shock, and so forth.

Summary

A new method of resuscitation after respiratory and circulatory arrest is described which has been successfully employed on eight children. There has not been one single fatality. The method consists basically in intermittently flexing and extending the whole body, to which may be added positive-pressure inflation of the lungs with oxygen.

It is believed that the method represents a sound and effective approach to dealing with cardiac arrest in children. Though it has been used by us only in the operating theatre, we think it may have wider applications.

It is more rapidly and more easily applied than other methods.

Five illustrative cases are reported.

We wish to acknowledge our debt to many house officers, anaesthetists, and nursing staff who have at various times helped us in the management of patients. We also thank Mr. John Holloway for the diagrams and Miss Barbara Houlton for preparing the manuscript.

THE CLINICAL APPLICATIONS OF TRIIODOTHYRONINE

BY

A. W. G. GOOLDEN, M.B., D.M.R.T.

Radiotherapist, M.R.C. Radiotherapeutic Research Unit, Hammersmith Hospital, and New End Hospital

AND

CRAIG D. BURRELL, M.B., Ch.B.

From the Department of Medicine, Postgraduate Medical School of London, W.12

Until recently thyroxine was considered to be the active thyroid hormone; however, its characterization by Harington (1926) and Harington and Barger (1927) was not followed by its extensive clinical use, desiccated thyroid being in general preferred. Gross and Pitt-Rivers (1952a) identified as triiodothyronine an unknown iodinated compound in the sera of patients treated with therapeutic doses of ^{131}I . Later this amino-acid was detected (Roche, Lissitzky and Michel, 1952a, 1952b; Gross and Pitt-Rivers, 1953a) in thyroid substance. The high biological potency of triiodothyronine, first observed by Gross and Pitt-Rivers (1952b) in rats, and by Gross, Pitt-Rivers, and Trotter (1952) in hypothyroid humans, has now been amply confirmed (MacLagan, Sprott, and Wilkinson, 1952; Colville and Bonnycastle, 1953; Deltour and Karamourtzounis, 1953; Heming and Holtkamp, 1953a, 1953b; Tomich and Woollett, 1953, 1954; Anderson, 1954). The results have shown that triiodothyronine is approximately five times as active as thyroxine on a molar basis. Some experiments, however, on intact animals have not shown any significant difference between triiodothyronine and thyroxine (Gemmill, 1953; Heming and Holtkamp, 1953a; Brown-Grant, 1955).

Various workers have compared the physiological effects of L-triiodothyronine and L-thyroxine in myxoedematous patients (Asper, Selenkow, and Plamondon, 1953; Lerman, 1953; Rawson, Rall, Pearson, Robbins, Poppell, and West, 1953; Blackburn, McConahay, Keating, and Albert, 1954; Blackburn and Keating, 1954; Starr, Snipes, and Liebhold-Schueck, 1955; Selenkow and Asper, 1955). It has been shown that L-triiodothyronine is three to five times as active as L-thyroxine on a molar basis: although there is a significant difference in the speed with which L-triiodothyronine produces metabolic changes, it appears to be qualitatively identical to L-thyroxine.

It has been suggested that triiodothyronine is formed as the result of the reductive deiodination of thyroxine (Gross and Pitt-Rivers, 1952b, 1953b) or by the coupling of one molecule of moniodotyrosine with one molecule of diiodotyrosine (Roche, Lissitzky, and Michel, 1953). It is evident that coupling, as described above, can be expected to occur only in the thyroid gland. It has been shown by *in vivo* experiments on animals that thyroxine is converted to triiodothyronine in the peripheral tissues (Gross and Leblond, 1951; Flock and Bollman, 1955; Kalant, Lee, and Sellers, 1955; Hogness, Berg, Van Arsdell, and Williams, 1955). Pitt-Rivers, Stanbury, and Rapp (1955) demonstrated that triiodothyronine can be formed from thyroxine in human subjects in the absence of the thyroid gland. On the other hand, Roche and

Michel (1954) and Roche, Michel, and Tata (1954) have been unable to demonstrate the formation of triiodothyronine in the peripheral tissues, and have concluded that the thyroid gland is the only source of circulating triiodothyronine. Benua, Dobyns, and Nimner (1955) studied the rate of appearance of triiodothyronine in the plasma of patients given therapeutic doses of ^{131}I for hyperthyroidism or cardiac disease, and concluded from its early appearance in the serum that it was released from the thyroid gland and was not simply a result of the deiodination of thyroxine in the peripheral tissues.

In vitro experiments have shown that conversion of thyroxine to triiodothyronine can occur in kidney slices (Albright, Larson, and Tust, 1954; Larson, Tomita, and Albright, 1955) and in homogenates of liver, kidney, and other tissues (MacLagan and Sprott, 1954). It is evident that the exact mechanism for the biological synthesis of triiodothyronine requires further study.

The iodinated organic compounds of the blood are closely associated with plasma protein and are precipitated with it. It has been shown by paper electrophoresis that thyroxine is associated with a globulin fraction between α_1 and α_2 (Deiss, Albright, and Larson, 1952; Robbins and Rall, 1952). Triiodothyronine is associated with this same protein fraction, but the α -globulin-triiodothyronine complex is less stable than that of thyroxine (Deiss, Albright, and Larson, 1953). This may account for the more rapid disappearance of triiodothyronine from the serum shown by Sterling, Lashof, and Man (1954), who compared the disappearance rates of ^{131}I -labelled thyroxine and triiodothyronine from the serum in euthyroid subjects.

Triiodothyronine differs from other thyroxine analogues in that it is a normal constituent of human plasma and is the only substance so far detected which has a greater activity than naturally occurring thyroxine. It differs from thyroxine in its speed of action, but there is no evidence of any qualitative difference between triiodothyronine and thyroxine. Any clinical applications must obviously depend on its rapid effect. It may be of interest to discuss certain conditions in which we have had experience of its use during the past two years.

Rapid Correction of Hypothyroidism

It is not usually necessary or even desirable to correct myxoedema rapidly. On rare occasions the correction of hypothyroidism may be a matter of urgency; this is illustrated in the following case history.

Case History

A man aged 52 was given a therapeutic dose of ^{131}I in December, 1953, to ablate the thyroid gland. He had suffered from severe angina of effort for several years, which was becoming progressively worse. He had been maintained on carbimazole prior to ablation of the thyroid, and had been greatly benefited by this treatment.

Following ablation of the thyroid he was kept on a maintenance dose of 0.1 mg. of L-thyroxine daily, on which dose he remained almost free of angina and was able to resume light work. He obtained his supply of thyroxine from hospital until September, 1954, at which time it was arranged that he should obtain further supplies from his local chemist. At his next attendance, in February, 1955, it was noted that his weight had increased by a stone (6.4 kg.), but he was otherwise well. Five weeks later, in April, 1955, he was seen at the request of his doctor, who reported that he had developed religious mania. His wife confirmed that

he had taken his dose of thyroxine regularly and that he had become mentally abnormal quite suddenly about a week before.

On examination it was apparent that he was suffering from a paranoid psychosis. He was not retarded, and maintained a degree of animation which might have been considered incompatible with a psychosis due to hypothyroidism. Knowing his usual appearance, a slight alteration in his facial expression and some puffiness of the lower lids was noticeable. The skin of his forearms was dry and scaly, but there were no other signs of hypothyroidism. It was thought that the paranoia had been precipitated by hypothyroidism, and a plasma cholesterol of 510 mg. per 100 ml. confirmed this opinion. It was difficult, however, to understand why this should have occurred after he had been maintained in a satisfactory state on a maintenance dose of 0.1 mg. of thyroxine daily for over a year.

Before he could be admitted to hospital he became violent and was admitted to an observation ward. He was transferred to Hammersmith Hospital the following morning. On admission he was given 10 μg . of L-triiodothyronine intravenously followed by a maintenance dose of 0.1 mg. of L-

FIG. 1.—Effect of L-triiodothyronine and L-thyroxine on plasma cholesterol and body weight in a patient with hypothyroidism.

thyroxine orally. A perceptible increase in the peripheral circulation with cutaneous flushing was noted within two hours of giving triiodothyronine. Triiodothyronine was given by intravenous injection daily, the dose being increased by 10 μg . a day. By the fourth day he was receiving 40 μg ., which together with the daily dose of 0.1 mg. of thyroxine constituted a full replacement dose of thyroid hormone. He now showed some evidence of hyperthyroidism with a marked increase in peripheral circulation and sweating of the palms of the hands, but there was no tachycardia or recurrence of angina. He was less co-operative and wished to be discharged from hospital. The dose of triiodothyronine was reduced. During the course of the next week noticeable improvement occurred from day to day, and within three

weeks of admission his mental state was normal. His progress is shown in the accompanying chart (Fig. 1). He has remained well since and has shown no further tendency to psychiatric disturbance.

It was later found that he was being supplied by his chemist with 0.1 mg. of DL-thyroxine,* thus explaining the development of hypothyroidism. Rapid correction of hypothyroidism was desirable because of the onset of mania, but a delicate balance had to be maintained to avoid any recurrence of angina. Triiodothyronine was eminently suitable in these rather unusual circumstances.

Thyroid Carcinoma

Patients with functioning thyroid carcinoma may require several doses of radioactive iodine: treatment is usually given at intervals of approximately three months. Thyroxine is given in the intervals between treatment, but has to be stopped at least one month before a further dose of radio-iodine is given. The schema of treatment has been clearly described by Hilton, Pochin, Cunningham, and Halnan (1956). If triiodothyronine is substituted for thyroxine the period of disability due to hypothyroidism is reduced to a minimum. A patient maintained in a euthyroid state on triiodothyronine becomes myxoedematous within 12–14 days of stopping the drug. A therapeutic dose of radio-iodine may then be given and triiodothyronine started again within 24 hours with a rapid return to the euthyroid state. Triiodothyronine used in this way has proved most useful in the management of patients with thyroid carcinoma.

Diagnostic Suppression of Thyroid Function

It has been shown that thyroid function is suppressed in normal subjects given desiccated thyroid (Stanley and Astwood, 1949; Greer, 1951) or thyroxine (Morgans, Oldham, and Trotter, 1952). Triiodothyronine was shown to be effective in suppressing thyroidal uptake of radio-iodine in normal subjects in a dose as low as 8 µg. daily (Starr and Liebhold-Schueck, 1953), but doses as large as 2 mg. a day did not affect thyroidal uptake of radio-iodine in Graves's disease (Werner and Hamilton, 1953). It was shown that euthyroid patients could be differentiated from hyperthyroid patients by their response to the administration of desiccated thyroid (Greer and Smith, 1954), or triiodothyronine (Werner and Spooner, 1955; Perlmutter and Slater, 1955).

The suppressive effect of thyroid substances on thyroid function is useful in determining the thyroid status in some patients in whom conventional radio-iodine tests are inconclusive. Triiodothyronine, which has a more transient effect, is probably preferable to thyroxine for this purpose, although it has not been shown that it suppresses thyroid uptake more rapidly than thyroxine.

The following examples show how euthyroid and hyperthyroid patients may be differentiated by their response to the administration of triiodothyronine.

Case 1.—Radio-iodine tests of thyroid function were carried out on a patient with suspected thyrotoxicosis. The results (Table I) show values for thyroid clearance (Myant, Pochin, and Goldie, 1949) and protein-bound ¹³¹I (P.B., ¹³¹I) (Ansell, Macgregor, Miller, and Wayne, 1953) to be within normal limits, but the "T" index derived from the figures for urinary excretion (Fraser, Hobson, Arnott, and Emery, 1953) is within the range for hyperthyroidism. The administration of 40 µg. of L-triiodothyronine thrice daily for nine days resulted in suppression of

*Pitt-Rivers and Lerman (1948) assayed the D- and L- forms of thyroxine in myxoedema; they found that the L- form was 8–10 times as active as the D- form. Tomich and Woollett (1956, personal communication) found that the potency of D-thyroxine was 5–10% that of L-thyroxine in experiments on oxygen consumption in intact rats. Sodium DL-thyroxine was introduced into the *British Pharmacopoeia* in 1932 and deleted in 1948. It was included in the 1954 edition of the *British Pharmaceutical Codex* and deleted in 1949. Sodium L-thyroxine was introduced into the 1954 edition of the *B.P.C.*, but is not at present in the *B.P.* We understand that it will probably be included in the next edition of the *B.P.*

thyroidal uptake of radio-iodine as judged by *in vivo* and urinary excretion measurements. Serial measurements of thyroidal uptake with ¹³¹I suggest that suppression occurred gradually (Fig. 2). (The ¹³¹I curves of thyroidal uptake have not been corrected for extrathyroidal activity to allow comparison with those made with ¹²⁵I.) The results make a diagnosis of thyrotoxicosis extremely unlikely.

TABLE I.—Effect of Triiodothyronine on Thyroid Function in a Euthyroid Patient

Date	Isotope	Thyroid Uptake of Administered Dose (A.D.) at 1 Hour	Thyroid Clearance	Urinary Excretion	Plasma 48 Hours Protein-bound ¹³¹ I (P.B.I.)

thyroidal uptake of radio-iodine (Fig. 3) or produce any significant change in the urinary excretion pattern. The results supported the clinical diagnosis, and further confirmation was obtained by the patient's response to treatment with potassium perchlorate.

FIG. 3.—Effect of L-triiodothyronine on thyroidal uptake of radio-iodine in a patient with recurrent thyrotoxicosis (Case 2).

Therapeutic Test in Hypothyroidism

Mild hypothyroidism, giving rise as it does to symptoms without clinical signs, is difficult to diagnose and often overlooked. Laboratory tests provide little help in such cases and will confirm the diagnosis only where this is clinically obvious. It is perhaps not sufficiently realized that many symptoms such as irritability, nervousness, depression, restlessness, palpitations, fatigue, paroxysmal flushing and sweating, and loss of weight are common to both early hypothyroidism and hyperthyroidism. Other symptoms, such as insomnia, paraesthesiae, cramps, muscular and joint pains, headache, and angina, while commonly seen in hypothyroidism, are by no means specific. A doubtful diagnosis of hypothyroidism is best established by a therapeutic test with thyroid hormone. The therapeutic response to triiodothyronine is evident within two or three days, and is more readily appreciated by the patient in contrast to the less dramatic effects of thyroxine therapy.

Hypometabolism

It has been claimed that a condition of non-myxoedematous hypometabolism exists (Kurland, Hamolsky, and Freedberg, 1955; Tittle, 1956). The clinical features of this syndrome are said to include lethargy, nervousness, irritability, emotional instability, sensitivity to cold, headache, ill-defined muscular and skeletal pains, and periorbital puffiness. The B.M.R. is below normal, but other indices of thyroid function are within normal limits. There appears to be no difference between this new "syndrome" and a mild hypothyroidism. It is difficult to understand why a new name should be applied to a condition which, from its clinical description, seems unquestionably due to thyroid hypofunction. Moreover, it is well recognized that a lowered B.M.R. is the most sensitive index and may be the only confirmatory evidence of hypothyroidism.

It has been reported that these patients are refractory to thyroid therapy, but respond to treatment with triiodothyronine alone or in conjunction with thyroxine. Explanations put forward to account for this phenomenon include possible defects in absorption or peripheral utilization of thyroxine or thyroid extract. These hypotheses might well be confirmed by studies with labelled thyroxine, but in the meantime the evidence for the existence of this syndrome is not convincing.

Myxoedema Coma

During the past three years 16 cases of myxoedema coma have been reported in this country (Le Marquand, Haus-

mann, and Hemsted, 1953, 1955; Summers, 1953; Malden, 1955; Karhausen and Zylberszac, 1955; Reid, 1955; Marshall and McCaughey, 1956; Dyson and Wood, 1956; Anderson and Hausmann, 1956). All these patients died except one in the series reported by Malden. The case reported by Dyson and Wood and that of Anderson and Hausmann were treated with triiodothyronine and thyroxine. It is well recognized that thyroid hormone must be given in small dosage and with extreme caution to patients with severe myxoedema. An even more conservative policy is indicated in the treatment of myxoedema coma. From examination of the case histories of patients with myxoedema coma it would almost appear that the administration of thyroid hormone caused further deterioration, the majority dying within two to four days of starting treatment.

We have not had an opportunity of using triiodothyronine in the treatment of myxoedema coma. In addition to measures to combat hypothermia and adrenocortical failure, triiodothyronine would seem to be the drug of choice in this condition. The therapeutic value of triiodothyronine, however, cannot be properly assessed when given in conjunction with thyroxine or thyroid extract. We would suggest that initially 10 µg. should be given every 12 hours by intravenous injection and the dose modified according to the response. There is evidence that a higher dosage may be dangerous in patients with extreme deficiency of thyroid hormone, and it must be emphasized that in any chronic hypothyroid state caution in therapy is strongly indicated because of the risk of acute heart failure.

Discussion

Most of the conditions discussed here in which triiodothyronine has proved useful are not commonly encountered in general medical practice. Triiodothyronine will be of value mainly in thyroid clinics and to individuals with a special interest in the treatment or investigation of patients with thyroid disease. It will, however, have a wider application as a therapeutic test in the diagnosis of equivocal hypothyroidism. Its use in this respect should be restricted to cases where there are reasonable grounds for a clinical diagnosis of hypothyroidism.

As already mentioned the metabolic effects of triiodothyronine have been studied after the administration of a single dose. Relatively enormous doses (up to 1 mg.) have been given to obtain measurable effects: this may have led to some confusion regarding the dose required to correct myxoedema. Although hypothyroidism of recent origin may be corrected rapidly with safety, a similar attempt to correct long-standing myxoedema rapidly may be fatal.

L-triiodothyronine has been estimated to be three to five times as active as L-thyroxine on a molar basis (Lerman, 1953; Blackburn *et al.*, 1954; Blackburn and Keating, 1954; Selenkow and Asper, 1955; Frawley, McClintock, Beebe, and Marthy, 1956). We estimate L-triiodothyronine to be about five times as active as L-thyroxine on a molar basis. This observation is based on studies in athyroidal patients who have been maintained in a euthyroid state with each compound. The replacement dose of triiodothyronine is 60–80 µg. daily, and 20 µg. of triiodothyronine is therefore approximately equivalent to 0.1 mg. of L-thyroxine or 1 gr. (65 mg.) of thyroid (B.P.).

Summary

Certain aspects of the biosynthesis and biological activity of triiodothyronine in animals and humans are discussed and the literature is reviewed. The use of triiodothyronine is preferable to that of thyroxine when its rapid action and transient effect are advantageous: hence its clinical applications are limited.

Triiodothyronine has proved very suitable in the treatment of a patient with coronary insufficiency who developed paranoia of hypothyroid origin.

The use of triiodothyronine in the management of patients with thyroid carcinoma and in the diagnosis of borderline hypothyroidism and thyrotoxicosis is described.

Some suggestions regarding its use in the treatment of myxoedema coma are made and the dangers in the treatment of this condition emphasized.

We are indebted to Dr. R. Pitt-Rivers, F.R.S., for her criticism and advice, and to Dr. William Phillips for reading the manuscript. We wish to thank Miss J. M. Gartside for technical assistance. Sodium L-triiodothyronine has been kindly supplied by Glaxo Laboratories.

MEASUREMENT OF GASTRO-INTESTINAL BLEEDING USING RADIOACTIVE CHROMIUM

BY

R. M. BANNERMAN, B.M., M.R.C.P.

Medical Registrar, St. Thomas's Hospital, London

There are a number of satisfactory chemical tests for the detection of occult blood in stools, but a precise quantitative method of measuring gastro-intestinal blood loss has not been available until recently. Owen *et al.* (1954a) used radioactive chromium for this purpose experimentally in dogs, and also applied the method to man (Owen *et al.*, 1954b; Cooper *et al.*, 1955). Radioactive iron has also been used in attempting to measure blood loss in hookworm infestation (Gerritsen *et al.*, 1954).

The purpose of this communication is to describe a simple method for the quantitative estimation of faecal blood loss, using radioactive chromium in tracer doses. The method is illustrated by detailed results in three patients selected from a small series. A comparison has also been made between the quantity of blood in the stool estimated by this method and the result of a commonly used benzidine occult blood test.

Radioactive Chromium Method

The principle consists in labelling circulating red cells with radioactive chromium and subsequently measuring and comparing the radioactivity of samples of venous blood and faeces.

Red-cell Labelling.—The patient's own red cells are tagged with ^{51}Cr , using a modification of the established method (Gray and Sterling, 1950; Mollison and Veall, 1955; Cooper and Owen, 1956). 20 ml. of venous blood is withdrawn into a sterile bottle containing 1,000 international units of heparin. The bottle is centrifuged and the supernatant plasma removed. A few millilitres (100–200 microcuries) of a sterile isotonic solution containing ^{51}Cr as sodium chromate, Na_2CrO_4 , in saline, is then mixed with the red cells and allowed to stand for half an hour at room temperature. The ^{51}Cr solution, which is obtained already diluted and sterilized from the Radiochemical Centre, Amersham, has an initial activity of 100 μC . per ml. and a specific activity of approximately 30 μC . per μg . After standing, the red cells are twice washed with saline to remove free unattached ^{51}Cr , and are resuspended in saline to a volume of 22 ml. Then 20 ml. of this suspension is re-injected intravenously into the patient. All these manipulations are carried out with the usual aseptic precautions. 1 ml. of the remaining suspension is diluted to 100 ml. with water in a volumetric flask, and the radioactivity of a 5-ml. aliquot is measured in order to calculate the total dose administered to the patient.

Sample Counting.—Venous blood and stool sample counts are made on 5-ml. aliquots placed in small flat-bottomed glass tubes, in a well-type scintillation counter. The scintillation counter is that described for use in routine radioactive iron studies (Wetherley-Mein *et al.*, 1956). All measurements are corrected for background activity and for radioactive decay.

Blood Radioactivity.—Blood samples are taken at intervals of one to three days, the activity is measured, corrected for background and decay, and plotted on a simple linear graph. From this graph the blood radioactivity at any time is calculated in counts per second per ml. (c./sec./ml.) (see Chart).

Stool Radioactivity.—All stools passed by the patient are collected in successive 24-hour periods during the investigation. The faeces are transferred from a bedpan into weighed jars, or directly into the metal container of an ordinary domestic electric mixer. Each 24-hour collection is weighed and a known amount of water added, so that after mixing a thick homogeneous suspension is obtained. The quantity of water added depends on the consistency of the stool, and it is usually necessary to dilute the stool to about twice its original volume. After mixing, approximately 5 g. of the diluted suspension is poured at once through a funnel into a weighed counting-tube, which is reweighed so that the exact amount of the diluted sample is known. The radioactivity of the sample is measured and the result corrected for background and decay. From the activity of the sample the total radioactivity of the 24-hour collection is determined.

Calculation.—The amount of blood in millilitres present in each 24-hour collection is then obtained from the expression:

$$\frac{\text{Total activity of stool collection in counts per second}}{\text{Activity of blood in counts per second per ml.}}$$

Since the exact time at which bleeding occurred, and thus the time the blood has spent in the bowel, is unknown, an assumption has to be made to decide which blood-activity value is to be used in the calculation. In this study the value two days before the stool was passed has been used. In practice the fall in blood radioactivity during the test period is usually so gradual that the possible inaccuracy of this assumption has little effect on the result.

Occult Blood Test

The occult blood test employed in this study, which is a modification of the Gregersen benzidine test described by Needham and Simpson (1952), is that used in routine practice in this hospital (J. S. Staffurth, 1952, personal communication). A smear of faeces from each 24-hour collection is made on a filter-paper before dilution. A suspension of the prepared powder (a mixture of benzidine hydrochloride, 25 mg., and barium peroxide, 200 mg., individually wrapped in waxed papers, and supplied by Messrs. Allen & Hanburys) in 5 ml. of glacial acetic acid, is poured on the smear. The appearance of a deep blue colour indicates a positive reaction, and the speed with which it appears is some measure of the amount of blood present. The gradations recognized are as follows: strongly positive (++), an intense colour appearing immediately; positive (+), a deep blue colour appearing within 15 seconds; weakly positive ($\pm$), a greenish-blue colour appearing within 30 seconds; negative (—), no colour within 30 seconds.

Results

To illustrate the results which may be obtained with this method, the findings in three patients are set out in detail in the Table. These have been selected from the small series of nine cases, each followed for at least 10 days.

The first was an elderly man apparently bleeding from a hiatus hernia. Using this method, his daily blood loss, averaged over 10 days, was estimated to be 14 ml., with a range of 3 to 46 ml. It will be seen that there was no significant radioactivity in the stools passed during the first four days after cell labelling, although the benzidine test was positive throughout. Provided that the patient is passing stools regularly, such a delay in the appearance of radioactivity in the stool samples may be interpreted as indicating that the blood is coming from high up in the gastro-intestinal tract, a conclusion in accord with the clinical diagnosis in this patient.

The second patient, again an elderly man, had iron-deficiency anaemia due to chronic intestinal bleeding for which no cause could be found. His average daily loss over 14 days was 6 ml., with a range of 3 to 25 ml. The early appearance of radioactivity in the stools suggested, in contrast to the previous patient, that the site of bleeding was low in the gastro-intestinal tract. This has not yet been confirmed, and the patient is still under investigation.

The third patient, a middle-aged woman, had a profound iron-deficiency anaemia—initially 4.14 g./100 ml. (28% Haldane)—due to menorrhagia and to the bleeding from a

Results in Three Cases

duodenal ulcer. Her average daily loss over 10 days was estimated to be 3 ml., with a range of 3 to 14 ml. (the daily average is low because she did not pass a stool every day; the average per stool collection was approximately 7 ml.). During the period of investigation there was no uterine bleeding, and, in spite of continued bleeding from the ulcers, the haemoglobin rose very rapidly with iron therapy. This is explained by the very small daily loss demonstrated.

The quantitative estimate of blood loss by this method usually corresponded well with the results of the benzidine test. As would be expected, the bulk of the stool, and hence the dilution of the blood in the faeces, is important in determining the intensity of the reaction. For example, a relatively large amount of blood in a bulky stool—for example, 20 ml. measured by the chromium method, in 470 g. of faeces—has given only a weakly positive ($\pm$) benzidine reaction, whereas in stools of average bulk (50–200 g.) only 7 ml. upwards has been required to give a ++ reaction, 3–14 ml. has given a + reaction, and 0–10 ml. a $\pm$ reaction.

At times a lack of correspondence has been observed between the two methods. On the one hand, significant radioactivity has been found with negative benzidine tests (as in days 3 and 4 of Case 2); and on the other, weakly positive benzidine reactions have been observed with no significant radioactivity in the faecal samples. These discrepancies have always been when the amount of blood was small as indicated by one test or the other.

Discussion

Quantitative chemical methods for determining the amount of blood present in faeces are laborious and inexact (Andrews and Oliver-González, 1942). For this reason very little information is as yet available about the daily blood loss in many common diseases.

The radio-isotope method is simpler, and its general validity was carefully worked out in experiments with dogs by Owen *et al.* (1954a). They labelled dogs' own red cells with ^{51}Cr , placed known quantities of this labelled blood in the dogs' stomachs, then measured the faecal radioactivity and obtained very good correspondence. They also found that in dogs with ^{51}Cr -labelled red cells the amount of ^{51}Cr passing into the bowel in the absence of bleeding was less than 0.1% of the original dose daily, equivalent to less than 1 ml. of blood daily. A larger amount (1% a day), was excreted in the urine. They concluded that the method can reasonably be applied to man (Owen *et al.*, 1954b; Cooper *et al.*, 1955).

The studies reported here confirm their view that the ^{51}Cr method provides a simple reliable way of quantitatively estimating faecal blood loss. Our experience with patients in whom chronic or subacute gastro-intestinal bleeding was known or suspected indicates that the method may be of considerable value not only in research but also in diagnosis. It may give evidence not only of the quantity of blood lost daily, but also sometimes an indication of whether the site of bleeding is high or low in the gastro-intestinal tract.

The accuracy of the ^{51}Cr method described is clearly least when the blood is in high dilution, because the radioactivity of the stool sample becomes nearer background activity. The present findings show that the method is not capable of measuring accurately very small amounts of blood—that is, of the order of 3 ml. or less—in an average stool. It is thus probably less sensitive in detecting bleeding than is the Gregersen benzidine test. This is a limitation of the method which must be accepted, for, although it could be overcome by using a larger dose of ^{51}Cr , a dose greater than 300 μC is probably not justified (Mollison and Veall, 1955).

The present study also confirms the conclusion of Needham and Simpson (1952) on the value of the modified Gregersen benzidine test. They found that a minimum of 3 to 5 ml. of blood administered by stomach-tube was necessary to produce a positive (+) result. In the present study + results were obtained with stools of average bulk (50–200 g.) when they contained 3–14 ml. of blood as estimated by the ^{51}Cr method. The Gregersen benzidine test is, of course, not intended to be quantitative, and, as pointed out above, the gradations in intensity noted have relatively little significance unless the bulk of the stool is taken into account. For example, on different occasions in this study a blood loss of 10 ml. has been associated with benzidine test results of $\pm$, +, and ++. Further, as Needham and Simpson pointed out, occasional false positives are obtained, and the test is most useful when it is repeated on a series of samples.

Summary

A method using tracer doses of ^{51}Cr for the quantitative estimation of gastro-intestinal blood loss is described. Detailed results from three patients are given to illustrate the value of the method in expressing clinical observations in quantitative terms, and sometimes in indicating the possible site of bleeding. A comparison is made between the findings with this method and results of a commonly used qualitative benzidine occult blood test.

On the whole there is good correlation between the tests. The chromium method has least value when blood loss is 3 ml. or less in the stool samples analysed.

I am grateful to Dr. G. Wetherley-Mein for his advice and encouragement, and to Dr. J. L. Pinniger for allowing me facilities in the Louis Jenner Laboratory and for reading the manuscript. I thank the physicians of St. Thomas's Hospital for permission to investigate patients under their care.

ADDENDUM.—Since submitting this paper for publication the technique has been much simplified by the introduction of a modified turrett counter of the type described by Veall (Veall and Vetter, 1952). This was constructed by the hospital Physics Department. Each stool is collected into a large wax carton which can be placed directly in the counter. The activity of the whole sample can thus be determined without the elaborate manipulations described in the text.

LEUKAEMIA, AMYLOIDOSIS, AND RENAL VEIN THROMBOSIS IN IRRADIATED ANKYLOSING SPONDYLITIS

BY

JOHN B. PENFOLD, M.B., B.S.

Consultant Pathologist, Essex County Hospital, Colchester

AND

R. D. S. RHYS-LEWIS, M.D., D.M.R.

Consultant in Radiotherapy, Essex County Hospital,
Colchester

Interest has recently been stimulated in two syndromes—namely, leukaemia following irradiation for ankylosing spondylitis (Court Brown and Abbott, 1955; Abbott and Lea, 1956) and renal vein thrombosis following amyloidosis (Harrison *et al.*, 1956). A case, in our experience unique, is reported showing both syndromes.

Clinical History

A store manager aged 32 was discharged from the Army in 1945 with a diagnosis of ankylosing spondylitis. From 1945 to 1948 he was treated by deep x rays to his spine. The total dose received was about 1,200 r. He was subsequently encased in a spinal jacket, which he had worn for the nine months previous to his first presentation at our hospital in June, 1948.

He then complained of pain in the back of both thighs and in the back on sitting down. His spine was completely rigid and movement of the hips was limited. The Wassermann and Kahn reactions were negative, the E.S.R. was 40 mm., and the x-ray examination was typical of spondylitis. He removed to another area and from 1948 to 1950 he was treated at another hospital with further deep x rays to the spine to a total dosage of between 1,000 and 1,500 r.

In 1953 he had renal symptoms for the first time. At one hospital he complained of left and then right renal colic,

and his renal function was found to be poor. This was confirmed at another hospital, where he was shown to have a high blood urea and anaemia with a normal blood pressure. Chronic nephritis possibly due to irradiation was diagnosed, and he was treated with multiple transfusions.

In February, 1954, he was readmitted to our hospital with renal symptoms. He was "clinically anaemic," the blood pressure was 140/90, the fundi were normal apart from pallor, and the only oedema he showed was a slight swelling of the left ankle. The remainder of the clinical examination revealed nothing abnormal. The blood urea was high (156 mg./100 ml.) and gradually rose throughout the year to his death in October (390 mg.). On several occasions between February and September, 1954, the serum proteins were between 4 and 5%, with the albumin about 2.5%. During the same period several urine examinations showed a severe albuminuria, few white and red cells, but no casts. A blood count in February, 1954, showed: red cells, 1,900,000 per c.mm.; Hb, 41% (6.07 g./100 ml.); white cells, 5,700 per c.mm. (polymorphs 68%, eosinophils 4%, lymphocytes 25%, monocytes 2%, basophils 1%). Anisocytosis and poikilocytosis were severe, and polychromatophilia and basophil stippling of the red cells were present. He was given multiple transfusions and discharged.

He was readmitted to our hospital on September 27, complaining of vomiting, sometimes "black," for six days, and severe backache. On examination he was obviously very ill, and was very pale, with ulceration of his throat. He was tender over the spine and other bones. The glands were not enlarged and the liver, spleen, and kidneys were not palpable. His blood urea was 390 mg. per 100 ml.; he had a severe albuminuria and the serum proteins were reduced. A blood count showed: red cells, 2,700,000; Hb, 47% (6.9 g./100 ml.); white cells, 13,600 (polymorphs 7%, eosinophils 1%, lymphocytes 18%, monocytes 1%, "blasts" 73%). Severe anisocytosis and poikilocytosis were present; the red cells were small and pale, with a few larger polychromatic cells. Platelets were scanty. The peroxidase stain of the "blasts" was negative. Acute leukaemia was diagnosed, and it was thought to be lymphatic in type. A marrow examination confirmed this, 87% of the cells resembling lymphocytes or lymphoblasts.

The patient had various further haemorrhagic episodes, and he died on October 8, 1954.

Post-mortem Examination

A thin young man with dark-brown pigmentation of the skin except in the bathing-trunk area. **Bones:**—Ankylosing spondylitis. Rich grey-red marrow in femur, sternum, and vertebrae. **Heart and vessels:**—Normal apart from the renal veins, which are described below (see "kidneys"), and occasional scattered atheromatous plaques in the aorta. **Respiratory tract:**—Mucous haemorrhages in nose and nasopharynx with ulceration. Oedema of both lung bases. **Alimentary tract:**—Multiple erosions in lower oesophagus and in stomach, where they were widely scattered. Much altered and fresh blood in stomach and throughout the bowels. **Liver:**—Swollen, pale, smooth, and shiny. **Spleen and lymph nodes:**—Spleen normal size, firm, even, red-dish brown. Slight generalized enlargement of lymph nodes. **Thyroid, parathyroids, adrenals, pancreas:**—Normal. **Skull, meninges, brain, cord, and middle ears:**—Normal.

Left Kidney (11 by 6 by 4 cm. Weight 126 g.).—Aberrant renal artery at lower pole. Cortex 10 mm. deep, pale, with small haemorrhagic areas. Medulla also pale. Pelvis normal. Capsule thickened and did not strip readily. Surface finely granular, pale, with spider areas upon it. Renal arteries appeared to have normal walls and lumen. Marked narrowing, thickening, and distortion of the renal vein near the kidney after commencing normally. Calcified areas in the narrowed portion of the renal vein, its branches, and in the medulla.

Right Kidney (9 by 4.5 by 2.5 cm. Weight 70 g.).—Cortex 5 mm. deep, pale, with darker radial streaks. Medulla

appeared normal apart from calcified areas mentioned later. Calcified areas in linear form apparently following vessels in the pelvic area, while other similar calcified areas were present in the medulla. Capsule thickened, not stripping readily, leaving a finely granular pale surface with spider areas. Renal arteries apparently normal. Renal vein commenced normally, but was completely obliterated near the kidney, appearing as a thickened firm cord with calcified areas.

Post-mortem Histology.—Renal arteries and veins extra-renal:—Arteries normal, but calcified thrombus in renal veins. **Kidneys:**—Severe amyloid change. Extensive small round-cell infiltration of leukaemic type. Veins in pelvis and medullae were obliterated by old thrombi, which were frequently calcified. The arteries were clear. **Liver, spleen, and adrenals:**—Severe amyloid change. **Marrow and lymph nodes:**—Lymphatic leukaemic change. **Heart and stomach:**—Normal.

Post-mortem Radiography.—The kidneys were radiographed after removal at necropsy, and both showed an unusual calcification—the left more than the right—linear in type and most pronounced at and near the pelvis. This confirmed the calcification noted at necropsy and showed that it was more extensive than at first appeared.

Discussion

This complicated case, showing ankylosing spondylitis, for which irradiation was given, amyloidosis, "chronic nephritis," renal vein thrombosis, and leukaemia, was difficult to explain at the time it occurred. Since then papers having a bearing on certain aspects of this case have made apparent the probable course of events.

Amyloidosis is known to occur in occasional cases of ankylosing spondylitis (W. St. C. Symmers, 1957, personal communication), and there is evidence that renal vein thrombosis may occur in amyloid disease (O'Beirn, 1953; Harrison *et al.*, 1956). The patient's clinical "chronic nephritis" would appear to have been due to amyloidosis and renal vein thrombosis. The thrombosis had to a large extent organized, with resultant sclerosis, calcification, and loss of lumen of the renal veins. What part, if any, the irradiation played in the production of the thrombosis is difficult to assess. The dose of x rays was not excessive, and renal complications of irradiation have not often been reported. The most important series of cases of renal damage following radiotherapy is that of Luxton (1953), who described 27 cases irradiated for seminoma. Of these, 13 developed symptoms of acute nephritis, 12 of chronic nephritis, and 2 of malignant hypertension. Similar cases have been reported by other workers, and Smith and Wynn Williams (1955) described in detail, with a full necropsy report, a further case of irradiation nephritis.

It must be emphasized that all the cases we have seen reported received a comparatively heavy dosage of x rays for malignant conditions varying from about 3,000 to 6,000 r in four to five weeks. This is in marked contrast to our own case, in which the dose has been calculated not to have exceeded 500 r at the medial surface of the kidney and 100 r at the renal parenchyma over a period of three years. In our experience such a dosage has not been known to produce renal damage. Furthermore, vascular damage caused by irradiation is arterial and is an endarteritis obliterans while the veins remain clear. In our case thrombosis, sclerosis, and calcification occurred in the veins, the arteries apparently being spared. X rays may have been partly responsible for the renal-vein lesions, but we think this unlikely. It is more likely that they followed the amyloidosis.

The accumulation of evidence that leukaemia is apt to occur in cases of ankylosing spondylitis given irradiation continues, and Abbott and Lea (1956) have theorized on the possibilities at play. Although the x-ray dosage in our case was within reasonable limits, the possibility that the leukaemia followed the irradiation is undeniable. The leukaemia has usually been described as an acute myeloblastic type in the reports. We considered our case to be

an acute lymphoblastic leukaemia, being, of course, fully aware of the difficulty of classifying very primitive and atypical cells.

The series of related events in our case might be expressed as :

Summary

A case of ankylosing spondylitis complicated by amyloid disease and renal vein thrombosis is described. Treated by irradiation, the patient subsequently developed acute leukaemia, probably lymphatic, and succumbed. The interrelation of the various conditions is discussed.

We wish to thank Dr. S. A. Probert for permission to publish the case and Professor W. St. C. Symmers for his helpful criticism.

ENTEROPATHOGENIC ESCHERICHIA COLI SEROTYPES: INFECTION OF NEWBORN THROUGH MOTHER*

BY

H. W. OCKLITZ, Dozent Dr.Med.

AND

E. F. SCHMIDT, Dr.Med.

From the Paediatric Clinic of the University of Rostock, Germany

The epidemiology of gastro-enteritis caused by the enteropathogenic *Escherichia coli* serotypes has hitherto been studied, with exceptions, in paediatric clinics and nurseries (Taylor *et al.*, 1949; Rogers and Koegler, 1951; Rogers, 1951; Taylor, 1951; Taylor and Charter, 1952; Ocklitz and Schmidt, 1954; Adam, 1956; Rogers and Cracknell, 1956). Outside these establishments it has been difficult to follow the chain of infection (Braun, 1956).

In the children's hospital or ward the primary infection usually originates in the sick babies, but occasionally adults in the nursing staff are carriers of the germ (Ocklitz and Schmidt, 1955), although not ill. The spread of the infection in hospitals may also be caused through contamination of food of babies during preparation (Ocklitz and Schmidt, 1954).

Contact between infants outside hospital is possible too; in Germany the babies are often assembled in the waiting-rooms of the child welfare institution, and they may get infected in the consultation-room. There may also be cross-infection from infant to infant in the family

*Paper, in extract, read by one of us (H. W. O.) at the eighth International Congress of Paediatrics in Copenhagen, Denmark, July, 1956.

itself. But all these factors fail to explain the relatively high percentage of healthy carriers among the infants in the general population.

During earlier investigations we found pathogenic *E. coli* in 5.8% of the infants who had not had contacts with infected babies (Ocklitz and Schmidt, 1954). These results correspond with those of other authors (Taylor, 1953; Braun, 1956). In explaining such results, it is again necessary to consider the part played by the contamination of food. This leads us to the person who cares and cooks for the baby every day—namely, the mother—and her epidemiological role in *E. coli* diarrhoea.

We have tried to examine the factors which link the mother and her baby, especially the newborn baby, in this infection. In our examination we identified pathogenic strains of the well-known *E. coli* O groups 111, 55, 26, 86, and 44, and the type O25:L11:H6, which we isolated in a ward of our hospital during a severe epidemic of coli-enteritis (Ocklitz and Schmidt, 1952). We can only briefly deal with serological methods, referring to other more detailed literature (Kauffmann, 1954; Kauffmann and Ørskov, 1956).

Material and Method

Cultures were made from the faeces and lochia of women, lochial specimens being collected on throat swabs. From newborn infants rectal swabs were taken, using a sterile Drigalski spatula, care being taken to obtain traces of faeces. Media were inoculated at once at the patient's bedside. To avoid a confluent growth we inoculated several culture dishes, using Endo, Drigalski, and Leifson media (Schmidt, 1956). At the same time the antibiotic resistance was tested.

After 18 hours' incubation, and after the exclusion of the *Salmonella* and *Shigella* groups of bacteria, the *E. coli* colonies were tested with diagnostic sera by way of slide agglutination. We examined at least 10 single colonies or a sample of the bacterial growth, using two polyvalent sera of the following *E. coli* types:

Serum I: O111:B4:H-; O55:B5:H-; O26:B6:H-.
 Serum II: O25:L11:H6; O86:B7:H34; O44:L74:H18.

These sera were so composed as to avoid overlapping reactions of their antigens. In this way a preliminary diagnosis was made which was confirmed in further tests. Having taken pure cultures, we started with the tube agglutination. In this agglutination we tested separately the O and B antigens. At the same time the strain was examined in a U-tube for its motility in semi-stiff medium (Kauffmann, 1954). If the strain was motile we identified the H antigen by means of the immobilization test, using H sera (Kauffmann and Ørskov, 1956).

Results

Mothers in the maternity wards of the gynaecological clinic of the University of Rostock were examined. In 22 (8.8%) of the 250 specimens, pathogenic *E. coli* serotypes were isolated from the stools or lochia before or after the delivery (Ocklitz and Schmidt, 1955) (see Table I). The fact

TABLE I.—Results of Examination of Women in the Gynaecological Clinic

that the percentage of positive results was higher after delivery than before indicates the role of the hospital environment as an infecting agent.

The nurses change the napkins and feed the babies. In our clinic we found *E. coli* on the hands of the nurses, in spite of washing and disinfecting; we also found *E. coli* on the rubber teats after they were put on the bottles by the nurses. We found, too, that the nurses were carriers of pathogenic *E. coli* in their own stools. In the gynaecological clinic we found that, at times, almost one nurse out of four working in the labour and other maternity wards for mothers and their newborn babies had enteropathogenic *E. coli* serotypes in her stools (see Table II). As the

TABLE II.—Results of Examination of Nurses in the Maternity Clinic

		O111:B4	O55:B5	O26:B6	O25:L11	
In labour room	17	—	—	2	4	6
In maternity wards	16	—	—	—	3	3
In rooms for newborn babies	10	—	—	—	2	2

nurses in the gynaecological clinic have to care for both babies and mothers, the possibility of the nurse infecting them both is evident. In the spread of pathogenic coli infection, direct contact plays the dominant role compared with both infection of feeds and aerial spread. While infants are touched by doctors only during examination, and not at all by cleaners, they are in the closest contact with the hands of the nurse.

Of approximately 2,000 newborn infants that have passed through our clinic during the last five years, 68 were found to be excreting pathogenic *E. coli* serotypes. All these infants were admitted during the first 12 days of life. The first rectal swab was taken within the first hour after their admission, the second swab some days later. From 16 of these 68 babies positive results were obtained from second swabs only, the first swabs having proved to be negative. In other words, these results were from babies who had, with reasonable certainty, been infected in our hospital, and, in view of this, we excluded these babies from any further consideration (see Fig. 1).

Fig. 1.—Number of newborn infants found with enteropathogenic *E. coli* in the first swab (white columns) and second swab (shaded columns).

We were therefore left with 52 newborn babies in whom the first rectal swab immediately after admission gave a positive result (see Fig. 1). *E. coli* O111:B4:H2, isolated from 35 cases, was the most frequent type, being twice as common as all other types—O26:B6:H11, nine cases; O55:B5:H6, five cases; and O44:L74:H18, three cases.

How could the newborn infant have become infected? Let us consider first the steady increase in positive findings from the third day onwards (Fig. 1). This cannot be due entirely to infection of infants by attending nurses, as about a third of the deliveries were at home, and therefore the mother could have been the infecting source, although we were unable to investigate this. But that such a post-natal infection of the infant by the mother is possible can be seen from our findings in another context—the isolation of pathogenic coli from stools and from breast milk collected from milk donors. In order to investigate this possibility we examined the donors of human milk, and found in the milk and in the faeces the same type of enteropathogenic coli bacteria (Ocklitz and Schmidt, 1955). Those mothers who gave positive results were delivered in the gynaecological clinic of Rostock University. In this earlier investigation the infection of infants by mechanically collected raw breast milk was demonstrated. Frequently an infant may be fed with the milk pumped from its own mother at the end of the preceding feed; in this instance, too, infection of the infant by its mother is possible, while an infant fed exclusively at the breast may escape infection.

From Fig. 1 it is obvious that a steep decline in the number of positive results occurs during the first two days; this precedes the gradual ascent. This change during the first two days is explicable only in connexion with the delivery. It would not be reasonable to regard the nurse as the only source of infection, as a high percentage of women are delivered without nurses in their own homes. As proof that the baby was infected by its mother during delivery, the same *E. coli* serotype would have to be found in the mother's stool before delivery and in that of the baby immediately after birth.

We made such an investigation. From women coming for consultation to the antenatal clinics we collected stools and investigated them bacteriologically. After delivery we examined the newborn babies in the same way with rectal swabs. This investigation has not yet been completed. The preliminary results obtained from the examination of 111 mothers and their babies are as follows: in five cases pathogenic *E. coli* strains were found in the stools of the mothers alone, and in three cases in the infant only. The coincidence of positive results in mother and baby was less often seen. In one case we found the same enteropathogenic *E. coli* serotype in the mother's stool on the last day before her admission to the clinic and, after delivery, in the rectal swab of the newborn. This we may regard as proof of infection during birth. Furthermore, the fact emerges that the possibility of such infection is greater than is often realized.

One may logically include the possibility of an *intrauterine* infection too, as, for example, in a case of premature rupture of the membranes. It is very difficult to obtain evidence of such an infection—much more so than an infection during delivery. In the following case we succeeded.

A newborn baby was delivered by caesarean section because of a premature rupture of membranes, cessation of labour, and inertia uteri after a delayed birth of four weeks. The baby was admitted to the children's clinic within half an hour of birth. On immediate examination we were struck by the penetrating smell pervading it—an odour like that of semen and typical of the enteropathogenic *E. coli* O111. The diarrhoeic stool passed during the examination had the same odour, and was unlike meconium. We immediately took a rectal swab; bacteriological examination of this revealed, apart from *Pseudomonas pyocyanea*, the enteropathogenic *E. coli* O111:B4:H2. The maternity hospital informed us that the amniotic fluid had been a faded muddy-green, formed us that the fluid was not made. Mother and child were treated with chlortetracycline and made a satisfactory recovery, without complications.

It was not possible to pin-point the actual time of infection. In all probability it occurred during rupture of the membranes. The fact remains that the infection was intrauterine.

It was noticed that the earlier in life these babies were infected the milder was the infection (see Fig. 2).

FIG. 2.—Severity of infection.

Conclusion and Summary

It can be assumed that in the maternity clinics, where child-bearing mothers are assembled, the possibility of infection with pathogenic *E. coli* types exists in just the same way as between infants in the infant wards. The transmission of these pathogenic germs may be from infant to infant through the nurses and other medical staff. In the same way, the mother may be infected by the nursing or medical staff. The latter possibility, if perhaps not frequent, is still of epidemiological importance; for the mother, who will in the future nurse the baby, leaves the hospital carrying the infection with her. Furthermore, we may assume the possible transmission of pathogenic *E. coli* serotypes from mother to child in all phases of delivery and after.

The relatively high percentage of positive isolations of *E. coli* serotypes obtained from babies born at home suggests that not all their mothers could have been infected in hospital. This does not detract from the importance of the clinical infective chain suggested in this communication.

The results of these investigations show the urgent need of an increased stress on prophylaxis. This will mean intensive instruction of the nurses and medical staff, and bacteriological control of all their work in hospital (Ocklitz, 1956). At home such prophylaxis is more difficult to attain. It is evident that our prophylactic efforts in and outside the hospital may be useful not only in controlling infections such as infantile diarrhoea, but also in combating all other infections, especially those caused by strains of staphylococcus.

Medical Memorandum

Mongolism in a Twin

Mongolism as a clinical entity has attracted a great deal of attention in the literature of oligophrenia, and its occurrence in one of twins has been considered to be so rare as to justify case reports. In a summary of such case reports it was suggested by Morris and MacGillivray (1953) that "mongolism in one of twins is not so rare in British literature as has been suggested," and two such cases were reported, bringing the total to 14 since 1876. A further case is here put on record.

CASE HISTORY

The father, aged 66, is a tradesman, and has been separated from the mother for 16 years; his history indicates that he may have been a psychopath. The mother, aged 65 years, is of normal intelligence. There were four other children, born in 1914, 1915, 1922, and 1924. All are married and there is no sign of abnormality in their offspring. There was no history of miscarriages. The paternal grandparents were normal, having four male and two female children. Of this family, one girl had twin daughters and one brother twin sons. The maternal grandparents were normal and had 14 children without history of twinning.

The twins were born on June 11, 1927, after a normal pregnancy, the boy first of normal weight and the patient, a girl, one hour later; she was only 4 lb. (1.8 kg.) in weight, was heavily jaundiced, and was an obvious mongol. The boy was normal and healthy up to his death in a road accident at 13 years of age. The girl was cared for by her mother until her excitable and destructive behaviour and her mother's ill-health necessitated admission to this hospital. She developed major epilepsy at the age of 14 and has had seizures at intervals since.

The patient is a typical mongol. She is 4 ft. 2 in. (1.27 m.) tall and weighs 9 st. 1 lb. (57.6 kg.). She has a brachycephalic skull, fissured tongue, and low-set ears with rudimentary pinnae. Her eyes are blue; her hair scanty, straight, and light brown. The arms are short, the fingers stubby, the little fingers incurved, and the thumbs low-set and short; all joints are hyperextensible. The lower limbs are short; there is some bowing of the tibiae, and marked separation between the great and adjoining toes. She averages one major fit a month; menstruation, established at 15 years of age, is normal and regular; her W.R. and Kahn reactions are negative.

She has a mental age of 2½ years on the Terman-Merrill Revision of the Binet scale, Form L, and a social age of 2 years on the Vineland scale. Her speech is mainly an incoherent babble, and her feeding and toilet habits are at the 18 months level. She frequently shows violent temper tantrums, spitting and scratching at those near her. These outbursts are accompanied by head-banging and pulling at her teeth. She has been observed to show aggressive homosexual behaviour.

COMMENT

In this case few aetiological factors emerge, beyond a history of twinning on the paternal side, and, as Benda (1947) concluded that only 63 cases of mongolism in one of twins reported in world literature could reliably be used in discussion, it was considered advisable to report this case.

My thanks are due to Miss C. M. Mathieson, our Senior Clinical Psychologist, for psychometric assessments, and to Mr. A. C. Adams, Group Psychiatric Social Worker, for detailed family investigations.

J. V. MORRIS, M.D.,
Little Plumstead Hospital, Norwich.

Reviews

NEW ZEALAND ARMY MEDICAL SERVICES

Official History of New Zealand in the Second World War, 1939-45. New Zealand Medical Services in Middle East and Italy. By T. Duncan M. Stout, M.B., M.S., F.R.C.S., F.R.A.C.S. (Pp. 721+xv; illustrated. No price.) Wellington, New Zealand: War History Branch, Department of Internal Affairs, 1956.

Mr. Stout, the editor of the official history of the New Zealand Medical Services in the Middle East and Italy, might have said to Professor Crew, editor of the official history of the Medical Services in the second world war, as W. S. Gilbert put it in *The Mikado*, "... and I am right and you are right and all is right as right can be," for it would be difficult elsewhere to find two such contrasting methods of dealing with a similar subject. Professor Crew adopts the almost impersonal approach—very few individuals are mentioned by name; Mr. Stout takes the opposite line and deals with his problem on a very "family" footing, not only mentioning names as well as appointments of many of the characters in this drama of war, but giving the life history of the persons involved in small print at the bottom of the page. The result is that this history is a very intimate picture of a large family at war; it is a perfect example and description of a "private army" at work; it is the story of New Zealand's own army from the medical angle. There are accuracy and substance in the narrative, and immense research must have gone into the compilation of this large volume. To arrive at such accuracy of detail the New Zealand war diaries must have been models of all that a war diary should be.

It is the story of a very gallant and capable family of doctors, nurses, and medical corps men and women—a story typical of the independence of spirit of the New Zealander, a spirit at times slightly critical of any opinion except his own. "And I am right" seems to thread its way through the whole history. To pick out one example, there is the almost fanatical adherence to the entirely laudable theory that the surgeon must be brought to the wounded soldier—at times, it seemed, no matter what the actualities of the situation might be. Gradually learning the hard way, that same spirit of independence became capable of self-criticism, leading to the admission that flexibility is a prerequisite of success and that "And you are right" might be a possibility, thus bringing the realization, for so long advocated by British surgeons, that, no matter how skilled your surgeons may be when operating in very advanced positions, so far as the patient is concerned surgery and essential post-operative care with skilled nursing in the comparative peace and quiet of a casualty clearing station are of more importance than early operation under stress and strain in the immediate fighting zone, where at best the post-operative care must be primitive.

The great size of the volume is accounted for as much by the mass of detail covering personal reminiscences, citations, and reports of conferences as by the factual descriptions of the functioning of the medical units themselves. Such intimacy has much to commend it, and this history must be and will remain a story of great interest to those whose names and exploits appear in the text. It will, we hope, be read by those that come after them, and the lessons, taught and bought by hard experience in a merciless war and so ably tabulated, digested to the advantage of the wounded of the future. The editor and his collaborators are to be congratulated on a most interesting and readable account of the Medical Services attached to the New Zealand Forces in the Middle East and Italy. "And all is right as right can be" is vividly demonstrated in the method of presentation.

TEXTBOOK OF RADIOLOGY

Roentgen Signs in Clinical Diagnosis. By Isadore Meschan, M.A., M.D. With the assistance of R. M. F. Farrer-Meschan, M.B., B.S. (Pp. 1,058+xx; illustrated. £7.) Philadelphia and London: W. B. Saunders Company, 1956.

The author has sought to produce a comprehensive textbook of radiology covering all its many aspects within the compass of one volume of about a thousand pages. He discusses the normal radiographic anatomy, the radiological signs of disease processes, and their differential diagnosis in relation to the various systems. The book may be divided for descriptive purposes into five sections. The first deals with apparatus, radiographic technique in general, personal protection, and radiological terminology; the second, of 400 pages, with the skeletal system; the third, of 250 pages, with diseases of the thorax; and the fourth, of similar length, with the abdomen and the genito-urinary and alimentary tracts. The last section is a short one devoted to obstetric and gynaecological radiology. The reader will be impressed by the quantity of information presented in each chapter, though in some he may find the text tedious and even irritating. The author has made lavish use of diagrammatic illustrations; and chapters on the radiography of the heart and on congenital heart disease—subjects benefiting from clear diagrammatic presentation—are among the best in the book. Even in these chapters more real radiographic reproductions of the conditions discussed would have been helpful to the student. It is unfortunate that many of the diagrams are too small for the indicated features to be readable without a hand magnifying-glass; thus one half-page bears four drawings of a skull and one of these has 25 named parts with dotted-line indications attached.

In a book into which so much has been condensed one expects to find some inadequacies and omissions, and these are encountered. Nevertheless the attempt to produce a one-volume textbook of radiology of value to the student has not been unsuccessful.

F. PYGOTT.

THE ADRENAL CORTEX

The Adrenal Cortex. By I. Chester Jones. (Pp. 315+x; illustrated. 37s. 6d.) Cambridge University Press, 1957.

This book is written by a distinguished zoologist from the point of view of "experimental biology" and contains a study of the adrenal cortex of animals from marsupials to fish. For the scientific physician the most useful part of the book is contained in the sections on the adrenal steroid hormones, their biosynthesis and mechanism of secretion control; on consideration of the function of the adrenal cortex in relation to carbohydrate, protein, and fat metabolism; and on the adrenal-gonad relationship. We are reminded that the steroids are basically related to cholesterol (solid bile), and that in 1936 Callow and Young first proposed the name "steroid" for all those substances based on the reduced cyclopenteno-phenanthrene system. It might be considered puerile to indicate that "deoxy-" denotes loss of oxygen and that it is preceded by a number giving the carbon atom at which this occurred; "dehydro-" denotes loss of hydrogen; "hydroxy" an -OH group; and Δ (delta) denotes unsaturation, the superscript indicating the number of the carbon atom holding the double bond; but the uninitiated enthusiast will appreciate this and many other guides, especially when it is remembered that 29 adrenal steroids are now known. It is also of interest to find a table of common "trivial" names compared with "systematic" names; thus cortisone, or 17-hydroxy-11-dehydrocorticosterone, has a systematic name, Δ⁴-pregnene-17α:21-diol-3:11:20-trione, which must be regarded as an elucidating "simplification," although perhaps not so easy to pronounce or remember as Kendall's term "compound E."

A succinct section is given to aldosterone, the most recently characterized adrenocortical steroid, the 18-aldehyde of corticosterone, demonstrated in beef and pig adrenal extracts

and adrenal venous blood of dog, monkey, and man, and now accepted as the naturally occurring mineral corticoid. The word "cortisol" has crept into the literature, and I must admit to not realizing initially that this was identical with hydrocortisone, which is 17-hydroxycorticosterone, or Kendall's compound F. The chemist, but not every physician who uses the term or suffix, knows that "-ol" denotes the substitution of a hydroxyl group for one of the hydrogen atoms attached to a carbon atom; and that "-ol," "-diol," "-triol," etc., give the number of occurrences of such substitutions, and that a further number indicates the carbon atom at which the substitution took place—all very elementary to the initiated, but valuable to the student and practitioner.

From the dynamic functional angle, the chapter on the control of adrenocortical secretion, including corticotrophin, is admirable and informative. The adrenal-gonad relationship is analysed and unravelled with exceptional skill and knowledge. The clinical sections, such as those on Addison's disease and Simmonds's disease, are too brief to be of any great value, and the clinical findings and observations are not sufficiently integrated into the earlier sections dealing with the important problems of salt depletion, water depletion, "haemoconcentration," and water intoxication—concepts of a comparatively new and difficult field which requires interpreting to the clinician in a terminology to be agreed upon and explained, and in relation to the clinical states he meets with and has to treat. It is an important part of adrenal cortex function.

I cannot appreciate with full knowledge the stimulating sections on Pisces, Amphibia, Reptilia, Aves, Prototheria, Metatheria, and embryology, but they all appear to attain a high standard of scientific approach. Altogether this is an invaluable book, which should be read by everyone working in this field.

S. LEONARD SIMPSON.

FLUID BALANCE

Technique of Fluid Balance: Principles and Management of Water and Electrolyte Therapy. By Geoffrey H. Tovey, M.D. (Pp. 100+viii. 12s. 6d.) Edinburgh and London: Oliver and Boyd. 1957.

The more important facts about derangements of fluid balance have been known for many years, but the dissemination of this knowledge has been slow. Many students still grow up in the belief that problems about electrolytes are an esoteric pursuit of professorial units, and that in so far as they are of any practical importance they are the province of departments of biochemistry. Many doctors pay more attention to the amount of food their patient is getting than to the amount of water and salt. Yet patients rarely die of starvation; but they do die from having had too little or too much of water and salt. One of the difficulties is that, although the medical training is supposed to be a scientific one, students may pass through it without realizing that one of the principal tools of science, including biological science, is measurement. And some are afraid even of the simplest arithmetic when it concerns disease.

There are now many good reviews of fluid balance in medicine; but often they are written for people already interested and, if not in the habit of thinking in terms of quantities, willing to make the effort. These works, however, do little for the man who needs to be persuaded that the simpler problems of fluid balance encroach on most branches of medical practice, that they are important and easily understood. For him Dr. Tovey's book provides an excellent introduction. It is short, clear, and explicit in its guidance on the prevention and treatment of disorders of the body fluids. It explains how a great deal can be done, even without batteries of chemical determinations, if only some attempt is made to keep records of the gains and losses of various fluids. The author gives his own examples of charts that may serve for keeping these records. As the reader comes to apply his knowledge he will discover there are many problems he cannot solve: an important function of an introductory work is to arouse curiosity. It is unfor-

tunate that Dr. Tovey has not provided some references for further reading—a failing common to many popular elementary books in this country.

PAUL FOURMAN.

A PSYCHOLOGICAL AUTOBIOGRAPHY

Being Lived by My Life: A Sort of Autobiography. By Charles Berg. (Pp. 256. 21s.) London: George Allen and Unwin Ltd. 1957.

In this book Dr. Berg, whose publications on various aspects of medical psychology, written with a mainly psycho-analytical slant, have brought him a not inconsiderable reputation, has cheerfully embarked on one of the most difficult of literary enterprises, namely, that of autobiography. By the same token he has lightened the task of the reviewer by choosing as his subtitle the qualifying phrase "a sort of autobiography." Obviously captivated by the view of the late Dr. Groddeck, that the ego is first and last the servant of an impersonal "it" (a term later canonized in a modified form by Freud himself and now familiar to the latinized English as the "id"), the author seeks to demonstrate the validity of this view, using as case-history his own life and the inner motives that led him to the practice of medical psychology. But Dr. Berg's own ego does not always take too kindly to this arbitrary clinical process and at times kicks over the traces. Sandwiched between chapters on unconscious motivations are a number of quite conventional sections giving descriptive surveys of different phases of his life and work. And throughout the whole book he keeps a wary eye on the prospective reader, on whom, indeed, he turns his accustomed battery of skilful and at the same time persuasive propaganda in favour of taking unconscious motivations and mechanisms seriously. His penultimate chapter on "patients" might well have appeared in a popular textbook of medical psychology. The general reader, possibly under the impression that the subtitle of the book might well have run, "Is there a Medical Psychologist in the House?" will no doubt enjoy the work thoroughly, particularly those parts dealing with medical practice. But to say this is to do less than justice to Dr. Berg's seriousness of intent and capacity for presenting a difficult subject in a palatable form. In point of fact, it should be read by his psychiatric colleagues, who may perhaps read between the lines at some points, possibly even fit the cap proffered them so ingenuously by the author.

EDWARD GLOVER.

UROLOGICAL SURGERY

Urological Surgery. By Austin Ingram Dodson, M.D., F.A.C.S. With nine contributors. Third edition. (Pp. 868; illustrated. £7 10s.) London: Henry Kimpton. 1956.

It is difficult to realize that six years have elapsed since the second edition of this book appeared; the success of the author as a teacher and his reputation as a urologist have made another edition necessary. Some of the previous sections have been shortened, and the chapter on radiation therapy has been omitted because it has become too big a subject to form only part of a book. Three new contributors have been introduced for special subjects, and it must be a source of gratification to the author to have two such excellent sections as those on the adrenal glands and on uretero-sigmoidostomy written by his son. There is a new chapter on post-operative urinary incontinence which was presumably written too early to include any reference to the French symposium on this subject in 1955. We should, however, have expected to find in 1956 some reference to the use of the ileum in urology. The book is essentially practical and includes accounts of almost every standard urological operation. The production is excellent, and the illustrations are clear and on a generous scale. That the price has increased by £2 15s. is an index of the times in which we live, but the book is well worth it.

MAN IN SPACE

Now that an artificial satellite is circling the earth, can manned space-ships be far behind? The weight of the satellite, the Russians themselves have stated, is 184 lb. (84 kg.)—equivalent to that of a well-built man. The vehicle's skin cannot weigh much, nor, probably, do the recording instruments. Most of the weight must be accounted for by the batteries that keep (or kept) the "bleep-bleep" going. Take out these batteries, put a man in their place—rather a skinny one for preference—and there you are. Or are you?

First, a sphere of 2 ft. (60 cm.) diameter is hardly the most comfortable shape for such an experiment. Major David G. Simons, who recently spent 20 hours at over 100,000 ft. (30,000 m.) suspended from a polythene balloon, was enclosed in a cylindrical "capsule" just large enough for him to stretch his limbs. Moreover, to ensure that it was airtight and would not burst owing to the low external pressure, it had to weigh at least 700 lb. (320 kg.).¹ Then there is the acceleration at take-off, for which the Russians have not disclosed their figure, though it is unlikely to produce the drastic effects we are sometimes shown in science-fiction films. The proposed American satellite is expected to leave the earth with an acceleration of only 8 ft. (2.4 m.) per second, or one-quarter of the acceleration of gravity² (usually designated as g), but this will increase as the fuel is used up, and the final acceleration of the satellite up to its orbital speed of 5 miles (8 km.) a second will have a value of more g than a man can tolerate in the sitting posture. Lying on the back, he can bear 10 g for nearly 2 minutes and 7 g for just over 10 minutes³; so our passenger-carrying satellite must be given a diameter at least equal to the length of the passenger, and that means more air resistance during the launching and more rocket fuel to overcome it.

The medical problems that will arise as our man gets out into space partly depend on the definition of

space. There is an "interplanetary gas," whose estimated density is about one hydrogen atom per cubic centimetre,⁴ and the top of the atmosphere must merge into it almost imperceptibly, so it is hard to say where the one ends and the other begins. Dr. Hubertus Strughold, head of the department of space medicine, founded in 1947 as a section of the U.S. Air Force School of Aviation Medicine, has got round this difficulty neatly and at the same time justified the existence of his department, which might otherwise appear to be dealing with a non-existent science. Strughold⁵ has proposed the term "space equivalent condition" for the level above which any particular physiological phenomenon behaves as it would in empty space. For instance, above about 50,000 ft. (15,000 m.) the lungs are unable to absorb oxygen from the atmosphere because the pressure at this height, equivalent to 87 mm. Hg, is equal to the combined pressure of carbon dioxide and water vapour in the alveoli. The next "space equivalent" level is 63,000 ft. (19,000 m.), where atmospheric pressure is only 47 mm. Hg and body fluids are on the point of boiling, as they would in empty space. Beyond 80,000 ft. (24,000 m.) a pressurized cabin, such as is used now in high-altitude aircraft, becomes impracticable because of excessive heat generated by the necessary compression of the outside air; moreover, at that height there is enough ozone in the air to be poisonous. A hermetically sealed cabin is needed, just as it would be in outer space, and the traveller must carry enough oxygen for the voyage, together with some means of absorbing carbon dioxide and excess water vapour. Strughold designates three other important "space equivalent" levels. Above 120,000 ft., or about 23 miles (37 km.), primary cosmic radiation is at full blast, because there is not enough air to disintegrate it into the "secondary" variety. Then, above 28 miles (45 km.), shielding from the sun's ultra-violet rays is essential. And finally, above 75 miles (120 km.) there is not enough atmospheric friction to burn up meteors, so they may hole the cabin wall and reduce the air pressure within to a "space equivalent condition."

Meteors, according to the astronomers, are of all sizes, ranging from small minor planets down to the finest dust particles; but there is a lot of room in space, and the bigger ones are rare enough for the risk of collision to be negligible compared with other dangers which are likely to beset the space traveller. But the precise frequency of meteors of different sizes is unknown, and one object of sending up artificial satellites is to get information on this point. At the latest Congress of the International Astronautical Federation, held at Barcelona last month, Dr. Fred

¹ Simons, D. G., "Applications of Satelorb," read to 8th International Astronautical Congress, Barcelona, Oct., 1957.

³ Ballinger, E. R., *J. Aviat. Med.*, 1952, 23, 319.
⁴ Langer, H. M., *Physical Review*, 1939, 66, 423.
⁵ Strughold, H., *Astronautica Acta*, 1955, 1, 32.
⁶ Gerathewohl, S. J., *ibid.*, 1956, 2, 203.
⁷ Ross, H. E., *Bull. Brit. Interplanetary Soc.*, 1946, 1, 49.
⁸ Bowman, N. J., *J. Brit. Interplanetary Soc.*, 1953, 12, 159.
⁹ Campbell, P. A., *ibid.*, 1955, 14, 5.

Whipple, of Harvard College Observatory, estimated that an earth satellite with a radius of 20 in. (50 cm.) and a skin thickness of half a millimetre of aluminium would be punctured by a meteor on the average once every five days. He has proposed that a space-ship should have a thin extra skin, standing a few inches away from its main outer surface, to act as a "meteor bumper" by absorbing these impacts. But if the cabin is holed, what then? Experiments have shown, according to Strughold, that if the loss of air pressure is so sudden as to be almost instantaneous, the occupant will have only 15 seconds of "useful consciousness" in which to recompress himself presumably in a pressure suit. Major Simons, during his balloon ascent, wore a pressure suit, deflated but ready for inflation at a moment's notice; but he told the Barcelona Congress that the wearing of it was the most uncomfortable feature of his trip.

As to cosmic radiation, experiments on animals suspended from balloons at over 100,000 ft. (30,000 m.) for a day or more have shown inconclusive results. Major Simons, seven weeks after his ascent, had suffered no obvious ill-effects from this cause. Since the weight of protective shielding would be prohibitive, it seems that space travellers of the future will have to put up with whatever damage this radiation is capable of inflicting.

Then there is "weightlessness," which will supervene as soon as the rocket motor is stopped. Unlike excessive g, it is a condition which cannot be imitated on earth for any length of time. But passengers in an aircraft can be made "weightless" for a large fraction of a minute if it is flown on a parabolic path similar to that of a thrown stone, using just enough engine power to overcome air resistance. S. J. Gerathewohl, who subjected a series of 16 people to this experiment, found that eight of them actually liked it⁶ (one said: "I've never been so bloody comfortable in all my life!"), three were indifferent to the experience, and five suffered from motion sickness. Animal experiments have shown that, if their balancing organs in the inner ear have been extirpated and they have had time to get used to the loss, they show no discomfort or disability during weightlessness. So human beings who come into Gerathewohl's third category, and are determined nevertheless to go space-voyaging, will have to enlist the services of an aural surgeon.

Food, water, and oxygen needed for a space voyage have been estimated by H. E. Ross⁷ as amounting to 6.3 lb. (2.7 kg.) per man per day; so they would not amount to much for a voyage to the moon and back, lasting little more than a week. For longer voyages, such as a return trip to Mars, which would take over

two years, N. J. Bowman⁸ has worked out a scheme for carrying plants, preferably unicellular algae, to absorb carbon dioxide, give out oxygen, and provide food, thus forming a closed system by converting the ship into a miniature replica of the earth itself. One man's needs would be satisfied by 24 lb. (11 kg.) of algae suspended in 44 gallons (200 l.) of water. The algae would be fed on human excreta, and, Bowman alleges, would have removed all traces of their meal in 24 hours and then be fit to eat. This statement may be technically correct, but nevertheless it sounds a good deal worse than drinking one's own bathwater.

Finally, the space traveller has to get back to earth alive. This has so far proved to be the most intractable problem among the would-be astronautical fraternity, for any object entering the atmosphere at 5 miles (8 km.) a second or more will go up in smoke like a shooting star unless something is done to prevent it. Wings should be of some help, and the aerodynamicists have tackled the problem of dissipating the heat by radiation and conduction from the leading edge of the wing. Not much heat can be conducted into the interior of the ship, though the human body, lightly clothed and at rest, can, according to P. A. Campbell,⁹ withstand an air temperature of 194° F. (90° C.) for 40 minutes and 239° F. (115° C.) for 20 minutes. In fact, so many different methods of surmounting this difficulty have been proposed that we may probably assume, as one does when many diverse treatments are recommended for the same disease, that none of them can be much good.

TOXOPLASMIC UVEITIS AND PYRIMETHAMINE

Toxoplasmic choroiditis was probably first noted over 30 years ago.^{1,2} The syndrome of neonatal or infantile choroido-retinitis—often with hydrocephalus or microcephaly, convulsions, calcification, or other signs of cerebral damage, and sometimes with widespread visceral disease—due to intrauterine infection by *Toxoplasma gondii* was established by A. Wolf and D. Cowen³ in 1937 and has been amply confirmed.⁴ The part played by toxoplasmosis in adult uveitis is less certain, however. Toxoplasma-like protozoa have been found in choroido-retinal lesions by H. C. Wilder⁵ and by others,⁶ while L. Jacobs and his colleagues⁷ isolated the parasite from the eye of an adult with acquired choroiditis. By means of the cytoplasm-modifying dye test,⁸ complement-fixation test,^{9,10} or the toxoplasmin skin test,¹¹ it has been clearly shown that patients with uveitis yield a higher proportion with immunological evidence of toxoplasmosis than is found in the general population.¹²⁻¹⁵

The fact that positive results are commonly found in the "normal" population¹⁶⁻¹⁸ has cast doubts on the specificity of the tests. I. A. B. Cathie¹⁹ recently discussed the alleged false-positive reactions from infection with *Sarcocystis*, *Trichomonas*, *Trypanosoma cruzi*, *Salmonella typhi*, and malaria. He concluded that so far as the human subject was concerned the reliability of both the dye test and the complement-fixation test was upheld. There has been much discussion about the level at which titres become significant, and, although some authors "would not pay much attention to a dye-test titre of 1:64 with a negative complement-fixation test"¹⁹ as an indication of systemic toxoplasmosis, these were the very titres reported in a patient blind with recurrent choroiditis from whose blinded eye viable parasites were isolated.⁷ It is thus certain that the eye may harbour active toxoplasmic lesions without evoking high dye-test titres or positive complement-fixation tests, or that the titres may quickly fall to low levels²⁰ after an initial rise.

E. S. Perkins and his colleagues¹⁵ in the uveitis clinic of the Institute of Ophthalmology have reported the results of a controlled clinical trial of an antitoxoplasmic drug, pyrimethamine ("daraprim"), in the treatment of uveitis. This drug, primarily an antimalarial agent, was chosen because it has an antitoxoplasmic effect in experimental infections,²¹⁻²³ a weak action on bacteria, and no influence on allergic conditions. J. K. A. Beverley²⁴ recently described the great variations in effect of various antitoxoplasmic drugs in different animals: pyrimethamine along with sulphadimidine is thought to be effective in human infections. The trial carried out at the Institute of Ophthalmology was on 164 unselected patients with active uveitis who in addition to orthodox treatment with mydriatics and cortisone were given either pyrimethamine (25 mg. daily) or inert tablets. After four weeks the response was assessed on objective changes by observers who were unaware which patients had received pyrimethamine. The high proportion of positive results to tests for toxoplasmic infection among patients with uveitis was confirmed. The dye test was positive to 1:4 in 59.2% with anterior, 79.2% with posterior, and 45.9% with pan-uveitis. The corresponding figures for the complement-fixation test were 9.2%, 24.1%, and 5.4%. In 66 patients in whom the tests were negative there was no significant difference in the course of the disease between the 29 who received pyrimethamine and the 37 who did not, and their rate of improvement was about the same as that of the 42 toxoplasma-positive cases (dye test 1:4 or over) given inert tablets. In the positive group treated with pyrimethamine (56 cases) there was a markedly higher improvement rate

—76% improvement for the treated and 50% for the controls. The improvement was greatest in the positive cases with posterior uveitis (88%). If the complement-fixation test was positive the patient was more likely to respond than if only the dye test was positive. There was no significantly better response to pyrimethamine in cases showing a high titre to the dye test than in those with a low positive titre (1:4 to 1:16). This confirms the view that these low titres are specific for toxoplasmic infections and that a small active toxoplasmic lesion within the eye may not raise the serum antibodies very greatly. The results strongly suggest that toxoplasmosis is an aetiological factor in 25% of cases of uveitis with a positive dye test (1:4 or over).

So far as the individual patient with toxoplasmosis is concerned, the problem is rather like that of tuberculosis. Tests suggest infection but do not establish that the eye disease is due to it. If the clinical picture resembles other proved cases the diagnosis is more likely, and a response to specific therapy may increase the probability. From the recent trial it appears that a titre of 1:4 or more to the dye test indicates that a particular patient may respond to pyrimethamine; he is more likely to respond if the complement-fixation test is also positive. The only apparent side-effect of 25 mg. of pyrimethamine daily was some depression of erythropoiesis, with a tendency to normochromic macrocytosis, and because of this treatment was discontinued in one case. These changes are said to be reversed by folic acid,²⁵ but it

would be advisable to carry out regular blood examinations during the administration of the drug.

The common finding of antibodies to toxoplasma in apparently healthy individuals and the important part which the infection appears to play in causing disability and blindness through uveitis pose some clinical and epidemiological problems. How does the infection spread? What are its reservoirs? What is the clinical nature of the primary infections from which uveitis develops by parasitaemia? The parasite is almost universally distributed among warm-blooded animals—cats, dogs, farm animals, and rabbits being often infected.^{26 27} Eating or handling raw meat is an obvious, but probably infrequent, source of infection. Isolation of the parasite from saliva in a human case²⁸ suggests a method of human-to-human transmission. Proved human infections²⁹ have taken the form of exanthematous fevers like those of rickettsial origin,^{30 31} pneumonitis,³² acute encephalitis,³³ myositis,³⁰ and myocarditis.³⁴ Syndromes resembling glandular fever, however, are the most commonly recognized toxoplasmic illnesses^{28 29 32 35-38}; they account for 8% of cases of lymphadenopathy.²⁶

The parasites have been isolated from saliva,²⁸ blood, and lymph nodes,^{32 37} and choroiditis has been seen to occur during the glandular stage.³⁶ The great majority of toxoplasmic infections, however, must be subclinical or pass unrecognized and run a benign course. Toxoplasmosis, in fact, rarely causes clinical illness unless by chance the foetus or eye is infected. The occasional highly virulent toxoplasma which kills the host and attracts medical attention is probably an abnormal variant.^{26 27} The antibody and other defence mechanisms in the brain and eye are probably less effective than elsewhere, so that a small choroidoretinal lesion may develop, persist, or become reactivated when systemic infection has waned and serum antibodies have fallen to a low level, and it is only in the eye that a minute lesion would cause symptoms and come under observation.

STENOSIS OF THE SPHINCTER OF ODDI

Recently R. B. Cattell and his colleagues reported¹ 100 cases of benign obstruction at the sphincter of Oddi, their experience covering a period of forty consecutive months. All were demonstrated at operation and in most instances the lesion seemed to be a fibrous stricture. They hazard the view that this might well have been the original cause of the biliary disorder. This is no new concept. In 1928 D. del Valle² wrote of a "retractile or fibrous odditis." J. P. Trommald and D. B. Seabrook³ thought some strictures were a local manifestation of cholangitis, and W. von Hess⁴ has gone

so far as to state that "stenosing papillitis" occurs in a third of his cases of cholelithiasis. It is a pity that we are left to guess the number of biliary cases seen at the Lahey Clinic for the period reviewed by Cattell and his associates, because their series is extraordinarily large. The problem is to sort out the cases with a papillary fibrosis from those with chronic spasm of the sphincter or even a normal anatomical variation. Moreover, scarring might follow upon the presence of stones in the common bile duct or the careless use of dilators.

Most patients with stenosis of the sphincter of Oddi give a history of a previous operation which has done them little good. Pain is the commonest symptom, intermittent in character and often severe; and it affects mainly the right subcostal and epigastric areas. In the series reported by Cattell and his associates jaundice was present in 46 patients. Their other operative findings are worthy of record: 51 cases with calculi or sludge in the common ducts; 28 with remnants of cystic duct and even gall-bladder, some with stones; 6 with associated strictures due to a previous cholecystectomy; and 15 with pancreatitis. It is thus not clear how many did suffer primarily from the effects of stenosis of the sphincter. The radiological approach to diagnosis will depend on the presence or absence of jaundice. With the new intravenous methods a duct appearing greater than 15 mm. wide is almost certainly obstructed; between 8 and 15 mm. it may or may not be so. R. E. Wise and R. G. O'Brien⁵ think the time-density relation is more dependable. This is simply a comparison between the shadow cast at 120 minutes with that at 60 minutes, and if there is little difference obstruction is a likelihood provided the gall-bladder is absent.

An orifice of less than 3 mm. across is regarded as being stenosed. Under normal conditions the measurement is 3 to 7 mm. as recorded in terms of the largest sound that will slip through from duct to duodenum.⁶ The surveys carried out at the Massachusetts General Hospital^{6 7} of the results of operations on the biliary tract do not mention primary stenosis of the sphincter, and the interest lies in the fact that methodical dilatation of the sphincter has been practised at this institution for many years as part of the routine in exploring the bile ducts. To exceed 1 cm. is doubtless courting trouble. For the relief of stenosis, bouginage via the common duct is often successful, the surgeon making sure what he is doing by opening the duodenum.⁸ Tight strictures are probably best treated by sphincterotomy. Surgeons disinclined to tamper with the sphincter can adopt the advice offered recently in this *Journal* to form a side-to-side union between duct and duodenum.⁹ In short, stenosis is an entity which must be counted among the causes of persistence of symptoms after cholecystectomy, but the evidence available is insufficient to justify raising it to the rank of a primary disorder.

INFLUENZA EPIDEMIC

Though several reports on the influenza epidemic abroad have appeared in the medical press, information on its course in Great Britain has necessarily been scanty. We have therefore asked some general practitioners to describe the disease as it has appeared in their practices, and their reports are published in the Vital Statistics section of the *Journal* this week. While few patients are ill enough to go to hospital, and some do not feel the need for medical advice, the majority have evidently been sufficiently ill to call in their family doctor. General practitioners are therefore in a key position to make observations on this disease. The data they record this week will be a valuable supplement, from first-hand experience, to the reports published week by week based on such national and local statistics as are available. As a rule the disease has had a sudden onset and an uncomplicated if unpleasant course, and has affected children more often than adults. It is probably past its peak incidence now, though still spreading in southern England especially. There are many instances of a recrudescence of the disease, and the possibility also exists of a second wave among people who escaped infection in the first wave; for, though the rate of infection has been high, many, especially adults, have so far escaped. The development of an effective vaccine thus remains an important task, particularly since it might give some protection if the present disease becomes more virulent.

CYANOSIS IN INFANCY

Of the many worrying things that can happen in the newborn period there are few that can be more alarming than cyanosis, either intermittent or continuous. What does it portend? There are occasions when the cause, and the prognosis, can be stated with certainty, but often the explanation is lacking. Particularly is this so in premature infants.

Continuous cyanosis may be due to a congenital anomaly of the heart with or without any audible murmurs, to persistent atelectasis, to pulmonary collapse, or to diaphragmatic hernia. Intermittent cyanosis, particularly when associated with feeding, suggests some congenital defect such as tracheo-oesophageal fistula, or, occurring after feeds, may be due to excessive abdominal distension or to the inhalation of milk. It may, however, be due to some intracranial injury. In premature infants periods of disturbed respiratory rhythm—often complete apnoea—may occur, and the necessity for giving oxygen naturally arises. Its administration calls for care lest exposure to excessive oxygen tension result in retrolental fibroplasia. Although these periods of apnoea and cyanosis may be associated with intracranial damage, or be merely a reflection of the immaturity of the respiratory centre or system, they often occur when there is no reason for suspecting any serious lesion. The prognosis is, on the whole, poor.

In a recent investigation Professor R. S. Illingworth¹ reported his findings in 170 infants showing cyanotic

¹ Illingworth, R. S., *Arch. Dis. Childh.*, 1957, 32, 328.

attacks; 103 (60%) were premature. On careful inquiry into the antenatal history he found evidence of some maternal illnesses (chiefly toxæmia and antepartum haemorrhage) in no fewer than 106 cases. 82 of the infants died (48%), the commonest necropsy finding being atelectasis. However, in comparing these with a similar number of premature and full-term infants (in the same proportion) who had died without having any cyanotic attacks, he found that the incidence of atelectasis was almost identical. One point of difference was that there was a greater incidence of anoxia at birth among the infants who had cyanotic attacks than among the controls (24% against 6%).

As might be expected, small size of infant, early onset of the cyanotic attacks, great frequency of attacks, and any association with twitching or convulsions are all of serious prognosis. The best prognosis would seem to be when the attacks are due solely to obstruction of the respiratory tract by mucus or milk. Special care, therefore, is necessary in the feeding of infants, particularly when they are premature, and there is much to be said for delaying the initial feed until the infant demands it. In small infants this is usually between 65 and 75 hours after birth, and if the first feed is not given until then the incidence of cyanotic attacks may be appreciably reduced.

NOBEL PRIZE

The award of the Nobel Prize in Medicine and Physiology (worth £14,500) to Professor Daniel Bovet marks the success of a great research worker on sulphonamides, antihistamines, and muscle relaxants. Professor Bovet, now aged 50, was born in Neuchâtel, Switzerland, the son of a Swiss psychologist, Pierre Bovet, and is now a naturalized Italian. He graduated at the University of Geneva in 1929, and for nearly twenty years was associated with Professor Fourneau in the pharmacology department at the Institut Pasteur, Paris. In 1947 he moved to Rome to become director of the pharmacology department at the Istituto Superiore di Sanità. With others, Professor Bovet studied prontosil in the early 1930s, identifying the sulphonamide group as having the antibacterial action; they then introduced sulphanilamide into clinical use. He was the first to synthesize an antihistamine compound and did much to develop the range of these drugs that have found such wide application in medicine. Turning from antihistamines to muscle relaxants, Bovet was again successful. His research on compounds with curare-like effects led to the introduction of the short-acting muscle relaxant succinylcholine into modern anaesthesia. He is now investigating the groups of compounds commonly known as tranquilizers. Professor Bovet's wife, Filomena Bovet-Nitti, has collaborated closely with him in some of his main researches.

The next session of the General Medical Council will open on Tuesday, November 26, at 2.15 p.m., when the President, Sir David Campbell, will take the chair and deliver an address.

Correspondence

Because of heavy pressure on our space correspondents are asked to keep their letters short.

Use and Abuse of Blood

SIR,—In supporting Drs. C. Bowley and J. Darnborough (*Journal*, October 19, p. 940) I would qualify their dictum and say, "One of the primary functions of a blood transfusion service is to provide blood needed for transfusion." I would prefer to summarize Mr. A. Ruscoe Clarke's thesis (*Journal*, September 28, p. 721) as that the only effective treatment of shock is by a blood transfusion equated to the blood lost, at the earliest possible moment, and that the actual blood loss, as measured by radio-chromium, is greater than might have been thought from older plasma volume methods, also that a normal blood-pressure reading may mask a considerable blood loss.

In the type of case under discussion, the gravely injured casualty, it may reasonably be expected that the patient's treatment is being directed by a surgeon of consultant standing, and I would hesitate to make a general charge against such surgeons as liable to adopt a too casual attitude towards transfusion. I think we should refrain from anything savouring of a general accusation of extravagance on the sole grounds that the use of blood in hospitals has been rising over the last nine years. It may be justified, but I would like to see the evidence before recording the conviction. It may well be, however, that in less dramatic and more frequent circumstances the consultant who is supervising a hospital patient may delegate the dosage as well as the administration of blood to a junior, and it is conceivable that this junior, who is admitted by all to be still in training, may lack the mature judgment expected from his chief, with consequent extravagance in the use of blood arising out of an anxiety to do the best for the patient. It is therefore necessary, in the interest of sound treatment as well as of economy, that the officer in charge of the blood bank shall be sufficiently senior in rank to withstand what he considers to be an unreasonable demand by a trainee, and to take the case to a consultation between himself and the consultant in clinical charge. The object of this consultation would not be to save blood, but to try to ensure that the patient got the right dose and not an overdose, since over-transfusion is not merely wasteful but is harmful to the patient.

It is indeed true that the blood is provided by a small altruistic section of the population, and that the transfusion service is merely the channel of transfer of blood from donor to recipient. It is also true that the first half-million donors are the easiest to recruit. That is why they are the first half-million. It is not, however, justifiable to go on to argue that, because the efforts which produced the first half-million did not produce more, then no more are available without extreme effort. This reasoning would be an excuse for stopping funds for donor recruitment at any arbitrarily predetermined point, and then saying that saturation point had been reached.

It seems, Sir, that the first requirement in reviewing the use and possible abuse of blood is to assess the needs of the patients in a dispassionate manner, completely apart from questions of supply, and to this Mr. Ruscoe Clarke has made an extremely valuable contribution in his field. Dr. H. A. Reid, of Penang (*Journal*, October 19, p. 942), is following a similar line of thought in another field when he says, "In treating patients with severe viper poisoning, I believe far the most important single measure is adequate blood transfusion. Many pints may be needed—unfortunately, a counsel of perfection in most hospitals treating these victims." It is not to be supposed that Dr. Reid would regard a sudden increase in the use of blood in Malaya to be synonymous with extravagance.

After such surveys, it would be possible to see whether present-day usage in this country is excessive or not. If the optimum is greater than the present volume being used, there

will be no object in making unsupported charges of waste in hospitals. On the contrary, it would be for us to put our house in order and for those responsible for the administration of the Health Service to decide whether they are able to provide the money needed if the blood needs of the public are to be met, always remembering that, as each thousand new donors are recruited, the next thousand are going to be a little more difficult and expensive. This rule is general in all forms of canvassing, and is not peculiar to blood donors. On the other hand, if clinical consultants find that their patients really are being over-transfused by their house officers, they are not likely to have need of advice as to the procedure to be adopted.—I am, etc.,

Cambridge.

C. B. V. WALKER.

SIR,—The letter by Drs. C. Bowley and J. Darnborough (*Journal*, October 19, p. 940) again raises the question of the amount of blood wasted by clinicians. While everybody must admire the achievements of the blood transfusion service, we clinicians cannot help feeling that appeals for economy ring hollow when a great deal of blood is wasted because the bottles are supplied without pilot tubes, and the blood in the bottle itself must be sampled for the purpose of cross-matching. Some pathologists insist that this blood must be wasted if the blood which has been matched is not used within 24 hours. Others permit its use for 72 hours after sampling, or even for a longer period, but may insist that one bottle should not be cross-matched more than twice. In any case the date at which the bottle expires becomes very much earlier after cross-matching than the normal third or fourth week after collection. As a result the wastage of blood is greatly increased, and some conscientious pathologists try to solve the problem by the dangerous practice of ringing up the houseman and saying, "If you don't use the blood we have matched for you by this evening it will be wasted." It is obvious that there are very many cases in which it is the clinician's duty to order blood to be cross-matched, but in which it may be undesirable or dangerous to use the blood unless the necessary circumstances arise. For example, when a patient with haematemesis is admitted to hospital or when an operation for, say, mitral stenosis or patent ductus arteriosus is to be done, blood must be matched and kept in readiness for immediate use if an emergency arises, although probably none of this blood will be used. It is well known that the answer to the wastage of matched blood is pilot tubes, but we are told that these are dangerous because they can come apart from the parent bottles and get mixed up and also that they are easily broken. Both statements are true, but that does not mean that it is impossible to make a blood-transfusion bottle which has a pilot tube firmly attached to it that is not easily broken. Surely if we consulted the glass industry a suitable pattern would be provided. No doubt the bottle would cost more, but the saving would be far greater.

With improvements in surgical technique to treat hitherto inoperable conditions (such as advanced cardiac lesions), the demand for blood is certain to increase. If Dr. Bowley and other regional transfusion medical officers succeed in developing a blood-transfusion bottle which will prevent wastage of blood due to cross-matching, they will have done a very great service to the community.—I am, etc.,

Urmston, Lancs.

M. S. BEARE.

Blood Concentration of Tetracyclines

SIR,—In your leading article on the pulmonary complications of influenza (*Journal*, October 12, p. 872) the statement is made, "... Tetracyclines; they have the disadvantage that an effective blood concentration cannot be achieved in under twenty-four hours." We feel that this opinion should not be allowed to pass unchallenged, since there is a large amount of evidence to show that effective serum levels can be, and indeed usually are, obtained within four to six hours of an adequate oral dose. In what is perhaps the most recent review of antibiotics Florey¹ writes, "Oxytetracycline reached its maximum concentration in the blood at

about the 4th hour after it had been given by mouth and the concentration then slowly declined during the following 24 hours. With oral doses of 0.5, 1.0, and 2.0 g. the maximum concentrations reached were of the order of 1, 3, and 4 µg. per ml. respectively." Writing of tetracyclines, the same author² says: "After the administration of capsules or tablets containing 1.0 g. maximum levels in the blood stream were reached between 2 and 6 hours later. Concentrations of 1 to 4 µg. per ml. were attained and were maintained for about 8 hours." Musselman³ observes, "After a single dose of 1 g. it [oxytetracycline] can be found in the serum after one or two hours. It reaches its maximum concentration of about 3 µg. in four to six hours, after which the level falls off but some activity persists for as long as 24 hours." There would appear therefore to be conclusive evidence that the tetracyclines do produce adequate serum levels within 4 to 6 hours of administration by mouth of a dose of 1 g., and it has also been shown that this concentration can be maintained by subsequent doses of 250 mg. every six hours. It would perhaps be a pity if a mistaken impression that the tetracyclines are slow-acting should preclude their employment in suitable cases of influenzal lung infections.—We are, etc.,

Foreign Body in Stensen's Duct

SIR,—Further to the case reported by Dr. D. Hardy Kinmont (*Journal*, August 10, p. 356) it may be interesting to recall a similar case in my practice some time ago. A colleague's wife brought her 6-months-old child to me with a spot on its right cheek. I misdiagnosed an infected scratch. The baby also had feeding troubles, but as it was a first baby I put it down to inexperience. I did not examine the baby's mouth and was rather nonplussed when the mother produced a feather the following day. She had felt a sharp centre in the spot and had pulled it with her fingernails. A belated examination of the baby's mouth then showed a redness in the corresponding Stensen's duct. I feel sure this was the mode of entry.—I am, etc.,

Launceston, Tasmania.

H. SPENCER ROBERTS.

Blood Transfusion in Obstetric Haemorrhage

SIR,—The paper on recent advances in haemorrhage and shock by Mr. A. Ruscoe Clarke (*Journal*, September 28, p. 721) was most interesting, and the subsequent article on transfusion in obstetric haemorrhage by Mr. W. G. MacGregor and Dr. A. D. Tovey (*Journal*, October 12, p. 855) carries the same attitudes into the field of midwifery. I find it hard to reconcile my own experiences among casualties in wartime and among obstetric problems since then with all the suggestions made.

One would readily agree that blood loss may be easily underestimated, and that a patient with a "normal" blood pressure may still be on the edge of collapse. One would also agree that accurate knowledge of the circulating blood volume would be of great assistance, but is it not an oversimplification of the problem to attribute everything to the loss of whole blood, with treatment consisting simply of the transfusion of great quantities of blood, often greatly in excess of the most liberal estimate of the amount of loss? In surgical practice, the patient whose known blood loss is small, with warm extremities and a good colour, with a blood pressure in the region of 80 mm. Hg systolic at the end of an operation, is the product of a hot theatre and a pre-existing vasomotor instability; the vasomotor system has failed to react by peripheral vasoconstriction. By contrast, the obstetric emergency, brought in with cold, white extremities and a "normal" blood pressure with a history of heavy blood loss, is the product of an effective vasoconstriction which may yet collapse completely with a loss of a few more ounces of blood.

It seems to me that insufficient credit is given to the ability of the body to deal with haemorrhage by its own physiological methods; this is particularly effective in the obstetric patient. Surely by knowing these mechanisms and their clinical manifestations, and by supporting them in the right way and at the right time, we need not aim at artificial targets, nor constantly overinsure with extra litres of blood.—I am, etc.,

Ashton-under-Lyne.

T. B. FITZGERALD.

Ménière's Disease

SIR,—Your leader (*Journal*, September 28, p. 754) summarizes very fairly the past and present views on the aetiology and treatment of this condition. It is, however, interesting to note that, just as the evidence showing the association of cigarette-smoking and lung cancer accumulated in advance of orthodox medical opinion, so the evidence pointing inescapably to the vascular origin of Ménière's disease is still unrecognized by the vast majority of physicians and others dealing with this disorder.

The role of reassurance and sedation in treatment is, as you say, of the utmost importance and may be all that is required to prevent the trigger mechanism of anxiety and mental tension operating again upon the all-important vessels supplying the inner ear. If, however, reassurance and sedation are not sufficient to check the progress of the disorder, must we wait until all useful function has departed and then perform labyrinthectomy? Is this the way to treat two of our most vital special senses?

If an attack of Ménière's disease with acute vertigo can be dramatically cut short by sympathetic block,¹⁻³ if hearing improvements of as much as 50 decibels can result within half an hour of sympathetic block,¹⁻³ if disordered caloric function can return to normal after sympathetic block and after sympathectomy,⁴ and if vertigo can be improved or cured by sympathectomy,¹⁻³ the clinical evidence that circulatory changes influence labyrinthine function becomes incontrovertible. The experimental work of J. C. Seymour in the Ferens Institute of the Middlesex Hospital goes far towards explaining the actual mechanism involved.

The reason for the conflicting reports of the results of sympathetic block and sympathectomy is clear. There is inadequate appreciation of the "time factor,"⁴ which is of vital importance both in prognosis and treatment. In Ménière's disease there is a reversible stage and an irreversible stage—to attempt to cure the latter by vasodilatation therapy, by sympathetic block, or by sympathectomy is like attempting to cure a gangrenous foot by similar means. Labyrinthectomy (amputation) is still necessary, but its use should steadily decrease. If the treatment of Ménière's disease is to show any significant advance every one of the therapeutic measures so far used may still have its part to play, but the emphasis must be put upon early restoration of blood flow to the inner ear and not upon destructive operations in the later stages of the condition.—I am, etc.,

Harveian Oration

SIR,—In his condensation of the substance of the Harveian Oration which I had the honour to deliver last week before the Royal College of Physicians of London your reporter has misquoted me (*Journal*, October 26, p. 994). In speaking of "sharp silicon dust" he commits the double mistake of implying that *silicon* dust rather than *silica* dust is responsible for the silicotic nodule and of claiming that the causation of silicosis is mechanical. Your readers, Sir, will be well aware of the weight of evidence in favour of a chemical origin of the silicotic nodule. But the Orator did not use the words quoted above. What he did say was that Inigo Jones, a friend and neighbour of Harvey,

"exploited the use of the beautiful white dolomite from Portland Bill," thus setting up an architectural style which not only continues to beautify London but also has been the means of saving hundreds of stonemasons from the risk of silicosis."—I am, etc.,

London, E.1.

DONALD HUNTER.

Chlorpromazine Jaundice

SIR,—Within the past two years considerable attention has been drawn to chlorpromazine jaundice. In your leading article (*Journal*, February 5, 1955, p. 338) you stated, "The effects of chlorpromazine are prolonged and for the most part cannot be reversed. This fact and the evidence that some patients become jaundiced owing to a toxic action on the liver seem the strongest reasons for caution in its use." In your annotation (*Journal*, September 14, p. 635) the question of pathogenesis was examined and more convincing evidence was advanced in favour of acquired hypersensitivity. I should like to mention some observations in favour of the hypothesis of racial hypersensitivity. This opinion is strengthened by clinical observations among Chinese and African patients.

At Aro Hospital, Western Region, Nigeria, we have treated over 1,600 patients with these drugs over a period of three years, and for reasons we cannot as yet fully understand "toxic" reactions which have been reported in other countries are conspicuously absent in the African. Patients receiving chlorpromazine even in high doses and over long periods have failed, in the presence of exhaustive clinical examination, to show any of the frequently reported reactions—e.g., depression, agranulocytosis, fever, eosinophilia, jaundice, and skin eruptions. In some cases of extreme agitation, motor hyperactivity associated with anxiety and tension, doses up to dangerous levels have been instituted with only minor side reactions, which are usually of intense soporific or hypnotic nature. We do not carry out liver function tests routinely, but routine blood tests are done in most cases. This observation has also been recorded in various parts of Africa. Margetts¹ writes from Kenya: "No deaths at Mathari have been attributed to the drug. I have not yet observed jaundice in Africans, though two of our very few Europeans (using the same drug supply) did develop this complication. This fact seems most extraordinary, but I do not know at this time whether it is important or not. Blood dyscrasias have not been diagnosed here. Blood examinations are not routinely done, nor liver function tests. I do not think them necessary, provided keen clinical assessment is maintained. Allergic reactions (skin rashes, asthma) have not been noticed in our Africans so far. Gastro-intestinal complaints are uncommon. . . ." Yap² also states that the usual complications have not been encountered in his psychiatric practice among the Chinese in Hong Kong even though he has on very many occasions used very large doses. Forster,³ in Ghana, shares the same experience in his practice among the various tribes in Ghana.

So far as one can judge, these observations seem to point to the fact that chlorpromazine jaundice may be associated with two factors—a toxic effect of chlorpromazine and racial susceptibility, since it seems to be more frequent in the white race than in the coloured. There is no information, however, on the incidence of chlorpromazine jaundice in the Negroes in America. Even if evidence is produced to show that there is no difference between the incidence of chlorpromazine jaundice in the coloured and whites in America, it still remains a fact that present observations among the Chinese and African patients show that the chlorpromazine jaundice is largely confined to European and American patients and probably to those who exclusively share their habits and habitat. It has also been reported that the "reaction-rate" is probably higher than has hitherto been reported in patients receiving chlorpromazine; for liver biopsies from these patients, in the absence of clinical jaundice, often show cholestasis. In spite of this, clinical evidence of this distinct syndrome is lacking among African patients receiving chlorpromazine.

This observation, though fragmentary and inconclusive, would seem to support the hypothesis of allergy. It can be mentioned that the well-known hepatotoxic, carbon-tetrachloride, and infective agents which cause liver injury

have also been known to produce jaundice and other manifestations of damaged liver in the African. The (racial) selective nature of chlorpromazine jaundice can therefore only be explained on the basis suggested above—i.e., certain races are more immune even in large and repeated doses, while others are much more allergic to chlorpromazine.—I am, etc.,

Delayed-action Stabs

SIR,—I was interested to read Mr. Harry M. Windsor's account of three cases of traumatic diaphragmatic hernia (*Journal*, June 8, p. 1344), as I recently saw such a patient in the follow-up clinic at the Mansfield and District General Hospital.

A man of 35, admitted under the care of Dr. J. C. Pease in February of this year, had been in normal health until five days previously. He then complained of nausea followed immediately by upper abdominal pain and the vomiting of a small amount of clear brown fluid. Dark brown material was vomited almost continually after this and the pain soon radiated through to the back. Four years previously he had fallen from the top of a caravan on to a spiked fence, suffering a puncture wound to the left loin. A splenectomy was performed for traumatic rupture of the spleen at Nottingham General Hospital. A chest x-ray prior to discharge at that time showed only a trace of fluid at the left lung base. His condition after this had been normal until his present illness.

On admission he looked ill and complained of continuous upper abdominal pain and copious vomiting of dirty brown fluid. Chest x-ray was interpreted as showing a high left diaphragm with obliteration of the costophrenic angle, a result of the previous operation. Continuous gastric aspiration and intravenous fluids failed to improve his condition. Laparotomy was performed by Mr. J. N. Ward-McQuaid four days after admission. The greater curve of his stomach, followed by the greater part of the stomach, was found to have herniated through a hole in his diaphragm about 1 in. (2.5 cm.) in diameter and 1 in. (2.5 cm.) to the left of his oesophageal opening. The opening was enlarged, and gangrenous stomach together with gangrenous left lower lobe of lung was brought into the peritoneal cavity. A sleeve resection of the stomach was carried out with an end-to-end anastomosis of the remnant. The large chest cavity was drained by an intercostal tube and the diaphragmatic opening repaired. After operation his general health improved rapidly, but multiple fluid levels in the left chest and a fever necessitated further drainage of his chest. Later a partial rib resection was performed in the chest unit of the Nottingham City Hospital by Mr. Barclay. The patient is now well.—I am, etc.,

Mansfield, Notts.

C. A. HOBBS.

Malignant Change Following Herpes Simplex

SIR,—In reply to your correspondent Dr. Henry Haber (*Journal*, September 28, p. 765), commenting on my statement (*Journal*, September 14, p. 615) that there is nothing specific in the inflammatory changes in the skin in cases of herpes simplex, in his letter he himself states that the changes in cases of herpes simplex are similar to those found in zoster and varicella. Surely this means that the inflammatory changes in herpes simplex are non-specific, as I suggested.

As regards Dr. F. F. Hellier's criticism (*Journal*, October 5, p. 825), I would like to say that the possibility of molluscum sebaceum was kept in mind in these cases. The histological diagnosis of squamous carcinoma was made in a laboratory very conscious of the condition of molluscum sebaceum and from which an important paper on the condition was published.¹ Moreover, clinically there were certain

features which indicate that the diagnoses of squamous carcinoma were correct: (1) As they did not appear at the time to have a bearing on the diagnoses, the after-history of the cases was not mentioned in the paper. In Cases 3 and 4 x-ray treatment was followed by recurrence of the tumour, and later surgical removal was undertaken with block dissection of the lymph nodes of the neck, in which metastases were found. (2) The full life-cycle of the lesion of molluscum sebaceum, including inchoative, progressive, vegetative, and retrogressive changes to complete spontaneous disappearance, is usually about 21 weeks. In nearly all cases it is completed within 4–6 months,¹ though regression begins well before this. For various reasons, before x-ray treatment was eventually begun 19 weeks had elapsed in Case 1 after the lesion first appeared, 23 weeks in Case 2, 21 weeks in Case 5, and 13 months in Case 6. In each case the lesion was still increasing in size and showed no evidence of regression. Case 6 was thus certainly not an example of molluscum, while, if the lesions in Cases 1, 2, and 5 were those of molluscum, they would have shown signs of regression after such an interval. (3) So far as I am aware, herpes simplex does not predispose to the development of molluscum sebaceum in the affected area, nor the latter develop out of the herpetic lesions. (4) In Case 2 a benign tumour (wart) also developed at the site of recurrent herpes. In other precancerous skin lesions malignant change is commonly associated with warty formations. (5) In Cases 5 and 6 repeated herpetic lesions were produced by exposure to sunlight. The latter is well known to be a factor predisposing to malignant change.

I hope these observations will answer Dr. Hellier's doubts.—I am, etc.,

R. WYBURN-MASON.

REFERENCE

- 1 Fourcres, F. A., and Whittick, J. W., *Brit. J. Cancer*, 1953, 7, 58.

SIR,—Dr. R. Wyburn-Mason, writing on six cases of squamous carcinoma of the skin consequent upon herpes simplex (*Journal*, September 14, p. 615), stated: "No mention of herpes simplex as a premalignant condition has been found in an exhaustive search of the literature." Without claiming to have observed what no one else ever observed—for I think the observation is not unusual—I wrote in 1939: "Dense perivascular infiltration with small round cells underlies the vesicles [of herpes simplex] and follows the vessels deep beneath the surface lesion. This infiltrate resembles the infiltrate always associated with carcinomatous epithelium. It seems to provide fertile soil for cancerous proliferation, for neoplastic leucoplakia is commonly incited into invasion of the mesoderm at the site of labial herpes simplex." I have subsequently used quite similar words in describing this phenomenon.^{1–4} Hazardous it is to claim to have seen what nobody else ever saw.—I am, etc.,

"Endografin" as a Medium for Hysterosalpingography

SIR,—Radiologists appear to hold opposing views as to the value of "endografin" as a medium for hysterosalpingography. In March, 1956, when I had completed a trial run of 16 cases at the request of the manufacturers, I reported to them that 11 had considerable peritoneal irritation, sufficiently severe that I did not care to use the substance again. They indicated that my findings were unique and that other radiologists did not share my experience. It is interesting to note that Drs. D. K. L. Davies, H. J. Fisher, and I. Rocker (*Journal*, October 12, p. 859) have confirmed my findings¹ in a more extensive series. They also note that the pain is of late onset, usually 4 to 6 hours afterwards, and that the history of pain was often elicited only by direct questioning.

This confirms my suggestion to the manufacturers that, unless the radiologists undertaking these trial runs do an adequate follow-up and ask patients specific questions after the examination, evidence of pain may not be obtained. The fact that complaints are not sometimes voluntarily made speaks much of the uncomplaining suffering women are prepared to undergo in their endeavour to become pregnant. The absence of complaints is therefore not evidence, and research workers in this and allied subjects should be on their guard against this fallacy. The disadvantages of "bili-grafin" are not present with "ethiodan," which I can recommend after five years' use as being a safe, painless contrast medium which is fully excreted from the body.—I am, etc.,

Antibiotics in Otitis Media

SIR,—I have seen a number of cases of mastoiditis recently which have been treated with as many as three different antibiotics before being referred to an otologist. In all cases the initial treatment has been with oral penicillin.

I have the impression that this is not the best treatment for acute otitis media, but I only see the failures and I do not know how often this treatment is successful. I consider that the treatment of choice is still a course of parenteral penicillin. I use five single daily injections of 600,000 units of procaine penicillin G for both children and adults. The daily injections have obvious disadvantages in general practice, and, if it cannot be arranged, I think some other antibiotic that can be administered by mouth should be used.

I would like to suggest that cases of acute otitis media should be referred to an ear, nose, and throat clinic if the discharge has not cleared and the hearing very much improved at the completion of a five-day course of some antibiotic. If a mastoidectomy becomes necessary it can then be performed before the organisms are resistant to more than one antibiotic.—I am, etc.,

Truro.

T. M. BANHAM.

Homoeopathy

SIR,—Dr. F. W. Campbell in his letter on homoeopathy (*Journal*, October 12, p. 882) expresses his desire to organize controlled experiments on homoeopathy. On the same page Dr. R. A. Holman, in his letter on peroxide and cancer states: " . . . Hydrogen peroxide should theoretically behave like many other anti-cancer agents and itself be carcinogenic." That is generally accepted and is the basis of homoeopathy—*similia similibus curentur* (let likes be cured by likes).

I am willing to co-operate in the proposed experiments and would offer some suggestions. A controlled experiment using a single drug is futile, since homoeopathy treats the individual patient and a series of patients bearing the same disease label would require a number of different drugs. Diseases selected for the experiments should not be of variable course—e.g., duodenal ulcer, disseminated sclerosis—or requiring a lengthy treatment—e.g., epilepsy. My choice would be migraine, and there are thousands of sufferers waiting to be cured. Well?—I am, etc.,

Manchester, 20.

WESLEY C. NEWPORT.

Testosterone and the Pathological Testis

SIR,—Although the effect of testosterone on the normal rat testis and on the sperm count of oligospermic men with normal testes^{1,2} has been thoroughly investigated, no serious attempt has been made to investigate the effect of testosterone injections on the histology of testes undergoing degenerative changes. In other words, although the effect of testosterone and testosterone propionate treatment on the normal testis and relatively normal spermatogenesis is known,^{3–5} it is not clear what effect, if any, such treatment may have on testes undergoing pathological change, although it is obvious that such information is urgently required.

particularly since testosterone propionate is now being used extensively in the therapy of cases of male infertility, in which degenerative changes are likely to be occurring in the testes.

We mention this matter because our attention has only just been drawn to a review⁹ of a book¹⁰ edited by one of us (R. G. H.) and containing a criticism of a paper¹¹ in the book. The reviewer is not clear "why it is of any value to know that the rapidity of degeneration following chronic ischaemia in the rat testis is directly proportional to the amount of testosterone injected intraperitoneally." In fact, the results of the research alluded to in the book demonstrate that, in the doses used, testosterone propionate has a very adverse effect on the progress of degenerative changes in the rat testis. It is submitted that knowledge of the effect of diverse doses of various hormones on the *pathological* testis is deficient and that even more extensive research work on these lines should be performed.—We are, etc.,

Standard of Press Reporting

SIR,—I was surprised to read in the *Daily Mail* of October 4 an article which implied that the *British Medical Journal* had warned parents that cod-liver oil is a dangerous substance and may cause many unpleasant symptoms and even fatalities. I checked on your annotation "Vitamin-D Intoxication" (*Journal*, October 5, p. 813) and found no mention of cod-liver oil, which has always struck me as a particularly safe way for children to take vitamins A and D because the oily nature of the vehicle tends to prevent overdosage.

The standard of popular press reporting of medical matters has risen very considerably over the last few years, but this alarming and misleading paraphrase of your annotation seems to me to be one of the worst examples of wild journalism. It appears to have no other purpose than to alarm parents about something which their medical advisers are supporting and be to the detriment of the children's health and to the peace of mind of their mothers.—I am, etc.,

London, W.C.1.

JOHN BURTON,

Medical Director,
The Central Council for Health Education.

Shock in Phaeochromocytoma

SIR,—Since we have had to deal with the problem of shock in phaeochromocytoma on two occasions in the last two years, we were particularly interested in the informative article on this subject by Dr. N. Gjøl and his colleagues (*Journal*, September 21, p. 673), in which they describe the management of this situation with noradrenaline. In our first case we also used noradrenaline, and finally sent the patient to surgery after a stormy pre-operative course. His condition was difficult to manage during the operation, and, following a brief post-operative course, he succumbed.

With the second case, we argued that, since the hypotensive state was due to excessive adrenal medullary activity, whatever the exact mechanism, we would use phentolamine ("rogitine") to combat the hypotension, and, since the amine intravenously and for the entire pre-operative period. An intravenous drip of phentolamine was therefore commenced and maintained for the whole pre-operative period of about a week. Not only was the state of shock immediately controlled, but the patient remained normotensive for

the entire period, her general condition improved immensely, and she went to surgery in a most satisfactory condition. Her course during the operation and after surgery was remarkably free from anxiety.

We are at present preparing a report on these patients, which not only recommends the management of the state of shock with phentolamine rather than with noradrenaline, but also advocates what we believe may be an important new principle in the management of phaeochromocytomas—namely, the prolonged, uninterrupted, intravenous administration of phentolamine through the pre-operative period.—We are, etc.,

R. BARRATT TERRY,
JOHN R. TOBIN, jun.

Fallibility of Statistics

SIR,—Mr. Denis Browne (*Journal*, September 28, p. 766) champions the infallibility of proof by statistics. It may be salutary to recall the statistical history of the aetiology of coronary thrombosis.

Some years ago statistics were produced to show that coronary thrombosis fell heavily upon the learned professions because they bear the stress of responsibility, the clergy being protected by their spiritual tranquillity. Later, when it became fashionable to regard our professions with less respect, similar statistics proved that coronary thrombosis was due to lack of exercise from travelling by car, the clergy being saved on bicycles. Now that cars are in general use, comparable figures prove that fat is our downfall, the clergy being spared by a leaner diet.—I am, etc.,

Falmouth.

C. HEATH.

Chronic Bronchial Infection

SIR,—We agree with Drs. A. M. Brunton and R. H. Gosling (*Journal*, September 21, p. 713) and with Dr. B. H. Bass (*Journal*, October 5, p. 826) that in many patients with bronchitis there may be a net financial gain to the community in the long-term administration of antibiotics, due to reduced absences from work and admissions to hospital.

We would like to point out, however, that, in spite of the manifold increase in the consumption of the tetracycline group of drugs in the past few years, the price of these drugs has remained the same. This is in sharp contrast to experience with other drugs such as penicillin, streptomycin, and P.A.S. We acknowledge and are grateful for the free supplies of antibiotics for research purposes, but unfortunately this represents a drop in the ocean and we are disappointed that no reduction in price has yet been made and that there is apparently no competition between the firms concerned to achieve this.

Long-term treatment with these drugs is of undoubted value in a proportion of bronchitic and similar patients, but only a small fraction of this total can receive this treatment while the present cost is maintained, and private patients are, of course, almost totally excluded. We feel that a further increase in consumption would certainly follow a reduction in price and that there might well be a net gain to the manufacturing firms concerned.—We are, etc.,

Burnley.

W. H. HELM,
E. R. TALLETT.

Recent Advances in Haemorrhage and Shock

SIR,—May I comment upon two statements in Mr. A. Ruscoe Clarke's stimulating paper (*Journal*, September 28, p. 721)?

(1) "There is no first-aid treatment for shock" (p. 725). This sentence probably derives from the syllogism: The cause of shock is haemorrhage; the treatment needed is transfusion; the first-aid cannot give transfusion—therefore there is no first-aid treatment for shock. The impression actually conveyed to the first-aid is that he need not bother about shock because there is nothing he can do about it. I submit that the new conception of shock, very

clearly expounded also by Sir Heneage Ogilvie (*Journal*, January 15, 1955, p. 159), makes greater, not less, demand upon the skill of the first-aid to combat shock by the control of haemorrhage and the relief of pain. If the latter understands that in every serious injury, of body or of limb, there is concealed haemorrhage, whether blood is visible or not, then the required treatment falls into place: support in the most comfortable position; as little movement as possible; dry sterile dressing over any wound; firm bandaging over cotton-wool, whether the skin is broken or not; immobilization of the broken limb; elevation; gentle, firm lift on to the stretcher; steady loading into the ambulance without any jerk or jar; nothing by the mouth; no hot-water bottles; the casualty taken to hospital as soon as possible and kept cool, quiet, comfortable, and comforted on the journey.

(2) "When a patient is to be transported a short distance and will reach hospital within half an hour of injury, it is not justified to take 20 minutes to apply a Thomas splint when tying the legs together will do just as much good" (p. 724). This says, in effect, that severe recurring pain and continuing haemorrhage are unimportant for a period of half an hour. Not only half an hour, however, for the casualty is not magically relieved as he enters the hospital door. He must await the mobilization of the hospital resources, he must be handled, x-rayed, lifted perhaps to a trolley and to bed. A well-applied Thomas splint will be retained during this period—which may run into hours—in safety. I submit that tying the legs together, with one thigh broken, will never "do just as much good." A casualty hates having his legs tied together. Every movement of the sound leg, the pull of the muscles on the broken bone, the pull of gravity with every jolt of the vehicle augmented by the weight of the sound limb, will cause intense pain and is liable to increase or restart haemorrhage from the damaged blood vessels.

If, as Mr. Ruscoe Clarke has stated, one-third of all cases of severe injury coming to the Birmingham Accident Hospital are dead on arrival, is it not just possible that some might have been saved by competent first aid given before the "traumatizing experience" of the ambulance journey?—I am, etc.,

London, W.C.1.

M. A. DOBBIN CRAWFORD.

Analgesia with Opiate-antagonist Mixtures

SIR,—The paper by Drs. A. Herxheimer and C. Sanger (*Journal*, October 5, p. 802) interests me, as it confirms one of my own clinical findings in this field. My experience extends over four years and covers thousands of injections. It has been mostly with mixtures of pethidine and nalorphine, but levallorphan and other opiates have been used.

The possibility of mixing nalorphine with morphine or pethidine to antagonize respiratory depression occurred to me soon after I first received the drug. I found that a satisfactory ratio was nalorphine 5 mg. to pethidine 100 mg. This mixture was thoroughly tried in anaesthetic practice as a preliminary to its use in obstetrics, which seemed to me to be one of the most important clinical applications of the principle. The mixture was found to be safe and effective. Two years ago I independently introduced the use of this mixture into obstetrics at the maternity department of the Dartford group of hospitals with the co-operation of the obstetric staff. As far as I am aware, I was the first to do this. To date over 2,000 injections have been given to over 1,000 mothers, with excellent results. Careful records have been kept on specially prepared forms. The data from the first 300 cases were collected by my registrar, read as a paper in 1956, and published this year.¹ A further report is in preparation.

In obstetrics an injection of pethidine 100 mg. mixed with nalorphine 5 mg. causes as good as or better pain relief than pethidine 100 mg. alone. There is more sedation and amnesia, but co-operation is as good. Injections of this dosage can be safely and satisfactorily given from the time labour is well established right up to delivery, without

adverse effects on the baby. Our practice is to repeat the injections at hourly intervals as required, gas-air or trichloroethylene-air inhalation being allowed as necessary. During a long labour over 1,000 mg. pethidine has been thus given without causing neonatal asphyxia. Many mothers find the analgesia from the injections superior to that obtained from gas-air. The incidence of prolonged labour, operative interference, and post-partum haemorrhage is not increased. Similar results to the above have been obtained using a mixture of pethidine 100 mg. and levallorphan 2 mg.; it may be that less levallorphan would suffice.

In anaesthesia, paediatrics, and general medicine the same mixture has been extensively used for premedication, post-medication, as a supplement to nitrous oxide anaesthesia, as an analgesic for children, and in pulmonary diseases where depression of respiration or cough is to be avoided, with the expected results. My observations lead me to believe that the following side-effects of opiates are in varying degree antagonized by the addition of nalorphine (or levallorphan): depression of respiration and the cough reflexes, contraction of the pupil, euphoria, and dilatation of the skin vessels. It has also been shown that the rise in C.S.F. pressure is antagonized, and I believe venous pressure is also reduced in anaesthesia. The incidence of nausea and vomiting is not notably reduced.

The possibility that the additive properties of opiates are reduced by the addition of antagonists is being explored. If this can be established there will be a very strong case for premixing antagonists with opiates for general use, since addiction to pethidine in particular is, I believe, a real problem among doctors and nurses, quite apart from the problem in patients with chronic pain.—I am, etc.,

JOHN BULLOUGH.

Chislehurst, Kent.

Achalasia of the Crico-pharyngeus

SIR,—Dr. A. Gordon Beckett and Mr. A. G. Ellerker (*Journal*, October 12, p. 865) record an unusual case of complete obstruction to liquids at the entrance to the oesophagus associated with a large nodular benign retrosternal goitre, other urgent symptoms including inspiratory and expiratory stridor, but with an unobstructed trachea as ascertained by tracheoscopy. The laryngeal obstruction was completely relieved (after aspiration of the lower air passages by bronchoscopy) by intubation with an indwelling endotracheal tube.

Achalasia of the crico-pharyngeus^{1,2} will produce some degree of obstruction to swallowing at the pharyngo-oesophageal opening. It is usually only apparent on swallowing liquids rather than solids, and invariably accompanies a bilateral recurrent laryngeal nerve paralysis, which I have encountered with a large plunging benign goitre. Both vocal cords are paralysed and fixed in the paramedian position.

At a clinical meeting outside London some years ago, there were gathered together eight cases of post-operative bilateral recurrent laryngeal nerve paralysis after thyroidectomy. In six out of the eight, some obstruction to the swallowing of fluids could be demonstrated clinically by making the patient swallow half a tumbler of water. On stopping, after a perceptible interval, a bout of coughing followed. This is due to the retention of the swallowed contents in the hypo-pharynx and the spill-over into the larynx. The achalasia of the crico-pharyngeus can be confirmed radiologically by a lateral pharyngogram and repeated after three to five minutes. This will demonstrate the hold-up of fluid in the hypo-pharynx and pyriform fossa: the overflow fills the valleculae visible in the antero-posterior view with a horizontal fluid level. It may take up to five minutes to empty completely.

The severest form of achalasia of the crico-pharyngeus produces complete obstruction to the swallowing of fluids at the mouth of the oesophagus. This may result from a bilateral paralysis of the recurrent laryngeal nerves, especially if the onset is sudden—e.g., post-operative, or anterior

poliomyelitis.* Any attempt at swallowing fluids merely results in a spill-over into the glottis (already almost completely obstructed by the immobile abducted vocal cords), followed by paroxysms of coughing, extreme dyspnoea, and even cyanosis. The following case under my care in 1951 is an example of complete achalasia of the crico-pharyngeus. The patient was unable to swallow any liquid at all, any attempts resulting in the fluid overflowing immediately into the air passage.

A male, aged 65, with a loss of voice following a "cold" some weeks previously, developed inspiratory stridor. He noticed that, while he could swallow solids easily, liquids produced coughing—"it went the wrong way." There was loss of weight and some secondary anaemia. On mirror laryngoscopy he was observed to have a bilateral recurrent laryngeal nerve paralysis. A pharyngogram revealed achalasia of the crico-pharyngeus. Clinical and radiological examination (repeated) showed no chest physical signs. There were no neurological signs other than the bilateral recurrent nerve paralysis. Bronchoscopy and oesophagoscopy proved negative. The sputum was negative. Radiology revealed a complete achalasia of the crico-pharyngeus, with a spill-over into the glottis. All swallowed liquids by this time precipitated distressing bouts of coughing, increased the laryngeal obstruction, and produced cyanosis. An emergency tracheotomy was performed. After this, swallowed liquids or accumulation of saliva, etc., continued to be passed into the larynx and was coughed out through the tracheotomy tube. As he was in danger of developing an inhalation pneumonia the air passage was separated surgically from the food passage. Twelve weeks later he succumbed: the cause of death (apparent a few weeks before) was a carcinoma of the left upper lobe bronchus. In this case, the complete obstruction to swallowing liquids at the entrance to the oesophagus was caused by a complete achalasia of the crico-pharyngeus, a complication of bilateral recurrent laryngeal nerve paralysis.

It must be taken as established that a bilateral recurrent laryngeal nerve paralysis can produce at the same time an achalasia of the crico-pharyngeus. This manifests its presence by a partial or (as in the case of Dr. Beckett and Mr. Ellerker and in my case) a complete obstruction at the mouth of the oesophagus, especially for fluids.—I am, etc.,

Compulsory Powers over Mental Patients

SIR,—I fear that Dr. C. R. Birnie (*Journal*, October 5, p. 825) cannot have made himself familiar with the contents of the Royal Commission's report, or he would not have spoken of the guilty psychiatrist being haled before the review tribunal to account for his action in giving one of the recommendations for admission. Paragraph 445 makes it quite clear that review tribunals will have nothing to do with passing judgment on the admission proceedings, but will be solely concerned with the patient's condition at the time of the review. Dr. Birnie may have been thinking of the discharged patient's right to bring an action in an ordinary court of law. I dealt with this bogey in my original letter (*Journal*, August 24, p. 467); I might add here that his purely theoretical predictions are not supported by the practical experience of the last nine years in Northern Ireland, where the magistrate's order has been eliminated except for the few cases remaining in hospital after two years. No actions at all have been brought there since the 1948 Act came into force.

There are other parts of the report which Dr. Birnie cannot have read; for the conception of the "effective consensus of opinion" and the description of the magistrate as "an authority whose main function is the punishment of crime" are the Commission's own; I did not invent them in order to "defend" its recommendations. Without the consensus, the magistrate cannot act; after his action the consensus is the continuing cause of the patient's detention. But Dr. Birnie has put his finger on the very point that makes the abolition of the magistrate so desirable, for it is certainly the magistrate's order which inflicts "cer-

tified status" on the patient. He is quite right in thinking that the Commission has it in mind to alleviate the stigma; but this particular reform (for which I am sorry to see he uses the degrading word "tampering") is of course only one of many designed to that end.

Dr. Birnie must indeed be living in a different world from his colleagues if his patients never approach him with a request for discharge and if he never has to make a decision to recommend discharge or withhold it. If he does do these things he shares with the rest of us an inescapable responsibility. This responsibility is at present conferred on us in respect of each patient separately by an authority whose intervention has been judged to be inappropriate and harmful; the proposal is that in future our responsibility should derive directly from the terms of the law. I think we should welcome the change.—I am, etc.,

Coulsdon, Surrey.

ALEXANDER WALK.

The Mismamed Stethoscope

SIR,—The integrity of our speech, as we speak of the stethoscope, is immaculate. The best classical Greek authors use the second half of that word in the abstract sense of examining a problem. That is apt. On the other hand, 'phone is almost entirely restricted to the description of the articulated voice. If Dr. F. R. Langmaid (*Journal*, October 19, p. 943) fancies a change, he would be correct, and I dare say alone, in championing the use of the word stethacousticon.—I am, etc.,

Emsworth, Hants.

A. S. HARRIS

Cancellous Strip Grafting

SIR,—I was interested to read your annotation (*Journal*, September 28, p. 759) on cancellous strip grafting. As this procedure was used at the maxillo-facial units at both Hill End and East Grinstead from 1939 onwards, I would like to pay tribute to Rainsford Mowlem for his pioneer work in this field. He carried out many experiments in grafting bone to mandibles and demonstrated a perfected technique in 1940 which was used throughout the maxillo-facial units. His technique was described in our textbook,¹ and a colour film was made of this technique at East Grinstead. This film is now held by the British Council. Mowlem's technique must have saved many months of hospitalization for hundreds of patients during the war period.—I am, etc.,

Birmingham, Alabama, U.S.A.

Complications of Influenza

SIR,—In your leading article on the pulmonary complications of influenza (*Journal*, October 12, p. 872) you state that it is important that regular information about the progress and nature of the epidemic should be given as quickly as possible to the medical profession. The available methods of treatment of the complications of virus influenza have been vastly extended since the last pandemic occurred, and nowadays, more than ever before, up-to-date epidemiological information can be of real practical value to the doctor who has to treat the cases.

Yours is the most widely read medical journal in the country. During the past few weeks you have given us apart from the weekly statistical summary, a handful of scientific and leading articles and of letters on certain aspects of the epidemic, and these, as far as they go, have been of great interest and real value. But is this really the only useful information about the epidemic which could be given to the medical profession? You tell us that the epidemic will be with us for several months. If so, it will certainly cause much dislocation of economic and social life, a number of serious illnesses and fatalities, and a great deal of work for doctors. Would it not be appropriate while the epidemic lasts, to devote a few columns each week to an intelligence summary of its progress? The possible sources of information for this must be numerous if the

Obituary

CLIFFORD WHITE, M.D., F.R.C.P., F.R.C.S.
F.R.C.O.G.

Mr. Clifford White, consulting obstetric surgeon to University College Hospital, died at the hospital on October 24.

Clifford Sidney White was born in London in 1881, and was educated at University College, London. Receiving his medical training at University College Hospital, he qualified by taking the London Conjoint diploma in 1904, in which year he also obtained the London degrees of M.B., B.S., proceeding to the M.D. two years later. Elected a Member of the Royal College of Physicians of London in 1907, he became a Fellow of the College in 1924. He was admitted a Fellow of the Royal College of Surgeons of England in 1909 and elected a Fellow of the Royal College of Obstetricians and Gynaecologists in 1929. In 1938 he was elected a Fellow of University College.

After qualification Clifford White held the appointments of house-physician, house-surgeon, and outdoor and indoor obstetric assistant at University College Hospital, and for a time he was demonstrator in anatomy at University College. He was resident medical officer at Queen Charlotte's Hospital in 1907, when he was asked to go to the Samaritan Hospital for Women as house-surgeon. Later he became registrar there, acting as assistant to the late Mr. Cuthbert Lockyer. In due time he became senior surgeon at the hospital. From 1910 to 1912 he was obstetrical registrar at University College Hospital, and from 1912 to 1923 surgeon at Queen Charlotte's Hospital. In 1914-15, during the first world war, he was surgeon at the Belgian Army Hospital at La Panne. For many years he was consulting surgeon to the Metropolitan Hospital and to St. Mary's Hospital for Women, Plaistow.

Clifford White examined for the Universities of Cambridge, London, Liverpool, Durham, Cairo, and Alexandria, and for the English Royal Colleges. From 1940 to 1942 he served on the council of the Royal College of Physicians of London, and he was a former president of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine. He was editor and joint author of *Midwifery and of Diseases of Women*. He contributed to *Eden and Lockyer's New System of Gynaecology* and to *Lowrie's Gynecology*. He leaves a widow.

J. D. S. F. writes: Others better qualified to do so will write of Clifford White, telling of his academic distinction, contributions to the literature, and professional skill. I attempt the more difficult task of expressing on paper memories of a great man, memories shared in one way or another by patients, nurses, students, and colleagues alike.

Clifford was a colourful personality and a genius at teaching. His 12 o'clock "rag" classes at U.C.H. were always packed. Other great men might give equally learned instruction and bore the class to tears. With Clifford we were never bored. At first some were awed by him, but that soon passed. His, "Go on, old man, go on," thumbs in the armpits of his waistcoat, feet pointing at "ten to two," and his encouraging smile, extracted from us what little we knew and instilled into us facts which not only enabled us to pass examinations but which proved to be of lasting value whatever branch of medicine we eventually took up.

In addition to their work, he took a personal interest in his juniors. Dinner and a swim at the Bath Club, tennis, dances, and, above all, parties at his own home, wonderful parties which those of us privileged to participate in them will never forget. To the nursing staff he was considerate and polite. If he said he would operate at 2 p.m., he would start then and not a minute later, not drifting to the theatre at 2.30, thus upsetting time-tables such as the premedication

are sought. To give a complete picture week by week is obviously impossible. Intelligence to be useful must be accurate and up to date, but it need not aim at completeness, and this should be possible. It may be that, following on your leading article, you already have something on these lines in mind. If so, you will earn the gratitude of general practitioners, like myself, and of others, who are responsible for treating the patients.—I am, etc.,

Beaconsfield, Bucks.

R. M. SOLOMON.

Prevention and Treatment of Tetanus

SIR,—It is not clear whether your reference to "the Army" in your annotation (*Journal*, October 19, p. 930) is to the British or to other armies. If it is to the British Army the reference to an annual booster dose requires modification.

The annual boosting required until recently in the British Army applied to the use of the combined enteric and tetanus prophylactic T.A.B.T. and to the need for annual re-inoculation against enteric while an individual was "at risk"—e.g., while on an overseas tour. Otherwise boosting doses were required at three-year intervals. This period was also set primarily to maintain what was considered to be a necessary basal level of protective antibodies to enteric fever, immunity to tetanus being recognized as persisting for five years after a primary course or a later boosting dose.¹ It was recognized that too frequent dosage with tetanus toxoid may lead to a reduction rather than an enhancement of immunity. Annual doses during the whole length of service in the Army could, in the case of a regular soldier, constitute such overdosage, but after careful consideration it was decided that annual dosage while at risk and doses every three years at other times would not do so.

However, the current practice for maintaining immunity against enteric in the Army is to use T.A.B. vaccine (not T.A.B.T.) intradermally for all boosting doses. When this is done, immunity to tetanus is maintained by subcutaneous injection of tetanus toxoid at five-year intervals except when on active service, when the interval between doses will be yearly.²—I am, etc.,

London, S.W.1.

A Selfless Band

SIR,—In the early hours of the morning on Saturday, September 28, a Heron aircraft of the Scottish air ambulance service, operated by B.E.A., crashed on the island of Islay. The crew, Captain "Paddy" Calderwood and Radio Officer H. McGinlay and the nurse accompanying them, Sister Kennedy, of the Southern General Hospital, Glasgow, were killed instantly. They were attempting to land in impossible weather conditions in order to evacuate a patient in diabetic coma when the accident occurred.

These three brave persons had flown many times together, often in atrocious weather conditions when all normal passenger flights were cancelled. They had volunteered for these exacting duties, and were well aware of the hazards. These three have gone, but their place will be taken by others no less capable and courageous.

There are many people living in the islands around our stormy Scottish coast who are alive and well to-day only by virtue of the courage, capability, and experience of these three, who died so tragically. The general practitioners of these islands have many times had reason to be eternally grateful to this small but highly skilled and selfless band of men and women.

Those who will no longer grace the skies and our tables with their presence will never be forgotten by the islanders whose lives they saved, or by those of us fortunate indeed to call them friends. Our sincere good wishes go to those who will continue to serve in the ambulance flight; our heartfelt sympathy goes out to those bereaved.—We are, etc.,

Glasgow.

W. THORBURN.

A. Y. BARCLAY.

of patients to follow, nurses' off-duty times, etc. In whatever capacity, it was a pleasure to work for Clifford; he was always practical, just, and reliable. With his equals he was also dogmatic and at times obstinate. He was never a "Yes-man." This occasionally made him unpopular with them. He could not stand humbug in any form, be it in committee or personal relationship. All the more to his credit. He always treated his patients as people, not just cases, and made frequent excursions into his wards merely to encourage them. Many of his ward sisters could tell stories of his generosity, gifts of money handed quietly to them for the benefit of an impecunious patient.

To me he was more than a chief, he was a real friend, as he had been to so many others. No one realizes more than I that, had it not been for him, I should never have attained my present position at U.C.H., and I take the opportunity of expressing publicly my gratitude to him. In spite of all his work and social activity, Clifford was essentially a family man who liked nothing better than to be at home with his wife and family, and as one who has often been privileged to be at home with them I know what his leaving means to them. May they find a grain of comfort in knowing that Clifford was a great person, a true friend, and one of whom U.C.H. is proud to say, "He was a U.C.H. man."

G.-A. writes: The purlieu of Gower Street and Regent's Park will no longer see that tall gaunt figure that was for 40 years such a landmark. Clifford White was born and educated in London and never left it except for pleasure and the exigencies of the first world war. From the day he entered U.C.H. he never faltered. He gave of his best, and there must be many a gynaecologist and general practitioner who owes much to him, for he was not only a forthright practical teacher but a quick and sound operator of good judgment—one who was the very first to admit what he had learned from Herbert Spencer and Cuthbert Lockyer. But he was no aesthete, for, as a dancer, a skier, and a tennis player he was of high rank, and I can recall former days when in his Bentley he would disport himself at Brooklands and the same evening be seen at Ciro's. Examinations came easily to him, and it is not impossible that their invariably happy results were due in part to his handwriting, which was a joy to read. Indeed, oftentimes I have heard him moaning and groaning while at the task of correcting Cambridge M.B. examination papers.

Besides all this Clifford was a wise man of affairs and a first-class committee man, sticking to the point and seeing that others did the same, and, apropos of this, I think that, apart from his Fellowship of the three Royal Colleges, the thing that gave him most pleasure was his election to a Fellowship of University College. Behind a seemingly austere mien there was much fun, and I shall always remember him telling me not once but many times the advice he would give to all highbrows or those humbugs who ape the serious to obtain kudos. Here are the lines, though he could never tell me the author's name:

Give me a sense of humour, Lord,
The grace to see a joke,
To find some happiness in life
And pass it on to other folk.

When Comyns Berkeley was looking for a team to launch his "Ten Teachers," there is little doubt that Clifford was his first and aptest choice, for he was the one who had to carry the toughest burden over the years. One of his outstanding virtues was his loyalty, and after 50 years of friendship I can speak feelingly of this. He liked to let himself go, share confidences, argue opinions, and discuss ideas, books, and travel, for we had both seen much of mice and men. He greatly enjoyed travelling all over the Americas and the West Indies with his devoted wife, the two of them together being splendid and generous mixers, for that meant meeting all sorts and conditions of people whom he would not have met here. During the last few months I know he felt that his end was nearing. My deepest sympathy is for those he has left behind him in his delightfully happy home.

G. W. BODEN, F.R.C.P., F.F.R.

Dr. G. W. Boden, director of the radiotherapy department of the London Hospital, died on October 17 at the early age of 51.

Geoffrey Walter Boden was born on December 9, 1905. His distinguished career in radiotherapy may be said to have begun well before he entered the profession of medicine. Graduating B.Sc., with honours, in the University of London in 1928, he was almost immediately given the task of organizing a laboratory for the preparation and filling of radium sources for clinical use at Messrs. Johnson Matthey. This was about the time that Canadian radium first became available commercially, and, through Boden's laboratory, was distributed to Britain and Commonwealth countries. His inventive genius soon made its mark on radium laboratory technique, and the work of the Radium Commission in organizing the distribution of radium was greatly facilitated by the advances initiated by Boden. Indeed, it is not too much to say that the successful work of the Radium Commission in the organization of radium therapy in this country owed much to these advances.

Meanwhile Boden's increasing interest in the application of radium to the treatment of disease made him decide to take up the profession of medicine, and he entered the medical school of St. Bartholomew's Hospital in October, 1932, at the age of 26, retaining his association with Messrs. Johnson Matthey throughout his student period. He qualified M.R.C.S., L.R.C.P. in 1937, and after completing house appointments was appointed chief assistant (registrar) to Dr. Geoffrey Evans's medical "firm." He proceeded to the M.R.C.P. in 1939, and in the same year took the London D.M.R. He was elected F.F.R. in 1950.

On the outbreak of the second world war Boden joined the R.A.M.C., serving mainly in the Middle East until he was invalided home with a radiation epithelioma of a finger in 1944, for which amputation was necessary. On his return to England he took up the appointment of assistant physician to the department of radiotherapy at St. George's Hospital, to which he had been appointed in 1939, and on the temporary closing of that department at the end of the war he was appointed radiotherapist to the Christie Hospital, Manchester, which he left to assume the duties of director of the department of radiotherapy at the London Hospital in 1951. There Boden's talent for administration again showed itself, and the equipment and activities of the department were notably expanded under his directorship. His clinical acumen and the painstaking care which he devoted to every patient were recognized by all his colleagues, who held him in high esteem and affection. Among the many honours that came his way were two that he particularly valued—the Twining Medal of the Faculty of Radiologists in 1952 and the Fellowship of the Royal College of Physicians, to which he was elected only in the last year of his life. Boden was not a prolific writer, but whatever he wrote was informed by the same sound judgment and scrupulous care that he showed in his clinical work; and he never wrote unless he had something worth while to say.

Boden's gay and friendly disposition made him a delightful companion with a rare personal charm. He was very popular both in the hospitals which he served and in the societies of which he was a member. In those who knew him well he inspired a deep and lasting affection. He will be sadly missed, and the sympathy of all who knew him will be extended to his widow and two children in their loss.—W. M. L.

J. L. D. writes: Geoffrey Boden was on the staff of the Christie Hospital and Holt Radium Institute for only a few years, 1945 to 1950, but has ever since remained in our traditions. We like to think those were happy years for him, as they were for us. When he first paid us a short visit we soon realized that we had a guest of uncommon talents, which had brought him by uncommon ways, but inevitably, to medicine and radiotherapy. When, a little

later, we were glad to welcome Boden to a staff appointment, we did so, therefore, confident that he would contribute with distinction to the sum of our efforts. Our expectations were more than fulfilled. The peculiar excellence of character that we learned to appreciate might, perhaps, be described as a combined maturity and brilliance, lightly carried, free from pettiness or eccentricity. The effect was to give him an unquestioned position and an ever-increasing influence in both intellectual and practical affairs—an influence which made itself felt, although he seemed unconscious of it, in the standards he set us to emulate, and in the clarity and good humour of his counsel. His early death closes a career, already distinguished, which had by no means ceased to develop.

Boden never forgot he was a physician. His interest in neurology and his own powers of original clinical observation led him to the work for which he will be best remembered, and for which he was awarded the Twining Medal—the quantitative assessment of the effect of irradiation on the central nervous system. This work, carried out in Manchester, is assured of a permanent place in the foundations of radiotherapy. As a colleague he is remembered with much affection.

GERTY T. CORI, M.D., Sc.D.

Dr. Gerty Cori, who shared the Nobel Prize in medicine and physiology in 1947 with her husband, Professor Carl F. Cori, and Professor B. A. Houssay, of Buenos Aires, died at St. Louis, Missouri, U.S.A., on October 26. She was 61 years of age.

Gerty Theresa Radnitz was born at Prague on August 15, 1896, and graduated at the Realgymnasium of Tetschen (now Děčín) in 1914. Six years later she obtained the degree of M.D. from the German University at Prague. After graduation she held an appointment at the Children's Hospital, Vienna, until 1922, when she emigrated to the United States of America with her husband, whom she had married in 1920. From 1922 to 1931 she was assistant biochemist at the State Institute for the Study of Malignant Diseases, Buffalo. In 1931 she was appointed a research associate at Washington University Medical School, where, in 1947, she became professor of biological chemistry. In that year she and her husband, who were co-equal in their joint researches, shared half the Nobel Prize in medicine and physiology "for their discovery of how glycogen is catalytically converted," the other half of the prize going to Professor B. A. Houssay for his discovery of the part played by the anterior pituitary hormone in the metabolism of sugar. The Coris also received the Squibb Award in endocrinology in 1947. Both have conducted research on carbohydrate metabolism and enzymes. Dr. Gerty Cori was granted the Midwest Award by the American Chemical Society in 1946 and the Garvan Medal in 1948. She received the degree of Sc.D. from Boston University in 1948, and from Smith College in 1949.

LUDWIG TELEKY, M.D.

Dr. Ludwig Teleky, who had an international reputation as a specialist in industrial medicine, died at the Jewish Memorial Hospital, New York, on August 20. He was 85 years of age.

Ludwig Teleky, the son of a doctor, was born in Vienna on July 12, 1872, and graduated in medicine at the University of Vienna in 1896. Until the end of the first world war he was lecturer in social medicine in Vienna, and in 1921 he was appointed director of the Postgraduate Academy of Public Health and Industrial Medicine at Düsseldorf. He also became medical inspector of factories for the Rhineland and a member of the Central Council for Health in Berlin. In 1932, during the Nazi persecution of the Jews, he was deprived of these appointments and returned to Vienna. As

one of the founders of the Permanent International Commission in Industrial Medicine, he attended the annual congress at Frankfurt in 1938. The Munich crisis interrupted the congress, and it became necessary for his friends to get Dr. Teleky over the border into Switzerland for his safety. Finding refuge in the United States of America, he was appointed to a lectureship in the University of Chicago. In 1944 Dr. Leonard Greenburg, now commissioner of the Air Pollution Control Department of the New York City Council, invited Dr. Teleky to work with him in the labour division of the New York State Department of Industrial Hygiene. While in New York Dr. Teleky devoted much of his time to writing. His book, *The History of Factory and Mine Hygiene*, was published in 1948, and *Gewerbliche Vergiftungen* was published in Germany in 1955. The Permanent International Commission in Industrial Medicine elected him in 1951 an honorary life member in recognition of his eminent services. The Grand Cross of Merit was conferred on him by the President of the Federal German Republic, and a street was dedicated to his name in a new part of the town of Hamm, one of the ancient Hanse towns of Germany.

Dr. Teleky's wife died in 1953, and he is survived by two daughters, one of whom is a social science worker in London.

Medico-Legal

DAMAGES FOR BUTTOCK INJURY

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

In December, 1953, Keith Edward Wright, then aged 15, of Grays, Essex, was involved in a road accident. On being taken to hospital it was found that he had a deep laceration 8 in. (20 cm.) long on the left buttock and that his gluteus maximus muscle had been completely and his gluteus medius practically severed. He also had concussion and lacerations and abrasions on his head; x-ray examination showed no bone injury.

During the next 14 months he was treated for these injuries both as an in-patient and as an out-patient. During that time the condition of his left buttock deteriorated, and a hard lump about the size of a tangerine developed below the site of the injury. He had gone back to school early in 1954, but his leg was very painful; halfway through the term he started to get severe headaches, and failed his first attempt at his G.C.E. examination, although his schoolmaster had expected him to pass.

After leaving school he had become a sales clerk with an oil company, and the headaches, though still frequent, had become less severe. Ultimately a radiograph was taken of the lump in his leg, which revealed a metal object believed to be part of the door handle of the car which had knocked him down. This was removed by operation, but the scar was still tender.

On October 10, 1957, his action for damages against the driver of the car which knocked him over was heard before Mr. Justice Ashworth, and the defendant admitted liability. In his judgment the judge observed that a curious feature of the case was that the original radiograph had not revealed the presence of the piece of metal. Until its removal the boy had experienced far more pain than would normally have been expected from the injury he had suffered. He now had many difficulties in his daily life. It was painful for him to sit down, and this was likely to continue; it was painful to kneel, and he could not walk far. The judge was satisfied that the headaches were of sufficient severity coupled with the pain and discomfort in sitting down to cause the boy's examinations to be beyond him. For the physical disability, pain, and interference with his education the judge awarded £3,509 damages.

Vital Statistics

INFLUENZA EPIDEMIC

The main features of the Asian influenza epidemic in Great Britain are its high infectivity, sudden onset, and low incidence of complications. Special reports from eleven general practitioners, which we publish below, describe its symptomatology and give important first-hand information on these and other aspects of the disease. Among the points they make are, first, that some cases relapse or run a bi- or tri-phasic course; secondly, that infectivity is highest among children; thirdly, that severity is greatest among adults aged 45-55 and children aged 8-14; and, fourthly, that a puzzling bradycardia sometimes occurs.

The following Table shows the age distribution of deaths from influenza in the 160 great towns of England and Wales in recent weeks:

Week Ending	0-	1-	15-	25-	45-	65+
Sept. 14 ..	1	9	3	4	14	16
" 21 ..	2	18	8	17	39	37
" 28 ..	3	25	22	47	102	83
Oct. 5 ..	2	36	28	57	159	160
" 12 ..	4	36	32	58	213	248
" 19 ..	5	22	22	54	189	308

In the early stages of the epidemic an annotation in this *Journal* (September 28, p. 757) drew attention to the unusual age incidence of the patients reported to have died of influenza. The subsequent course of the epidemic has confirmed this estimate. From the week ending September 14, when deaths began to rise, to the latest for which figures are available, the week ending October 19, 2,083 deaths in England and Wales have been reported. Of these, 41% have been people aged 65 and over, 34% aged 45-54, 11% aged 25-44, and 14% aged under 25. These are in notable contrast to the figures for 1949, 1951, and 1953. Then the percentages of deaths of people aged 65 and over attributed to influenza were 67, 74, and 74, as opposed to 41 now. The surprisingly high 34% of deaths of people

aged 45-54 in the present epidemic so far may be compared with the percentages of 23 in 1949, 21 in 1951, and 19 in 1953. The deaths of people under 25 in the present epidemic, comprising 14%, are in contrast to 5% in 1949, 2% in 1951, and 3% in 1953. Thus deaths due to the Asian influenza seem to be more evenly spread over the ages than has been usual with influenza since the war in epidemics for which comparable figures are available.

At the highest weekly levels so far attained in the principal towns of Great Britain, deaths from influenza and

Deaths from influenza plus pneumonia as percentage of deaths from all causes in week ending October 5.

Deaths from influenza plus pneumonia as percentage of deaths from all causes in week ending September 14.

Deaths from influenza plus pneumonia as percentage of deaths from all causes in week ending October 19.

pneumonia combined have formed rather over 20% of deaths from all causes. The percentages they form of deaths from all causes in three selected weeks, including the latest for which data are available, are shown in the accompanying maps.

REPORTS FROM GENERAL PRACTITIONERS

Contrasts with Previous Epidemics

Drs. JOHN FRY and E. M. HUME, Beckenham, Kent, write: The long-awaited Asian 'flu arrived in this area in the second week of September and reached an apparent peak on October 7 and 8. Over 750 patients have been seen and diagnosed as suffering from influenza in this London suburban practice; this represents a rate of over 15% for the practice as a whole. But very large numbers of patients suffered the disease without finding it necessary to consult us. It is difficult to estimate these numbers, but they are probably around the 350 mark. In all we think that over 25% of all our patients at risk have been affected by influenza in this epidemic. This epidemic has differed appreciably from those in the past in a number of ways.

Age Distribution.—In contrast to previous epidemics, when the bulk of cases occurred in the 20-40 age groups, the present epidemic largely affected children. The first cases were children in the secondary school age groups—i.e., from 11 to 16. These then appeared to infect their parents and their younger brothers and sisters. Only 12 of our patients were over the age of 60—a rate of only 2%.

Infectivity.—Another feature of this epidemic was the very high rate of infectivity. In previous epidemics in this practice around 200 cases were seen, nowhere approaching this rate of 750 cases actually seen and diagnosed. It was a very common situation to see whole families struck down either simultaneously or one after the other, and the poor mother of the house endeavouring to nurse her afflicted family. The incubation period was approximately 48 to 72 hours, but in some families cases occurred at longer intervals.

Clinical Features.—Certain common and characteristic features were observed in our patients. The onset was sudden, in many cases as sudden as that of a perforation of a peptic ulcer, the patient being able to give the exact time of onset to the minute. The initial symptoms consisted of chills, "wobbly legs," and marked prostration. Sore eyes, running nose, and cough followed. The cough was characteristically sudden, bursting, and uncontrollable. It was unproductive and accompanied by a retrosternal rawness. Multiple aches and pains were complained of, particularly low backache, frontal headache, and pains in the limbs. These aches and pains were predominantly confined to adults; in children the only noteworthy pains were the headaches. High fever was frequent, and night readings of 105° F. (40.6° C.) and 106° F. (41.1° C.) often occurred. Severe and profuse sweats were especially notable in young males. Redness of the eyes was not a common feature. The fauces were not abnormally reddened and sore throat was not a frequent symptom. Among unusual features, swelling of the hands was noted in three women and an erythematous rash in two others. Nose-bleeds were a not uncommon occurrence in young children.

The course was benign in the vast majority; complications occurred in only 5%. The acute stage lasted on an average of three to five days. A variable degree of debility persisted for a further one or two weeks. Post-influenzal depression on the other hand was an unusual effect in contrast to previous epidemics. In 12 instances a recurrence of acute symptoms occurred about 10-14 days after the original acute episode and required a prolonged period of convalescence.

Complications.—A striking feature of this epidemic was the very low incidence of complications. During the period of the epidemic to date pulmonary complications were noted

in only 26 patients (3.5%). These complications were on the whole mild and responded quickly to penicillin or one of the broad-spectrum antibiotics. The mildness of the cases is evident from the fact that no patient required admission to hospital. Another striking feature was the lack of infection in the 150 known chronic bronchitics in the practice. During the epidemic only 5 (3%) developed influenza, and in only 3 of these were there any acute exacerbations of their chronic chest condition. Middle-ear infection complicated influenza in only 4 cases and responded rapidly to simple and non-specific measures. There have been no really serious complications and no deaths.

Management.—Simple symptomatic measures—aspirin and linctus—were the universal therapy. Specific antibiotics were required only in some of the small number of patients with complications.

Comments.—The most noteworthy features of this epidemic were the very high rate of infectivity, the age distribution, with a predilection for teenagers, and the very low rate of complications.

Biphasic Cases

Dr. R. E. HOPE SIMPSON (Cirencester, Glos.) writes: The epidemic began in mid-September. The peak has now probably been passed, but the conclusions given here must be considered to be provisional and the last few days may ultimately come to hold many more cases. The illness is ultimately biphasic and sometimes tri-phasic. The second phase falls 2-14 days after the first and is usually more severe. This complicates the measurement of the interval between cases. There appears to be no characteristic case interval in households. Both phases are often similar but wide variations are common.

Day 1.—Abrupt onset of frontal or occipital headache, fever, vomiting, and sore throat. Children may be terrified by an odd muscular difficulty in drawing breath, unaccompanied by tachypnoea or cyanosis but with upper retrosternal soreness, severe enough to stop them speaking. Night temperature 104-105° F. (40-40.6° C.), adults 2° F. lower. Delirium.

Day 2.—Vomiting. Anorexia. Small hard cough. Headache. Extreme weakness. Day and night temperature 103-105° F. (39.4-40.6° C.). Delirium. Very ill. Sore throat has gone.

Day 3.—Headache. Cough troublesome. Pain in neck and shoulders and one side of lower chest and upper abdomen. Except in asthmatics and bronchitics, physical signs in the chest are usually absent. Coryza begins. Earache occurs and old perforations may discharge, but intact drums show little change and do not perforate.

Days 4, 5, and 6.—Cough very troublesome. Temperature settles. Anorexia. Weakness.

Children, especially boys of 8-14 years old, suffer most severely, and indeed the virulence would only need to increase slightly to kill many in the first 48 hours. Vomiting,

which occurs in over 50% of cases, is often severe and protracted. An interesting variant of the disease causes swelling of the glands in one posterior triangle with painful neck and torticollis.

The incidence is high in affected households and schools, but it is too early to give figures. The Chronic Sick Hospital of 120 beds which lost 29 patients in 28 days in February, 1956, has so far had no case in this epidemic, despite a fair number of cases amongst the nursing staff.

The general dating of the epidemic can be seen in the accompanying figure, which is probably reliable as far as October 17. The percentages in the Table give no indication of the actual attack rates, because large numbers of

palate or uvula were often seen in those who complained of sore throat, seldom in those who did not. Laryngitis was present in four children out of 184 patients; in one child it was severe. No adult was much affected. Disproportionate tachycardia was present in 10 patients, 9 of them females aged from 9 to 24 years. Disproportionate bradycardia with variations in rate during examination was noticed in one youth of 19. Both types of abnormality were short-lived.

Complications have been few and there have been no deaths. Nose-bleed has occurred among children, as has sinusitis. Acute otitis media has been seen in only two out of 87 children. Bronchopneumonia was present in three men and two women when first seen (one-sixth of those over 45); the youngest was 47, the remainder between 67 and 74 years of age. On the other hand, among 87 children, two of whom had already had acute bronchitis since the summer holidays, no acute chest signs or symptoms developed. Depression requiring treatment has been seen in three out of ten women between the ages of 20 and 25, but not otherwise. Severe fatigue continuing into the second week of convalescence has occurred in adults of both sexes, but not so far in children.

Treatment.—Several patients had taken an antipyretic before asking for a visit; nearly all admitted that their headache had not been relieved by such drugs. 200 mg. of butobarbitone or 500 mg. of glutethimide, repeated in the night if needed, ensured a good sleep for adults; children were given proportionate doses, repeated if necessary. Each patient was given full doses of mist. salina B.P.C. four-hourly, when awake. Plain steam inhalations relieved the pain of coughing. No antibacterial prophylactics, antipyretics, or cough mixtures have been dispensed.

LATEST FIGURES

In the week ending October 19 deaths from influenza in great towns were as follows, with the figures for the previous week in parentheses: England and Wales 600 (591), Scotland 39 (90), Northern Ireland 26 (19), and Eire 6 (2). The incidence of the disease was still high in southern

England, but had declined in the north and midlands and in Wales. The number of deaths in Scotland dropped sharply from the previous week's total. Among the principal towns of Scotland, Glasgow recorded 17 deaths, Edinburgh 6, and Aberdeen 6. In England and Wales the great towns with 20 or more deaths were: Liverpool 27, Manchester 20, Birmingham 31, Stoke-on-Trent 30, and London 66. In Belfast 21 deaths were recorded, and in Dublin 2. The

accompanying graph shows numbers of deaths in the 160 great towns of England and Wales from early September to the latest date for which figures are available. For the first time since the summer the weekly number of National Insurance claims in England, Scotland, and Wales decreased. The total fell from about 570,000 to about 521,000. These are about 3½ times the usual figures for this time of year.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending October 12 (No. 41) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire. A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

† Includes primary and influenzal pneumonia.
§ Includes puerperal pyrexia.

Medical News

Society of M.O.H.s.—Dr. H. D. CHALKE, M.O.H. of Camberwell, delivered his presidential address to the Society of Medical Officers of Health on October 24 at B.M.A. House. His address was entitled "A Time of Change," and he discussed the public health implications of the changing social scene and the widening demands of preventive medicine. On the one hand, said Dr. Chalke, there were better education, full employment, and a free medical service; on the other, speed, unrest and tension, and what had been described as collective neurosis. "The world seems to be described as collective neurosis." There were changes in the structure of the population: despite emigration, for the first time in 80 years more people were entering Britain than leaving it. In housing overcrowding was much less than formerly, but the number of those living alone, two-thirds of whom were over 60, had doubled in the last 25 years. Two out of every three hospital beds were occupied by people over 65, or by the single, widowed, or divorced. There were also a quarter of a million caravans, half of them residential. A notable feature of the post-war scene had been the new attitudes towards the care of children and the disabled, and the beginning of a wiser approach to preventive psychiatry. The boundaries of public health practice—never narrow—had now been widely extended. And this, said Dr. Chalke in conclusion, after reviewing the Society's current activities, demanded fuller co-operation with others—"and the initiative must come from us." Afterwards, many members of the society and their guests attended the Society's annual dinner at the Royal College of Surgeons. Sir EDWARD BOYLE, Parliamentary Secretary to the Ministry of Education, said that his Ministry relied greatly on the advice given by the Society in matters relating to child health: the work of organizing refresher courses for doctors employed by local authorities was particularly welcome. The question was often asked whether there was still a need for a special health service for schoolchildren now that there was a National Health Service. He thought that answer was clearly "Yes." In reply, Dr. CHALKE said that the thread running right through public health work was education: medical officers of health were teachers. On a topical note Dr. Chalke said that medical officers of health were perplexed about the effects on the public health of radioactive emanations; they had not been taken enough into the confidence of those responsible for all the atomic work that was going on. Dr. H. M. COHEN, proposing the health of the guests, spoke of the excellent relations between the Society and the B.M.A. For this, he said, they owed much to Dr. AGNES KELYNACK, who had been described as "the Portia of public health." He was sure that the gathering would wish to send her a special message of greeting after her illness. Sir JOHN CHARLES, Chief Medical Officer to the Ministry of Health and Ministry of Education, replied to the toast.

Wellcome Trust Benefactions.—During the half-year ended September 30 the Wellcome Trustees made capital grants to the following institutions:

(1) *Medical Research Council*, up to £26,000 for a twin-engined motor-cruiser for use in the Gambia partly as a floating research laboratory and partly to assist communication between the Council's research laboratories at Fajara and the field station near Keneba. (2) *St. Mary's Hospital Medical School, London*, up to £70,000 for a research floor with animal accommodation in the new wing of the School. (3) *University of Glasgow*, up to £50,000 for the building of a small-animals experimental research unit near the Veterinary Hospital at Garscube. The unit will provide facilities to further research programmes in the various departments of the Medical Faculty and will offer opportunity for co-operative research by the departments of human and veterinary surgery. (4) *St. Thomas's Hospital Medical School, London*, up to £4,000 for extending the accommodation for research on the treatment of cancer by radiotherapy in high-

pressure oxygen. (5) *University College, Cork*, up to £2,000 for the cost of extending the research accommodation in the department of anatomy.

In addition, the Trustees have allocated a sum not exceeding £47,500 for the purchase of four electron microscopes, which will be placed upon indefinite loan with the London Hospital Medical College, the Birmingham School of Medicine, St. Bartholomew's Hospital Medical College, and the Faculty of Medicine at Edinburgh. The Trustees will also provide £2,300 towards the cost of the British component of the Anglo-American physiological expedition to Antarctica.

Windscale Accident.—In reply to questions in Parliament on Tuesday, the PRIME MINISTER promised the House a full statement on the accident to No. 1 reactor at Windscale as soon as there had been opportunity to assess the report of Sir William Penney's investigating committee. Mr. Macmillan added that at the suggestion of the Atomic Energy Authority he was asking the Medical Research Council to give their views on the public health aspects of the accident. The Prime Minister resisted a request for a further inquiry under a chairman not so closely concerned with security considerations as Sir William Penney.

Leverhulme Research Awards.—Senior British-born workers are invited to apply for Leverhulme fellowships and grants in aid of research. Preference is given to subjects where existing provision for research is inadequate, but no subject of inquiry is excluded from consideration. Awards are tenable for periods of between three months and two years. The closing date for applications is December 31. Further details are obtainable from the secretary, Leverhulme Research Awards, St. Bridget's House, Bridewell Place, London, E.C.4.

Postgraduate Travelling Fellowships.—The fellowships offered by the British Postgraduate Medical Federation (see *Journal*, October 19, p. 952) are not tenable at London University, but at university and other centres elsewhere in the United Kingdom or abroad. An advertisement about the fellowships appeared in our issue of October 19 (p. 51 of the advertisements), and further details may be obtained from the assistant director, British Postgraduate Medical Federation, 18, Guilford Street, London, W.C.1.

Unicef Greeting Card Fund.—The United Nations Children's Fund again offers greetings cards for Christmas and the New Year. About half the price of the cards goes towards the Fund, whose aim is the raising of the standard of health and welfare of children throughout the world. This year the following boxes, each containing 10 cards and 10 envelopes, are available at 7s. 6d. a box: "Music for the Children" (five designs); "The Brothers" (one design); "Community of Man" (one design); "The Sewing Lesson and Learning to Write" (two designs); and "Mother and Child" (one design). An illustrated brochure about the fund will be sent on application to the Fund at 14-15, Stratford Place, London, W.1.

Queen's University, Belfast.—Dr. J. PEMBERTON, senior lecturer in social medicine at Sheffield, has been appointed to the chair of social and preventive medicine. Dr. Pemberton was a Rockefeller travelling fellow in medicine in 1954. Dr. J. W. DUNDEE, lecturer in anaesthetics at Liverpool, has been appointed to a lectureship in anaesthetics, and Dr. I. C. RODDIE and Dr. E. W. CLARKE to lectureships in physiology.

N.A.P.T. Canadian Scholarship.—The National Association for the Prevention of Tuberculosis offers a Canadian scholarship of £350 to enable a British chest physician to visit Canada for three to six months in 1958. The tour in Canada will be arranged in conjunction with the Canadian Tuberculosis Association, and the scholar will probably be able to reside free of charge in Canadian sanatoria for part of the time. Applications should reach the secretary-general, N.A.P.T., Tavistock House North, Tavistock Square, London, W.C.1, not later than December 31.

R.C.S. Edinburgh.—At a meeting of the Royal College of Surgeons of Edinburgh on October 16, the honorary fellowship was conferred on Sir HARRY PLATT, F.R.C.S., and on Professor R. I. HARRIS, of Toronto.

Professor J. H. Gaddum, F.R.S., will succeed Dr. I. DE BURGH DALY, F.R.S., as director of the Agricultural Research Council's Institute of Animal Physiology at Cambridge when the latter retires at the end of next September. Professor Gaddum has been professor of materia medica at Edinburgh since 1942.

Professor W. Melville Arnott, professor of medicine at Birmingham, was admitted to the honorary fellowship of the Royal College of Physicians and Surgeons of Canada at a convocation in Montreal on October 19. Professor Arnott is a Sims Commonwealth professor of medicine and had given the annual lecture in medicine.

COMING EVENTS

Bradshaw Lecture.—Professor AUBREY LEWIS will lecture at 5 p.m. on November 7 at the Royal College of Physicians, London, on "Between Guesswork and Certainty in Psychiatry."

The Leeuwenhoek Lecture.—Professor WILSON SMITH, F.R.S., will lecture at 4.30 p.m. on November 7 at the Royal Society, Burlington House, London, on "Virus-Host Cell Interactions."

Contraceptive Technique.—Lecture and demonstration by Mrs. MARIE STOPES, D.Sc., at the Mothers' Clinic, 108, Whitfield Street, London W.1, on November 7 at 2.30 p.m. No fee is charged, but tickets must be obtained in advance.

Royal Photographic Society Exhibition.—Medical Group, annual exhibition, November 7-21, 10 a.m.-5 p.m. daily (excluding Sundays), at 16, Princes Gate, London, S.W.7. Professor MICHAEL BOYD will open the exhibition at 7.30 p.m. on November 7.

Bethlem and Maudsley Biennial Dinner.—November 11, at 7.30 for 8 p.m., at the Connaught Rooms, London. Details from the secretary (Biennial Dinner), Maudsley Hospital, Denmark Hill, London, S.E.5.

Langdon-Brown Lecture.—Dr. R. BODLEY SCOTT will lecture at 5 p.m. on November 12 at the Royal College of Physicians, London, on "The Chemotherapy of Malignant Disease."

British Society for Immunology.—Autumn meeting, November 15 and 16, at the Wellcome Foundation, Euston Road, London, W.C.1. The first day will be devoted to a symposium on "Immuno-haematology."

British Medical Students' Association.—Annual meeting, November 15-17, at the Maternity Hospital, Royal Infirmary, Cardiff. The meeting, which will include a symposium on "The Teaching of Sexual and Marital Relations to the Medical Student," will be opened by Sir TUDOR THOMAS, the honorary president-elect.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Tuesday, November 5

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, W.C., 5.30 p.m., Professor J. V. Dacie: Acquired Haemolytic Anaemia.

ILFORD MEDICAL SOCIETY.—At King George Hospital, Ilford, 8.45 p.m., Dr. B. H. Kirman and Dr. R. C. Greenberg: The Backward Baby: Its Ascertainment and Placement. Members of the Stratford Division, B.M.A., are invited.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. P. F. Borrie: Circulatory and Vascular Reactions.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., Professor Gosta Dohlman (Lund): Treatment of Pharyngeal Diverticulum.

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Mr. E. G. Tuckwell: Operations on the Sympathetic Nervous System.

ST. MARY'S HOSPITAL MEDICAL SCHOOL (WRIGHT-FLEMING INSTITUTE THEATRE).—5 p.m., Mr. F. E. Stabler: Endometriosis.

WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. Colin C. Edwards: Neurological demonstration.

Wednesday, November 6

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Tinea Capitis. **INSTITUTE OF DISEASES OF THE CHEST.**—5 p.m., Mr. V. C. Thompson: Constrictive Pericarditis.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., Dr. I. Friedmann, Dr. D. A. Osborn, and Dr. S. Epstein: clinico-pathological conference. **INSTITUTE OF NEUROLOGY.**—5.30 p.m., Dr. R. A. Henson: Localized Infections and Infestations.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. H. G. Hanley: Tuberculosis of the Renal Tract.

MANCHESTER MEDICAL SOCIETY: SECTION OF MEDICINE.—At Large Anatomy Theatre, Manchester University, 4 for 4.30 p.m., Wing Commander F. Latham: Medical Problems of Flight.

MIDLAND MEDICAL SOCIETY.—At General Hospital, Birmingham, 8.15 p.m., clinical meeting.

NORTHAMPTON MEDICAL SOCIETY.—At Northampton General Hospital, 8 for 8.30 p.m., Dr. F. Dudley Hart: Present Place of the Corticosteroids in Medicine.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. S. W. Stanbury: Renal Function.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. J. D. N. Hill: Epileptic in the Community (illustrated).

Thursday, November 7

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, W.C., 5.30 p.m., Dr. H. Lehmann: Variations in Haemoglobin Synthesis.

FACULTY OF HOMOEOPATHY.—5 p.m., Dr. T. Douglas Ross: Richard Hughes—To-day.

HONYMAN GILLESPIE LECTURES.—At University New Buildings, Teviot Place, Edinburgh, 5 p.m., Mr. A. W. Wilkinson: Basis of Healing.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—4.30 p.m., Mr. J. Howkins: Advanced Carcinoma of the Cervix and its Treatment.

LIVERPOOL MEDICAL INSTITUTION.—At Surgery Theatre, Liverpool University, 5 p.m., Mr. William Doolin: Tale of the Ligature.

LONDON UNIVERSITY.—At Wright-Fleming Institute Lecture Theatre, St. Mary's Hospital Medical School, 5 p.m., special university lecture in medicine by Dr. B. B. Crohn (New York): Life History of Regional Ileitis.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Bradshaw Lecture by Professor A. J. Lewis: Between Guesswork and Certainty in Psychiatry.

ROYAL MEDICAL SOCIETY, EDINBURGH.—At Royal College of Physicians, Edinburgh, 7.15 for 7.30 p.m., President's Annual Dinner.

ROYAL SOCIETY.—4.30 p.m., Leeuwenhoek Lecture by Professor Wilson Smith, F.R.S.: Virus-host Cell Interactions.

SCIENTIFIC FILM ASSOCIATION.—At Royal Photographic Society, 7 p.m., Exhibition of Medical Photography opened by Professor Michael Boyd.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.—4.30 p.m., demonstration and discussion of clinical cases.

Friday, November 8

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. P. D. Samman: clinical demonstration.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. Smart: clinical demonstration.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., clinical discussion for general practitioners by Mr. Maxwell P. Ellis: Nasal Catarrh. 5.30 p.m., clinical lecture by Mr. S. E. Birdsall: Cancer of the Larynx.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Professor M. F. A. Woodruff: Methods of Skin Replacement with Special Reference to the Use of Homotransplants. 4 p.m., Professor A. C. Frazer: Differential Diagnosis and Treatment of Scleroderma.

ROYAL MEDICAL SOCIETY, EDINBURGH.—8 p.m., dissertation by Mr. D. A. R. Robertson: X-ray as an Aid to Diagnosis in the Acute Abdomen.

YORKSHIRE THORACIC SOCIETY.—At Instructional Block, General Infirmary at Leeds, 5.10 for 5.30 p.m., clinical meeting.

Saturday, November 9

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—11.15 a.m., Mr. A. L. Gunn: Use and Value of Kielland's Forceps.

Sunday, November 10

COLLEGE OF GENERAL PRACTITIONERS: MIDLAND FACULTY.—At Board Room, Worcester Royal Infirmary, 11 a.m., Dr. W. H. Lyle and Dr. R. J. Henderson: The Practitioner, Virus Studies, and the Routine Laboratory.

APPOINTMENTS

ELITHORN, ALICK, M.D., M.R.C.P., D.P.M., Consultant Physician in Psychological Medicine to Royal Free Hospital.

NEYLON, JOHN PATRICK, M.B., B.Ch., B.A.O., D.P.H., D.C.H., Medical Officer of Health for Biston Municipal Borough and Assistant County Medical Officer, Staffordshire.

STORY, PETER, M.D., Part-time Consultant in Clinical Pathology at St. Bartholomew's Hospital, London, E.C.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Lennox.—On October 23, 1957, at Irvine Central Hospital, Ayrshire, to Dr. Elizabeth Leslie (formerly Handasyde), wife of Dr. Ian Gordon Lennox, a brother for Lynda—Ian Bruce.

Young.—On October 19, 1957, in Saskatoon, Canada, to Margot, wife of Dr. F. O. Young, a son—Peter Leslie.

DEATHS

Bennett.—On October 10, 1957, at Green Gables, Shrivensham, Berks, Alexander William Charles Bennett, M.R.C.S., L.R.C.P., aged 71.

Kinloch.—On October 11, 1957, at Elidon View, Redpath, Earlston, Berwickshire, Peter Stewart Kinloch, M.B., Ch.B.

Landsborough.—On October 11, 1957, at Redhill, Surrey, David Landsborough, M.D., late of Formosa, aged 87.

Metcalfe.—On October 5, 1957, at Island House, Liskeard, Cornwall, Brian Bentley Metcalfe, M.R.C.S., L.R.C.P., J.P., aged 75.

Urquhart.—On October 10, 1957, at Glebe House, Crook, Kendal, Westmorland, George Hector Urquhart, F.R.C.S.Ed., late of Clifton Drive, St. Annes-on-Sea, Lancs.

Wilson.—On October 7, 1957, in a nursing-home, Ambrose Cyril Wilson, M.R.C.S., L.R.C.P., late of 17, Harley Street, London, W.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Congenital Virus Infections

Q.—If a mother suffers a virus infection in late pregnancy can she transmit the disease to her infant so that it is born with it or develops it shortly after? Can this also happen if the mother suffers a subclinical infection?

A.—Congenital (intrauterine) chicken-pox is known and the virus, like many other viruses, can pass through the placenta, though it is possible for a pregnant woman to suffer from chicken-pox or other virus disease without transmitting the disease to the foetus. Cases of smallpox, measles, and mumps occurring within the first few days of life are also on record. Subclinical infections with all virus diseases are common; variola sine eruptione is a well-known syndrome, though perhaps it can scarcely be called subclinical: probably it denotes viraemia. A similar condition may reasonably be expected to occur in chicken-pox, and, if so, there would be nothing to prevent intrauterine transmission to the foetus. Whether the infant developed spots or not would depend on the balance between the load of virus and of antibody transmitted from the mother.

Fibrocystic Disease of the Pancreas

Q.—What is known about the familial incidence of fibrocystic disease of the pancreas? If the first child of a family is affected, what is the risk to subsequent children?

A.—All the available evidence supports the idea that fibrocystic disease of the pancreas is genetically determined and that it is carried by a recessive gene. The number of family histories recorded makes it reasonably certain that this is correct, although it cannot be said to be absolutely proved. The risk that a child of parents who carry the recessive gene will be affected is 1 in 4. The gene seems to behave as a simple recessive with no linkages, and therefore it makes no difference whether the child is the first, second, third, or a later one—the risk remains the same.

The usual reason for wishing to know the incidence is the need to advise parents who have had one affected child and who wish to have another baby. The answer is difficult, but it is possible to say that the odds against any further child being affected are 3 to 1, and therefore if they have no unaffected children and are very anxious to have children of their own it is a risk that is worth taking. On the other hand, if they already have one or more unaffected children or feel that they cannot face the anxiety or do not think it fair to bring yet another child into the world with this condition, then the risk is obviously too high. In practice, many parents who have lost one or two babies with this condition have taken the risk and have found it worth while, in order that they may have a normal child of their own.

Another anxiety for the future is whether children with the condition who grow up and marry will have affected children. This has not yet occurred, as, in the past, death has prevented sufferers from this disease reaching marriageable age. If a person with fibrocystic disease does in the future (as is quite possible) live long enough to bear children, then there is a risk that his or her children will be affected if he or she happens to marry a carrier of the recessive gene. There is also an increased risk that the normal brothers and sisters of an affected child will carry the gene and will therefore have a slightly increased risk of having affected children, but only if they marry another carrier of the gene. The marriage of cousins in families with this condition should be discouraged because of the increased risk that each will carry the recessive gene and that therefore their children will be liable to the disease itself.

Ratio of Non-paralytic to Paralytic Poliomyelitis

Q.—During a non-epidemic period last spring when we saw six cases of paralytic poliomyelitis in our practice there were only about five or six other cases clinically suggestive of the disease. Surely this is a very low incidence? We were very much on the lookout for the condition at the time, as the first paralytic case took us unawares.

A.—Far from being unusual, this low incidence of suspects is to be expected in the vicinity of cases of poliomyelitis. If cases of indefinite illness or meningism, or benign meningitis without paralysis, are numerous, it is wise to think of a cause other than poliomyelitis virus. Outbreaks of neurotropic infections of uncertain origin are discussed on p. 68 of the Chief Medical Officer's report "On the State of the Public Health" for the year 1955,¹ which provides the following table:

Poliomyelitis, Corrected Notifications

Total	Non-paralytic Cases as Percentage of Total	Non-paralytic Cases as Percentage of Total by Quarters			
		1	2	3	4
1950 ..	7,760	23.8	22.5	30.9	24.9
1951 ..	2,614	41.5	45.6	52.7	30.8
1952 ..	3,910	23.2	32.9	32.3	22.8
1953 ..	4,547	34.6	20.4	26.1	39.3
1954 ..	1,960	32.7	24.7	28.7	37.6
1955 ..	6,331	41.4	18.7	30.3	46.5

In 1950, 1952, and 1954 the ratio remained surprisingly constant, about one-third of the cases being non-paralytic with only slight variation from week to week. Consequently the curves of the two forms were approximately parallel throughout the year. In 1951, 1953, and 1955 the pattern was different, and during a period of a few weeks in each year the ratio of non-paralytic to paralytic approached or exceeded 50% of the total notifications of poliomyelitis and the curves of the two forms became independent. The ratio between the two forms (paralytic and non-paralytic) was disproportionate in a few localities only, and when investigations were made in these areas it was found that in most of them outbreaks simulating poliomyelitis but not due to polio virus were occurring.

Release Pain as Sign of Peritonitis

Q.—What is the reliability of "release pain" as a sign of peritonitis in suspected cases, especially when guarding is absent? What is the explanation of the sign?

A.—Not too much attention should be paid to release pain in suspected cases of acute peritonitis. The explanation of the sign is that when the peritoneum is inflamed any quick movement of the affected area will be painful, so if the parietal peritoneum is inflamed under the site of palpation the patient will feel pain when the hand is quickly removed. Different patients may or may not interpret the same stimulus as pain, and signs which rely on the patient's conscious response must always be treated with reserve. Peritonitis which affects a part of the parietal peritoneum of the anterior abdominal wall will almost always be accompanied by some degree of rigidity; in the absence of any guarding, release pain can almost certainly be ignored as evidence of acute peritonitis.

Heparinized Plasma for Cross-matching

Q.—In emergency blood transfusion, when there is no time to wait for the recipient's blood to clot, is it permissible to use plasma from heparinized blood for compatibility testing?

A.—It is not wise to use heparinized plasma for cross-matching, because the fibrinogen will interfere by producing

rouleaux and making it very difficult, or impossible, to read the result. Clotting can usually be completed within a few seconds by adding a drop of thrombin solution or a fragment of solid thrombin. Thrombin is sold commercially and should be available in all hospital laboratories.

It must be very unusual to have to give blood so quickly that one cannot wait for the blood to clot; the only such occasion the writer can remember was with a bleeding haemophiliac, but his blood was clotted quickly with thrombin. In nearly all desperate emergencies infusion of plasma or dextran will maintain blood volume and blood pressure for long enough to permit cross-matching by one of the rapid methods (for example, by the tube-centrifuge method); and, if this takes too long, one may have to use un-cross-matched blood of Group O, preferably Rhesus negative. This should be a very rare necessity—perhaps once in several thousand transfusions.

Treatment of Progressive Exophthalmos

Q.—What treatment is advised in cases of exophthalmic goitre where the condition is well controlled by propyl thiouracil but the patient is developing severe exophthalmos?

A.—Exophthalmos may develop or become more marked in patients with Graves's disease whether treated by anti-thyroid drugs, radio-iodine, or partial thyroidectomy. It has been suggested that, as treatment reduces the plasma level of thyroid hormone, the pituitary secretes increased amounts of thyrotrophin (which causes enlargement of the thyroid gland) and of the hypothetical exophthalmos-producing substance (which increases the proptosis). In an attempt to suppress pituitary overactivity thyroid extract, 2–3 gr. (0.13–0.2 g.), or thyroxine, 0.2–0.3 mg., may be given daily concurrently with antithyroid treatment; this usually prevents further thyroid enlargement and may arrest further progression of the exophthalmos.

If the exophthalmos increases despite this treatment, a variety of other measures may be tried, their large number indicating that none is invariably effective—bed rest, heavy sedation, cortisone, x-ray therapy to the pituitary or orbital tissues, or, in severe cases when sight is threatened, decompression of the orbit by the temporal route. The eye symptoms are usually self-limiting, and after a variable time the exophthalmos stops progressing and may even recede a little, but the cosmetic result is seldom good.

Taste and Odour of Milk

Q.—What substances in milks of different origin—human, cow, goat, etc.—account for their different tastes and odours?

A.—The differences in the tastes of the milks of different species, provided the milk has been produced under clean conditions by healthy animals and kept under cool conditions, are due to the variations in the actual and relative proportions of lactose, various salts, fat, proteins, etc., present, and to differences in pH. The constitution of the fat, and the fat globule size, may also play a part, but the lactose and salts have the greatest influence. For example, human milk has a much higher lactose content, and a lower sodium chloride content, than cow's milk, and it is higher in pH.

Odours are seldom detectable in really clean, fresh milk, although under poor conditions odours are readily picked up from the animal and its surroundings. But if the milk is kept under conditions which favour even slight bacterial or enzymic breakdown of its constituents, then odours—different odours—arise from the varying types and proportions of volatile acids, etc., resulting mainly from the decomposition of the fats and lactose. The milk fats of the different species differ markedly in the proportions of combined fatty acids present, and this affects the odour; for example, goat's milk fat contains an unusually high proportion of capric acid ($C_{10}H_{19}COOH$)—hence the acid's

name—which has a characteristic "goaty" odour in the free form in which small amounts are liberated by the action of lipase.

Alcohol in Peptic Ulcer

Q.—Is it still regarded as necessary to ban alcohol completely in peptic ulcer, or are drinks of low alcoholic content, such as beer, harmless in moderate quantities for such cases? What about wines?

A.—There is no convincing scientific evidence that alcohol is harmful to patients with peptic ulcer. There is, however, a strong impression that certain types of alcohol are worse than others, and it is known that alcohol is a strong stimulant of gastric secretion. It is probably wise to forbid alcohol altogether during the stage of active treatment of an ulcer, and this ban should possibly be maintained for as long as three months. After that time there would seem no reason not to allow beer, diluted spirits, or wine, so long as the quantity taken is moderate and they are not taken on an empty stomach. There is a strong impression that brandy is particularly liable to bring on pain and that red wine is worse than white wine. In both cases the effect may be due to the presence of irritant substances other than alcohol.

Massage for Unwelcome Contours

Q.—Can massage disperse local accumulations of fat? If so, where do they go?

A.—Fat, being semi-fluid at body temperature, can be "shifted about" to some extent by a skilled masseuse or with a vibrator. But massage, while being possibly able slightly to alter contours, will not reduce weight. There is no easy short cut to loss of weight or girth in massage.

Metallic Taste in Mouth

Q.—What are the possible causes of an unpleasant metallic taste in the mouth, and how may it be prevented?

A.—An unpleasant metallic taste in the mouth is occasionally caused by galvanic action taking place between two dissimilar metals—for example, when gold dentures are in intermittent contact with amalgam fillings. In the majority of cases there is, however, no local cause for this symptom, which must be regarded as functional. It is rather common in women over 50 years of age.

Correction.—In the list of "Approved Names" printed in our issue of October 26 (p. 995), hydroxydione sodium succinate should have been described as an intravenous basal anaesthetic.

Collected Articles from the "British Medical Journal"

The following books are available through booksellers or from the Publishing Manager, B.M.A. House. Prices, which include postage, are now the same for both inland and overseas.

Emergencies in General Practice (26s. 9d.).

Refresher Course for General Practitioners, Volumes 2 and 3 (26s. 9d. each).

Clinical Pathology in General Practice (22s. 3d.).

Any Questions?, Volumes 2 and 3 (8s. 3d. each).

NERVE REPAIR IN CIVIL PRACTICE RESULTS OF TREATMENT OF MEDIAN AND ULNAR NERVE LESIONS

BY

O. R. NICHOLSON, F.R.C.S.

Orthopaedic Surgeon, Middlemore Hospital, Auckland, New Zealand; late Clinical Research Assistant, Institute of Orthopaedics, London

AND

H. J. SEDDON, C.M.G., F.R.C.S.

Director of Studies, Institute of Orthopaedics, University of London

TABLE I.—Cases Available for Analysis

Nerve	Sutured Alone	Both Nerves Repaired	Total	Total Repairs	Total Patients
Ulnar	135	28	163	305	277
Median	114	28	142		

The results of nerve repair carried out in Great Britain during the second world war have been analysed and reported by the Nerve Injuries Committee of the Medical Research Council in "Peripheral Nerve Injuries" (1954). This report is often referred to, and for the sake of brevity is described as the P.N.I. Report.

Most of the patients treated in the wartime nerve injuries centres suffered injuries that were a direct result of war, but in some cases the injuries were the same as those encountered in civil life, such as lacerations with broken glass. The latter were too few to be compared with the war injuries, but it seemed likely that the results of treatment were better. Civil wounds are for the most part cleaner and less extensive, secondary suture can be undertaken earlier, the loss of nerve tissue is less, and the resection required is shorter. Both of these factors have been shown to give better results (P.N.I. Report, p. 367).

Sufficient time has now elapsed for the accumulation of a series of repairs following civil injuries, and, as the median and ulnar nerves are by far the most commonly involved, this study is confined to the results of repair of these nerves. The results of digital nerve repair are excluded.

Cases Available for Assessment

1. *Cases of Civil Injury Treated at the Oxford Nerve Injuries Centre from 1941 until 1948* (this unit was transferred to the Royal National Orthopaedic Hospital in 1948).—The records of the Oxford cases were available and a number of the patients attended for re-examination.

2. *Patients Treated at the Royal National Orthopaedic Hospital from 1948 until the End of 1954*.—Cases due to gunshot and similar wounds have been excluded.

3. *Cases of Primary Suture, for the most part Performed Elsewhere and Referred for Supervision*.—A number of patients in whom primary suture had been performed were referred because recovery had been poor and secondary suture was carried out. For this reason the results of primary nerve suture in this series do not give an exact picture of the reliability of the operation.

The number of cases followed up is shown in Table I. These figures do not represent the relative incidence of single and combined nerve injury. In a number of cases in which both nerves had been injured and repaired the

patients were referred for further treatment following failure of suture in only one of them, and consequently only one was resutured.

Method of Analysis of Recovery

The method of analysis of recovery recommended in the P.N.I. Report has been followed without modification, except that cases in which less than three years has elapsed since the time of repair have been included. The patients who attended for re-examination were examined by one of us (O.R.N.) with the assistance of Dr. Constantin Schuler, of Zurich. Thus they were examined by two observers, neither of whom had carried out any of the operations in this series.

Duration of Post-operative Observation

Recovery was not considered maximal until at least three years had elapsed since the time of repair. Cases in which less than three years had elapsed since the time of repair were included in the tables in order to show the grade of recovery that could be expected in the earlier years. This may be of assistance in deciding whether a sutured nerve should be re-explored. Patients who were followed for less than one year have been excluded. A total of 132 repairs have been followed up for five to fifteen years.

Lapse Rate

The lapse rate for cases in which a three-year follow-up was possible is shown in Table II. A number of patients who failed to attend were operated on towards the end of the Oxford period and were unable to travel the extra distance to London for re-examination.

TABLE II.—Lapse Rate at Three Years

Nerve	Total Cases	Repaired More than 3 Years Previously	Follow-up at 3 Years	Lapse Rate
Ulnar	163	142	103	39/142 (36.4%)
Median	142	119	95	24/119 (20.8%)

As in the P.N.I. Report, all lapsed cases have been excluded from the analysis year by year. In view of the number of patients achieving a useful grade of recovery in less than three years it was tempting to include them in the final analysis and to present two possible extremes of recovery rate, in the first assuming that all lapsed cases had failed to show further recovery, and in the second assuming that all lapsed cases recovered satisfactorily. This method, however, was not adopted so that it might be possible to compare the results in the present series directly with those in the P.N.I. Report. It is even more probable in the present series than in those described by Zachary in the Report that this has resulted in an underestimate of the proportion of recoveries, because civilians seem less likely to continue to report if recovery is satisfactory than pensioners, who are required to attend for periodic re-examination.

Grading of Recovery

Sensory Recovery.—This is designated by the letter S followed by a figure for the grade of recovery. 0=absence of sensibility in the cutaneous zone supplied exclusively by the nerve concerned (the autonomous zone). 1=recovery of deep cutaneous pain within the autonomous zone. 2=return of some degree of superficial pain and tactile sensibility within the autonomous zone. 2+=return of tactile and pain sensibility throughout the autonomous zone but with persistent overreaction. 3=return of superficial pain and tactile sensibility throughout the autonomous zone with the disappearance of overreaction. 3+=as for grade 3, with good localization of stimuli and some return of two-point discrimination. 4=complete recovery.

Motor Recovery.—This is designated by the letter M followed by a figure for the grade of recovery. 0=no contraction. 1=return of perceptible contraction in the forearm muscles. 1+=median: forearm muscles able to contract against gravity but paralysis of the thenar muscles; ulnar: forearm muscles able to contract against gravity but paralysis of the ulnar intrinsic muscles of the hand. 2=median: forearm muscles able to contract against gravity and feeble action in the thenar muscles; ulnar: forearm muscles able to contract against gravity and some power in the hypothenars, but little or none in the interossei. 2+=ulnar only: forearm and hand muscles all active, but the first dorsal interosseous unable to contract against resistance. 3=median: forearm and thenar muscles able to contract against resistance; ulnar: forearm muscles, hypothenars, and first dorsal interosseous able to contract against resistance. 4=median: all muscles able to contract against strong resistance with some independent action; ulnar: all muscles able to contract against resistance with some independent lateral movement of fingers. 5=full recovery in all muscles.

Useful Grade of Recovery in Relation to Level of Injury

The useful grade of recovery for each nerve was defined in the P.N.I. Report and has been followed here. The following have been adopted as definitions of the level of injury:

Nerve	Proximal	Intermediate	Distal
Ulnar	Above branches to flexor carpi ulnaris	Between branches to flexor carpi ulnaris and flexor digitorum profundus	Distal to branches to flexor digitorum profundus
Median	Above branches to pronator teres	Between branches to pronator teres and flexor pollicis longus	Distal to branch to flexor pollicis longus

Ulnar Nerve.—The useful grade of recovery in distal and intermediate repairs is that in which all the hand muscles are active (M2+) and there is return of tactile and pain sensibility throughout the autonomous zone but with overreaction (S2+).

Median Nerve.—The useful grade of recovery in distal and intermediate repairs is that in which the thenar muscles are able to contract against resistance (M3) and there is return of tactile and pain sensibility throughout the autonomous zone but with overreaction (S2+).

After proximal repairs return of power in the long flexor muscles (M1+) is regarded as a useful grade of recovery—that is, sufficient to warrant the performance of the operation.

For the purposes of analysis of recovery all patients in whom the muscles are able to contract against strong resistance with some independent action (M4), and where there is good localization of stimuli and some return of two-point discrimination (S3+), are considered as one group. Patients showing no recovery are grouped with those in whom recovery is so slight as to be valueless.

The Injuries

Types of Wound.—Most of the wounds were lacerations and were usually caused by broken glass—milk bottles, windows, and glass doors. This accounted for 287 nerve injuries (94%). Incised wounds caused by a knife or similar instrument accounted for only 14 (4.6%). Traction caused disruption of a nerve in two cases (0.7%), while compression causing a lesion in continuity, for which resection and suture was carried out, accounted for a further two (0.7%).

Associated Injuries.—(a) Other nerves. In 45 of the 142 median nerve lesions (31.3%) the ulnar nerve was also involved to some extent, while in 33 of the 163 ulnar nerve lesions (20.2%) the median nerve was also involved. (b) Significant tendon injury—that is, involving the long tendons of the digits—was present in 85 of the 142 median nerve lesions (59.9%) and 66 of the 163 ulnar nerve lesions (40.5%). (c) Fractures occurred in nine of the median cases and five of the ulnar cases. (d) Sepsis of a degree greater than slight redness of the skin edges occurred in only three cases (1.08%) following the primary treatment of the wound and in none following second suture.

Results of Repair of Ulnar Nerve

In this series there was a great preponderance of distal repairs of the ulnar nerve, whereas in the series presented in the P.N.I. Report nearly one-third of the sutures were proximal. Consequently no comparison of the two complete series is admissible.

Distal Repairs

Table III shows the return of motor function after all distal repairs of the ulnar nerve irrespective of the gap after resection and of the delay before repair. A useful grade of

C%=Cumulative percentage throughout tables.

recovery (M2+) occurred in 81.7% of cases, while no less than 35% regained some independent lateral movement of the fingers (M4).

The incidence of useful recovery may be compared with that in the most favourable group of distal ulnar sutures in the P.N.I. Report (delay before operation less than six

months and a gap of less than 5 cm.—Table 91, p. 378). This is to some extent weighting the balance against the present series, because not all the lesions in the latter were distal, not all the gaps were short, and not all the repairs were undertaken within less than six months from the time of injury. There was useful recovery in 78.5% of the cases in Table 91, and 16% regained some independent lateral movement of the fingers. The overall recovery rate is not significantly better in the present series, but the proportion regaining independent movement is higher—35%. A further breakdown of the present series in order to make the groups exactly comparable is not warranted and would confuse the general aim of presenting the average grade of recovery that may be expected after the average type of civil injury. The results are shown graphically in Fig. 1.

FIG. 1.—Ulnar nerve. Distal repair; motor recovery. Compares Table III with the P.N.I. Report, Table 91.

Useful sensory recovery (S2+) occurred in 82.5% of cases, and 68.5% reached grade S3—that is, overreaction was absent (Table III). These figures compare with 64.6% reaching grade S2+ and 49.5% reaching grade S3 in the most favourable group of the P.N.I. Report series (Table 92, p. 379). The results are significantly better in the present series, and are shown graphically in Fig. 2.

FIG. 2.—Ulnar nerve. Distal repair; sensory recovery. Compares Table III with P.N.I. Report, Table 92.

The results may be summarized by saying that four out of five distal repairs of the ulnar nerve led to a useful sensory and motor recovery; two out of three reached the grade of sensory recovery in which there was no overreaction; one case in three showed some independent finger movement. However, the independent finger movement was never perfect, and was usually readily apparent only in the index finger. Even so, it materially improved the function of the hand.

Intermediate Repairs

The number in this group is small and cannot be compared with the distal repairs, but seven out of eight patients who attended at the end of three years had made an adequate motor recovery and five out of nine an adequate sensory recovery. This discrepancy in numbers is due to all the intrinsic muscles of the hand being innervated by the median nerve in one patient (Table IV).

Proximal Repairs

The number in this group is also small, but at the end of three years all patients had made an adequate motor recovery—that is, the long flexor muscles contracted against gravity—and indeed seven of the nine patients showed useful recovery in the intrinsic muscles of the hand and six had made an adequate sensory recovery (Table V).

Results of Repair of Median Nerve

As with the ulnar nerve, a satisfactory comparison can be made only of the results of distal repair.

Distal Repairs

Table VI shows the return of motor function in all cases of distal repair of the median nerve irrespective of the gap

after resection and of the delay before repair. A useful grade of recovery (M3) was obtained in 65.4% of cases compared with 42.6% in the most favourable group of distal median sutures in the P.N.I. Report (delay less than six months and gap less than 5 cm.—Table 93, p. 379). The results are shown graphically in Fig. 3.

Fig. 3.—Median nerve. Distal repair, motor recovery. Compares Table VI with P.N.I. Report, Table 93.

Sensory recovery of a useful grade (S2+) occurred in 79.3% of cases and 64.2% reached the higher grade of S3—that is, overreaction was absent (Table VI). These figures compare with 68% reaching grade S2+ and 52% reaching grade S3 in the most favourable group of the P.N.I. Report series (Table 94, p. 380). The results in the present series appear slightly more favourable but are not significantly better (Fig. 4).

Fig. 4.—Median nerve. Distal repair, sensory recovery. Compares Table VI with P.N.I. Report, Table 94.

The results may be summarized by saying that two out of three distal repairs of the median nerve led to useful motor recovery, four out of five gave a useful grade of sensory recovery, while two out of three reached the grade of sensory recovery in which overreaction was absent.

It may seem that the results of median nerve repair are inferior to those of the ulnar, but the respective definitions of useful motor recovery are different. In the case of the ulnar nerve all muscles are required to be active—that is, contracting against gravity—and this, in the interosseus, is useful. In the case of the median nerve the thenar muscles are, in addition, required to contract against resistance, as this power is essential in grasping.

Intermediate Repairs

The number in this group is small and cannot be compared with the distal repairs, but two of the three patients seen at the end of three years showed adequate motor and sensory recovery (Table VII).

Factors Influencing Recovery

The factors influencing recovery considered in the P.N.I. Report (p. 366) were the level of injury, the delay before repair, and the extent of the gap to be closed. It was not considered justifiable to break down the series into groups corresponding to other factors. In the present series the nature of the wound was essentially the same throughout, and an attempt has been made to assess the effect of other factors.

Age

The age distribution of the combined group of 305 ulnar and median nerve repairs was: 0–10 years, 32 repairs; 11–20 years, 86 repairs; 21–50 years, 174 repairs; over 50 years, 13 repairs.

The numbers in each age group are smaller when cases operated on less than three years previously and lapsed cases are excluded, and too small for any significant deduction to be made on the influence of age on recovery, apart from patients in the 0–10 years group. Twenty-three distal repairs were carried out on 22 patients; sensory recovery was adequate in all, and in only one case was motor recovery defective. It may be just worth mentioning, though the figures are not strictly significant, that seven patients out of the 13 over 50 were followed for three years or more, and two showed adequate motor and four adequate sensory recovery.

Level of Lesion

The large number of proximal sutures described in the P.N.I. Report made it possible to demonstrate that the more

proximal the lesion the worse the prognosis. The influence of this factor cannot be assessed in the present series, but no further demonstration is necessary.

Extent of Gap

As might be expected the average gap after resection in this series was small. The figures are shown in Table IX.

TABLE IX.—Distribution of Cases According to Gap After Resection

Gap in cm.	Ulnar Nerve		Median Nerve	
	No.	%	No.	%
2.5 or less	91	56.2	52	36.6
2.6–5	59	36.4	72	50.7
5.1–7.5	11	6.8	10	7.1
Over 7.5	1	0.6	8	5.6
Total No.	162*	100.0	142	100.0

* In one case the gap was not recorded

It has been shown in the P.N.I. Report (p. 374) that a gap of over 5 cm. is prejudicial to recovery. For any given gap the mobilization required to permit satisfactory apposition of the nerve ends is more extensive in a child than in an adult; hence in comparing recovery in relation to the gap after resection only adults are considered—that is, patients over the age of 17 years. In distal repairs of the median nerve a higher proportion recovered after a short resection (up to 2.5 cm.) than after a longer one (2.6–5 cm.), but the groups are small and the difference is hardly great enough to be significant (Table X). There was no significant differ-

TABLE X.—Median Nerve Recovery in Relation to Gap (Distal Repairs—Patients Over 17 Years)

Gap in cm.	No. of Cases	No. Reaching M3	No. Reaching S2+

2.6–5	32 motor 33 sensory	16 (50%)	20 (60.6%)

ence between the two groups in distal repairs of the ulnar nerve (Table XI). In the ulnar nerve a more extensive gap may be overcome by anterior transposition of the nerve and there is little chance of intraneural changes occurring as a

TABLE XI.—Ulnar Nerve Recovery in Relation to Gap (Distal Repairs—Patients Over 17 Years)

Gap in cm.	No. of Cases	No. Reaching M2+	No. Reaching S2+
2.5 or less	42 (motor and sensory)	34 (80.9%)	33 (78.6%)
2.6–5	26	21 (80.7%)	18 (68.9%)

result of post-operative stretching; but in the median nerve there is no comparable method of closing an extensive gap, and this may be the reason why the results of suture of the ulnar nerve are rather better than those of the median.

Extent of Mobilization

In cases in which there was a large gap the lower recovery rate might be due to: (1) disparity in size of the proximal and distal stumps of the nerve, making satisfactory suture difficult; (2) incongruity of the funicular pattern at the suture line; or (3) the adverse effect of mobilization of the nerve which was required in order to close the gap. It is possible that the nerve is partially devascularized by the mobilization, although it has been shown that adequate recovery can occur through free grafts of the ulnar to the median nerve (P.N.I. Report, Table 112, p. 406).

An answer to this question is provided by the results of median nerve suture at the wrist, for which alternative methods of mobilization are available for the closure of gaps of comparable extent. A gap of up to 2.5 cm. may frequently be closed by local mobilization of the nerve, flexing the elbow to 90 degrees and the wrist to 30–45 degrees. Alternatively, in order to allow the wrist to remain in the neutral position, full mobilization of the nerve to the

elbow may be carried out by division of the radial head of flexor sublimis digitorum and also, if necessary, reflection of the superficial head of pronator teres and mobilization of the branches of the nerve.

The numbers in the groups studied are small, but a higher proportion reached the higher grades of motor recovery after only local mobilization (Table XII). The grade of sensory

TABLE XII.—Median Nerve. Effect of Mobilization on Recovery (Age Group 11–50. Gap up to 2.5 cm.)

	No. of Cases	No. Reaching M4	No. Reaching S3
Local mobilization	13 motor 14 sensory	10 (72.0%)	12 (85.7%)
Extensive mobilization	9	2 (22.2%)	7 (77.7%)

recovery does not appear to be affected by the extent of the mobilization. This suggests that devascularization may to some extent impair recovery, and mobilization should not be more extensive than is necessary to close the gap without tension. In distal lesions of the median and ulnar nerves alike, a gap after resection of over 2.5 cm. will nearly always require full mobilization. This is described above for the median nerve; for the ulnar nerve, anterior transposition of the nerve at the elbow is required.

If further flexion, beyond the angles mentioned above, is required in order to close the gap harmful intraneural fibrosis is likely to develop as a result of stretching of the nerve in the post-operative period. The alternative, nerve grafting, may be preferable. In this series nerve grafts were used in the repair of seven ulnar and 19 median nerve lesions. The grafts were used (1) where the gap was too great to be closed by the usual methods of mobilization—21 cases; and (2) where there was a partial (funicular) lesion of the nerve—five cases. The results in this group are not presented, as they have already been reported by Brooks (1955).

Delay Before Repair

It has been shown in the P.N.I. Report that a delay before suture of over six months is prejudicial to recovery. The delay before repair in the present series is shown in Table XIII; 78.4% were repaired within six months, and

TABLE XIII.—Ulnar and Median Nerves. Delay Before Repair

Delay	No. of Repairs	Percentage
Up to 3 months	165	54.2
3–6	74	24.2
6–9	27	8.8
Over 9	39	12.8
Total No.	305	

thus the factor of delay was not strongly operative. Adequate recovery may still occur if the delay before repair is more than six months; in ulnar nerve repairs 64.7% made an adequate motor recovery and 68.8% an adequate sensory recovery, while in median nerve repairs 56.7% made an adequate motor recovery and 67.7% an adequate sensory recovery (Table XIV). Although a long delay

TABLE XIV.—Recovery in Cases Repaired After Six Months

Nerve	No. of Cases	No. Reaching M2+ (Ulnar) M3 (Median)	No. Reaching S2+
Ulnar	17 motor 16 sensory	11 (64.7%)	11 (68.8%)
Median	30 motor 31 sensory	17 (56.7%)	21 (67.7%)

before repair is undesirable, late repairs should still be done in the knowledge that a good return of function may be obtained in a reasonable proportion of cases. However, this is true only when most of the lesions are distal and the regenerating axons have therefore to traverse a short length of nerve.

Histological Grading

The nerve ends resected at the time of operation were usually examined histologically, and these findings have been investigated with a view to determining whether poor recovery could be correlated with the state of the resected stumps. It should, however, be noted that all the material in this series fulfilled the gross criteria of an adequate resection—i.e., there was no palpable induration of the nerve, the nerve bundles were easily distinguishable, and the epineurium was mobile.

The histological evidence of adequate resection is a normal arrangement of bundles in both stumps of the nerve and absence of endoneurial fibrosis. Perineurial fibrosis is unimportant. In most cases the resection was adequate, and where there was some degree of endoneurial fibrosis it was usually in the distal stump. This emphasizes the particular difficulty in deciding whether the distal resection is adequate. The proximal nerve bundles, which contain myelinated fibres, look like ground glass when cut across, but the distal bundles are much smaller, and, being devoid of nerve fibres, do not stand out so clearly from the interfascicular tissue. It is also likely that the sclerosing changes in the distal stump are more extensive as a result of ischaemia caused by interruption of the longitudinal blood supply (P.N.I. Report, p. 123).

When the cases of poor recovery after suture were examined there did not seem to be any histological feature to account for the failures.

Primary Suture

Sixteen primary sutures of the median nerve and 22 primary sutures of the ulnar nerve were seen in this series. Most of these cases had been operated on elsewhere; they had been referred for supervision and no resuture was performed. The results in patients with an adequate follow-up are summarized in Table XV.

TABLE XV.—Results of Primary Suture in Cases Followed Up for Three or More Years

Grade of Recovery	No. of Cases	Cumulative Percentage of Total Number
Ulnar nerve (16 cases):		
M3	8	50.0
M2+	4	75.0
S3	11	68.8
S2+	2	81.3
Median nerve (13 cases):		
M4	6	46.1
M3	3	69.2
S3	8	61.5
S2+	3	84.6

In this small group the proportion reaching the higher grades of recovery is not significantly better than in the total results, and only one case was seen of an exceptionally good recovery after primary suture.

There is then no reason to modify the previously published statement that early secondary suture offers equally good prospects of recovery and is best used routinely because of its greater reliability. Primary suture may be carried out in the rare clean incised wound where there is minimal tendon and soft-tissue damage. Nevertheless re-exploration of the suture site should be carried out if there are no definite signs of recovery by the end of six months or if a palpable neuroma develops at the suture site within this time. Further delay may be harmful. Yet even in these uncommon cases there are technical objections to primary suture. The fresh epineurium is often too thin to hold sutures securely, whereas by the time secondary suture is undertaken it is two to four times its normal thickness and holds sutures well. Furthermore, there may have been interstitial damage to the nerve, the extent of which cannot be determined at the time of injury but which is clearly manifest a few weeks later as palpable, and, on section, visible intraneural fibrosis.

It is unfortunate that, although primary suture still has its advocates, there is no series available for comparison in which a strict grading of the degree of recovery has been recorded.

Associated Tendon Injuries

Significant tendon injury occurred in almost half the cases in this series. The most satisfactory results were seen after the following programme of treatment. The flexor tendons are sutured immediately and the nerve ends simply approximated in their correct orientation. Every effort is made to obtain full mobility of the digits, the only treatment of the nerve injury being galvanic stimulation of the paralysed muscles of the hand to prevent progressive wasting. When the tendons are acting well a secondary nerve suture is performed. There is no disturbance of the tendons, because they lie deep to the nerves, and, for the same reason, movement of the fingers does not disturb the line of suture of the nerve. At the time of secondary suture the amount of nerve to be resected is readily ascertained and if the nerve ends have been approximated initially the gap after resection is minimal.

It is also worth mentioning that the surgeon, at the end of a long primary operation for tendon and wound repair, is less likely to perform a technically satisfactory nerve suture than when repairing the nerve alone at a secondary operation undertaken at leisure.

Summary

During the second world war surgeons in Great Britain who were specially devoted to the investigation and treatment of peripheral nerve injuries devised a precise method for the assessment of recovery, and the results, presented in the Report of the Nerve Injuries Committee of the Medical Research Council, are perhaps the most accurate that exist. The same method has now been applied in a study of the commonest nerve injuries encountered in civil practice, those of the median and ulnar nerves. This paper is concerned with the end-results of nerve suture after 305 repairs in 277 patients, most of whom had suffered injury in the region of the wrist. The period of post-operative observation was three years or more in 198 of the 305 sutures. Many patients made a good recovery within less than three years, and, for reasons that have been given, it is probable that the prognosis is rather better than that recorded in this paper.

In a high proportion of cases—94%—the injury was caused by broken glass. Incised wounds accounted for only 4.6%. Associated injuries were of three kinds: the companion nerve was frequently involved, a major tendon injury was present in about half the cases, and fractures were rare. Sepsis was negligible.

In distal injuries—that is, at the level of the wrist—two out of three sutures of the median nerve were followed by useful motor recovery and four out of five made a good sensory recovery. The results of ulnar nerve suture at the wrist were slightly better; four out of five led to useful sensory and motor recovery and in one case out of three some degree of independent lateral movement of the fingers was regained. There were comparatively few injuries in the forearm and at the elbow, but the results were little inferior. As might be expected, these results were better than those seen in the war series.

Several factors affecting the prognosis were examined. In children recovery was rather better than in adults; all the 22 children up to the age of 10 made an adequate sensory recovery, and in only one was there poor motor recovery. The extent of the gap to be closed by suture was a much smaller problem than in war injuries, and in only 21 was it necessary to employ an autogenous graft for repair of the nerve. Generous mobilization was employed to permit easy apposition of the nerve stumps after resection, but there was a little evidence that very extensive mobilization affected the prognosis adversely. No apparent harm resulted from a delay of six months between the injury and nerve suture, and a delay of rather over six months was still compatible with recovery.

However, the reason for this may be that almost all the lesions were distal and the distance to be covered by the outgrowing axons was therefore not great. Secondary suture should be undertaken as soon as the primary wound has healed and the tissues are free from induration. Primary suture proved an unreliable operation, although some good results were seen. There are important technical reasons why secondary suture is more satisfactory. If, as is often the case, there has been intraneural damage it is much easier to recognize it some weeks after the injury than at the time, because it reveals itself as a palpable and, on section, visible zone of intraneural fibrosis. The resection can be planned accordingly. Furthermore, the epineurium becomes thickened after the injury, and after a few weeks is an ideal structure for holding fine sutures. Most of the repairs reported were secondary.

Where there is associated damage to tendons it is best to repair them at the time of injury and simply to approximate the severed nerves. When mobilization of the digits is well advanced secondary suture of the nerves is performed without disturbance of the tendons, which, at the wrist, lie on a deeper plane, and continued movement of the fingers has no adverse effect on the nerve suture.

ASPIRIN AND DIABETES MELLITUS

BY

JAMES REID, M.D., M.R.C.P.

A. I. MACDOUGALL, M.B., B.Sc.

AND

M. M. ANDREWS, B.Sc.

Clinical Chemotherapeutic Research Unit of the Medical Research Council, Western Infirmary, Glasgow

Rheumatic fever and diabetes mellitus rarely coexist (Joslin *et al.*, 1952). An opportunity to investigate this unusual combination of disease was provided by a young male diabetic (Case 1), known to take insulin, who was receiving full salicylate treatment for acute rheumatism when admitted to hospital. At the outset we were confronted with a problem, for his urine was sugar-free and the fasting blood-sugar level was normal, though he was receiving only aspirin. The possibilities first entertained were that the previous diagnosis of diabetes was inaccurate or that spontaneous remission of the disease had occurred; neither seemed likely, and the diagnostic dilemma was resolved by the reappearance of sugar in the urine one week after discharge from hospital, when aspirin had been discontinued. On re-examination at this time he was found to have glycosuria, a high fasting blood sugar, and a diabetic glucose-tolerance curve (Fig. 1).

These findings imply that rheumatic fever and diabetes mellitus are in some way incompatible, or that aspirin, the drug used in treatment of acute rheumatism, is anti-diabetic. Earlier reports indicate that salicylate was in fact used in the treatment of diabetes and that it prevented glycosuria (Gross and Greenberg, 1948). This information, together with the striking findings in our patient, led us to reinvestigate the effect of aspirin in diabetes mellitus, beginning with mild forms of the disease and, if necessary, progressing to severer types.

Fig. 1.—Results of oral glucose-tolerance tests in a diabetic patient (Case 1) while he was receiving aspirin treatment for acute rheumatism, and after the drug had been discontinued. During aspirin therapy the curve was almost normal; after stopping the drug it was diabetic.

Clinical Particulars and Methods

The effect of aspirin in another seven diabetics has been investigated. Four belonged to the overweight mild type; the other three were lean, more severe diabetics. Each patient was given a constant low-carbohydrate diet throughout the whole investigation, and this was given for about two weeks before aspirin administration to establish the effect of diet alone. Further particulars of the patients and the diets are given in Table I.

TABLE I.—Clinical Particulars of Patients

Case	Sex	Age in Years	Weight (Kg.)	Duration of Disease (Months)	Standard Diet	
					Carbohydrate (g.)	Calories

8	F	15	44.5	1	130	1,700

* Patient with diabetes mellitus and acute rheumatism.

Aspirin Dosage.—An intensive course of aspirin controlled by serum salicylate estimations (Trinder, 1954) was given to each patient for 10 to 14 days. Doses of 1 to 1.6 g. were taken four-hourly, omitting one dose in the middle of the night, to maintain as high a serum salicylate level as possible without inducing serious undesirable symptoms. The effect of this intensive course of aspirin on the clinical manifestations of diabetes as well as on the principal biochemical features of the disease has been investigated. Blood sugar was estimated by Lehmann and Silk's (1952) modification of Folin and Wu's method, glycosuria by Benedict's (1911) method, and ketonuria by the method of Greenberg and Lester (1944). Oral glucose-tolerance tests were also carried out; in addition, basal metabolic rates (B.M.R.) of four patients, calculated by the method of Robertson and Reid (1952), were determined before, during, and after aspirin therapy in view of the recent establishment of the drug as a peripheral-acting metabolic stimulant (Sproull, 1954).

Fasting Blood Sugar

Table II shows the fasting blood sugars of all the seven patients at intervals throughout the investigation. The results during the week preceding aspirin administration indicate a comparatively stable pre-treatment state in all patients and

TABLE II.—Aspirin and Fasting Blood Sugar

Case	Fasting Blood Sugar (mg./100 ml.)						
	Before Aspirin		During Aspirin			After Aspirin	
	Day 4-5	Day 0	Day 3	Day 7-8	Day 13-14	Day 3-4	Day 6
2	140	121	76	80	73	76	98
3	163	178	108	97	80	118	—
4	196	186	140	118	95	125	129
5	194	196	212	111	—	125	148
6	196	212	186	101	106	102	105
7	213	220	188	92	78	116	198
8	280	225	214	189	122	140	—
Mean	197	191	161	113	92	115	136

* Treatment with aspirin was given for only 10 days in this patient and the blood sugar on the 10th day was 104 mg./100 ml.

provide a satisfactory baseline to judge the effect of the drug. Without exception, aspirin reduced the fasting blood sugars and brought them to normal or near normal by the end of the course of treatment, and after it was discontinued the sugar concentrations started to rise again. These findings are well illustrated by the mean values of the group. Pre-salicylate blood sugars of 197 mg./100 ml. four to five days before and 191 mg./100 ml. on the actual day of starting aspirin fell to 161 mg./100 ml. after three days' treatment. The fall continued to 113 mg./100 ml. at the end of one week and to 92 mg./100 ml. after two weeks of aspirin administration. When the drug was discontinued the mean value rose to 115 mg./100 ml. on the third to fourth day, and to 136 mg./100 ml. on the sixth day.

These striking results indicate that a short but intensive course of aspirin lowers the fasting blood-sugar level in diabetes mellitus.

Glycosuria

The amount of sugar in the urine was estimated daily in six of the seven patients during the month that the investigation lasted. Difficulty in condensing all the results for presentation in a reasonable space made it necessary to confine our attention to the urinary glucose excretion on the days corresponding to fasting blood-sugar estimations, though such arbitrary selection in no way altered the general trend of the results presented in Table III. In two patients sugar either disappeared from the urine or only a small quantity persisted towards the end of the preliminary dietetic control period. The other four patients had considerable glycosuria at the end of the control period which progressively diminished during the period of aspirin administration, indicating that the drug had the same striking effect on glycosuria as it had on blood sugar.

TABLE III.—Aspirin and Glycosuria

Case	Total Urinary Sugar (g./24 hours)						
	Before Aspirin		During Aspirin Therapy			After Aspirin	
	Day 4-5	Day 0	Day 3	Day 7-8	Day 13-14	Day 3-4	Day 6
2	7	4	7	7	5	0	0
3	21	34	6	5	5	0	10
5	0	0	4	7	—	0	0
6	22	20	3	3	3	0	0
7	88	117	61	43	4	7	0
8	55	55	38	17	7	39	15
Mean	32	38	20	14	5	8	5

* Total urinary sugar on the 10th day was 2 g.

One minor feature of the results requires amplification. It will be observed that the two patients with slight or no glycosuria at the end of the initial control period both had glycosuria amounting to 4 to 7 g. per 24 hours during the period of aspirin therapy: only after discontinuing the drug was the urine free from reducing substance. This paradox was cleared up when it was found that intensive treatment of rheumatic fever with salicylate may lead to the appearance of reducing substance in the urine, probably a salicylate conjugate, in amounts equivalent to about 5 g. of glucose per 24 hours. A blank value of up to 5 g. per 24

hours may thus be subtracted from the reducing substance found during the period of salicylate administration to the diabetics (Table III), and this will make the glycosuria negligible.

Oral Glucose-tolerance Tests

The next investigation was the response of the diabetics taking aspirin to a test dose of 50 g. of glucose by mouth. Glucose-tolerance tests were carried out before, during, and after aspirin, or during and after aspirin in five patients, including the original patient with acute rheumatism. The

TABLE IV.—Oral Glucose-tolerance Tests

B, D, and A—before, during, and after aspirin treatment.

results (Table IV and Fig. 1) show that the blood-sugar curves during aspirin administration were uniformly lower than the values either before the drug was given or after it was discontinued, even though in three of the patients the fasting blood sugar had not reached its lowest value from aspirin therapy when the test was carried out.

Ketonuria

The effect of aspirin on another important abnormality of the disease—ketosis—has been studied by estimating the total ketone excretion of the only two patients in the group who had a positive Rothera test when admitted to hospital. Quantitative estimations of urinary ketones were carried out by the method of Greenberg and Lester (1944). The upper limit of normal ketone excretion has been taken as the recommended 50 mg. in 24 hours. By this standard only the two patients with a positive Rothera test had an abnormally high excretion of ketones before salicylate administration. The complete results in both patients, shown in Fig. 2, indicate that the ketone levels fell to normal at the end of the second week of aspirin treatment. This fall was preceded in one patient by fluctuation in ketone excretion

FIG. 2.—Daily urinary ketone output of two diabetic patients (Case 8, above; Case 7, below) before, during, and after a two-week course of aspirin. In both patients ketone excretion was normal at end of second week of treatment. In one the fall was precipitous and started immediately after aspirin therapy began. In the other ketonuria fluctuated during the first week and then fell to normal.

during the first week the drug was given. In the other the fall was precipitous and started when aspirin therapy began.

Body Weight

Seven patients were weighed a few days before aspirin was given, on the last day of aspirin therapy, and during the week after discontinuing the drug. One overweight patient lost 2.3 kg. during the period aspirin was given, but the other patients, including the lean and more severe diabetics, showed no significant weight change. All except two patients, however, lost 1 to 2.7 kg. in the week after aspirin was discontinued, and this was associated with a diuresis. A similar loss of weight, accompanied by diuresis, follows salicylate treatment of rheumatic fever (Reid, Watson, and Sproull, 1950).

Clinical Manifestations

So far it has been shown that aspirin has a definite beneficial effect on the blood sugar, glycosuria, and ketone excretion in diabetes of mild to moderate severity. It is therefore not surprising that the clinical symptoms of the disease, such as thirst, polyuria, and pruritus, which are in-ease, completely related to the high blood sugar and glycosuria, were completely relieved by the drug. The course of treatment was purposely intensive, particularly in the rapid build up to a high serum salicylate level shown in Table V, as we

TABLE V.—Serum Salicylate During Aspirin Therapy

Case	Serum Salicylate (mg./100 ml.)			
	Day 3	Day 7-8	Day 13-14	Day 2-4 After Aspirin

8	42	46	38	0
Mean	44	42	37	0

* Level on 10th day, when aspirin was discontinued, was 46 mg./100 ml.

were anxious in this preliminary study to investigate the effect of maximum tolerated doses. This naturally led to the appearance of more serious side-effects like persistent nausea in two patients which went on to intermittent vomiting in one during the initial two or three days of treatment. At this time both patients had very high serum salicylate levels (52 mg./100 ml. on the third day of therapy), but these symptoms soon disappeared on reducing the dose and thereby lowering the salicylate level.

While serious side-effects from salicylate were relatively uncommon and easily controlled, the less disturbing but nevertheless annoying symptoms of tinnitus and deafness were more frequent during the period aspirin was given. Two patients complained of tinnitus, but seven of the eight had dulling of hearing, which was mild in three and more severe in the other four. These symptoms also disappeared soon after aspirin was discontinued.

The only other noteworthy clinical observation during aspirin therapy was a change in vision in one patient (Case 7) reminiscent of the effect produced by sudden changes in blood sugar.

The final inquiry was to find out if the drug acts as a metabolic stimulant in diabetics as it does in normal individuals and in rheumatic (Cochran, 1952, 1954) and myxoedematous patients (Alexander and Johnson, 1956).

TABLE VI.—Aspirin and Basal Metabolic Rate

Case	B.M.R. (% Normal)

6	98	120	95
7	108	160	104

Aspirin and the B.M.R. in Diabetes Mellitus.—The B.M.R. of four patients was determined before, during, and after aspirin; and from the results in Table VI it will be seen that diabetics behave in the same manner as other subjects, both in health and in disease, by showing a definite increase in metabolic rate in response to the drug.

Discussion

A short intensive course of aspirin lowers fasting blood sugar and leads to disappearance of glycosuria and reduction of ketonuria in mild to moderately severe diabetes mellitus. Clinical remission coincides with biochemical improvement, but diabetic symptoms are replaced by annoying side-effects from salicylate, principally tinnitus and deafness, which develop with serum salicylate levels required to control blood sugar. More serious symptoms, such as persistent nausea and vomiting, arise with higher drug concentrations, and their presence indicates immediate reduction in dosage unless "starvation ketosis" is to be added to existing abnormalities of the disease.

The findings presented in this paper are in keeping with earlier observations with salicylate in diabetes reviewed by Gross and Greenberg (1948) and fit in with recent results in experimental forms of the disease in rats. Ingle (1950) has shown that aspirin reduces glycosuria after removal of part of the pancreas, and Smith, Meade, and Bornstein (1952) demonstrated a similar effect in alloxan-diabetic rats. Thus, while the effect of aspirin on blood sugar and glycosuria of diabetes is indisputable, its mode and site of action are not so clear-cut. Theoretically, blood sugar may be lowered by increased renal excretion of glucose, by faulty assimilation of carbohydrate, and by increased utilization or storage in the tissues. The reduction in fasting blood sugar in our patients who were receiving a constant carbohydrate diet coincided with disappearance of glycosuria, indicating that the fall was not due to alteration in the renal threshold for glucose. Absorption of glucose was not impaired as judged by oral glucose-tolerance tests, and, while we have no direct information of the effect of aspirin on carbohydrate digestion, the observation of Dibeneditto dell'Aquila and Angarano (1954), that a single intravenous injection of sodium salicylate immediately lowers the fasting blood sugar in diabetes, points to the tissues as the site of action of aspirin. This deduction is of interest in the light of the recent establishment of salicylate as a peripheral-acting metabolic stimulant (Sproull, 1954).

While it would be premature to suggest that aspirin might regain a place in the treatment of diabetes mellitus, indications in favour and against such a possibility may briefly be considered. As already indicated, aspirin was used in treatment of diabetes mellitus and rejected because of serious toxic effects, probably the development of ketosis resulting from nausea and vomiting due to salicylate overdose. These symptoms arise with blood concentrations of the drug that are higher than required to control hyperglycaemia, so that with proper control of therapy they need not appear. Minor symptoms such as tinnitus and dulling of hearing may be expected, but experience in other diseases requiring prolonged salicylate therapy indicates that they become less troublesome as time goes on. If there is a genuine need for an oral compound to control diabetes mellitus, aspirin has an obvious advantage over the sulphonylureas, in that it may be given for prolonged periods without risk of agranulocytosis. Another point in its favour is that maximal tolerated doses such as were given to our patients lower the fasting blood sugar to normal without inducing hypoglycaemia. There would therefore seem to be little risk of serious hypoglycaemic attacks from aspirin. Its place in the treatment of diabetes mellitus, however, will require further investigation, and in the last resort will depend on how well therapy can be controlled.

Summary

Disappearance of glycosuria and the return of fasting blood sugar to normal in a young diabetic during aspirin

treatment for acute rheumatism led to reinvestigation of the effect of salicylate in diabetes mellitus.

An intensive two-weeks course of aspirin abolished glycosuria and lowered the fasting blood sugar to normal or near normal in seven mild to moderately severe diabetics.

No decisive effect on glucose tolerance was obtained, though the blood-sugar curves were always lower during aspirin administration than they were either before or after.

Moderate ketonuria in two patients was reduced to normal with aspirin.

Clinical improvement accompanied the biochemical changes induced by aspirin, and, while serious toxic manifestations were not conspicuous, tinnitus and deafness were annoying. The possible place of aspirin in the treatment of diabetes mellitus is discussed.

The action of aspirin in diabetes mellitus has been located in the tissues, and this is of interest in the light of the proper establishment of the drug as a peripheral-acting metabolic stimulant.

We thank Miss M. McCombie and staff of the dietetic department of the Western Infirmary for careful preparation and supervision of the diets.

METABOLISM OF ⁵⁹FE-DEXTRAN COMPLEX IN HUMAN SUBJECTS

BY

A. J. GRIMES, Ph.D.

Louis Jenner Research Fellow

AND

M. S. R. HUTT, M.D., M.R.C.P.

Assistant Physician to the Clinical Laboratories

St. Thomas's Hospital and Medical School, London

The introduction of an iron-dextran complex ("imferon") isotonic with tissue fluids and having a pH of 6-7 enabled intramuscular therapy to be established in the treatment of certain iron-deficiency anaemias (Fletcher and London, 1954). The efficiency and advantages of this form of iron therapy have been shown in a number of papers (Baird and Podmore, 1954; Cappell, Hutchison, Hendry, and Conway, 1954; Cope, Gillhespy, and Richardson, 1956; Scott, 1956), and there is information concerning its rate of release and utilization as determined by serial serum iron and haematological measurements (Baird and Podmore, 1954). The metabolism of this compound has been further studied in animals, using histological and chemical techniques (Pinniger and Hutt, 1956; Beresford, Golberg, and Smith, 1957; Golberg, Smith, and Martin, 1957), and these results have indicated the pathways followed by the complex after intravenous and intramuscular injection.

Despite these studies certain problems require clarification in the metabolism of this compound in man. These include information concerning the clearance from intramuscular sites and the percentage of iron utilized for haemoglobin synthesis in different circumstances. It was felt that the production of an iron-dextran complex containing radioactive iron would enable some of these problems to be elucidated. Such a product was prepared by Bengers Ltd., and as a result of their co-operation these studies were made possible.

Materials and Methods

A radioactive iron-dextran complex was prepared by Bengers by incorporation of an isotope of iron (⁵⁹Fe) into a small process unit similar to that used in routine manufacture. The tracer dose of radioactive iron did not appear to affect the biological properties of the compound, and *in vitro* and animal experiments conducted by Bengers showed the radioactive complex to be similar to that in routine use. This radioactive preparation was administered so that a normal dose of iron (250 mg. in 5 ml.) contained approximately 10 microcuries of radioactivity.

The measurements of radioactivity were made by techniques described previously (Wetherley-Mein, Hutt, Langmead, and Hill, 1956). External body surface counts were made over the liver, spleen, sacrum, and heart, and after intramuscular injection external body surface measurements were recorded as the maximum radioactive counting rate over the site of the injection. Control measurements were made over the opposite buttock so as to correct for the radioactivity of blood flowing in the area measured by the scintillation counter.

Estimation of the percentage of the iron utilized in haemoglobin formation was calculated from the activity of the injected dose and the activity in whole blood after various time intervals. Blood volume was calculated either from the body weight and venous haematocrit (Mollison, 1951) or from plasma clearance data.

Results are expressed as plasma and buttock clearance rates and, with surface counting measurements, as a counting rate—that is, counts per second—at various times.

Patients Studied

The limited supply of radioactive iron-dextran and its decay rate necessitated the investigation of cases that happened to be available for studies lasting up to two weeks. They therefore fulfilled rather wider criteria than would have been decided by choice.

The studies were designed to follow the metabolic routes of the iron-dextran compound after intravenous and intramuscular injection in both normal and iron-deficient subjects. In some cases further doses of non-radioactive imferon were given as required for the clinical management of the patients. Data for the patients studied and the doses administered are shown in Table I.

Results After Intravenous Administration

The object of intravenous injection of iron-dextran was to follow the metabolic pathways of the material uncomplicated by its slow release from the temporary depot site produced by intramuscular injection.

1. *Plasma Clearance*.—In Fig. 1 is shown the plasma clearance of iron-dextran from the five patients studied (Cases 1-5). Despite the differing doses administered (Table I), the general configuration of the clearance is similar in all cases. When these figures are plotted with a logarithmic ordinate scale expressing the activity injected, the clearance initially approaches an exponential form. In those cases where it was followed in the later stages the clearance was asymptotic. No significant difference was observed between the clearances of normal and of iron-deficient subjects (Table II).

TABLE I.—Summary of Cases

Case	Sex and Age	Programme of Dosing Values in mg. Iron on Day				Radioactivity Injected in Counts/sec.	Absolute Values at Zero Time			Diagnosis
		0	1	2	3		Hb %	P.C.V. %	M.C.H.C. %	
1	F 34	275*	—	—	—	23,840	97	41	35	Normal
2	M 54	100*	—	—	—	18,840	104	43	35	Carcinoma of lung
3	F 16	250*	100	—	—	26,050	33	20	24	Menorrhagia
4	M 66	200*	—	—	—	30,000	59	32	26	Iron-deficiency anaemia
5	M 60	250*	250	250	—	23,840	58	30	28	Carcinoma of caecum
6	M 43	250*	—	—	—	24,860	105	43	36	Duodenal ulcer (no bleeding)
7	M 84	250* R	—	250 L	—	29,980	32	24	20	Peptic ulcer
8	M 80	215*	—	—	—	24,035	80	27	27	Carcinoma of stomach
9	F 58	250 L	250 R	250 L	200* L	24,590	54	28	28.5	P.U.O.
10	F 45	250*	—	—	—	28,850	75	36	31	Rheumatoid arthritis

* Denotes iron-dextran containing ⁵⁹Fe. R and L denote right and left buttock respectively.

Fig. 1.—Cases 1-5. Clearance and re-entry in whole blood after intravenous injection of iron-dextran.

TABLE II.—Clearance and Utilization of Radioactive Iron-dextran After Intravenous Administration

Case	Plasma Half-clearance in Hours	Percentage Utilization of Dose	Time in Hours	Blood Volume in ml.	
				P.C.V./WT.	Iron-dextran
1	26	48	504	3,341	3,406
2	14	60	720	5,300	5,340
3	17	93	342	3,418	3,006
4	19	93	370	3,820	4,610
5	23	53	290	4,400	3,909

As is apparent from Fig. 1, the values for the percentage utilization are not the highest values attained even at the times given, since in none of the cases had an equilibrium been reached.

2. *Utilization of Injected Iron for Haemoglobin Synthesis*.—In Fig. 2 is shown the distribution of radioactivity between plasma and red cells in Case 2. It is apparent that radioactive haemoglobin appears in the circulation within a few hours of an intravenous injection of iron-dextran. The rate of this appearance reaches a maximum at about 150 hours and then declines to substantially steady values. In Case 5 the utilization of the radioactive material in an iron-deficiency state appears low because of the subsequent administration of non-radioactive imferon, but in Cases 3 and 4 utilization of the injected iron is almost complete after 350 hours, being more than 90% (Table II). Cases 1 and 2, in which there was normal erythropoietic function, are of particular interest. In these two patients there was no evidence of depleted iron stores, but 48 and 54% of the dose respectively was incorporated into haemoglobin after 21 days.

Surface Counting Patterns.—The patterns obtained by the external body-surface counting technique have certain features in common. There is a conspicuous increase in activity over the liver, marrow, and spleen; and the take-up of ⁵⁹Fe in these organs reached a maximum within 100 hours

Fig. 2.—Clearance and re-entry of radioactive iron (injected as iron-dextran) in the plasma and red cells of a normal subject.

Fig. 3.—Body surface counts after intravenous injection of iron-dextran. The curves are for a normal subject.

(Fig. 3). This concentration of activity in the three organs was paralleled by a decreased radioactivity measured over the heart, reflecting plasma clearance. Subsequent to this maximum there was a decline in activity measured over the liver, spleen, and marrow, with a complementary increase in activity over the heart as radioactive erythrocytes appeared in the blood. The decline of the liver curve from the maximum was greatly retarded in Cases 1 and 2, and in fact appreciable activity was present at the conclusion of the experiment. This finding is supported by the lower utilization of ⁵⁹Fe in these two subjects. The curves obtained by measurement over the heart were similar in form to those

obtained from the whole blood activity. It is of interest to compare this pattern with that obtained after the intravenous injection of a tracer dose of inorganic ^{59}Fe (10 $\mu\text{C.}$) (Wetherley-Mein *et al.*, 1956).

Results After Intramuscular Injection

Following intramuscular injection there was a very variable clearance rate, which, in our studies, does not depend on the presence or absence of iron deficiency (Fig. 4). The disposal after clearance is similar to that which might be expected after a very slow intravenous infusion: there is a slow rise of blood activity, and the surface counts show

FIG. 4.—Cases 6–10. Clearance of iron-dextran from site of intramuscular injection.

delayed rises in the liver, sacrum, and spleen, followed by slow falls as these reticulo-endothelial sites are cleared and the iron is used for erythropoiesis.

The curves also show clearly that a certain proportion of the injected dose remains at the local site and that after about 140 hours little further absorption occurs for periods up to 400 hours. Table III shows an estimate of the percentage

TABLE III.—Clearance and Utilization of Radioactive Iron-dextran After Intramuscular Administration

Case	Buttock Half-clearance in Hours	Percentage Utilization of Dose	Percentage Utilization of Absorbed Dose	Time in Hours	Percentage Dose Remaining at Site
6	28	29	44	450	34 (450)
7	10	63	76	522	17 (528)
8	140	*			45 (474)
9	66	6†	10	385	40 (1,224)
10	110	44	63	456	30 (400)

Figures in parentheses in last column indicate times in hours corresponding to the percentage dose remaining at the site.

* Not estimated because of bleeding from primary lesions

† Low figure accounted for by previous high dosage of imferon.

utilization of the total dose of injected iron and also of the percentage utilization of iron assumed to be absorbed from the buttock. It is evident that the effective utilization in the normal subject (Case 6) is similar to that found after intravenous injection. In Case 7, an iron-deficiency anaemia, the effective utilization was high, 76%, and would probably have been greater if a further dose of non-radioactive imferon had not been given. The lowest utilization, in Case 9, resulted from giving the radioactive iron-dextran after three injections of non-radioactive imferon. This explains the storage of iron in the liver in this patient as shown by the concentration of activity throughout the period with no apparent clearance from this organ.

In one of the patients (Case 10) the radioactivity of the stools was measured during the experiment. The procedure adopted was that of R. O. Bannerman (1956, personal communication) where the radioactivity was determined on a weighted aliquot of macerated 24-hour stool. No evidence could be obtained that after intramuscular injection into the

patient, who subsequently utilized 44% of the dose, there was any excretion of iron-dextran. In this same patient when surface count measurements were made over the testes there was no evidence of testicular deposition of iron-dextran.

Discussion

The results of these studies confirm the metabolic pathways taken by the iron-dextran compound previously studied by serum-iron estimations in man and by histological techniques in animals.

Following intravenous injection the compound is cleared by the reticulo-endothelial system, where the iron is rapidly liberated from the dextran complex and enters the labile iron pool, from which it passes to erythropoietic tissue, where it is utilized for haemoglobin synthesis. The initial exponential clearance is unaffected by iron deficiency and reflects reticulo-endothelial activity. The failure of the plasma clearance to maintain an exponential clearance may be due to alterations of the iron-dextran complex after its injection or to alterations of reticulo-endothelial activity. The utilization of the iron injected intravenously appears to be virtually complete in iron-deficient subjects, and the high utilization of the iron in the normal subject bears out the concept of a metabolically labile iron pool which is used preferentially.

Following intramuscular administration a variable proportion of the dose is very rapidly absorbed, the remainder appearing to be fixed locally, or only slowly absorbed, for periods up to four weeks. The curves obtained from the buttock clearances are similar in form to those found in experimental animals by Beresford *et al.* (1957), though the percentage absorption in animals is much greater. Our absorption figures are also less than those observed by A. R. Stevens (1957, personal communication), who found 90% clearance of ^{59}Fe iron-dextran from the vastus muscle of an iron-deficient patient and confirmed this clearance by demonstrating 87% utilization of the injected dose after 30 days.

The discrepancy between our results and those of Stevens may be related to anatomical differences at the sites of injection and/or to differences in the surface counting measurements. There is histological evidence (Cappell *et al.*, 1954) and further evidence from ^{59}Fe iron-dextran studies that a proportion of the residual dose is retained for some time in local lymphoid tissue following administration into the buttock (Lynn Evans and N. W. Ramsey, 1957, personal communication). It follows that absorption data based on surface counting measurements must be interpreted with the proviso that such measurements do not distinguish between unavailable iron remaining at the site of injection and available iron in regional lymph nodes (Beresford *et al.*, 1957).

A further possibility accounting for the lower absorption figures is that a small proportion of the dose became trapped in the subcutaneous fat. In view of the occasional gross skin-staining seen after injections of imferon the usual precautions were taken to ensure deep intramuscular injection. None of these patients showed skin-staining, though one cannot exclude that some of the dose might enter fatty tissue, particularly in obese subjects (Scott, 1956). A further factor influencing absorption is the mobility of the limb following intramuscular injection. Four of our patients were confined to bed at the time of injection, and the most immobile showed the least eventual clearance. The results emphasize that injections of this complex must be given with care, and suggest that if the limb is exercised afterwards absorption may be increased.

The clinical value of imferon has already been established, and our results indicate the ready utilization of the iron-dextran complex after absorption. The variable absorption patterns demonstrated may explain some of the delayed responses occasionally seen after intramuscular injection, and suggests that one should administer a dose slightly higher than the calculated requirement of iron, particularly in obese immobile patients.

Finally, we would emphasize that in our experience the iron-dextran complex can be administered intravenously

without reactions and that this results in a more rapid utilization of the injected iron when treatment is urgently required.

Summary

A radioactive iron-dextran complex was administered intravenously and intramuscularly to normal and iron-deficient patients. Measurements were made of the distribution and movement of the complex.

After intravenous injection the complex was cleared from the plasma by the reticulo-endothelial system, and the iron was then utilized for haemoglobin synthesis. In iron-deficient patients there was substantially 100% utilization of the injected dose.

After intramuscular administration approximately 60% of the injected dose was rapidly absorbed; thereafter clearance occurred only slowly.

Our thanks are due to the physicians of St. Thomas's Hospital for permission to study the patients under their care, and to Benger Laboratories Ltd. for their co-operation in the preparation of the radioactive iron-dextran. The expenses of this investigation were partly defrayed by a grant from the Endowment Fund of St. Thomas's Hospital.

HAEMOPHILIA-LIKE DISEASE DUE TO AN AUTO-ANTIBODY

BY

A. M. NUSSEY, M.D., F.R.C.P.

Senior Physician, Selly Oak Hospital, Birmingham

AND

D. W. DAWSON, M.B., M.R.C.P.Ed.

Senior Registrar in Pathology, Selly Oak Hospital, Birmingham

Haemophilia is a congenital disease which is determined by the well-known mode of inheritance. Occasionally it arises *de novo* as a fresh mutation. Recently there has been an increasing awareness of the existence of a haemophilia-like state which affects patients hitherto free of bleeding disorders. Such a condition may be brought about by the development of a factor (antithromboplastinogen) which interferes with plasma thromboplastin formation. The interference may take the form of destruction or neutralization of one or more of the components of thromboplastin or, as Hougie and Fearnley (1954) suggest, of inhibition of interaction between these components. The recorded examples comprise in the main those encountered in pregnancy and, relevant to this paper, a more heterogeneous group where a haemophilia-like state appeared after a variety of disorders (Lozner *et al.*, 1940; Conley *et al.*, 1948; Quick and Stefanini, 1948; Dieter *et al.*, 1949; Tzanck *et al.*, 1949; Singer *et al.*, 1950; Collins and Ferriman, 1952; de Vries and Shafir, 1952; Nilsson and Wenckert, 1953; Hardisty, 1954; Bartorelli and Vanacore, 1955; Evans,

1955). In a number of cases no association with another disease was established (Joules and Macfarlane, 1938; Harrington *et al.*, 1950; Pons and Torregrosa, 1952; Hougie, 1953; Spaet and Kinsell, 1954; Evans, 1955).

Other inhibitors of coagulation have been recorded, and one of these is a heparin-like material (Biggs and Macfarlane, 1953). In the case described below there is reason to believe that both an antithromboplastinogen and an excess of a heparin-like material were present.

Case History

A married woman aged 46 was admitted to hospital on January 1, 1956, with a history of tonsillitis three weeks previously. This throat infection subsided after three injections of penicillin, an antibiotic she had never had before. A day or two after the injections a papulo-vesicular eruption appeared on the palms of her hands. This eruption became infected and caused much burning and itching. It gradually became more widespread, involving mainly the limbs. Soreness of the throat recurred after a further few days. On December 25, 1955, she developed a pleuritic pain in her right lower chest, and her right knee became red, swollen, and painful. A day or two later the left big and second toes became similarly affected. The patient was febrile but did not feel particularly ill, and an attempt to treat her with chlortetracycline was given up because she was unable to tolerate it.

On admission she showed discrete papules, some of which were infected, on her hands, arms, abdomen, back and to a less extent on her legs. There were effusions into the right knee and into the joints of the left big and second toes. The chest was clear. Blood cultures were sterile. A swab from a skin pustule grew coagulase-negative staphylococci only. She was treated with systemic penicillin and streptomycin, and locally by chlortetracycline cream. On this treatment the pustules began to clear, but the fever continued and the affected joints remained swollen. The arms were noticed to be oedematous too. Her temperature eventually began to settle, and, although the right knee was still stiff and swollen, her condition was sufficiently improved for her to be allowed up on January 17. Three days later she became pale and was found to have many spontaneous bruises in all limbs. The legs assumed an icteric tinge. Her haemoglobin, which on admission was 11.2 g. per 100 ml., was found to have fallen to 4.6 g.

She was placed on prednisolone, 20 mg. three times a day for two days, and thereafter the dose was reduced to 10 mg. three times a day. A transfusion of 5 pints (2.8 litres) of blood was given without any reaction, although cross-matching was difficult owing to rouleaux formation.

It was observed that a venepuncture performed for the transfusion went on oozing for two days, and a wound in the arm, made to expose another vein to complete the transfusion, continued to bleed for four days. Thereafter the patient began to improve, although on February 3 the cut used for the transfusion began to bleed again, and continued to do so for another four days. The total period during which she bruised and bled intermittently extended over 18 days.

The prednisolone was reduced gradually until by February 22 the dose was only 5 mg. daily, and this was maintained for another three weeks.

When the patient left hospital (February 24) her haemoglobin had risen to 12.6 g. per 100 ml., and her general condition was fairly good. Subsequently she was seen in the out-patient department on several occasions. She gradually regained her strength, and up to the time of writing had not experienced any further bleeding. Two months after leaving hospital she had a recrudescence of the papulo-vesicular eruption on the palms of her hands, and this responded to chlortetracycline cream. On March 5 she was seen with a fresh crop of papules, mainly on her wrists and forearms, and a few on her trunk.

Laboratory Investigations.—On January 1 the W.B.C. was 10,000 per c.mm. (polymorphs 72%). Serum proteins (Table I) were first estimated January 12, when paper electrophoresis

TABLE I.—Serum Proteins (g./100 ml.)

Date:	12/1/56	21/1/56*	9/2/56	13/3/56	16/10/56	7/3/57

* By electrophoresis.

showed a considerable increase in gamma-globulin and a slight increase in alpha-globulin. On January 21 the direct Coombs test was positive; Wassermann and Kahn reactions were negative; bleeding-time (Duke) 5 minutes; clotting-time (Lee and White), clotting began at 20 minutes and was complete in 90 minutes; prothrombin time, 19 seconds (control 19 seconds); serum prothrombin time, 18 seconds; platelets, 219,000 per c.mm.

In the thromboplastin generation test the patient's plasma behaved in a grossly abnormal way, while her serum acted normally. Her plasma failed to correct the abnormal thromboplastin generation of haemophilic plasma. When her

FIG. 1.—Thromboplastin generation tests. Curve 1=control plasma. Curve 2=haemophilic plasma. Curve 3=equal parts of control and haemophilic plasmas. Curve 4=equal parts of control and patient's plasmas. Curve 5=equal parts of haemophilic and patient's plasmas. Normal serum and platelet suspensions used in all tests. These curves show that the defect in the patient's plasma was corrected by an equal volume of normal plasma, but that the defect was not corrected by haemophilic plasma. Curve 4 also shows that the patient had no immediate inhibitory effect on normal plasma.

tion resulted from incubation of the patient's serum with normal plasma and serum, and this defect could be corrected by adding antihaemophilic globulin (A.H.G.), but not normal serum, after the period of incubation.

An experiment was then carried out to ascertain whether the patient's serum was capable of inactivating A.H.G. This was done by comparing the influence of two mixtures on

TABLE II.—Inhibition of Plasma Thromboplastin (Biggs and Macfarlane, 1953)

Percentage of Plasma in Mixture		Calcium Clotting-time in Seconds	
Normal	Patient	Immediate	After 2 Hours at 37° C.
100	0	143	186
90	10	134	221
50	50	153	203
10	90	188	238
0	100	285*	345

* The relatively short calcium clotting-time of the patient's plasma in this test, at a time when her clotting-time (Lee and White) was 20 minutes, is attributed to changes in the plasma due to delay in setting up the test.

TABLE III.—Inhibitor of Plasma Thromboplastin

Period of Incubation (mins.):	Calcium Clotting-time (secs.)				
	0	5	10	15	60
Patient + 1/5 normal plasma	208	240	217	282	445
Haemophilic + 1/5 normal plasma	159	210	231	154	280

the thromboplastin generation of severe haemophilic plasma, one being the patient's aluminium-hydroxide-treated serum and A.H.G., and the other being normal alumina serum and A.H.G. In each case the mixture of A.H.G. and serum was first incubated for 10 minutes at 37° C. Serial dilutions of the normal serum and A.H.G. mixture were used to give a relationship between percentage A.H.G. and thromboplastin generation. In this way inactivation of A.H.G. by the patient's serum to a dilution of 1 in 5 was demonstrated (Fig. 2).

No trace of A.H.G. could be detected in the patient's plasma on assay (Douglas and Biggs, 1953), and A.H.G. precipitin tests (Hougie and Fearnley, 1954) were negative. No evidence of destruction of formed blood thromboplastin by the patient's serum was found (Spaet and Garner, 1955). On January 24 the plasma fibrinogen was 280 mg. per 100 ml.; the thrombin-fibrinogen reaction (Biggs and Macfarlane, 1953) was abnormal, and could be corrected by toluidine blue (Table IV).

TABLE IV.—Correction of Thrombo-fibrinogen Reaction of Plasma by Toluidine Blue

Thrombin Units Added to Plasma:	20	8	4	2	1
Clotting-time of Plasma in Seconds					
Control plasma	7.2	10.3	18.8	38.0	85.0
Patient's	8.4	18.6	37.0	368.0	1,500+
Control plasma + toluidine blue (50 mg./100 ml.)			20.2	54.0	
Patient's plasma + toluidine blue (50 mg./100 ml.)			22.2	73.0	

Evidence of the inhibitor of thromboplastin generation was obtainable until February 2. The clotting-time became normal on February 9, having varied between 11 and 22 minutes. On the same date the thromboplastin generation test became normal, and for the first time a quantity of A.H.G. (15–20%) was detected. The thrombin-fibrinogen reaction returned to normal on February 8.

Discussion

It is known that after several transfusions or injections of A.H.G. a small number of haemophiliacs become refractory to treatment because they develop an inhibitor of thromboplastin formation (Hougie, 1955). It is assumed that under those circumstances an antibody is formed in response to a foreign protein. In pregnancy cases isoimmunization is thought to explain the production of the antithromboplastinogen. In a high proportion of the reports, other than those associated with haemophilia or pregnancy,

there is a history of some antecedent illness, such as skin disorders (Quick and Stefanini, 1948; Dieter *et al.*, 1949; Tzanck *et al.*, 1949; Bartorelli and Vanacore, 1955) or lymphadenopathy (Lozner *et al.*, 1940; Conley *et al.*, 1948). Spaet and Kinsell (1954) suggest that the factor operative in such cases is an auto-antibody like that found in acquired haemolytic anaemia and idiopathic thrombocytopenic purpura. The positive Coombs test in our patient, although only transitory, the specificity of the anticoagulant which she was found to have, and the great increase in her gamma-globulin fraction all lend support to that theory.

There are a number of instances where a disorder of the serum proteins was found (Lozner *et al.*, 1940; Mueller *et al.*, 1951). Nilsson and Wenckert (1953), who reported a case of essential hyperglobulinaemia with an anticoagulant, express a belief that such dysproteinemia in itself interferes with the A.H.G. They consider that this explains the haemorrhagic disorder where there is no apparent trigger mechanism for auto-immunization. So far this theory has not been confirmed, and the fact that in our patient the highest level of gamma-globulin was found several days before clinical evidence of bleeding is not consonant with this idea.

It is known that our patient had been subject to dysidrosis for some time, and it is likely that her throat infection touched off the generalized rash and arthritis with which she first presented. We are inclined to think that these manifestations, the hyperglobulinaemia, and the circulating anticoagulant were all an expression of a reaction to the initial infection. Pregnancy can be ruled out as an operative factor because six years had elapsed since our patient had her last child, and prior to her illness she never had a blood transfusion.

The laboratory findings indicated an abnormality in thromboplastin production. The calcium clotting-times on mixtures of the patient's and normal plasmas (Tables II and III) did not reveal the presence of an anticoagulant. The test recorded in Table III shows lengthening of the recalcification time of the patient's and normal plasma mixture on incubation, but the control test, using haemophilic plasma in place of the patient's, gave similar results. Thus lengthening of the recalcification times in this test cannot be taken as proof of the presence of a plasma thromboplastin inhibitor. Further, the calcium clotting-time of normal platelet-poor plasma lengthens on incubation (see Table II), and this change makes the interpretation of results obtained with the mixtures difficult. The fact that antithromboplastinogens may take time to exert their full effect (Biggs and Macfarlane, 1953) explains why the ordinary thromboplastin generation test did not show the presence of an inhibitor. Only when the test was modified in such a way as to allow the inhibitor sufficient time to act was proof of the presence of the antithromboplastinogen obtained. Thus the absence of A.H.G. activity in our patient's plasma shown in the routine thromboplastin generation test must have resulted from the action of an inhibitor.

The normal prothrombin time showed that the formation of thrombin from prothrombin was not affected. The test of the final stage, the thrombin-fibrinogen reaction, was performed only when the case was reviewed, and was carried out on plasmas which had been stored up to 14 days at –20° C. The abnormality which was found could be corrected by toluidine blue, and thus was considered to be due to a heparin-like substance. It might be argued that this abnormality was caused by denaturation of fibrinogen during storage, but experiments with plasma stored for periods of up to four months at –20° C. showed that any deterioration could not be corrected by toluidine blue. On the other hand, the fact that a heparin-like substance was present clearly did not account for the disturbance in the thromboplastin generation test because the addition of toluidine blue did not improve the performance of the patient's plasma in that test. Also, on adding heparin to normal blood it was found that the prothrombin time was lengthened before

the thromboplastin generation test became abnormal, whereas in our case the prothrombin time was normal. We can offer no explanation for the hyperheparinaemia in our patient, and would refer to a paper by Waldenström (1948), in which he describes this condition in macroglobulinaemia.

The prognosis in cases such as ours is generally regarded as poor (Stefanini and Dameshek, 1955). The satisfactory outcome of our patient's illness may have been due to prednisolone, blood transfusions, or both, or else the disorder may have terminated spontaneously. If we accept that this patient's acute illness was in some way analogous to the disorders in which auto-antibodies form, then it is likely that prednisolone played an important part in her recovery. A review of the literature does not encourage this belief, though van Creveld *et al.* (1953), whose technique was criticized by Hougie (1955), thought corticotrophin was effective; and in the second patient described by Evans (1955) cortisone appears to have contributed to recovery. Stefanini and Dameshek (1955) found large doses of corticotrophin of temporary benefit in one of their patients with pemphigus. Their conclusion about corticotrophin and cortisone is that "these drugs have proved of little value in the management of those diseases, but their use is suggested by lack of other satisfactory therapeutic agents."

Our patient has not shown any further tendency to abnormal bleeding, but it is important to note that her plasma protein pattern remains abnormal and that she still suffers from time to time from a papular skin eruption.

Summary

The case of a woman aged 46 who developed a transient haemophilia-like state is described.

It is shown that this was due to the development of an antithromboplastinogen active against antihaemophilic globulin.

An increase in circulating heparin in this case is also recorded.

On October 23 the DUCHESS OF GLOUCESTER laid the foundation-stone of the new Ulster Hospital for Children and Women at Dundonald, on the outskirts of Belfast. It will provide 500 beds and cost about £2.5m. The new hospital is planned as four distinct buildings—for adults, children, maternity cases, and out-patients—and the end of each building will be left so that the hospital can be expanded easily if necessary. The first stage of the building will include a maternity unit of 44 beds, a children's section with 128 beds, radiology, laboratory, and physiotherapy units, and out-patient and administrative units.

CHLORPROMAZINE JAUNDICE IN A GENERAL HOSPITAL

BY G. S. GRAHAM, M.B., B.S. Senior Registrar, Cumberland Pathological Laboratory, Carlisle

Since the introduction of chlorpromazine hydrochloride ("largactil") into therapeutics in 1951 the drug has been widely used in psychiatry and general medicine, and the only serious complications of its use appear to be agranulocytosis and jaundice. The occurrence of the latter was reported early in 1954 by Lehmann and Hanrahan and by Winkelman, and its clinical features are well described by Cohen and Archer (1955) and by Stacey *et al.* (1955). There is general agreement that the jaundice is of an obstructive type due to a cholangiolitic hepatitis, and that it is a manifestation of a drug sensitivity.

A review of the literature reveals that about 100 instances of this complication have been recorded in varying detail and that the majority of reports are from mental hospitals and psychiatric units. Our experience in a moderate-sized general hospital and laboratory suggests that the condition may be more common than is generally appreciated, and that, in the absence of a full history, it may be treated as a surgical jaundice.

During the year ended September, 1956, five patients with chlorpromazine jaundice from the Cumberland Infirmary and two from other sources were investigated in the Cumberland Pathological Laboratory. A brief account of these is given below and their salient biochemical findings are presented in Table I. None

TABLE I.—Biochemical Findings in Chlorpromazine Jaundice

Methods: Thymol turbidity (MacLagan, 1944, buffer pH 7.55). Serum colloidal gold (MacLagan, 1946). Ammonium sulphate turbidity (Popper and de la Huerza, 1950). Serum alkaline phosphatase (King and Armstrong).

had a history of previous liver disease, allergy, contact with viral hepatitis, or a recent transfusion. The first two patients are of special interest, as they were admitted with jaundice and the diagnosis was not suspected until after laparotomy.

Case Reports

Case 1.—A woman aged 31, three months pregnant. About two weeks before admission she felt generally unwell, with headache, abdominal discomfort, nausea, and

vomiting. About three days later she became jaundiced, after which the general symptoms subsided. On admission she was cheerful, not ill, was afebrile, and complained only of itching and slight subcostal tenderness. Her haemoglobin, leucocytes, blood film, and serum proteins were normal. Her prothrombin activity, initially normal, fell to 54%; her stools were pale and her gall-bladder was not visualized by excretory cholecystography. As the jaundice was deepening and the serum flocculation tests were negative a laparotomy was performed 15 days after admission, when the gall-bladder and bile ducts were found contracted without obstruction. A wedge biopsy of the liver was taken and the abdomen closed. The jaundice increased for a further week and then gradually and uneventfully subsided; its total duration was about three months. The pregnancy was undisturbed. After laparotomy it was learnt from her doctor that she had been given chlorpromazine, 25 mg., three times a day during the 18 days preceding the jaundice.

Case 2.—A mentally defective woman aged 30 was referred to the surgical out-patient department with a right-sided lower intercostal neuralgia. Local applications, injection, and strapping were advised. Three weeks later she again attended, as the pains had increased and there had been itching and slight jaundice for a few days. She was then febrile, her E.S.R. was 41 mm. in the hour (Wintrobe); leucocytes and blood film were normal. Clinical assessment was difficult owing to her mental state, but a diagnosis of gall-stones was supported by the liver-function tests. She was admitted for laparotomy 10 days later, as the jaundice had increased. At operation the gall-bladder appeared normal, the bile ducts were not dilated, and no obstruction was found. A liver biopsy specimen was obtained. In the following week the jaundice had subsided; its total duration was about 23 days. Subsequent inquiry revealed that her doctor had given chlorpromazine, 25 mg. thrice daily, during the three weeks preceding the jaundice.

Case 3.—A woman aged 81, an in-patient in the Cumberland Infirmary suffering from senile dementia and *E. coli* cystitis, was given chlorpromazine, 50 mg. a day. On the eleventh day she developed a symptomless jaundice of about 10 days' duration.

Case 4.—A woman aged 73, an in-patient in the Cumberland Infirmary suffering from arteriosclerotic cerebral degeneration and hemiplegia, was given chlorpromazine, 25 mg. three times a day. There was a single evening pyrexia of 99° F. (37.2° C.) on the eighteenth day, followed two days later by a symptomless jaundice which persisted for 24 days. The liver edge was palpable and tender during the first 10 days.

Case 5.—A woman aged 83, an in-patient in the Cumberland Infirmary suffering from senile cerebral degeneration, was given chlorpromazine, 50 mg. a day. On the eighteenth day a mild symptomless jaundice appeared which lasted about 16 days.

Case 6.—A woman, aged 37, an in-patient in a mental hospital, was given a course of chlorpromazine in dosage up to 300 mg. a day. On the twentieth day she complained of nausea and itching, and became jaundiced five days later. During the following month the jaundice steadily increased, constitutional upset and vomiting were severe, and her liver was enlarged and tender. Her condition caused some anxiety, but by about the middle of the second month she was on the way to recovery. The total duration of the jaundice was about three months. A subsequent cholecystography showed no abnormality.

Case 7.—A woman aged 50 had felt unwell and depressed for about three weeks, for which she was given chlorpromazine, 25 mg. three times a day, by her doctor. On about the twelfth day she developed a mild jaundice; this lasted about three weeks, and she was completely well, both physically and mentally, about one month later. The liver-function tests performed at the end of the second week of the jaundice when it was resolving were equivocal, and her doctor attributed the whole illness to infective hepatitis.

There was no history of contact, and the case is included as a possible chlorpromazine jaundice.

Liver Biopsies

Both Cases 1 and 2 showed intralobular bile retention with bile thrombi in the canaliculi, especially in the centrilobular zones, but no dilatation or plugging of the bile ducts. Apart from some granular bile deposition in the centrilobular zones the liver cells appeared healthy, with good glycogen content and no fatty vacuolation or nuclear irregularity.

In Case 1 the portal tracts showed a very scanty infiltration of lymphocytes with a few histiocytes and polymorphs, and only an occasional eosinophil. The infiltration in Case 2 was slightly more marked, and 1-3 eosinophils could be seen in almost every portal tract. In neither biopsy was there fibrosis or disturbance of the architecture to suggest previous liver disease.

Discussion

The relative frequency of chlorpromazine jaundice is established by a review of the clinical histories and findings of all patients upon whom liver-function tests were performed in the laboratory during the relevant year. In all, 151 patients were so investigated, of whom 65 were jaundiced. An analysis of the diagnosis of the latter is given in Table II, in which those patients seen in the Cumberland Infirmary are grouped separately.

TABLE II.—Diagnosis of Jaundiced Patients Reviewed

The Cumberland Infirmary (332 beds) is the main hospital admitting acute medical and surgical patients from a population of about 164,000, and there were approximately 7,000 in-patients during the year. Most of the cases of jaundice seen in the Infirmary were investigated in the laboratory, and the analysis in Table II is fairly representative of their distribution. Chlorpromazine accounted for approximately 1 in 10 cases of jaundice, and was seen with a frequency about equal to that of carcinoma of the pancreas, half that of viral hepatitis, and one-third that of cholecystitis and biliary calculi.

The aetiology of cholangiolitic hepatitis (primary intra-hepatic cholestasis of Popper and Schaffner, 1952) has been reviewed by Johnston and Doenges (1956), and its clinical similarity to extrahepatic obstructive jaundice is well known. In cases due to a virus the clinician may become aware of the possibility of the condition by a history of contact with or during an outbreak of infective hepatitis (Sherlock, 1956) or by knowledge of a recent transfusion, and arsphenamine, methyltestosterone, and thiouracil would probably be evident in the clinical history as the drugs implicated.

Chlorpromazine, however, as judged by the pharmaceutical literature and the correspondence columns of the medical journals, is extensively used in general practice. In the literature the overall incidence of jaundice is about 1.5% of patients receiving the drug, and it may be that it is now one of the commonest causes of cholangiolitic hepatitis. Our first two cases show that the administration of this drug may escape notice when a jaundiced patient is referred to hospital, and that the condition may then quite reasonably be considered and treated as a surgical jaundice.

In chlorpromazine jaundice, apart from the occasional finding of a blood eosinophilia, the clinician can expect very little help from the laboratory in the differential diagnosis. The findings in the usual liver-function tests are those of obstructive jaundice, and a liver biopsy would be unlikely to differentiate it from an extrahepatic obstructive jaundice of comparable duration. A non-specific cellular infiltration of the portal tracts is variable and common to both extra-hepatic and intrahepatic obstruction, and, though eosinophils in numbers may be significant, they were present in only one of our two biopsies and are mentioned in but 2 of 10 others in the literature (Zatuchni and Miller, 1954; Hartnett, 1955; Hodges and La Zerte, 1955; Lemire and Mitchell, 1955; Van Ommen and Brown, 1955; Whitfield, 1955).

It should also be noted that the gall-bladder may not be visualized by excretion cholecystography and may therefore be presumed to be diseased, as occurred in our first patient.

Our experience suggests that specific inquiry regarding chlorpromazine administration may be worth while in cases of obstructive jaundice of doubtful origin, as when jaundice occurs in a patient so treated it is more likely to be due to the drug than to a neoplasm or calculus. As a guide to suspicion, jaundice due to chlorpromazine in the majority of cases recorded in the literature has occurred during the second to the fourth week of treatment, with a range of six days to six weeks, and it has arisen up to 14 days after the termination of therapy. Its incidence bears no relation to the dosage of the drug or to the previous or present health of the patient.

If the condition is suspected it would seem reasonable to adopt an expectant policy for a few weeks, during which most cases would resolve. The prognosis of uncomplicated chlorpromazine jaundice is uniformly good and the only dangers appear to be those occasioned by surgery—there has been one fatal rupture of the liver due to needle biopsy (Stacey *et al.*, 1955). In most cases the jaundice lasts for two to four weeks, but it may be prolonged, and there are six reports of a duration of over three months. However, progression to biliary cirrhosis appears to be unlikely. While in one reported case cortisone had no effect (Hodges and La Zerte, 1955), in view of the recent evidence of its diagnostic value in the viral type of cholangiolitic hepatitis it may be worth a trial before resorting to surgical exploration in the more protracted case.

Summary

A review of 65 jaundiced patients investigated during a 12-months period showed that in seven the jaundice was due to chlorpromazine. Five of the latter were seen in a general hospital, and in two the condition was not suspected before laparotomy. It is suggested that chlorpromazine jaundice may be more common than is generally appreciated and that without a full history it may be treated as a surgical jaundice.

I am indebted to the medical staff of the Cumberland Infirmary for allowing me to publish details of their patients, and to Dr. J. Steven Faulds and Mr. R. M. Hill for their encouragement and advice.

CHRONIC BRUCELLOSIS IN GENERAL PRACTICE*

BY

J. E. DAVIES, M.B., B.S.

General Practitioner, Carmarthen

Acute brucellosis is a disease entity the clinical picture of which is fully described in all standard textbooks of medicine. Only in recent years, however, has it become recognized that brucellosis may present and persist for many years in a more chronic form. Evans *et al.* (1938) and Evans (1939) emphasized that many cases of brucellosis were overlooked because of the chronic and insidious nature of the disease. Spink (1951), recognizing the controversy that existed with regard to the reliability of the criteria for diagnosis, followed up 65 cases of proved acute brucellosis that had not been treated by any antibiotic known to be effective in brucellosis and found that 46% were still complaining after 12 months. In a second series that had had antibiotic treatment, 39% were still unwell after a year. He concluded that, in spite of effective antibiotic treatment, a small but significant number of patients continued to show manifestations of active disease.

In this country, Dalrymple-Champneys (1952) and Barrett and Rickards (1953) have described the condition in detail, and the latter workers, in an excellent survey of 35 cases occurring in Lancaster, have shown how chronic brucellosis can occur without a preceding recognizable acute attack. They have drawn attention to the value of aspiration liver biopsy in assisting in the diagnosis.

The present investigation was carried out in general practice and was originally prompted by the fact that I contracted brucellosis four years ago and became aware that several patients who were repeatedly attending my surgery on account of chronic and recurrent ill-health had themselves the same symptoms and signs. It is the purpose of this paper to discuss 11 cases all occurring in one rural practice. Two of the 11 had acute brucellosis in the beginning and, after being followed up for nearly a year, failed to show a return to normal health, and had manifestations of active disease, although during this time the agglutination titre had become negative. The other nine cases were diagnosed in their chronic state.

Great attention was paid to the history, and wherever possible a verbatim description of symptoms was used in the history-taking. The results of clinical and haematological investigations have been recorded, together with temperature charts. Use has been made of the intradermal brucellin test and the subsequent rise in antibody titre that followed. Wherever appropriate, full investigation has been carried out to exclude alternative conditions.

The one constant symptom has been periodic muscle weakness with easy fatigability. In view of the similarity of this to periodic familial paralysis, and remembering that chronic brucellosis is presumed to be due to an intracellular parasitism by the brucella organisms, and also that nine-tenths of the potassium in the body is intracellular, it was decided to investigate the serum potassium levels in these patients. These have been recorded at different phases of the disease.

*Charles Oliver Hawthorne Prize Essay, 1957.

Table I provides a summary of the principal features of the cases under review. The agglutination titres recorded are the highest titres reached. The serum potassium figures are the readings obtained before and after antibiotic treatment. Details of treatment are given at a later stage of this paper.

Symptomatology

The cardinal symptoms of chronic brucellosis noted in this series of cases were: (1) muscle weakness with easy fatigability and generalized lassitude; (2) muscle pains and joint pains; (3) sweats and chills; (4) abdominal symptoms, chiefly of pain and flatulence; and (5) neurological symptoms.

1.—*Muscle Weakness.*—This is the only symptom common to all cases. It is periodic, in that it is present at certain times and not at others, it comes on suddenly, and it usually gets worse at the end of the day. It bears no relation to the amount of work done. Apart from a generalized lassitude, weakness is maximal in the upper arms and legs, particularly in the extensor muscles of the arm and the quadriceps group of muscles in the legs. There is a rapid fatigue of these muscles, especially when used to maintain a posture, and patients often state that they cannot stand for any length of time, and that their arms soon tire when they are holding up a book to read or are shaving. General lassitude produces a disinclination for exercise, and weight increase is often the result. It is easy to understand why many of these patients, often looking fairly well and yet complaining of a degree of lassitude that is out of all proportion to their appearance, are labelled neurotic, neurasthenic individuals. Spink (1954) has shown how these symptoms can be reproduced in a clinically cured case by the injection of a brucella endotoxin, and they could be partially allayed by the intravenous injection of 20 mg. of corticotrophin. The former is a lipoprotein carbohydrate which resides on or near the surface of the bacterial cell from smooth cultures.

2.—*Muscle and Joint Pains.*—These are transitory and are felt chiefly in the limbs, the back of the calf muscles, and the back of the neck. Three patients complained of pain in the pectoral and subscapular group of muscles. Transient enlargement of the posterior triangle cervical glands may occur. Other groups of glands may also enlarge and become tender. Joint involvement is usually transitory and any joint may become painful and swollen for a few days. Case 10 showed a bilateral hydrarthrosis of knee-joints, destructive changes were not noted in the inflamed joints, and the sedimentation rate, radiological appearances, and blood uric acid were within normal limits. Apart from local symptoms, several patients complained of a generalized stiffness, most commonly felt in the early mornings. One patient remarked that it was just as if he had done a hard day's haymaking the day before. Another likened it to the morning after the first game of football of the season. Stiffness would seem to be out of all proportion to the previous day's exercise. Harris (1950) quotes the remarks of a physician suffering from chronic brucellosis—he states: "If fatigue is due to neurosis, continuation of graded exercise should result in improvement and greater tolerance; in chronic brucellosis, if one continues to exercise in spite of fatigue, then exhaustion, tremor, lack of muscular control and co-ordination develops." He points out that the muscular sensation of the patient who has brucellosis is exactly similar to that of the well person who has exercised too vigorously.

3.—*Sweats.*—Excessive sweating was noticed in five cases. It was most pronounced in the two acute cases, but became less noticeable in the chronic state. Recurrence of sweating seemed to herald the return of a bout of brucellosis and was particularly marked at night.

4.—*Abdominal Symptoms.*—Eight patients complained of abdominal pain. This was described as an ache in the right iliac fossa or in the right hypochondrium. The former

suggested an appendicular origin, and two cases had had an appendicectomy without relief of symptoms. Four complained of excessive intestinal flatulence associated with the passage per rectum of an irritating mucous discharge which excoriated the perianal skin. The latter symptom was noted before antibiotic treatment, was not associated with any radiological or bacteriological abnormality in the bowel, and was cured by antibiotic therapy. Case 5, besides complaining of lassitude and sweats for several years, had a history of chronic pain in the right loin with frequency of micturition. The day after an intradermal brucellin skin test he developed a frank haematuria and a fever. Laboratory examination of the urine showed no organisms or casts, and culture for tubercle bacilli was negative. The intravenous pyelogram was normal. This case and all the others were relieved of their abdominal symptoms by antibiotic therapy. Abernathy *et al.* (1955) reported a remarkable case of proved brucella pyelonephritis. Their patient, who underwent nephrectomy, exhibited caseation and calcification, and microscopical examination showed multinucleated giant cells in numerous granulomatous lesions: in fact, macroscopically and microscopically, lesions typical of tuberculosis, and yet the Mantoux test was negative and no tubercle bacilli were isolated from the kidney. They concluded that in all chronic granu-

lomatous lesions the specific aetiological agent should be found, and suggested that in the search for the aetiological agent the index of suspicion for brucellosis should be high.

5.—*Neurological Symptoms.*—Two of the cases showed signs of a peripheral neuritis and also had blurring of vision. Another patient, not included in the series, though suffering from multiple sclerosis, showed a strongly positive brucellin test and developed a sustained antibody rise. She was so improved after combined antibiotic and steroid therapy that one could not but wonder whether her neurological condition might have been related to a brucella hypersensitivity.

Physical Signs

Physical examination of these cases revealed the following features.

1.—*Hepatic Enlargement in All Cases.*—The liver edge was found to be firm, tender, and smooth. The degree of enlargement was between 1 and 2 in. (2.5 and 5 cm.) below the right costal margin. Barrett and Rickards (1953) have shown by aspiration liver biopsy that there is a return to normal hepatic cytology in brucellosis after antibiotic therapy.

2.—*Splenic Enlargement.*—This was detected in two cases. It was not tender. Neither hepatic nor splenic enlargement could be detected after adequate antibiotic therapy.

TABLE I.—Summary of Cases

Case No.	Age and Sex	Duration of Disease	Milk Supply	Symptoms	Physical Signs		Agglutination Titre		Treatment	Serum Potassium (mg./100 ml.)		Results
					Hepato-megaly	Spleno-megaly	Before Skin Test	After Skin Test		Before Treatment	After Treatment	
1	40 M	9 mths	Pos. Brucella isolated from own milk	Fever, sweats, muscle pains, lassitude	Yes	No	1:640	Not done	Combined antibiotics (4 courses)	16.5	21.0	Afebrile. Symptom-free, back at work as nurse
2	36 M	3 years	" "	Lassitude, muscle pains, abdominal pains	"	"	1:1,000	1:30	Combined antibiotics (3 courses)	17.2	21.5	Afebrile. Only minimal symptoms after second course of antibiotics
3	40 F	4 "	Abortion in own herd 4 years ago	Lassitude, fever, sweats, joint pains, abdominal pains	"	"	Negative	1:160	Combined antibiotics (2 courses) antibiotic + prednisone	16.8	18.5	Afebrile. No symptoms, working well as farmer
4	50 M	12 mths	Raw milk drinker	3 febrile bouts, prodromal lassitude, aching in arms	"	"	"	1:80	Combined antibiotics (2 courses)	Not examined	17.8	No further bouts of fever, feels well. Working as shop assistant
5	31 M	4 years	Abortion in own herd 4 years ago	Chronic lassitude, sweats, muscle pains, dysuria, abdominal pains	"	Yes	"	1:640	Combined antibiotics (2 courses) antibiotic + prednisone (1)	16.4	17.5	Afebrile. Working as farmer, greatly improved. Minimal symptoms
6	33 F	10 "	Raw milk drinker	Lassitude, persistent fever, muscle and joint pains, abdominal pains	"	No	"	1:160	Combined antibiotics (2 courses)	16	17	Was greatly improved after 2nd course but had recurrence now of polyarthritic symptoms. Working Afebrile. Only partial improvement
7	67 M	6 mths	" "	Lassitude, muscle and abdominal pains, colitis	"	Yes	"	1:160	" "	17	20	No symptoms. Has plenty of energy
8	47 M	2 years	" "	Lassitude, easily fatigued, pains in arm and neck	"	No	"	1:40	" "	15.5	21	Afebrile and back at work but still has minimal symptoms
9	58 M	2 "	" "	Lassitude, sweats abdominal pains	"	"	"	1:2,560	" "	16	23	Back at work as farmer. No sweats or fatigue. Abdominal symptoms cured
10	38 M	4 mths	" "	Lassitude, muscle pains, bilateral effusion in both knees	"	"	"	1:80	Combined antibiotics (1 course)	16.5	17.5	No symptoms, except both knees are stiff and swollen
11	63 M	2 years	" "	Weakness, sweats, pain in calves, abdominal symptoms + colitis	"	"	1:160	1:1,280	" "	17	21.5	Has only recently completed treatment. Afebrile. No abdominal symptoms, but not yet regained full strength

3. Evening Pyrexia.—In this series of cases, six were found to have an evening pyrexia which disappeared after treatment. Griggs (1942), in a survey of 100 cases of chronic brucellosis, recommended that the temperature should be recorded for five minutes night and morning. He detected a pyrexia of 1° F. or more in 20% of cases. The same procedure was adopted.

Haematological Investigation

In all cases a full blood count was made and the sedimentation rate estimated. Two cases showed a mild degree of iron-deficiency anaemia. The sedimentation rate was normal in all cases. Scarlett (1948) regarded this as an important aid in differential diagnosis. Lymphocytosis was noticed in five cases. Where appropriate, blood sugar and uric acid were estimated. Blood culture, using Castañeda's (1946) technique, was carried out in five cases. All were negative. This has been the experience in larger series of cases.

Intradermal Skin Test

All the cases had a positive skin reaction. Brucellin, a killed whole organism suspension prepared and supplied by the Central Public Health Laboratory, Colindale, has been used as the intradermal antigen.

Technique.—0.1 ml. was injected intradermally in the right forearm. In most cases a short-bevel needle was used and care was taken to see that a visible and definite vesicle was produced. In a few cases the Heaf multiple-puncture technique was used; this had no special advantages. The test was read at 48 hours, and after one week: a positive reaction was interpreted if there was (1) induration of the site, (2) erythema of 1 cm. or more, (3) or both erythema and induration. Harris (1950) classifies the positive results of the skin test as (1) weakly positive (+), this being a reddened indurated area of about 5 mm. in diameter appearing from the fourth to eighth day; (2) positive (++), an area of induration of more than 5 mm.; (3) strongly positive (+++), an area of redness and marked induration greater than 10 mm.; (4) a violent positive reaction (++++), which is a

markedly swollen indurated area with erythema, often with lymphangitis, axillary adenitis, systemic reaction, and occasionally with central necrosis. This classification was used to read the results of the skin test. Equivocal results encountered in a series of controls were clarified by the inspection one week after the skin test. In most of the positive cases the intradermal mark could still be detected several weeks afterwards.

The significance of the skin test is analogous to the tuberculin test. A positive skin reaction indicates past or present infection, but does not in itself indicate current infection.

Thanks to the co-operation of the medical staff of the hospitals in this area, it was possible to estimate the incidence of the positive skin reaction to brucellin in a group of patients. In this survey I was greatly assisted by the consultant bacteriologist, and we conducted skin tests on a group of patients in the mental hospital, the sanatorium, and the medical ward in the general hospital. The results are shown in Table II.

TABLE II.—Results of Skin Tests

Hospital	No. of Cases Tested	Positive Tests	
		No.	%
Male wards of mental hospital	40	11	27
Female admission block of mental hospital	33	7	21
Medical ward of general hospital	24	3	12
Sanatorium	29	6	20
Total	126	27	21

The incidence of dermal sensitivity to brucellin in a group of controls was found to be 21%. This would suggest that in a rural area risk of exposure to brucella has not been insignificant.

Agglutination Reaction

The agglutination response to *Brucella abortus* in the patients of this series are recorded in Table III. Three cases had an agglutination titre prior to skin testing. Cases 1 and

TABLE III.—Agglutination Response to *Br. abortus*

Case No.	Date and Result of Brucellin Test	Agglutination Titres (with Dates)							
		10/4/56	13/4/56	28/4/56	28/6/56	7/9/56	15/9/56		
1	Not done	1:640	1:640	1:250	1:640	Trace 1:50	Neg. (less than 1:20)

	++	Neg.	Neg.	1:80	Neg.				
11	27/6/56 ++	1/10/54	27/6/56	17/7/56	25/10/56				
	++	Neg.	1:160	1:2,560	1:320				

2, in that they had a titre which was diagnostic of acute brucellosis at the onset of their disease, were not subjected to a diagnostic intradermal test, although Case 2 received several intradermal doses of 1/1,000+1/100 brucellin in January, 1956, as vaccine therapy. It will be noted that after two years, during which time the agglutination titre had fallen to less than 1:20, antibodies were found to reappear in the case as a result of the antigenic stimuli. Case 11 had a titre of 1:160 prior to the skin test.

The appearance of antibodies in the blood following skin testing was first noted by Giordano (1929). He showed that a response could occur in skin-positive or skin-negative cases. Since then much controversy has occurred, and a wide variation in the response has been reported by different workers (Goldstein, 1934; Elton, 1948; Carpenter *et al.*, 1950). This controversy has arisen chiefly on account of the variation in dosage and the type of antigen used. Krakauer *et al.* (1951) studied the effect of brucellergen on the agglutination titre of 34 cases suffering from probable brucellosis whose serum, prior to skin testing, failed to agglutinate brucella in a significant titre. A titre of 1:80 or above developed in 32 out of the 34. In contrast, 85 patients suffering from diseases other than brucellosis failed to show any antibody rise. Elton (1948), in a survey of the literature on this point, concluded that the antibody response following skin testing is chiefly dependent upon the amount and type of antigen used.

It was therefore decided to estimate the antigenic power of the solution of brucellin which had been used in the present series of cases. Patients in the mental hospital, in a near-by sanatorium, and in general practice were examined and tested as controls. A sample of blood was taken before the skin test in order to ascertain that there were no antibodies to *Br. abortus* in the circulating blood. The intradermal test was then carried out, recorded, and after 14 days the blood was re-examined for antibodies. In a number of cases the blood was re-examined 28 days and 56 days after the intradermal test. The results are given in Table IV.

TABLE IV

	No. of Cases	Agglutinations Present Before Skin Test	Negative Agglutination 14 Days After Skin Test	Positive Agglutination 14 Days After Skin Test
Mental hospital	40	0	32	8
Sanatorium	21	0	15	6
General practice	11	0	10	1
Total	72	0	57	15

Of the 72 controls examined, 57 demonstrated no rise in antibodies 14 days after a brucellin skin test. In the remaining 15 the agglutination was positive at 1:25 in 6, 1:50 in 6, and 1:125 in 3.

Those cases in the general practice and sanatorium groups which had shown this antibody rise were examined again 28 days after the skin test. They were then all found to be negative.

In the mental hospital group of controls, serial blood examination was carried out on all 40 cases. The results are shown in Table V.

TABLE V

	Total No.	No. of Cases with Negative Agglutination	No. of Cases Showing Positive Agglutination
14 days after test	40	32	8 (6, 1:25; 2, 1:50)
28 " " "	40	37	3 (1:25)
56 " " "	40	40	0

It was also found that of the 15 controls showing an antibody rise five were skin positive and ten skin negative.

The results of this experiment showed, therefore, that (1) the intradermal injection of brucellin resulted in the appearance of antibodies in a group of controls in a small number of cases; (2) this non-specific rise in antibody titre, when it appeared, was neither of high titre nor sustained;

and (3) the appearance of antibodies was not related to the original dermal sensitivity of the case.

These results are similar to those of Huddelson *et al.* (1939) with brucellergen. They stated that "one injection of brucellergen may give rise to brucella agglutinins in a small proportion of cases."

Diagnostic Criteria

The above findings suggested that emphasis could be laid on the following diagnostic features. (1) A typical history, especially of muscular weakness, together with positive physical signs. (2) In the presence of the history, either (a) the isolation of the organism from the blood or tissues or the detection of antibodies to *Br. abortus* in the blood, or (b) the appearance of antibodies in high or sustained titre following a positive intradermal brucellin test. If these conditions ascertained, antibiotic therapy was begun and the response provided the third criterion. (3) Therapeutic result: three patients, not included in this series, with suggestive symptoms and a positive skin test failed to show any antibody response or any improvement following antibiotic therapy.

Serum Potassium

For reasons already mentioned it was decided to determine the level of serum potassium in all 11 cases. Estimations were made in the chronic phase of the disease. The potassium was calculated by the use of a flame photometer employing coal-gas and compressed air, a light-filter system, and an external standard.

The results, which are expressed in mg. per 100 ml., are shown in Table VI.

TABLE VI.—Serum Potassium Values Before and After Treatment

Case:	1	2	3	4	5	6	7	8	9	10	11	Mean
Before	16.5	17.2	16.8	Not done	16.4	17	17	15.5	16	16.5	17	16.59
After	21	21.5	18.5	17.8	17.5	17	20	21	23	17.5	21	19.6

In a group of controls from patients in the mental hospital and the sanatorium the figures shown in Table VII were obtained.

TABLE VII.—Mean Serum Potassium Values in Controls

	Female	Male	Total
No. of cases	30	36	66
Mean serum K (mg./100 ml.)	18.7	19.2	19.0

The level of the serum potassium in the cases of chronic brucellosis before they had effective treatment were all below the mean figure obtained from the controls. Josephson and Dahlberg (1952), in a survey of a number of healthy men and women, calculated the mean values for potassium, and these are shown in Table VIII.

TABLE VIII.—Mean Serum Potassium Values (mg./100 ml.) in Healthy Men and Women

	Men	Women
20-30 years	18.67 ± 0.43 σ2.05	18.49 ± 0.35 σ1.55
16-50 "	19.34 ± 0.16 σ1.9	18.5 ± 0.14 σ1.7
<50 "	20.5 ± 0.25 σ1.92	20.03 ± 0.25 σ1.81
>70 "		

Wootton and King (1953), in an analysis of the inter-hospital differences for the normal constituents of blood, have shown that it is necessary to return to the use of ranges of normality. Whilst the figures obtained for the serum potassium in this series of cases all fall within this range, it may be of some significance that they are all at the lower level.

Serial examination of the serum potassium at times seemed to show some correlation to the clinical state of the patient. Potassium chloride tablets, 15 gr. (1 g.) three times a day

given by mouth, however, had no effect on the symptomatology or fever of the patient, although a rise in serum potassium level was observed after their administration. An improvement in the general health of patients was noticed when the serum potassium level rose as a result of antibiotic therapy; no such amelioration of symptoms was noticed when potassium chloride was given by mouth to four cases for a short period, even though the serum potassium might have increased. It seems possible that the intracellular potassium metabolism is disturbed by the activity of the *Br. abortus*, and the serum potassium figure is an index of the activity of this organism.

Electrocardiographic tracings of Cases 1, 3, 5, and 6 showed no evidence of potassium deficiency.

It is quite obvious that no conclusion can be drawn from such a small number of cases of brucellosis, especially as basal conditions were not assured. Nevertheless, so far as this series was concerned, a low "normal" value for the serum potassium was observed in all the cases. Furthermore, there was a general correlation between the clinical improvement of the patient and the level of the serum potassium after treatment. It may well be that these fluctuations are coincidental, but they are described in the hope that workers with large series of cases at their disposal might feel that in view of the above findings the fluctuation of the serum potassium in chronic brucellosis is worth looking into.

Treatment

Combined antibiotic therapy was used in all cases. Tetracycline and streptomycin sulphate were given for 14 days in most instances. Tetracycline, 2 g., was given daily and streptomycin, 5 g., by injection night and morning. In several instances it was necessary to repeat this course two or three times on account of a relapse. An improvement was noticed about one week after the completion of a course, and even if there was a return of symptoms there seemed to be an overall improvement after each course of antibiotics. Cases 3 and 5 were the exception in that they showed only a transient improvement with the above routine. It was necessary in these cases to combine the antibiotics with prednisone. Prednisone was used because of its property in reducing hypersensitivity and its ability to liberate organisms from a fibrotic lesion. The dosage was 15 mg. twice daily for the first two days, 10 mg. twice daily for the next two days, and 5 mg. twice daily for the rest of the 14 days. The usual precautions for steroid therapy were taken (preliminary radiograph of chest and inquiry about any history of peptic ulceration) and supplementary vitamin-B therapy was given with the antibiotic.

The results of treatment are given in Table I. It is not possible to speak in terms of a cure in a disease that is notorious for its tendency to relapse, but the results of treatment have been assessed with regard to improvement of symptoms and ability to carry on a normal day's work.

Discussion

The study of these cases of chronic brucellosis would seem to suggest that the disease is a relatively common one. On the basis of these observations it must surely be of significance that 11 cases have occurred in one rural practice in less than a year. Survey of the herds in this area in recent years has not suggested that infection with *Br. abortus* is any more prevalent here than in other rural areas. There has, however, been a considerable decline in the drinking of pasteurized milk, largely as a result of the publicity given to the Tuberculosis Milk Scheme. The tuberculin-tested milk has come to be regarded as a synonym for the "safe milk," and little attention has been paid to the brucella risk.

That this risk is not insignificant is suggested by Dalrymple-Champneys (1950) in a survey of the incidence in cattle in this country. He has reliably estimated that 15 to 20% of our adult bovine cattle are infected. It is further suggested by the results of the examination of a group of

controls in this series: these have shown that at some time or another approximately 20% of the adult population have had their tissues infected with the *Br. abortus*, with the results and production of skin allergy to brucellin.

Analysis of the mode of onset of the 11 cases has shown that in one only was the onset of the disease heralded by a high fever; all the other cases demonstrated a period of ill-health with no recognized acute onset—in fact, one case was found to have a positive titre as high as 1 in 1,000, although on no occasion did the fever exceed 99° F. (37.2° C.). It was further noted that in three cases a bout of brucellosis was either precipitated or aggravated by a surgical operation. As these operations were performed in different hospitals and the milk supply in one of them was known to be pasteurized, it was unlikely that the hospital milk supply was at fault. The impression was gained that trauma excited a latent brucella focus.

When it is recognized that infection with *Br. abortus* can present and persist in this insidious way, it is obvious that many cases are either missed altogether or not diagnosed in the acute stage. It is only in the acute stage of the disease that laboratory diagnosis, by blood culture or high agglutination titre, is positive. It is necessary to utilize ancillary laboratory procedures in the diagnosis of the chronic state. The follow-up of the agglutination titre in these cases has shown that there is often a high and sustained agglutination response following a single intradermal injection of brucellin. There was also a strongly positive skin reaction and a low normal serum potassium. In view of the fact that these criteria were not found in the controls, it is not justifiable to dismiss the *Br. abortus* in any investigation on the strength of a single negative agglutination in the blood.

The importance of recognizing the chronic brucella state serves a twofold purpose. Firstly, in order to raise the index of suspicion of brucella in several chronic debilitating diseases. It has already been mentioned that transient polyarthritic symptoms were found to develop and reoccur in two of the cases, and a third case showed features suggestive of chronic brucella pyelitis. In view of Spink's remarkable case of chronic brucella pyelonephritis which showed caseation, calcification, and giant cell formation, it is surely justifiable to apply full brucella diagnostic procedures to most chronic granulomatous conditions where no pathological organism has been isolated. Secondly, to offer hope to a not insignificant group of patients who have often wandered from physician to physician (or surgeon) ever hopeful of seeking help and relief from their symptoms, and who, if left undiagnosed, may remain in chronic ill-health for many years.

It has been the purpose of this paper to attempt to show that these cases may be diagnosed if care is taken in interpreting the patients' histories, if the physical examination is thorough, if the temperature is recorded for five minutes, and if the laboratory and dermal sensitivity findings are all correlated together.

Summary

The essential clinical and laboratory features of cases of chronic brucellosis which have occurred in a rural practice are described.

In a survey of a group of people in a rural area the incidence of sensitivity to brucellin was found to be 21%.

The single intradermal injection of brucellin in a group of controls was followed by the appearance of antibodies in only a small number of cases. Such a rise, when it appeared, was not of high titre nor was it sustained.

The possible disturbance of potassium metabolism resulting from the intracellular habitat of *Brucella abortus* is discussed.

I thank the medical staff of the three hospitals involved in this survey for their kind co-operation in making available their

patients for skin testing. I also thank Dr. Gwenvron Griffiths and Dr. M. Hughes for their assistance in the biochemical and bacteriological aspects of the work involved, and especially Dr. W. Kwanters for his encouragement and his help in the skin-testing survey.

PREGNANCY AFTER PNEUMONECTOMY FOR PULMONARY TUBERCULOSIS

BY

LESLIE WILLIAMS, M.B., B.S.
Melbourne, Australia

During the past decade a number of patients have undergone pneumonectomy as part of their treatment for pulmonary tuberculosis, and some of them have subsequently returned to a life of reasonable activity. They have almost invariably had a prolonged and severe illness. Work with patients needing such an extensive operation as pneumonectomy is usually regarded as largely salvage work.

It was inevitable that some of this salvage work would be done on women in the child-bearing period of life, and that sooner or later we would be asked to advise for or against pregnancy, and, if advising in favour of it, to care for the patient during and after pregnancy. The problem is twofold. Firstly, can a woman with only one lung undergo pregnancy and normal delivery safely? Secondly, can such a woman subsequently recover and maintain herself in sufficiently good health to undertake and continue with family responsibilities?

It is well known from past experience that a woman with extensive bilateral pulmonary tuberculosis and little respiratory reserve can deliver herself normally of a healthy infant. It would seem, then, on theoretical grounds, that the absence of one lung should be no bar to pregnancy and normal delivery. But the answer to the second part of the problem is not so easy to deduce, for no one can yet be sure of the ultimate prognosis of the patient with one lung and a past history of pulmonary tuberculosis.

When the first such pneumonectomy patient presented me with this problem late in 1950, I advised her, with a certain amount of trepidation, to carry on with the pregnancy. The problem had to be solved by clinical trial.

The patient seemed an admirable one as a test case; at term she would have survived more than a two-year period after pneumonectomy, she was multiparous, had excellent respiratory reserve, and was quite without apprehension regarding the outcome. The result of the trial was most encouraging.

Present Series

The following small series of cases illustrates this and some further experiences.

Eighteen cases are reported. Two patients who were advised against carrying on with pregnancy had the pregnancy terminated, and were sterilized. Sixteen have been delivered (see Table): twelve at the Queen Victoria Memorial Hospital, where I was personally able to supervise the chest condition; three at the Royal Women's Hospital; and one at the Base Hospital, Geelong. It is notable that one patient had pneumonectomy performed during pregnancy.

Details of Cases (16 Patients)

State of Chest	Primigravidae	Multi-gravidae
Left pneumonectomy; clear right lung	3	2
Right pneumonectomy; clear left lung	3	2
Right pneumonectomy; some disease right lung ..	4	1
Right pneumonectomy; some disease in left lung ..	0	1

The average time interval between pneumonectomy and delivery was 26 months (variation between four months and four years). The average length of labour for primigravidae was approximately 26 hours (variation between 3½ and 50 hours) and for multigravidae 4½ hours (variation between 1½ and 7½ hours).

With one exception (Case 9) labour proceeded without undue respiratory distress; with one exception (Case 12) a living healthy child was born. All patients have been followed up for a minimum of one year.

A certain number of complications were associated with these pregnancies and deliveries, both respiratory and obstetrical.

Respiratory Complications.—Immediate: Two patients suffered respiratory distress during labour, one very mild, one severe. Both recovered completely after delivery and have shown no evidence since of respiratory damage due to stress in labour. The patient with severe distress was sterilized after delivery; the other was later delivered of a second child without any distress whatever. Late: One patient reactivated disease in her remaining lung six months after delivery, and required further antituberculous treatment.

Obstetrical Complications.—One patient developed mild hypertension at 36 weeks. Two patients developed toxæmia, one mild, one moderately severe. One patient developed severe hydramnios at 38 weeks. One had a post-partum severe haemorrhage requiring blood transfusion. One had a pre-mature but healthy infant. One had a stillborn child due to blood incompatibility between mother and foetus. One later aborted a second pregnancy.

The following cases are selected from the series:

Case 1

The patient was found to have pulmonary tuberculosis in 1947, some time after the birth of her second child. She was then aged 26. After a period of sanatorium treatment, left artificial pneumothorax was tried, but it failed to control the disease. Bronchoscopy showed that there was acute disease of the left main bronchus. A small area of infiltration in the right lung had cleared without leaving radiological signs. After 22 months' sanatorium treatment left pneumonectomy was done for uncontrolled cavitation in

the left lung with tuberculous bronchitis of the left main bronchus. Convalescence was uneventful, and the patient was discharged very well. She eventually returned to full house duties.

Her third pregnancy was quite uneventful, and 26 months after pneumonectomy she was delivered normally, at term, under nitrous oxide and oxygen anaesthesia. There was no respiratory distress during labour. The puerperium was uncomplicated; lactation was suppressed. The right lung remained clear. She has remained well for over five years, doing all her own housework and looking after three children.

Case 7

At the age of 22 this patient had a left pneumonectomy for extensive progressing disease of the left lung, with infiltration in the right upper zone not yet controlled. Following pneumonectomy her improvement was dramatic in spite of convalescence being complicated by empyema of the residual left thoracic space, with wound infection which required further operation. She made an apparently good recovery and was discharged from sanatorium. Subsequently the disease in the right lung reactivated with cavitation, and another year's sanatorium treatment was required. She became very well, returned to an active life, and married.

Four years after pneumonectomy, and two years after final discharge from sanatorium, she was safely delivered at term of her first child, under chemotherapeutic cover. Pregnancy was normal throughout and she had an undistressed 3½-hour labour. She was delivered under local analgesia by episiotomy and elective low forceps. The puerperium was uncomplicated; lactation was suppressed. She remained well, doing full house duties, and 23 months after the first delivery was successfully delivered of her second child. Lactation was again suppressed, mainly on the grounds of her complicated chest history. Following this delivery she was sterilized. She has remained well, doing full house duties and looking after her two children, 3½ years and 17 months after first and second deliveries respectively. The disease in the right lung remains stable.

Case 8

In 1949, at the age of 22, this patient was found to have extensive right-sided pulmonary tuberculosis. After three months' treatment, during which time she had a series of brisk haemoptyses and the disease in the right lung became somewhat worse, it was decided to do an early right pneumonectomy. The left lung was clear of disease. After operation she made an excellent recovery and was discharged very well. She eventually returned to an active life, married, and became pregnant.

Pregnancy was normal, and four years after pneumonectomy she was delivered at term, after a 42-hour labour, under local analgesia, by episiotomy and elective low forceps. During labour she became tired, but had no respiratory distress. The puerperium was uncomplicated, and she breast-fed the baby for three months. Just over two years later she was successfully delivered of her second child. Pregnancy, delivery, and puerperium were uncomplicated, and she again breast-fed the baby for three months. Following this delivery she was sterilized. She has remained well, doing her own housework and looking after two children, 3½ years and 14 months after her first and second deliveries respectively. Her remaining lung is still clear.

Case 9

After two years' sanatorium treatment, including a failed left artificial pneumothorax, the patient had a left pneumonectomy for a contracted non-functioning upper lobe with uncontrolled cavitation of the lower lobe. She suffered an immediate post-operative spread of disease throughout the right lung and was very ill. This spread cleared very well radiologically with chemotherapy, although the sputum was

intermittently positive for the next year. On discharge from sanatorium she was fairly well and able to do light housework, although she tired quickly. She had had one child before her illness, and after discharge from sanatorium remarried.

Two years after operation she presented with a pregnancy she was anxious to carry on. Her respiratory reserve was not very good, but after consultation with the obstetrician, as the patient was so keen to have another child, and in view of our previous favourable results, it was decided to let her go on. At 28 weeks' gestation she was rather short of breath and had become very scoliotic. The shortness of breath improved considerably with correction of posture. At 38 weeks she was admitted to hospital very short of breath, and was found to have developed acute hydmniosis. Caesarean section was discussed, but as it was considered that the shortness of breath was greatly aggravated by the hydmniosis it was decided to precipitate labour by artificial rupture of the membranes. By this time she was near term. Following rupture of the membranes the onset of labour was immediate, and labour progressed rapidly. But as labour progressed so did the patient's respiratory distress. She became dyspnoeic and cyanotic. Oxygen was administered, and as soon as it was practicable anaesthesia was induced with cyclopropane and oxygen and she was delivered by episiotomy and mid-forceps four hours after the onset of labour. Once delivery was accomplished recovery was dramatic and complete. Within three hours she was sitting up eating a meal; her pulse rate was 84 a minute, her colour good, and her spirits high. She was so well that sterilization was carried out 24 hours later. Lactation was suppressed, and the puerperium was otherwise quite uncomplicated. The right lung remained stable radiologically. The patient regained her previous state of fair health, and remains unchanged two years after delivery.

Case 11

Early in 1949, at the age of 21, this patient was found to have bilateral pulmonary tuberculosis, with cavitation in both lobes of the left lung and infiltration in the right upper zone. Monaldi suction drainage was instituted for the cavity in the extensively diseased left upper lobe, and later right artificial pneumothorax was induced. In spite of clinical improvement and apparent arrest of the right-sided disease, the left-sided disease progressed, and after one year's treatment left pneumonectomy was decided on. Refills to the pneumothorax were carried on until shortly before operation. Convalescence following operation was uneventful and the patient was subsequently discharged very well. She married, and lived an active life, including lawn-cutting with a hand-mower.

When she became pregnant for the first time I felt there was no need for qualms about her respiratory reserve. She was well during pregnancy until 38 weeks, when she was admitted with moderately severe toxæmia. Labour was induced, and four days before term she was delivered successfully after a 42-hour undistressed labour by episiotomy and low forceps under cyclopropane and oxygen anaesthesia. This was over five years after pneumonectomy, during which time the disease in the right lung remained stable. After manual removal of a non-adherent placenta for blood loss the puerperium was uncomplicated. Lactation was suppressed. The patient has remained well, leading an active life, for a period of 15 months after delivery.

Case 12

This patient had been treated over a period of six years for pulmonary tuberculosis. For a time she had a right artificial pneumothorax for extensive right-sided disease, which resulted in a contracted upper lobe, a collapsed lower lobe, and a very emphysematous middle lobe. In spite of this she was well until she became pregnant for the second time in 1952 at the age of 25. Very early in pregnancy a large cavity opened up in the right upper lobe. The left

lung remained clear. After careful consideration it was decided to do a right pneumonectomy during the second trimester of pregnancy.

During operation 4 pints (2,270 ml.) of Rh-negative blood was given according to the patient's blood group. Post-operative convalescence was smooth and she progressed well until 36 weeks, when she started rapidly to develop a high titre of Rh antibodies. The foetus died *in utero*, and was delivered normally at term, in a macerated state, four months after pneumonectomy. Labour lasted 7½ hours, during which there was no respiratory distress. This was a tragic outcome after so much effort. The pneumonectomy had nothing to do with the death of the child. The sudden and rapid rise in the titre of Rh antibodies in the mother's blood could not have been affected by any operative intervention. The puerperium was uncomplicated and the patient was later discharged home, where she has remained well and active for the succeeding four years.

Pregnancies Not Carried On

A. This patient had had a right pneumonectomy at the age of 20. While convalescing from operation disease in the left lung broke down and cavitated. Though this healed, her respiratory reserve was so impaired that she was unable to walk from one room to another without respiratory distress. When she became pregnant four years after operation she was considered unfit to carry on, and as there was no hope of improved function the pregnancy was terminated and the patient sterilized. She remains alive and in the same state of health two years later.

B. This patient had had her left lung removed for extensive disease at the age of 22. Disease in the right lung appeared to be arrested at the time of operation. She already had four living children before tuberculosis was discovered, and when, within one year of pneumonectomy, she became pregnant and the right-sided disease reactivated, the pregnancy was terminated and the patient sterilized. Her disease responded to further treatment, and she remains fairly well, doing light house duties, three years later.

Discussion

From the small number of cases reported, it is unwise to draw definite conclusions. But it seems obvious that a woman who becomes fit to return to normal housework following pneumonectomy for tuberculous disease is able to undertake pregnancy and normal delivery without undue hazard. The follow-up period is short, but so far the results are encouraging. All delivered patients have been followed up for a minimum of one year after confinement. With few exceptions the pregnancies were planned. Excluding the patient who was operated on during pregnancy, the average time between pneumonectomy and delivery was a little over three years.

It is fairly widely accepted that after recovery from pulmonary tuberculosis two years of good health without any evidence of deterioration can be classed as "apparent cure." From the obstetrical point of view the young patient is preferable to the middle-aged. With these two points in mind, it would seem that if a tuberculous woman remains well for two years after discharge from sanatorium and wishes to become pregnant, then there is no indication to wait longer, provided she has the necessary respiratory capacity.

Respiratory capacity is the most important single factor in assessing the post-pneumonectomy woman's fitness to have children. This is best judged clinically by questioning the patient about her daily routine and her ability to do tasks such as the ordinary housewife does. Radiological evidence may be deceptive, as impairment of function is not necessarily evident in an x-ray plate.

From my own experience I would divide these patients into three groups. Those who become breathless with the least exertion or with talking are not fit to go through

pregnancy. Those who cope with routine housework without breathlessness or fatigue will have little or no difficulty with pregnancy, labour, or delivery. Those who can do light housework but who become breathless if they hurry, and tire quickly, are the difficult ones to assess. Without complications the latter may do quite well, but any complication may tip the scale against them and precipitate a respiratory failure, particularly in labour. Such patients can probably be carried on to term fairly safely, but delivery by caesarean section may be advisable if breathlessness increases near term.

The tuberculosis specialist will also be asked to advise on other matters such as anaesthesia for labour, breast-feeding, and should the patient have more children.

In the above series of delivered patients all types of anaesthesia, both local and general, were used with success; but if there is the slightest sign of respiratory distress, cyclopropane with its accompanying high proportion of oxygen would be my choice.

Breast-feeding has always been a controversial subject when a mother has had tuberculosis. If a post-pneumonectomy patient has domestic help and little in the way of other family responsibilities I see no reason, if she has reached the stage of "apparent cure," why she should not breast-feed if she is carefully supervised.

I suppressed lactation in the majority of my own patients, as these ideal conditions are seldom available. Most of my patients had very complicated chest histories; some had other children to look after; and some were not able to find anyone to help them with their domestic responsibilities. Under such conditions I felt it better not to add lactation to the mother's burdens.

The knottiest problem of all to decide is the optimum size of family for a woman with one lung and a past history of tuberculosis. I advise primigravidae amongst my own patients to stop after having two children. But two of the above series of patients had already had two children before contracting tuberculosis. These children were all of school age when their mothers wished to embark on further pregnancy, so that under these conditions a third child did not seem an unreasonable hazard to the mother's health.

Follow-up.—All the patients reported here have been followed up for a minimum of one year. In only one delivered patient (Case 3) did the pulmonary disease re-activate after delivery. This occurred in a woman who had an unplanned pregnancy, who was delivered 12½ months after pneumonectomy, and in whom the disease in the remaining lung had been regarded as of doubtful stability. All the other delivered patients have shown no change in their states of health which could be called deleterious or which could be ascribed to pregnancy, delivery, or the added responsibility entailed in caring for their children.

Conclusion

It would appear from this small series of patients that, once a woman who has undergone pneumonectomy for tuberculosis has reached the stage of "apparent cure," child-bearing presents no undue hazard provided her respiratory capacity is reasonably good. The follow-up so far has given no indication that the responsibilities of looking after a limited family are dangerous to her future health; but I feel that consultation between the obstetrician and the chest physician is of the greatest importance, as each has so much to contribute to the patient's welfare.

I thank all my colleagues in the tuberculosis service who have helped me to collect information; my obstetrical colleagues at the Queen Victoria Memorial Hospital, who so skilfully managed my patients there; the staff of the Royal Women's Hospital, who kindly permitted me to consult their records; Dr. H. Roland and Dr. M. W. Morris, of Geelong, who supplied me with obstetrical details of Case 16; and Dr. Martha Renth and Dr. Isobel Ireland for suggestions.

RHEUMATIC HEART DISEASE
COMPLICATING PREGNANCY

RESULTS OF CONSERVATISM

BY

M. K. O'DRISCOLL, M.B., M.A.O., M.R.C.P.I.
M.R.C.O.G.

A. P. BARRY, M.D., M.A.O., F.R.C.O.G.

AND

M. I. DRURY, M.D., F.R.C.P.I.

From the National Maternity Hospital, Dublin

A clinical study of rheumatic heart disease complicating pregnancy was begun at the National Maternity Hospital on January 1, 1948. During the first four years 250 cases were treated, and these have been analysed (Drury *et al.*, 1954). In that series there was no indirect case selection, and the patients were of an age and parity rarely seen elsewhere.

During the subsequent four years 289 similar cases have been observed. These are now presented to show the results that have been attained by conservative management. This series is comparable to the previous one except that, in reference to the mothers, it concludes at the end of the puerperium, a period of six weeks following delivery. It is intended that a prolonged follow-up of all these women will be presented later. During the four-year period some of the women had more than one delivery; each pregnancy is considered as a separate case.

Analysis of 289 Cases

Rheumatic heart disease was diagnosed in 1.4% of all obstetrical patients attending the hospital during the period. The average age of the affected women was 30.8 years and the average parity 3.4. Twenty-five women (8.6%) were older than 40 years and 81 (28%) were pregnant for at least the fifth time. The incidence of the valvular lesions was: mitral stenosis, 272; mitral stenosis and aortic regurgitation, 15; mitral stenosis and aortic stenosis, 2. Thirteen cases with harsh mitral systolic murmurs and a personal history of rheumatic disease are included as "mitral stenosis," in conformity with our original paper. There were five cases of auricular fibrillation and one of bundle-branch block. Subacute bacterial endocarditis was diagnosed once, and active rheumatic carditis three times. Following the recommendation of the New York Heart Association the grading of effort intolerance was: grade I, 130; grade II, 98; grade III, 37; grade IV, 24. There were 34 emergency admissions, and 17 of these were in the more severe grades (III and IV).

The methods of delivery were as follows:

Caesarean section	2
Forceps or breech extraction	41
Spontaneous delivery	236 (3 twins)
Evacuation of incomplete abortion	4
Complete abortion	6

Therapeutic abortion was not performed in any case. In no case was labour induced for heart disease. It was induced on six occasions for pre-eclampsia, on three for a minor degree of contracted pelvis with a history of dystocia, and on one occasion each for recurrent pyelitis and for post-maturity. No caesarean section was performed for heart disease. The incidence of this operation was 0.7%. The indication was central placenta praevia in one instance, and in the other was foetal distress which developed in the first stage of labour in a woman of 43 who had no living child. This woman, well compensated throughout (grade I),

developed heart failure in the puerperium (grade IV). Seven mothers who had previously been delivered by the abdominal route were delivered through the natural passages. The assisted vaginal delivery rate was 14%.

Maternal Mortality.—One mother did not survive the puerperium. Her case record may be summarized as follows:

Aged 37, gravida-3. Youngest child aged 10 years. Mitral stenosis and aortic regurgitation. Rheumatic fever at 7 and 15 years. Emergency admission at 20 weeks' gestation in congestive heart failure, grade IV. Frequent attacks of failure had confined her to bed for most of the preceding four years. She suffered from angina at rest. A radiograph showed marked cardiac enlargement. Electrocardiography indicated left bundle-branch block. Her condition remained stationary throughout pregnancy and labour. She died from congestive heart failure 17 days after vaginal delivery. Her infant survived.

We consider that this woman had reached the final stage of the disease, that pregnancy did not shorten her life, and that surgical intervention would not have prolonged it.

Foetal Loss.—To assess the effects of rheumatic heart disease on the foetal survival rate the survey was concluded at the end of the neonatal period (28 days). There were three sets of twins. The results were as follows: surviving infants, 269; stillbirths, 6; neonatal deaths, 7; abortions and miscarriages, 10. Of all conceptions seen, 92% resulted in infants who survived birth by at least one month. The cause of death, based on clinical and necropsy findings, are given in detail. The grade of the mother's heart condition is included. **Stillbirths** (2.1%):—Death was due to intracranial haemorrhage in three instances (grades I, II, and III). One baby died from asphyxia when labour had lasted 24 hours following a period of gestation of 42 weeks (grade I). In one case the foetal heart ceased abruptly early in normal labour. No explanation for the sudden asphyxia was found (grade II). **Neonatal deaths** (2.5%):—Two infants had gross congenital malformations (grades I and IV). Four died from intracranial haemorrhages (grades I, II, III, and IV). One showed cerebral congestion and atelectasis (grade III). **Abortions and miscarriages** (3.4%):—All were spontaneous. In eight cases the heart condition was grade I and in two it was grade II.

Commissurotomy.—Mitral commissurotomy was performed on three patients—at 16, 18, and 30 weeks' gestation. In each patient the subsequent progress was uneventful and the baby survived. When a patient with mitral stenosis responds favourably to medical treatment we defer operation until after delivery. The operation may be life-saving when performed during pregnancy, but such cases are rare. The last patient referred to was admitted to hospital when 12 weeks pregnant. She was a suitable case for operation, but as she responded to conservative measures this was postponed. It had to be undertaken at 30 weeks, when her condition deteriorated.

Conclusion

Because contraception, abortion, and sterilization are not practised by the community from which these women were drawn they were truly unselected. The average age and parity were unusually high. The majority came from poor homes, and there is no official provision for home help in this city. It may therefore be assumed that the series was an unfavourable one and severely tested the form of management adopted. This was strictly conservative, as outlined in our first paper.

The results were purchased at a price. To the individual patient and her family this was the inconvenience of increasing rest and eventual hospitalization. The average stay in hospital before delivery was 20.6 days. To the hospital personnel it was the pressure on antenatal accommodation. These women occupied the equivalent of four antenatal beds continuously over the whole period of four years.

The results justify the conclusion that, no matter how serious the rheumatic heart condition may be, pregnancy should not be terminated at any stage, nor abdominal delivery resorted to.

Summary

The case histories of 289 pregnancies complicated by rheumatic heart disease are analysed.

One mother died before the end of the puerperium (0.3%). Thirteen viable infants did not survive the neonatal period (4.6%). Mitral commissurotomy was performed on three occasions (1%). No caesarean section or induction of labour was performed for heart disease. No therapeutic abortion was performed.

We are grateful to our colleagues at the National Maternity Hospital for their co-operation in the management of these patients.

PROGNOSIS OF INTERMITTENT
CLAUDICATION

BY

R. L. RICHARDS, M.D., F.R.C.P.Ed.

Senior Lecturer in Medicine, Gardiner Institute, the
University and Western Infirmary, Glasgow

More than a century has passed since Brodie (1846) first described in man the symptom-complex which we now call intermittent claudication. He clearly recognized its association with obliterative arterial disease of the main arteries of the lower limbs, and he pointed out that it was frequently a premonitory symptom of what was then called "senile gangrene." Although we still recognize these associations there is little reliable information about the prognostic significance of intermittent claudication. Most physicians are familiar with patients who have had claudication for many years without developing gangrene or any other serious cardiovascular catastrophe, but they can also recall others who, within a short time of presenting with claudication, have lost a limb or suffered a myocardial infarction or had a cerebrovascular accident. Such patients are remembered, but it is difficult to obtain accurate data on what happens to the majority of patients who present with intermittent claudication.

Stammers (1954) has said that nearly all those who complain of claudication at the age of 55 to 60 years are dead within five years. Hines and Barker (1940) reviewed a series of 116 patients with arteriosclerosis obliterans many of whom had gangrene as well as claudication, and found that 54.5% were dead within three years. Spaulding (1956) reported that of 108 patients who had had claudication for more than three years only 13% had died. In a report on a clinical trial of the value of nicotiny alcohol tartrate in the treatment of claudication Gillhespy (1957) stated that 15 out of 50 patients died before the trial period of 18 months was completed. In view of these conflicting statements it seemed desirable to review a series of patients who had presented with intermittent claudication as their main symptom and who had been under observation for at least five years.

Clinical Material

The material consists of 60 patients who were seen at the Vascular Clinic of the Western Infirmary, Glasgow, prior to December 31, 1951, and who have been under continuous observation for at least five years or who are known to have died during this follow-up period. The presenting symptom in all the patients was typical intermittent claudication, and at the time of their initial examination none of them had more than slight nutritional changes in the feet. Patients with obvious ischaemia of the feet were excluded from the series, so that the results are applicable only to patients who have uncomplicated intermittent claudication. The duration of the claudication before the patients were seen varied from a few days to five years. There were 55 men and 5 women in the series. Their ages ranged from 24 to 69, with a mean of 52.9 years. Exactly half were in the sixth decade; 6 were under 40, and 15 were 60 or more. There were only four diabetics in the series.

Clinical Observations

Type of Peripheral Arterial Disease

Two of the youngest patients in the series, aged 30 and 36 respectively, had thrombo-angiitis obliterans; the remainder were thought to have atherosclerosis (arteriosclerosis obliterans). It is of interest that the youngest patient, who presented with claudication at the age of 24 and who died of myocardial infarction at the age of 27, did not have thrombo-angiitis obliterans but widespread atherosclerosis. The majority (41 patients) presented clinical findings which suggested arterial occlusion at the level of the lower part of the femoral artery or the proximal part of the popliteal artery—that is, they had good femoral pulses in the femoral triangle, but pulsation could not be felt distal to this. In this group the occlusion was initially bilateral in 29 patients and unilateral in 12 (Table I). Four patients

TABLE I.—Type of Peripheral Arterial Disease

Type of Arterial Disease	Unilateral	Bilateral	Total
Atherosclerosis with high occlusion	2	2	4
" " femoral or popliteal occlusion	12	29	41
Atherosclerosis with distal occlusion	2	2	4
" " asymmetrical occlusion	0	9	9
Thrombo-angiitis obliterans	1	1	2
Total	17	43	60

had high arterial occlusions: two had obstruction of the common or external iliac artery on one side only, one had a bilateral iliac occlusion, and one had an aortic occlusion. Four patients had a distal type of arterial disease—that is, they had good femoral and popliteal pulses but absent pedal pulses. In nine cases there was evidence of bilateral arterial disease, but the occlusions were at different levels on the two sides: five had a high arterial occlusion on one side with a femoral or popliteal occlusion in the other limb, and four had a femoral or popliteal occlusion on one side with a distal lesion in the other limb. Four patients, including one of those with thrombo-angiitis obliterans, presented with an acute arterial occlusion; in the remainder the onset of claudication was gradual.

Mortality

Seventeen patients (28.3%) have died during the follow-up period. The cause of death is known for all but two. Seven died of myocardial infarction, three of a cerebrovascular accident, two of congestive cardiac failure, one of the combined effects of diabetes mellitus, tuberculous empyema, and amputation of a leg for gangrene, and two of causes not directly connected with the cardiovascular system—perforation of a peptic ulcer and carcinoma of the pancreas. Analysis of the deaths shows that 13 occurred in patients who were over 50 at the time of their first attendance and only four in patients less than 50. Ten of the

patients who died had hypertension (more than one casual reading of diastolic blood pressure over 100 mm. Hg) and 15 had bilateral peripheral arterial disease when they were first seen. In this group the mean duration of life from the onset of claudication was exactly five years.

Progress of Peripheral Arterial Disease

In assessing the progress of the peripheral arterial disease minor changes in the patient's claudication distance have been ignored. It is well known that intermittent claudication is a variable symptom and that quite considerable fluctuations in its severity may occur spontaneously (Hamilton and Wilson, 1952). Unless a patient had marked reduction in his claudication distance associated with objective evidence of deterioration in the nutrition of the affected limb or limbs his condition has been assessed as unchanged or improved. Twenty-seven of the 43 survivors (60%) fall into this category (Table II). Definite evidence

TABLE II.—Survivors: Progress of Peripheral Arterial Disease

Unchanged or improved	27
Worse	14
Unilateral→bilateral	3
Acute arterial occlusion	3
Definite deterioration	5
Amputation	3
Quiescent thrombo-angiitis obliterans	2
	43

of progression of the peripheral arterial disease was observed in 14 cases; three patients who originally had unilateral involvement later developed claudication in the other leg, three had an episode of acute arterial occlusion, and in eight there was obvious gradual worsening of the state of the affected limbs with the development of marked nutritional changes and rest pain in some instances, but only three of these required amputation of a limb. In the two cases of thrombo-angiitis obliterans the disease has apparently been quiescent for two to three years. The mean duration of claudication in the group of 43 survivors is 7.3 years.

Evidence of Generalized Cardiovascular Disease

More than two-thirds of the survivors complained of breathlessness on exertion. No attempt was made to grade the severity of the dyspnoea, and it is known that some of these patients had chronic bronchitis. No significance can therefore be placed on this finding as an indication of cardiovascular disease. Thirteen patients (30%) had definite hypertension (more than one casual diastolic blood pressure reading over 100 mm. Hg). Seventeen patients (39%) complained of angina of effort, and 13 (30%) gave a good clinical history of a myocardial infarction. Only two patients had suffered attacks of congestive cardiac failure. Three had definite cerebrovascular episodes which left neurological sequelae. Considering the series as a whole, after five years, 13 patients had died from cardiovascular causes, and 31 (72%) of the survivors had definite clinical evidence of generalized vascular disease. There were only 12 cases in which the disease was still apparently confined to the lower limbs.

Electrocardiograms were obtained on 34 of the survivors. Only five electrocardiograms were regarded as within normal limits. The most common abnormality was definite evidence of myocardial infarction. This was present in 14 cases; 12 of these were cases in which there was a clear history of myocardial infarction; the electrocardiogram of the thirteenth patient who gave a history of infarction showed left bundle-branch block. There were two instances in which, although the electrocardiogram indicated infarction, there was no clear history of an episode which could be interpreted as an attack. In five cases the electrocardiographic pattern was that of coronary insufficiency, and in four patients, all in the hypertensive group, the electrocardiogram showed evidence of left ventricular hypertrophy. In six cases there were other electrocardiographic abnormalities, bundle-branch block, extrasystoles, or changes in the T waves.

Effect of Treatment

The critical studies of Hamilton and Wilson (1952) and Hamilton *et al.* (1953) have shown that it is difficult to prove that any form of medicinal therapy influences the progress of intermittent claudication. During the five-year period of most of the patients in the present series had courses of treatment with vasodilator drugs such as tolazoline hydrochloride ("prisco"), nicotinic alcohol tartrate ("ronicol"), or spasmocyclone ("cyclospasmol"), or with alpha-tocopherol (vitamin E). Some patients appeared to obtain benefit from one or other of these drugs, but no attempt was made to assess their value by objective tests or to carry out a controlled trial. It is probable that fluctuations in the severity of the claudication represented the natural history of the disease rather than the effects of medical treatment.

Opinion is divided about the value of lumbar sympathectomy in the treatment of intermittent claudication. American surgeons (de Takats *et al.*, 1946; Berry *et al.*, 1955; Edwards and Crane, 1956) are favourably impressed with the results, but most British surgeons (Learmonth, 1950; Mavor, 1955) feel that the operation is of little value in the treatment of the patient whose only complaint is of intermittent claudication. In the present series 27 patients had lumbar sympathectomy performed, unilateral in 21 and bilateral in 6. In Table III the progress of the patients

TABLE III.—Effect of Lumbar Sympathectomy

Status at 31/12/56	Medical Treatment Only	Lumbar Sympathectomy
Peripheral arterial disease:		
Unchanged or improved	20	7
Worse	5	9
Quiescent thrombo-angiitis obliterans	0	2
Dead	8	9
Total	33	27

who had sympathectomy is compared with that of those who had medical treatment only. The figures are too small to be of statistical significance, but they offer no evidence that the patients who were operated upon did any better than those treated conservatively. It will be noted that in the group which underwent sympathectomy there are a relatively large number of patients whose peripheral arterial disease was progressive. This is certainly due to the fact that the operation was performed in many of these cases because of the progression of the disease and with the hope of preventing the development of gangrene.

Discussion

Intermittent claudication is almost always a symptom of obliterative arterial disease affecting the blood vessels of the lower limb. The common cause of the arterial disease is atherosclerosis (arteriosclerosis obliterans). Thrombo-angiitis obliterans is a relatively infrequent cause of claudication; it is an uncommon disease, and patients who suffer from it more often present with ischaemic lesions of the feet. The ratio of one patient with thrombo-angiitis obliterans to 30 with atherosclerosis is probably about the average. The age-and-sex incidence of the present series, with a preponderance of patients in the sixth decade but with some younger patients and a number over 60, and with a ratio of 11 males to one female, is typical of degenerative arterial disease.

Atheroma may be confined to one artery or even to a portion of a single artery, but it is commoner for the process to be generalized, although it seldom affects all parts of the arterial tree to the same extent. Therefore it should not be surprising to find that in a group of patients with intermittent claudication there is a high incidence of cardiovascular catastrophes and of symptoms of both ischaemic heart disease and cerebrovascular disease.

McDonald (1953) has already commented upon the association of ischaemic heart disease with peripheral occlusive arterial disease. He studied 129 patients—79 who presented

with intermittent claudication and 50 who presented with angina of effort. When he followed the 79 patients with claudication over a period of two years he found that 23% had developed angina and that 31 of them had abnormal electrocardiograms. These figures may be compared with a 39% incidence of angina and 29 abnormal electrocardiograms in the 43 survivors of the present series. In his 50 patients who presented with angina McDonald (1953) found that four of these had also intermittent claudication and eight others had objective evidence of occlusive arterial disease. In this series the incidence of ischaemic heart disease is higher; if all cases of myocardial infarction, angina of effort, and congestive cardiac failure are included the figure is 57%. The present series may also be compared with that reported by Spaulding (1956). In his group of patients who were followed for three years he found claudication in 22 patients (20%) and electrocardiographic abnormalities in 47%. These figures are also lower than those noted in this study, and the implication must be that the longer a group of patients with claudication is followed the greater the number that will show signs of ischaemic heart disease.

The association of cerebral vascular disease with peripheral arterial disease does not appear to have been studied before, and the number of recognizable cerebrovascular episodes in the present series—6 out of 60, three of them fatal—is too small for any conclusions to be based upon them.

With regard to mortality, the only figures which can be compared with the present study are those recorded by Spaulding (1956). Of his 108 patients, 13% died within three years of the onset. Since not all his patients were followed for five years, he could give only an estimate of the five-year mortality, and this he put at 25%. There were 32 deaths in his series, and 21 of these were due to cardiovascular disease.

The mortality in the present series (28%) is higher than Spaulding's estimate, and the number of deaths from cardiovascular disease is also higher (13 out of 17). In this series, as in Spaulding's, there is evidence that the association of hypertension with occlusive peripheral arterial disease makes the prognosis worse: 60% of those who died were hypertensive, compared with 30% of the survivors. He also commented on the fact that the prognosis was on the whole better if the peripheral arterial disease was unilateral when the patient was first seen. This view is supported by the present study: in only two of the fatal cases was the arterial disease unilateral. The age of the patient at the time of the onset of claudication is probably also of prognostic significance. Spaulding (1956) noted that, in general, the younger the patient when his claudication began the longer its duration before death. This is also true of the present series, although there are notable exceptions—for example, the patient who developed claudication at 24 and died at the age of 27.

It is instructive to compare the mortality figures for these patients with intermittent claudication with the published results for the prognosis in cases of angina pectoris, and in cases where a patient has survived the immediate effects of a myocardial infarction. For angina pectoris the figures based on the largest number of cases are those of Block *et al.* (1952). They followed 6,882 patients who presented with angina; the average age of the patients was 58.8 years, and the duration of the angina at the time the patient was first seen varied from a few days to 18 years. The overall mortality five years after the patients came under observation was 42.2%. In a smaller series reported by White *et al.* (1943), the five-year mortality was 29.8%. Both of these mortality rates are higher than that observed in the present study. Considering myocardial infarction, Cole *et al.* (1954) found that, of 390 patients, 105 died in the first two months and 95 of the 285 survivors died in the next five years, a mortality rate of 33%. Although the numbers in the present series are small the results do suggest that the prognosis for

the patient with intermittent claudication is rather better than that for the patient who has angina pectoris or who has survived the immediate effects of a myocardial infarction.

With regard to the peripheral arterial disease itself, the present study indicates that the prognosis is relatively good. At the end of the five-year period more than half the survivors were no more disabled by their intermittent claudication than they had been when they were first seen, and several were convinced that they were better. In some cases this symptomatic improvement could be due to the fact that the patients were unable to walk so fast because of either angina of effort or cardiac dyspnoea, but, on the other hand, it is true to say that none of the patients in this group showed any objective evidence of progression of their peripheral arterial disease. The incidence of gangrene necessitating amputation is low; only six amputations were done in the 60 patients, whereas both Hines and Barker (1940) and Spaulding (1956) report a 25% amputation rate in their series. These good results are probably due not to any medicinal or surgical treatment but to the fact that the patients are a select group who have been kept under close observation during the five-year period by physicians and surgeons who have been keenly interested in their welfare and who have encouraged them to take good care of their feet and to be as active as possible within the limits of their disability. For the patient with intermittent claudication adherence to simple rules of foot hygiene and the taking of a moderate amount of regular exercise are probably more important therapeutic measures than the prescription of any drug or the performance of any surgical operation.

Summary and Conclusions

Intermittent claudication is generally regarded as a chronic but rather annoying symptom which is not of serious prognostic significance. This study of a select series of 60 patients, all of whom have been followed for at least five years or to death, indicates that claudication is often the first symptom of general cardiovascular disease which may prove fatal within a few years. The prognosis as regards life, however, is not as serious as that of angina pectoris or that of myocardial infarction from which the patient has apparently made a good immediate recovery. The outlook so far as the claudication itself is concerned, and also for the affected limb or limbs, is probably better than is generally realized, and as time goes on the patient is more likely to be disabled by the effects of coronary or cerebral arterial disease than by his peripheral arterial disease. These facts must be taken into consideration when any direct surgical approach to the treatment of intermittent claudication, such as arterial grafting, is being planned.

I should like to thank my colleagues in the Vascular Clinic, Professor W. A. Mackey, Mr. G. Smith, Dr. J. Allan, and Dr. J. Buchanan, for their help in compiling the excellent clinical notes which made this study possible.

SPLENIC NEUTROPENIA IN FELTY'S SYNDROME

BY

J. N. BLAU, M.B., M.R.C.P.

Late Medical Registrar, Mount Vernon Hospital

AND

A. WILLCOX, M.D., F.R.C.P.

Physician, the Middlesex Hospital and Mount Vernon Hospital

Felty (1924) described the cases of five patients who had rheumatoid arthritis, splenomegaly, and leucopenia. The concept of primary splenic neutropenia was formulated by Wiseman and Doan (1942) when they recorded five cases of neutropenia and splenic enlargement in which a normal white blood count was restored by splenectomy. Gauld (1949) described the success of splenectomy in a woman aged 38 with mild rheumatoid arthritis, splenomegaly, and severe neutropenia. This resembles in many ways the case described below.

Case Report

A retired female clerk aged 68 was admitted to Mount Vernon Hospital on December 1, 1955. She had been feverish and vaguely ill since an attack of herpes zoster in May. Twenty years ago she had had recurrent iritis and pyelitis. For four years she had had epigastric and retrosternal pain after meals, on stooping, and when in bed; she had vomited blood and passed a melaena stool twice during the previous seven months. Rheumatoid arthritis began in 1948, starting in the hands and gradually involving most joints. It had been treated by heat, massage, and aspirin, and had caused few symptoms in recent years. It was not a serious trouble to her on admission. The only medicines she had taken were antacid tablets and soluble aspirin. Her mother had suffered from arthritis of the knees, ankles, and shoulders in her later years and died of pneumonia, aged 73.

On examination the patient was obese and pale, with mild rheumatoid arthritis of the hands. The liver extended one fingerbreadth and the spleen three fingerbreadths below the

costal margin. The lymph nodes were not enlarged. The left eye had been damaged by iritis. Other systems were normal, but she was pyrexial; temperature 99.8° F. (37.7° C.), pulse rate 112.

The results of investigations were as follows: Hb, 55%; red cells, 4,140,000 per c.mm.; reticulocytes, less than 1%; P.C.V., 29%; M.C.V., 77 cubic microns; M.C.H., 33 μ g.; M.C.H.C., 25%; red-cell fragility, serum bilirubin, and urobilinogen in the urine all normal; occult blood in the faeces, negative; E.S.R., 31 mm. in one hour (Westergren); Wassermann reaction negative; barium meal x-ray film showed a small hiatus hernia.

A constant granulopenia and thrombocytopenia was found. The variations are shown in Fig. 1. On December 9 the white cells numbered 1,000 cells per c.mm., with only 60 polymorphs per c.mm. The platelets were 92,000 per c.mm.

A biopsy of the bone marrow showed a moderately cellular marrow with a shift to the left in the granular series, normoblastic erythropoiesis, and a myeloid/erythroid ratio of 2.1:1. Megakaryocytes were scanty, and some of the mature ones showed no granularity.

Cortisone was given for 15 days, starting with 300 mg. daily, the dose being gradually reduced. It caused no change in the blood count, but relieved the joint pains. She developed several infections, which included acute bronchitis (*Staphylococcus aureus* in the sputum), aphthous stomatitis, pharyngitis, laryngitis, and cellulitis of the arm. Penicillin was ineffective, but tetracycline caused a remission of fever and infection.

Mr. Ralph Marnham removed the spleen on January 24, 1956. It weighed 705 g. The cut surface was dark pink, with loss of the normal pattern. Microscopy showed non-specific hyperplasia of the pulp widely separating the Malpighian bodies. The sinusoids were congested, with increased cellular components, including reticulum cells.

The changes in the white blood count immediately after operation are shown in Fig. 2. The total number of polymorphs did not become normal until five and a half hours after the splenic pedicle was tied, when the count was: leucocytes, 4,200 (polymorphs 67%, lymphocytes 23%, monocytes 10%). The platelet count rose persistently until it reached 1,060,000 on the eleventh day after operation.

Post-operative progress was uncomplicated except for thrombophlebitis in the right calf, which resolved quickly with firm bandaging. Fifteen days after splenectomy the

Fig. 1.—White blood counts before and after splenectomy.

bone marrow showed a myeloid/erythroid ratio of 11:1. A relative increase in myelocytes was still present. When she left hospital on February 10 she had been free from infections since splenectomy and was in good health.

She was readmitted on May 26 for repair of a uterine prolapse. Since leaving hospital in February she had had

Fig. 2.—White blood count during the immediate post-operative period.

no further infections. The arthritis has not been unusually troublesome. The physical findings were unchanged. Blood counts (Fig. 1) showed a total number of white cells which was normal (between 6,000 and 8,000), but the percentage of polymorphs was often low, ranging between 20 and 60%. The number of polymorphs, however, was always above 1,500 per c.mm. The sternal marrow on June 21 was normal, with a myeloid/erythroid ratio of 5.5:1.

The prolapse was repaired by Mr. Arthure on June 21. Convalescence was interrupted by a respiratory infection, a burst abdomen, congestive heart failure, and an axillary vein thrombosis. However, she overcame these complications and left hospital on August 28.

When last seen, in June, 1957, she was well, apart from mild rheumatoid arthritis, and her blood count was normal.

Discussion

The severe leucopenia originally found in this patient was associated with crippling ill-health because of repeated infections, many of them serious. A few hours after splenectomy the leucocyte count became normal, and remained so, although the granular cells were sometimes at the lower limit of the normal range. The tendency to infection was unaffected, fully corrected. The rheumatoid arthritis was unaffected, remained mildly active, and may have been the cause of the occasional low neutrophil counts. Hutchison and Alexander (1954) describe a similar case of a woman of 50 who had had rheumatoid arthritis for twenty years. She was repeatedly admitted to hospital between 1950 and 1953 with infections and a persistent leucopenia, the neutrophil count ranging from nil to 730 per c.mm. An enlarged spleen, weighing 300 g., was removed in February, 1953, whereupon the leucocyte count rose to 5,000 per c.mm., the neutrophils to 2,500. Microscopy of the spleen showed no evidence of excessive phagocytosis, and neutropenia was thought to be due to maturation arrest. They review the literature concerning splenic neutropenia, and consider in particular the 21 cases recorded in which splenectomy led to recovery. The spleen showed signs of excessive phagocytosis in 11, 6 of whom had rheumatoid arthritis; in the other 10, of whom 2 had rheumatoid arthritis, the spleen did not show phagocytosis, but there was evidence of maturation arrest. In our patient the signs also were more suggestive of maturation arrest than of excessive phagocytosis.

Splenic neutropenia should therefore be considered when a patient with Felty's syndrome has repeated infections,

persistent fever, and ill-health which may be prolonged (Doan, 1955). The improvement after splenectomy can be impressive.

Summary

The results of splenectomy are described in a woman aged 68 with Felty's syndrome and neutropenia.

Rheumatoid arthritis had been present for seven years; its activity was unaltered by the operation.

She was admitted to hospital because of recurrent fever following an attack of herpes zoster seven months previously. Hepatomegaly and splenomegaly with a persistent leucopenia (total count usually below 2,000 per c.mm.) and granulopenia (polymorphs below 100 per c.mm.) were found; the leucocyte count was unaffected by treatment with cortisone. She developed many infections during the next six weeks.

Splenectomy was performed, the spleen weighing 705 g. and showing non-specific hyperplasia of the pulp with congested sinusoids.

Four hours after the splenic pedicle was tied the leucocyte count rose to 4,200 per c.mm. and has since remained at a normal level. The polymorphs have ranged between 60% and 20%, but the total has always been above 1,500 per c.mm. The patient has been afebrile and free from infections.

Medical Memorandum

Infection of Bone and Joint by *Salmonellae*

Abscesses and bony infections caused by the more invasive salmonellae, such as *Salmonella typhi*, are well known; it is not common, however, to find systemic infections of this nature caused by the less invasive members of the group, such as *Salm. typhimurium*. Neither are reports of such infections by *Salm. cholerae suis* frequent in this country (Boycott and McNee, 1936; Schwabacher, Taylor, and White, 1943; Laylee, 1957), although in America Saphra and Wassermann (1954) reported on a series of 329 patients infected with this organism, in which there were 144 instances of septicaemia with a positive blood culture and 53 cases of gastro-enteritis. The American variant of *Salm. cholerae suis*, which may be presumed to have infected the majority of Saphra and Wassermann's cases, is known to be much more invasive than the European or *kunzedorf* variant, and differs from it in a number of biochemical and antigenic particulars.

The two cases reported here, of infection with *Salm. cholerae suis* var. *kunzedorf* and *Salm. typhimurium* are presented because they demonstrate the circumstances under which may occur systemic infection by organisms which have poor invasive powers, and also for the intrinsic interest of the clinical findings.

CASE 1

A woman of 60 with diabetes of five years' duration was admitted in a debilitated state but with no abnormal physical signs. Her blood glucose level was 280 mg. per 100 ml., her temperature was 100.2° F. (37.9° C.), and she had severe ketosis. The diabetic condition was easily dealt with, but the fever remained. A leucocytosis of 12,000 cells per c.mm. (72% neutrophils) and an E.S.R. of 117 mm./hr. (Westergren) was found. A radiograph of the chest showed a diffuse fine nodular mottling in both lungs, and a diagnosis of miliary tuberculosis was considered. She was accordingly treated with streptomycin and P.A.S.

After a week of this treatment the high pyrexia and leucocytosis remained; serological investigations showed a titre of 1/5,120 against a non-specific *Salmonella* H suspension and of 1/320 against *Salm. paratyphi* C O, but less than 1/20 against *Salm. typhi* and *Salm. paratyphi* A and B. This clearly indicated an infection with *Salm. paratyphi* C or a closely allied organism, and a subsequent blood culture produced a growth of a member of the *Salmonella* group, sensitive *in vitro* to streptomycin, chlortetracycline, and chloramphenicol, and later identified as *Salm. cholerae suis* var. *kunzendorf*. Chloramphenicol (1.5 g. daily) was now administered, and the patient's temperature fell to normal in 48 hours. After a 10-days course her condition had greatly improved; blood culture at this time was sterile.

Ten days later she coughed up an ounce (28 ml.) of bright-red blood for which no cause could be found in the nose or throat; her temperature rose to 100.4° F. (38° C.) and her condition deteriorated. The appearance of the chest x-ray film was unchanged; the leucocytosis remained at 13,600 cells per c.mm. (81% neutrophils), while a blood culture once more produced *Salm. cholerae suis*.

Chloramphenicol was given for three weeks, and streptomycin at the same time for six weeks; a fortnight after this was begun a course of tetracycline (3 g. daily) was given for three weeks; the patient was also transfused with fresh blood.

A week later she complained of a sudden severe stabbing pain in the small of the back which gradually ceased during the next three days. A few days later she was found in an unconscious state, from which she recovered gradually and spontaneously after several hours, some weakness of the right leg being the only residual physical sign. A radiograph of the skull and lumbar spine at this time showed a normal appearance.

Her general condition remained very poor; the temperature was still 100–101° F. (37.8–38.5° C.), the E.S.R. was 112 mm./hr., and the leucocytosis had advanced to 29,200 cells per c.mm. (94% neutrophils). Two pints (1.14 l.) of blood were given, and 4 g. of chloramphenicol daily for six days was followed by 0.25 g. intravenously 4-hourly for 24 hours; penicillin was also given to deal with a mild urinary infection. Her temperature now remained normal, and treatment was directed at relieving congestive heart failure and dealing with hypoproteinaemia. At this time, for the only occasion during her illness, *Salm. cholerae suis* was isolated from the faeces; it could still be recovered from the blood. A radiograph of the spine showed a rounded soft-tissue shadow in the centre of the abdomen, and osteomyelitis of the third, fourth, and fifth lumbar vertebrae with collapse of the body of the fourth.

On the day following this radiograph a large abdominal mass was palpated near the body of the fourth lumbar vertebra. This was thought to be an aortic aneurysm, but because of the patient's condition laparotomy was not undertaken, and she died 10 days later.

Post-mortem Examination.—Apart from the findings in the abdomen and pelvis there were considerable emaciation, some pulmonary oedema, and a terminal pyelonephritis and cystitis. A large mass found in the abdomen consisted of a number of structures; there was an osteomyelitis of the bodies of the third, fourth, and fifth lumbar vertebrae with collapse of the body of the fourth. The aorta lying immediately in front of this had a perforation 3 mm. across in its posterior wall, and was surrounded by organizing blood clot, forming a false aneurysm; adherent to it was a mass of bowel, having several enlarged lymph nodes in its mesentery. *Salm. cholerae suis* was recovered from the lymph nodes, the blood clot of the false aneurysm, and the site of the osteomyelitis.

There was no evidence of pulmonary tuberculosis or of any cerebral vascular disease.

CASE 2

An emaciated man of 75 was seen with swelling of the right shoulder and inability to use the right arm. He could

not give a clear history, but admitted increasing tiredness for a year.

There was a fluctuant swelling of the joint and wasting of the right shoulder-girdle muscles with enlarged and tender axillary lymph nodes; no other abnormal physical signs were found. A radiograph showed only osteoarthritis of the acromio-clavicular joint. His temperature on the first two days after admission rose in the evening to 100° F. (37.8° C.). His E.S.R. was 104 mm./hr. (Westergren), and his total leucocyte count was 9,600 per c.mm. (neutrophils 76%, lymphocytes 22%, monocytes 2%). Aspiration of the joint produced an ounce (28 ml.) of thick blood-stained fluid which yielded a heavy growth of *Salm. typhimurium*.

This organism was obtained from the joint on one further occasion. Serological evidence of infection was found (titres of 1/800 against H and 1/1,200 against O suspensions); the organism was never found in the faeces. The sera of the patient's wife and daughter were investigated for evidence of infection, with negative results. Chloramphenicol (15 g. total) was administered, the shoulder became painless, the swelling did not recur, and his mental condition became much clearer. He was discharged after five weeks in hospital in excellent general condition, but with very limited movements of his shoulder-joint. A radiograph taken a few days before discharge showed well-marked osteomyelitis in all the bones round the shoulder-joint, with osteitis eroding the acromion process.

DISCUSSION

Among the *Salmonella* group of organisms, *Salm. typhi* and *Salm. paratyphi* B are the two most frequently responsible for bone infection. White and Meynell (1956) found only 28 reports of osteomyelitis caused by other members of the group, of which 17 were due to *Salm. cholerae suis* and 4 to *Salm. typhimurium*.

It is rarely possible to demonstrate the source of infection by *Salm. cholerae suis* in man. The natural host is the pig, and the organism is frequently found in cultures of the animal's mesenteric lymph nodes (Wilson and Miles, 1955); a probable source of infection is therefore undercooked pork.

Neither of the two organisms in this account seems to be capable of systemic invasion unless the resistance of the patient is diminished; this was clearly the case with the first patient. The second patient was an elderly man with bad teeth and in a poor state of nutrition; it required six days to saturate him with ascorbic acid instead of the normal one or two days.

It has been reported by several authors (Boycott and McNee, 1936; Goulder, Kingsland, and Janeway, 1942; Schwabacher *et al.*, 1943) that the formation of an abscess or sinular localization in *Salm. cholerae suis* infection is accompanied by a very high leucocytosis. In the first patient, although the site of the osteomyelitis did not at once declare itself, the persistence of the leucocytosis prompted repeated radiographic examination until the lesion was eventually found. In the second case there was no leucocytosis, and in spite of the radiographic changes the organism may not have invaded the bone to any great degree.

Our thanks are due to Dr. W. G. Oakley and Mr. A. J. Heriot for permitting us to refer to patients under their care; and to Dr. D. G. Rushton for the post-mortem report.

Reviews

CHEST INJURIES

The Initial Management of Thoracic and Thoraco-abdominal Trauma. By Lawrence M. Shefts, M.D. (Pp. 121+xviii; illustrated, 50s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

The treatment of any thoracic injury may be divided into several phases. The immediate and urgent remedy of shock or damaged chest physiology to save life is obvious, but the later stages which may or may not require operative treatment are often a matter of dispute. The author has a wide experience gained in Italy with the American Army, and discusses in this monograph the various features of injury and indicates what type of treatment is required and at what time. The opening chapters deal with the problem of shock and sucking chest wounds and the methods of dealing with open wounds into the pleural cavity. The author emphasizes the policy that early and complete aspiration of blood and air should be carried out and repeated as often as necessary. He also suggests the use of the term "progressive tension pneumothorax" to describe cases in which a continued leak of air into the pleural cavity builds up a dangerous degree of compression. Many practical points are given about the handling of patients in these early stages. For instance, untrained staff may easily on moving the patient raise a water-seal bottle draining the pleural cavity above the level of the patient and siphon the contents back into the chest. Severe chest-wall pain which inhibits respiration and coughing should be treated by a local anaesthetic block and occasionally by intravenous procaine. In assessing any penetrating wound the type and the course of the missile have to be considered. From the surgeon's point of view it is important to decide at what point, if any, operation should be undertaken, but, prior to this, restoration of the normal physiological conditions of the thorax is essential. For example, intrapleural tension must be relieved by needle aspiration or water-seal drainage. If a coexistent abdominal wound is suspected, that is a definite indication for surgery. Surgery is also needed when there is continual bleeding from the heart or from a large vessel and, less urgently, for the removal of foreign bodies. Bleeding into the chest may come from a variety of sources, but of these the lung is one of the least important, unless a major vessel has been torn. Similarly, and rather unexpectedly, a divided intercostal artery does not often give rise to continued bleeding. If there is injury to the heart or great vessels there will be free bleeding into the pleural cavity, and the clinical evidence of persistent haemorrhage will suggest that urgent surgery is required. Attention should also be given to the possibility of bleeding from the spleen or liver, which, if suspected, is a definite reason for operation because of intra-abdominal penetration.

Thoraco-abdominal wounds have a higher mortality rate than purely thoracic injuries, and the dangers of a left-sided abdominal injury are greater than those of a right-sided one. If at any time penetration of the diaphragm is suspected exploration of the abdomen must be undertaken. The abdomen always takes priority over the chest: perforated bowel if untreated may well be lethal, punctured lung requires little treatment. The author indicates the various possible routes by which operation can be undertaken and illustrates methods of visceral repair that may save a major incision. Heavy crush wounds that lead to a "flail" chest with paradoxical movement of a loose segment of chest wall can be controlled by pressure, but a better method is to apply traction to the loose segment by passing wires round the ribs and fixing them to a wire frame that is held a little distance from the chest wall on large "sorbo" pads. The final section of the book gives a number of useful illustrated cases which show the various features of the average case. The book is well illustrated throughout, and, though by no means comprehensive, is an excellent guide to those who may have to deal with injuries of the chest in civilian life as well as warfare.

GERONTOLOGICAL METHOD

Ciba Foundation Colloquia on Ageing. Volume 3—Methodology of the Study of Ageing. Edited by G. E. W. Wolstenholme, O.B.E., M.A., M.B., B.Ch., and Cecilia M. O'Connor, B.Sc. (Pp. 202+x; illustrated. 32s. 6d.) London: J. and A. Churchill Ltd. 1957.

The mediaeval quest for an elixir of life has had its modern complement in the search for a unitary ageing process, a search now happily abandoned in favour of a less exciting but more rewarding pragmatism. Each and every change with time in the living organism is now approached on its own terms, and with little hope that it will prove the key to all the others. Gerontologists are, however, still rather conscious of the need to establish the intellectual respectability of their procedures. The Ciba colloquium on the methodology of the study of ageing may serve to reassure them. All the twelve contributors—and this is rare in symposia of this sort—took their general theme seriously and were concerned to describe the limitations as well as the advantages of their different approaches. Since these covered ageing in macro-molecules, cells, tissues, organs, and whole organisms, and since they ranged from life-table studies in wild animal populations to the measurement of intelligence in human ones, the result is a very wide survey of gerontological method. As such it will have real value to all workers in the subject, though it has, perhaps, less to interest the non-specialist than the two earlier volumes in the series.

D. R. NEWTH.

THE SICK IN MIND

The Plea for the Silent. Introduction by Dr. Donald McL. Johnson, M.P., and Norman Dodds, M.P. (Pp. 176. 12s. 6d.) London: Christopher Johnson. 1957.

At the present moment public interest in mental hospitals is greater than usual. The Royal Commission of 1954–7 has reported, and a number of informative articles and broadcasts have drawn attention to the citizen's responsibility for the mentally sick. It has been indicated that as soon as possible legal effect will be given to the recommendations of the Royal Commission, and emphasis will be laid on the development of the mental health services so that the new legislation can be applied in the best interests of the patient. That the existing services are badly housed and understaffed, and that cohesion is often lacking between the different agencies of which they are formed, is common ground. Those who have to work in mental hospitals are often the first to say that overcrowding in outdated hospital buildings with large wards, an excess of locks, and difficulty in recruiting nurses leads to an undesirably low standard of care. This book contains the accounts given by eight certified patients who have written to the two editors, who are Members of Parliament. Each patient gives an account of his experiences which has been confirmed so far as official documents are able to do this. While they have for the most part omitted or glossed over the ways in which they have given trouble to the system, they give an account of the ways in which the system, legal and clinical, has troubled them. Many of the descriptions of treatment based on sketchy examinations, minor persecution by ignorant nurses, misunderstanding of their feelings, and artifices used to get them to enter hospital, ring very true, and, just like the intelligent patient's account of his operation, can be read by the doctor with advantage.

On the other hand there is an aspect of this plea for the sick in mind which is inopportune. When the Shaftesbury Act was passed in 1846 there was every reason to fear that the victims of mental illness might be "put away" by their relatives in a madhouse and kept there if they inconveniently recovered. When the Lunacy Act was passed in 1890 the emphasis was on safeguarding the liberty of the subject and ensuring that his detention was justified and his property safe from those who might take advantage of his defenceless legal position. By the time the Mental Treatment Act of 1930 was passed the emphasis was on treatment rather than alienation, and it was by then becoming more difficult to find

a place in a mental hospital than to get out of one. The report of Lord Percy's Commission gives effect to the present-day view that the Lunacy Act, by its emphasis on the liberty of the subject, may be restricting the opportunities for treatment in a mental hospital population which every year contains more voluntary patients. In this setting the idea that the Ministry, the Board of Control, and the psychiatrists are in a vast conspiracy of silence which renders persecution of the patients possible is an outdated attitude. The editors do not necessarily agree with the eight patients, who, they admit, are awkward people with grievances, but the book will have the unfortunate effect on the lay reader of emphasizing individual rights to such an extent as to minimize the greatest need of the moment—that is, to make the highest standard of treatment available to those who need it. Thanks to a gradually improved attitude on the part of the public towards its lamentable brothers, this Act is now out of date.

It is said that legal enactment must follow public opinion after a suitable interval. Parliament is the intermediary which should transform the one into the other. That the editors have visited mental hospitals in the course of their crusade no one will doubt, but they are not concerned to reveal anything on the credit side of this harassed branch of medicine. Had they published this book in 1886 it might have helped materially to bring about the passing of the Lunacy Act of 1890-1.

ALEXANDER KENNEDY.

HYDATIDIFORM MOLE AND CHORIONEPITHELIOMA

Trophoblastic Growths: A Clinical, Hormonal and Histopathologic Study of Hydatidiform Mole and Chorionepithelioma. By J. Smalbraak, M.D. Introduction by the late Emil Novak, M.D., D.Sc. (Pp. 342+xii; illustrated. 72s.) Amsterdam, New York, Princeton: Elsevier Publishing Company. London: Cleaver-Hume Press Ltd. 1957.

To produce a book of no less than 342 pages devoted to the subject of hydatidiform mole and chorionepithelioma may seem remarkable. This has, however, been done by Dr. J. Smalbraak, of Haarlem, working in association with the University of Utrecht. The text is in excellent English, and there is an introduction by the late Emil Novak; it must have been one of the last professional activities of that famous gynaecologist.

This is not an easy book to assess. Certainly it contains a wealth of information, and with 800 references to literature it is difficult to imagine anything more complete. Nevertheless, in the earlier chapters at least, the reader has difficulty in "seeing the wood for the trees," and in knowing how the author himself regards the many different views and opinions which he so freely quotes. But this criticism does the book less than justice. Much of the text concerns the detailed case histories of 74 cases of hydatidiform mole and 17 cases of chorionepithelioma. Furthermore, there is the concluding chapter of 10 pages in which the preceding sections are summarized. Here the author's own opinions are much more clearly set forth. This short concluding chapter is indeed well worth careful study. Among many other interesting remarks there is a warning against over-reliance on hormone excretion tests for the diagnosis of hydatidiform mole—a warning that will be supported by many gynaecologists in Great Britain, for the possibility of error both in the positive and in the negative sense is now being generally realized. Some scepticism is expressed regarding the prognostic value of Hertig and Sheldon's six histological divisions of hydatidiform mole. In the treatment of chorionepithelioma a local surgical excision (but with retention of the ovaries) is advocated. For inoperable cases heavy dosage with oestrogens (100 mg. stilboestrol daily) is advised. The illustrations are outstandingly good. Most of them are of histological sections, and some are in colour; they are quite the best collection of which I have knowledge. This is a book which should be in every gynaecological library.

J. CHASSAR MOIR.

PERSONALITY THEORY

Perspectives in Personality Theory. Edited by Henry P. David, Ph.D., and Helmut von Bracken, Dr.Phil. et Med. (Pp. 435+xii. 38s.) London: Tavistock Publications Ltd. 1957.

This book arose from a symposium on European theories of personality which was held at the International Congress in Montreal three years ago. Much has been added to what was said then, so that now over 400 pages are put before the reader, divided into six parts. In the first part, entitled "Overview," there is a lengthy chapter by Allport on European and American theories of personality. The second part, "European Trends," contains five chapters discussing personality theory in Germany, Switzerland, Great Britain, Italy, and France: this is probably the most interesting section of the book to most readers, who will have little knowledge of what is going on in many of these countries. The third part is entitled "Theory," and its eight chapters present a curious mixture, ranging from "Neuro-humoral Factors and Personality" to "Femininity and Existentialist Psychology." Part IV is entitled "Methodology," but contains only three chapters and does not deal at all with the more experimental methods. Part V, entitled "Commentary," is made up of three chapters critically evaluating some of the contributions; and Part VI, "Resources," presents a selected annotated bibliography and a note on the International Congress.

The book is difficult to review, being very much like the curate's egg. Some of the chapters are excellent and informative, such as Allport's introductory chapter, Franks's chapter on personality theory in Britain, or McClelland's commentary. Others, particularly those emanating from German "stratification" theory, are obscure and uninformative to a quite surprising extent. The main fault of the book probably is that, like Topsy, it just "grewed"; it does not appear to have been anybody's task to keep contributors in order or see that a proper coverage was achieved. As a consequence most readers will find something to interest them in this book, and also something to disagree with; perhaps it would be unreasonable to expect more than that from a venture of this kind.

H. J. EYSENCK.

Throughout the past century the problem of the disposal of the dead has become more acute, and Parliament has made many attempts to solve it. Mr. M. R. R. Davies, Ph.D., a member of the legal staff of the Nottinghamshire County Council, has now provided a clear and comprehensive statement of the important legal principles, provisions, and cases underlying the bewildering complexities of the law relating to the disposal and disinterment of the dead in *The Law of Burial, Cremation, and Exhumation* (Shaw and Sons, Ltd., Fetter Lane, London, E.C.4, 27s. 6d.). His work is divided into three sections: burials; cremation; and exhumation and disused burial grounds. The relevant portions of the statutes are quoted in bold type, and the author has added comments to aid in their interpretation, with references to illustrative legal cases. The book has a full subject index, tables of statutes and statutory instruments and of the legal cases quoted, and a directory of British crematoria. This should prove a useful work of reference for all who have to do with the disposal of the dead.

Dr. Agatha Bowley's *The Young Handicapped Child* (Livingstone, 1957; pp. viii+128; 10s. 6d.) is intended for the guidance of parents and teachers concerned with the education of blind, cerebral-palsied, and deaf children. The incidence, causes, and assessment of each of the three conditions are examined, and the principles and methods of psychological and educational care are described from considerable first-hand experience. The section on the young deaf child is contributed by Mr. L. Gardner.

British Chemicals and their Manufacturers is published biennially by the Association of British Chemical Manufacturers to provide information on the products made by its members. The 1957 edition, which lists over 12,000 products named systematically and in accordance with British Standard 2474, is now available from the A.B.C.M., 86, Strand, London, W.C.2, gratis to those interested in the purchase of chemicals.

LONDON

SATURDAY NOVEMBER 9 1957

APHTHOUS ULCERATION OF MOUTH

Ulceration of the mouth can occur in many circumstances. Sometimes there is direct infection of the tissues, as in Vincent's angina (trench mouth) or herpes simplex. It may occur as a manifestation of acute leukaemia or of agranulocytosis. It is common in some deficiency states, such as pellagra. Buccal ulceration is also found in conjunction with lesions in several diseases whose aetiology is but little understood. These diseases include pemphigus, erythema multiforme, the Stevens-Johnson syndrome (stomatitis, urethritis, conjunctivitis, and skin lesions resembling erythema multiforme), and Behçet's syndrome (oral ulceration, genital ulceration, and eye lesions such as conjunctivitis and iritis). But much the commonest type of buccal ulceration is that known as aphthous ulceration or canker sores. Characteristically these occur in crops several times a year. They appear on the buccal mucous membrane opposite the molar teeth and inside the lips. Sometimes other parts of the mouth, such as the tongue, may be affected. They are very painful but usually heal in a few days, though in some patients they run a protracted and severe course and give rise to prolonged pain and scarring. It is well known that some people are prone to attacks of these ulcers over the course of many years and may suffer much inconvenience from them.

An interesting article on the subject has recently been written by W. Sircus, R. Church, and J. Kelleher,¹ based on their studies of 120 patients with this disorder. Most patients begin with the trouble between the ages of 10 and 30 years. Women appear to be more commonly affected than men and to have more frequent attacks. They are much more likely than men to suffer from the disease after the age of 50, apparently because many of them develop the condition when they are menopausal. Attacks

may be produced by local trauma or irritation, but mental stress was the outstanding precipitant observed in this study. Investigations were carried out by the authors and by an associated group of virologists to determine how closely the subjects with recurrent aphthous ulceration resemble those with recurrent herpes simplex. It appears from complement-fixation tests that two components exist in the antigens, a sedimental (virus particle) material and non-sedimental (soluble) material. Human sera may contain antibody for one component and lack it for the other. By choosing appropriate antigens, it was shown that evidence of herpes infection is absent in cases of recurrent aphthous ulceration but always present in cases of recurrent herpes. It was also found impossible to grow virus from ulcer scrapings from the patients with recurrent aphthous ulceration. It seems plain that recurrent aphthous ulceration is not, as has often been thought, a clinical variant of recurrent herpes simplex.

So far as positive findings are concerned, "the present study has failed to provide any definite evidence regarding aetiology." While the authors found a strong association between mental stress and the onset and fluctuations of symptoms, they regard psychological factors as no more than the main aggravating or precipitating agent and not the cause of the disease. It is of interest that the first description of the condition given in a British journal also emphasized the importance of mental stress. The author, W. K. Sibley,² writing in the *British Medical Journal* of 1899, gave his article the title of "Neurotic Ulcers of the Mouth" and began the section on aetiology with the statement: "Mental trouble appears to be the cause of the ulcers in these subjects."

Many authors regard canker sores as being commonly due to sensitivity to an allergen. For example, W. T. Vaughan and J. H. Black,³ in a detailed analysis of symptoms in 150 cases of gastrointestinal allergy due to food, found canker sores in 13%. Indeed, food appears to have been the source of the allergen in most cases in which the evidence of an allergic basis is reasonably firm. L. Tuft⁴ states that nuts and chocolate are probably the most commonly reported offenders and gives the case-history of a man of 38 years with a 10-year history of recurrent aphthous ulceration which had become almost continuous. Removal from the diet of offending foods, especially nuts and chocolate, brought about complete disappearance of the ulceration, which recurred only if the patient failed to adhere rigidly to his diet. In a recent article Tuft and L. N. Ettelson⁵ describe a patient in whom recurrent canker

¹¹ Fisher, A. A., *N.Y. St. J. Med.*, 1955, 55, 2494.

sores were shown by clinical investigation to follow the ingestion of foods, drugs, or drinks containing citric acid. Direct application of a crystal of citric acid to the mucous membrane of the mouth was followed on the next day by a canker sore, which would heal in about ten days. Contact with the oral mucosa for only a few seconds was sufficient to cause a canker sore, though it would then be smaller than with longer contact. Acetic acid also had a similar effect, tartaric acid and lactic acid were mildly active, and most other agents were inactive. Control subjects were unaffected by all these agents.

It appears, therefore, that ulceration of the mouth can be an allergic lesion. How commonly this is the case is another matter. We should certainly be chary of labelling a condition as allergic merely because it seems a likely possibility. As F. J. Ingelfinger and his colleagues⁶ have said, "Gastrointestinal allergy is a diagnosis frequently entertained, occasionally evaluated, and rarely established. It offers, to its enthusiastic supporters, a reasonable explanation for many obscure abdominal complaints. To the sceptical, it frequently appears as a specious and unwarranted diagnosis." In any event, if some of the examples of recurrent aphthous ulceration are allergic in nature, this does not discount the importance of emotional stress as a precipitating factor. All physicians who deal with diseases such as asthma and hay fever are aware of the great importance of emotional factors even when a responsible allergen has been identified. Indeed, it has been said: "Since the allergic reaction consists primarily of vasomotor reactions, with oedema and infiltration of the tissues by leucocytes and eosinophils, it seems evident that these changes can also result from emotional disturbance."⁷

As to treatment, Sircus and his colleagues carried out "blind" controlled therapeutic trials with various forms of treatment to be found recommended in textbooks. Folic acid, nicotinamide, riboflavine, a vitamin-B mixture, small doses of cortisone by mouth, ethisterone for premenstrual aphthae, and local radiotherapy were given. All were useless. Local application of aureomycin appeared to speed up the healing of the ulcers but did not prevent recurrence. A patient with severe multiple buccal ulceration resistant to various treatments was treated as an in-patient with large doses of cortisone: healing was rapid. In spite of the largely negative results of these extensive trials, they have been of service in eliminating doubt. It is evident that no universally effective remedy has yet been found. The treatment of recurrent aphthous ulcers has been the subject of correspondence in our columns recently. After an article on the treatment of

ulcerative colitis by hydrocortisone applied locally,⁸ S. Hillman⁹ and D. Morton¹⁰ claimed excellent results from treating aphthous ulcers of the mouth by the direct application of hydrocortisone ointment. On the other hand, A. A. Fisher,¹¹ after treating various oral conditions with hydrocortisone ointment, states: "The ointment was not very helpful in the treatment of recurrent aphthae; five out of eight cases obtained no relief whatever." It is to be hoped that this form of treatment will be put to a formal test along the lines pursued so well by Sircus, Church, and Kelleher.

CHRONIC BRUCELLOSIS

The clinical features of chronic brucellosis are so indistinct that the disease remains undetected in many patients. Instead, their chronic ill-health may be attributed to psychoneurosis. This may prove a tragedy, for, once this label has stuck, nothing can more readily demoralize the sufferer from organic disease. All authorities on the subject have stressed this confusion, and more recently in this *Journal* H. R. E. Wallis¹ has emphasized the ease with which brucellosis may be overlooked in children. He cites ten cases of childhood infection in which initially the protean clinical manifestations made a variety of other diagnoses more probable, including psychological upsets, influenza, migraine, and sarcoidosis. Wallis forcefully points out: "Brucellosis is a disease of mistakes. If we do not think of it we miss it; or we may think of it and test for it, yet find nothing. It eludes us."

The causative organism, *Brucella abortus*, is conveyed by infected milk, against which the only adequate safeguard is pasteurization. The development of "safe" milk from tuberculin-tested cattle may have lessened the risk of transmitting tuberculosis, but paradoxically it has increased the insidious danger of brucella infection conveyed by tuberculin-tested unpasteurized milk. Because of the prevalence of pasteurized milk in towns, the risk of infection is greater in rural areas, where untreated milk is commonly drunk. This has been the subject of an illuminating survey by Dr. J. E. Davies, published this week in the *Journal* at p. 1082. He was able to uncover eleven instances of brucellosis in his rural practice in one year, and he suggests that these patients, who were repeatedly attending his surgery with vague ill-health, might have remained undiagnosed but for the fact that he had suffered from

¹ Wallis, H. R. E., *Brit. med. J.*, 1957, 1, 617.

² Barrett, G. M., and Rickards, A. D., *Quart. J. Med.*, 1953, 22, 23.

³ Abernathy, R., and Spink, W. W., *J. clin. Invest.*, 1952, 31, 947.

⁴ Spink, W. W., and Hall, W. H., *ibid.*, 1952, 31, 958.

brucellosis himself, for this personal experience enabled him the better to recognize the vague symptoms in others. This set in train a well-executed diagnostic survey of the disease in a rural practice, employing the brucellin skin test and serum-antibody levels as the principal criteria for confirming the clinical diagnosis. The evaluation of various diagnostic aids for recognizing brucella infections in rural communities in Great Britain had already been discussed by G. M. Barrett and A. D. Rickards² in their survey of the Lancaster area, and the results of their investigation laid the keel for this recent Welsh survey. Both surveys have endeavoured to correlate dermal hypersensitivity with the levels of serum agglutinins, for there has been a diversity of opinion on whether skin-testing may provoke a confusing non-specific rise in serum agglutinins. Barrett and Rickards concluded that the intracutaneous injection of brucellin in non-sensitized persons did not provoke a significant antibody response, and that a rise in titre of brucella antibodies after brucellin indicated previous or current infection. Their results also showed that repeated intracutaneous injections of brucellin do not sensitize normal persons to subsequent injections of antigen. Davies's results of skin-testing in a series of control subjects are in general agreement. Although 20% of these showed some rise of antibodies after skin-testing (and it appeared immaterial whether the skin test was positive or negative), this rise could be distinguished from that in patients with brucellosis, since the agglutinin titre never rose beyond 1 in 125, and this level was not sustained even as long as 28 days after the original intracutaneous injection. It seems clear therefore that, while the appearance of antibodies after a brucellin skin test is not in itself specific, a high rise to be significant. Davies has shown that the diagnosis of brucella infection is within the scope of general practice by careful correlation of symptoms, signs, skin-testing, serum-agglutination reactions, and an assessment of the effect of skin-testing on the levels of serum antibody. His further observations on the presence of low levels of potassium in the serum in chronic brucellosis remain at present unconfirmed, but deserve further investigation.

The usual treatment is tetracycline or a combination of tetracycline with intramuscular streptomycin daily for a course of two weeks. Further courses may be necessary, for relapses sometimes follow single courses. The chronicity of the disease and the relapses following therapy are partly due to the intracellular parasitism of the organism. In this sheltered position it finds a suitable medium for multiplication

together with protection against lethal phagocytosis. More successful treatment will depend on the development of chemotherapeutic agents which penetrate the host cell efficiently, or on some method of dislodging organisms from their intracellular habitat. This was the rational basis for R. Abernathy and W. W. Spink's³ studies on the influence of corticosteroids in experimentally infected animals. They concluded, however, that, in contrast to the abrupt changes induced in acutely infected animals, cortisone did not alter the course of chronic brucellosis. Somewhat similar findings were observed in the human disease,⁴ and the combination of the cortisone group of drugs with antibiotics is best reserved for the critically ill, toxic patient.

KNEE-JOINT INJURIES IN MINERS

In Britain the majority of knee-joint injuries occur on the football field or in the coal mine. Not the least of the hazards of winning coal is the liability in miners to internal derangements of the knee twice as great as that, for example, of steel workers. J. B. Atkins,⁵ drawing attention to the importance of this problem and making constructive suggestions for its solution, discusses the mechanism of injury and points out that tripping or slipping accidents account for a high proportion of meniscus tears, whereas I. S. Smillie⁶ attributes many of the injuries to the movement of getting up from the crouched or kneeling position. The knee-joint of the miner is, however, more mobile than average as a result of working in cramped conditions. That he has a greater degree of flexion than others is demonstrated by his ability to sit on his heels almost indefinitely. These are the circumstances which lead to the stretching of the peripheral attachments and thus predispose to tearing of the meniscus in a trivial slipping accident. It is the abnormal mobility of the meniscus too which leads to difficulty in diagnosis by the uninitiated. If synovial effusion is accepted to be one of the cardinal signs of a torn meniscus it certainly does not necessarily occur in miners. The meniscus is an avascular structure, and neither haemorrhage nor effusion can occur as a result of injury to the substance of the fibrocartilage alone. The effusion is due to the stretching or tearing of the synovial attachments. In the miner, with his stretched synovial attachments and mobile knee, the meniscus can be torn without consequent reaction.⁶

But there are other interesting points of difference between the internal derangement of miners and those of athletes and particularly football players. Smillie,⁷ recording more recent observations made at the operation in a series of 1,000 consecutive meniscectomies, noted 215 cases in which the anterior cruciate ligament

⁷ ———, *Sixième Congrès International de Chirurgie Orthopédique*, 1955, Brussels, p. 624.

⁸ Fairbank, T. J., *J. Bone Jt Surg.*, 1948, 30B, 664.

⁹ Duthie, J. J. R., and MacLeod, J. G., *Lancet*, 1943, 1, 197.

was either ruptured or grossly attenuated. Of these, 169 were associated with 659 lesions of the medial meniscus, establishing a definite relationship between lesions of the medial meniscus in particular and rupture of the anterior cruciate ligament. But these figures did not apply to miners. Included in the 1,000 meniscectomies were 256 coal-miners, who thus constituted 25% of the series. Among the miners there were only 27 lesions of the ligament, if 6 cases in which the accident occurred on the football field were excluded. The incidence, 1 case in 10, was thus much below the general average. The significance of the reduced incidence in coal-miners in comparison with football players is that the original accident, with subsequent locking incidents, occurs in the restricted space of a narrow seam. Thus the anterior cruciate ligament has not the momentum of superimposed body weight in violent motion to withstand when the locking incidents occur. Furthermore the nature of his occupation is such that a miner cannot work with a knee disability. He often knows himself what is wrong and as a rule receives early meniscectomy. His cruciate ligament therefore survives. But there are other advantages in early meniscectomy once the diagnosis is established with certainty. Whatever the relationship of meniscectomy to osteoarthritis, changes do occur in the knee-joint after operation.⁸ But they are nothing like those which occur if the patient has no operation. There can be no argument about the relationship between the recurring incidents produced by an untreated meniscus lesion and the subsequent arthritis. J. J. R. Duthie and J. G. MacLeod,⁹ in the series of meniscectomies they investigated, showed that an average interval of two years nine months existed between the original injury and the subsequent operation. That it really is the mechanical trauma of excessive weight-bearing activity which produces the arthritis is well seen in the old professional footballer even when he does not admit to more than the usual knocks of his trade. In a British mine, the coal-face worker at least takes his weight on but not through his knees. Perhaps it will be shown that his vulnerability to injury is compensated for by early meniscectomy and a decreased liability to osteoarthritis.

INTERFERON

Inoculation of two different viruses into an organism or a culture of susceptible cells often results in the suppressed multiplication of one of the agents inoculated. This phenomenon, known as interference, has been extensively investigated with a variety of virus-host systems. It may be observed with pairs of related or unrelated viruses and can be induced by both live and inactivated preparations. How the interference occurs is not yet clearly understood. It has been shown in many instances not to be dependent on humoral immune resistance. Since extracellular virus particles do not interact with each other, the mechanism of interference has to be explained on the basis of virus-host inter-

actions. The interfering agent might act, for instance, by preventing the suppressed virus from attaching to or penetrating into the susceptible cells; alternatively, it might block or compete for some key enzyme necessary for virus replication or maturation. Recent work by A. Isaacs and his colleagues^{1 2} promises to shed some light on this problem. These workers, studying interference with the growth of influenza virus by heat-inactivated preparations of the same agent, observed that incubation of pieces of chick embryo chorio-allantoic membrane with inactivated virus resulted in the production and release of a new factor called "interferon," capable of inducing interference in preparations of chorio-allantoic membrane. Interferon was shown to suppress the multiplication of influenza-A, Sendai, Newcastle-disease, and vaccinia viruses. The nature of interferon has not yet been determined and it is not known whether it derives from the original virus or from the membrane or from both. It may have some effect on experimental influenza infections in animals, and further reports are eagerly awaited. Such studies are likely to yield results of importance not only on the academic aspects of virus multiplication, but perhaps also on its possible practical application for the control of virus diseases.

HOUSEHOLD SPENDING

The spending habits of the British people are documented as never before in an official publication which appeared last week.³ In the twelve months from January 26, 1953, the Ministry of Labour collected from some 13,000 households details of their expenditure over a period of three consecutive weeks. The first use of this survey was to revise the retail price index from the beginning of last year, but the material has since been sifted to show how these 1953 household budgets varied with income, size of family, occupation, and locality.

Unfortunately, but not unexpectedly, expenditure on two of the most interesting items—drink and tobacco—was badly understated. From independent checks it seems that altogether people disclosed less than half their expenditure on drink and little more than three-quarters of that on smoking. Even so, two-thirds of households admitted to spending over £1 a week on these two items, and the sums recorded accounted for 9% of total expenditure in the south and east, and for 10 to 12% in Wales, the midlands, and the north. As would be expected, expenditure on wines and spirits rose sharply with income, and families with gross incomes of over £20 recorded twice as much for drink as families with half that income. But the more well-to-do families spent only about one-fifth or one-quarter more on tobacco than families with medium incomes. In so far as the figures in this volume are any guide, they suggest that manual workers smoke more than others. Where a manual worker was head of the household, its weekly consumption of cigarettes (priced at 3s. 2d. for 20) worked out per adult at 46 when the gross household income was between £10 and £14 a week and 54 when

it was over £20 a week. Corresponding figures for professional households with similar incomes were 36 and 46, while for business households (where the head was classed as managerial or executive) they were 38 and 46.

A family earning £20 a week does not spend twice as much on food as one earning £10 a week: it spends about a quarter as much again. A couple with two children in 1953 spent 42% of a weekly budget of £8 on food, but only 24% of a £24 budget. As income increases, families spend less on bread and potatoes and more on meat, milk, and vegetables, and much more on fruit. Expenditure on butter and margarine is little affected by income. Regionally, the proportion of spending taken by food was slightly higher in the north than in the south. The extent to which the large family has to skimp on food comes out clearly in this survey. Food expenditure in households with a gross income of between £10 and £14 (the most common level of household income in 1953) was only 16s. a week per head for a family with four children, 22s. per head for a childless couple, pensioners living on their own spent about £1 a week per head on food. To check on changes in spending habits, the Ministry of Labour is running another survey this year, but on a much smaller scale.

DISCIPLINARY PROCEDURE

The Home Secretary's announcement last week of the Government's acceptance of the Franks Committee's report¹ on administrative tribunals and inquiries, so far as it affects the National Health Service, fore-shadows changes in the way of adjudicating on patients' complaints against general practitioners. Embodied in regulations governing service committees and the tribunal, the disciplinary procedure under the N.H.S. has its roots in the National Health Insurance service. It has evolved over the years from discussions between the profession's representatives and the health departments and has proved in the main acceptable to doctors. Only recently a subcommittee of the Association's G.M.S. Committee has concluded, in conjunction with the Ministry of Health, an exhaustive review of the regulations, and as a result numerous amendments have been made. But, unlike the Franks Committee's proposals, these will not alter materially the actual arrangements for considering patients' complaints, which, in outline, are as follows. A complaint is first investigated by a committee of the executive council—the medical service committee—consisting of an equal number of lay and medical members, with a lay chairman. This committee reports its findings of fact and recommendations to the executive council. If the latter considers that the practitioner should be removed from its list—in effect, from the Health Service—it so informs the National Health Service Tribunal, which consists of two members appointed by the Minister, one of

them a medical practitioner, and a legally qualified chairman appointed by the Lord Chancellor. There is no appeal from a decision by the tribunal that a practitioner should not be removed from the list, but a practitioner whose removal is recommended has a right of appeal to the Minister, whose decision is final. Before deciding appeals from the tribunal or from executive councils in other disciplinary cases, the Minister appoints two or three persons *ad hoc*, one of whom is a lawyer of standing, to hear the appeal and advise him. If an executive council considers that a lesser penalty than removal of a practitioner's name from the list meets the case or that no action should be taken, both the practitioner and the complainant have the right to appeal to the Minister against the council's decision. Disciplinary proceedings are conducted in private, and only if a practitioner's name is removed from a list is his identity made public. At a hearing before a service committee doctor and patient may present their case with the help of some other person provided that he is not a counsel, solicitor, or "other paid advocate." Evidence is not taken on oath.

While in general the Franks Committee maintains that, in the interests of openness, fairness, and impartiality, the hearings of all administrative tribunals should be in public, it agrees that cases involving professional reputation justify exceptional treatment at a stage when the complaint has still to be substantiated, and therefore does not recommend any change in the privacy of medical service committee proceedings. It can see no reason, however, why evidence before these committees should not be on oath, especially in view of the potentially serious outcome of the complaint for the practitioner. The committee was also reluctant not to recommend the right to legal representation at service committee hearings, concluding that, on balance, legal representation would not benefit the patient, who would not have the resources of a professional organization behind him. Instead it recommends that complainants should be entitled to apply for the services of a departmental or executive council official to assist them in presenting their case.

The Franks Committee, however, takes a different view of privacy in the proceedings of the National Health Service Tribunal. When matters have reached this stage, the committee considers that "a strong prima facie case has therefore been established in circumstances which substantially protect the practitioner from publicity." The proper working of the adjudicating system and the public interest therefore, in its view, demands that the proceedings before the tribunal should in general be public. On the question of appeals, the committee sees no justification for the practitioner's present right of appeal from the tribunal to the Minister, and it recommends that this be abolished. The committee argues that if the tribunal has power to decide the most serious disciplinary cases there is no reason why the Minister should retain appellate jurisdiction in the less serious cases. It therefore proposes that the tribunal and not the Minister should adjudicate on all appeals from disciplinary decisions of

¹ Isaacs, A., and Lindenmann, J., *Proc. roy. Soc. B.*, 1957, 147, 258.

executive councils. The committee, however, recommends that when the tribunal hears appeals against decisions by executive councils in the less serious disciplinary cases it should do so in private when the appeal is lodged by the complainant.

In carrying out its remit, the Franks Committee cannot be accused of departing from its overriding consideration for the need for openness, fairness, and impartiality in the business of administrative tribunals. The profession, however, with a long experience of medical disciplinary tribunals, has always felt that the existing system in practice works fairly enough as it is, and has not been aware of any injustice to patients. But the committee seems to have thought that the scales were weighted in the doctors' favour. The statutory disciplinary machinery does not in any way affect the patient's ordinary legal rights of redress against a practitioner, and, on present showing, there is no reason to believe that the patient thinks it does.

STRONTIUM-90 IN BONE

Recent analyses of strontium-90 in human bone in Great Britain deserve attention.¹ A post-mortem specimen from a 1-year-old Keswick (Cumberland) child showed 2.3 strontium units, and one from a 6-months-old Liverpool child showed 2.4 S.U. These figures are about one-quarter of the figure (10 S.U.) which the Medical Research Council recommended^{2,3} should arouse "immediate consideration." Since there is still some strontium-90 in the upper atmosphere as a result of testing atomic weapons, higher figures may be expected in future even if no more tests are held.

The figures obtained from these analyses in 1955, 1956, and part of 1957 show a wide scatter, ranging from 0.05 to 2.4 S.U., but no consistent trend is discernible. Moreover, the later figures are derived from children and infants, while many of the earlier were from adults. This presumably reflects a greater awareness of the special danger of strontium-90 to children. Their bones take up on an average about five times more than adults,⁴ and children are more sensitive to the β rays which the strontium emits. Though these do not cause genetic damage, they may increase not only the risk of leukaemia but, owing to radio-strontium's relatively long biological half-life of 7½ years, the risk of bone sarcomas also.

Strontium-90 comes mainly from the fall-out resulting from tests of atomic weapons. The question of how it enters the body is discussed in the report, and milk is considered to be the main source. The amount of strontium-90 inhaled in respiration is apparently exceedingly small. Rain-water contributes little except to the few people, if any, who drink considerable quantities of it raw, for the water of rivers and lakes contains at least ten times less strontium than does rain. Though adequate data are said to be lacking, the amount of strontium in cereals and vegetables is about the same as in milk. The importance of milk in the diet of most

children probably makes it the main source of radio-strontium for them. The radioactivity of milk rose sharply from 2 to 5 S.U. in the spring of 1955 and has since stayed fairly constant. Activity is apt to be higher in the north and west of the British Isles than in the south and east, probably owing to the higher rainfall there.

ELECTIVE CARDIAC ARREST

Cardiac arrest on the operating table has so far been a dreaded surgical emergency, but the advent of heart-lung machines has made it possible to stop and restart the heart's action at will in intracardiac operations. This technique provides a relatively bloodless operative field, with the heart motionless and flaccid, so that exact placing of sutures is facilitated. W. J. Kolff and his colleagues,¹ reporting their results in 37 patients undergoing open heart operations, describe how they brought about complete temporary arrest of cardiac movement by injecting potassium citrate into the root of the aorta according to the method originally described by D. G. Melrose and his colleagues.² The period of cardiac arrest varied between seven and 40 minutes, during which time the circulation was maintained by the use of a heart-lung machine.³ Normal cardiac rhythm returned afterwards in all but two patients, in whom heart block developed and persisted after operation. Thirteen of the 37 patients died after operation, but 10 of these were judged to be surgical failures. All nine patients with Fallot's tetralogy survived.

It is too soon yet to assess the value and safety of this method of arresting the heart's action during intracardiac operations, since many different factors must influence the results. The patients chosen for operation have for the most part been suffering from the severer forms of congenital heart disease which have a bad prognosis and for which the operation itself is new and of unproved benefit. In addition, the use of a heart-lung machine introduces a definite danger. Whether elective arrest of the heart in conjunction with the use of a heart-lung machine increases or decreases the risk of operation is still uncertain. Theoretically it has the advantage that during arrest the oxygen requirements of the heart are small and hence the danger of cardiac damage from hypoxia during this period is reduced. The technical advantages offered to the surgeon in providing a bloodless and motionless operative field inside the heart are great, but there is also the disadvantage that when large defects are closed in the flaccid heart distortions and tensions may appear on resumption of cardiac contraction. In general, the recent advances in intracardiac surgery have been made possible by a combination of different surgical and anaesthetic procedures rather than by reliance on any single method, and it is likely that a place will be found for the use of potassium to arrest or at least to slow the heart beat as an adjuvant to the complicated techniques now required for the performance of intracardiac operations.

A VISIT TO CHINA

BY

F. AVERY JONES, M.D., F.R.C.P.

During the summer of 1957 invitations were sent to a number of British doctors from the Chinese Medical Association asking them to visit China, and in early August a party of nine* left London. Their flight to Peking took them via Brussels, Prague, Moscow, Omsk, Irkutsk, and finally across the Gobi desert. From Prague to Moscow, the party flew in the new Russian jet, a flight memorable for the immensely powerful but noisy plane, with its curious Victorian interior decoration and the excellence of the free vodka. After a brief stop at Moscow airport, the party left by slow plane across Asia and saw much more of the countryside than they would have done had they taken the weekly jet Trans-Siberian service. The arrival at Peking was preceded by a wonderful view of the Great Wall of China silhouetted against the undulating mountains, and this was followed by a magnificent view of the Summer Palace just before the plane came in to land. The party was met by representatives of the Chinese Medical Association and taken to the Peking Hotel, a vast building with all modern amenities.

After discussing the various interests of members of the party their Chinese hosts worked out a three-and-a-half-weeks programme. This provided for 10 days in Peking and a visit to the industrial north-east region, including Mukden and Changchun. The party then went south to Tientsin and Shanghai. Then came a short rest period at beautiful Hangchow, which combines the charm of the Italian lakes with the Chinese scenery. The party went on to Canton, finally leaving for Hong Kong. The first three days in Peking were spent sightseeing.

General Impressions

Throughout the tour the party was tremendously impressed by the hospitality provided. Every consideration was given to the wishes of the visitors and their needs were quietly anticipated. With one exception the hotels were first-class, with private bathrooms and even billiard rooms. At each centre the party was entertained by members of the Chinese Medical Association, who made certain that the visitors saw not only the medical centres but also the local places of interest. The party was accompanied by a bilingual Chinese doctor, a Chinese interpreter, and a secretary. Cars were placed at the disposal of the members and at any time it was possible to go off on photographic or shopping expeditions.

There were a number of excellent Chinese banquets, memorable not only for the exquisite food but also for the charm of the Chinese hosts and their delightful sense of humour. Each dinner began with tea and finished with soup, with some 12 to 16 courses intervening. "After-

*Dr. A. L. Cochrane, M.R.C. Pneumoconiosis Research Unit; Dr. T. F. Fox, editor of *The Lancet*; Dr. F. Avery Jones, physician, Central Middlesex Hospital; Dr. H. M. C. Macaulay, S.A.M.O. North-west Metropolitan Regional Hospital Board; Professor B. G. Macgregor, professor of tropical medicine, Liverpool; Professor B. S. Platt, professor of human nutrition, London School of Hygiene and Tropical Medicine; Professor E. T. C. Spooner, professor of bacteriology and immunology, London School of Hygiene and Tropical Medicine; Professor A. W. Woodruff, professor of clinical tropical medicine, London School of Hygiene and Tropical Medicine; Professor J. Yudkin, professor of nutrition, Queen Elizabeth College, University of London.

dinner speeches" were given at the beginning and then everyone could settle down to enjoy the meal.

Two long overnight journeys by train were purposely arranged and gave an excellent impression of the countryside. Everywhere there were little villages with the intervening land cultivated to the last square foot, except for the ancestral burial mounds to be seen in so many of the plots. The inter-city trains were spotlessly clean and of a high standard of comfort with very adequate couchettes. The party was delayed one day as a track had been washed away by flood, but the damage was repaired with great speed. The air journeys were made in the same type of plane which flew the party across Asia—small 20-seater twin-engine standard Russian planes with Chinese air-crews. The air services, like the hotels, were mainly used by delegations and official visitors. Chinese doctors attending conferences apparently always go by train.

One's first impression in Chinese cities, as in the countryside, was one of over-population, with crowded streets, pavements thronged with playing children, and on the roads great numbers of bicycles, mule and donkey carts, pedicabs, and carts, but very few cars and buses. It was always a scene of great activity with everyone working with a will, and this was specially obvious on building sites and road work. The cleanliness was impressive, with complete absence of litter and filth and practically no flies. Many litter boxes were to be seen, particularly in the parks. Even the mules had dung sacks under their tails to prevent them soiling the streets. The eradication of flies had been the result of a national campaign and had proved an important contribution towards the public health. Sparrows, alas, were seldom seen, for they had been classed with flies and rats as public pests. Dogs were few, but this has always been so in China. Living conditions were simple; the national policy was against extravagance. The people were plainly dressed. The majority of women wore blue and white blouses and blue slacks; none were wearing the lovely Chinese silk. The beautiful traditional Chinese costumes were seen in Chinese plays and operas, which remain a great attraction in all the cities.

Medical Schools

Outside the main cities, and indeed in the cities too, the medical care of the 600 million Chinese is largely undertaken by the "traditional doctors," who learn by apprenticeship. These traditionalists practise the ancient rites of acupuncture, sticking needles in selected sites and prescribing a profusion of herbal drugs. In addition there are some 70,000 doctors trained along Western lines. There appeared to be good relations between the traditionalists and orthodox doctors. In every hospital there is a department of traditional medicine, which no doubt proves useful for managing the more chronic cases.

The Chinese policy is to expand rapidly the number of Western-type doctors, and last year there were over 8,000 medical students starting a five-year course. They are trained at medical colleges, which are not part of the university. In most of the medical colleges the students are trained in public health or paediatrics as separate specialties, alongside those training in general medicine. The Peking Medical College is the largest of the 36 medical colleges in China, with a staff of 540 teachers, who have an incredibly heavy load of teaching. They admit about 600 students a year. The students attend lectures in groups of 150, but for practical work the classrooms hold under 20. The practical subjects of the five-year curriculum are essentially the same as in Western medical schools. Part of the last year is spent working in hospitals as junior staff. All students learn either English or Russian. A simple examination in pharmaceutical Latin is the only written examination during the entire training. Final examinations are all oral. The pass rate is extremely high and only a small proportion are referred for a few months.

Students live in hostels in the grounds of the colleges, sleeping four in a room. They are expected to contribute to the cost of their food, but it is possible for them to obtain financial assistance on the recommendation of their group leader. An unselected group of women students met at Peking were a happy, friendly crowd, and very interested to hear about British medical students.

At Shanghai the number of undergraduate medical students had increased from 300 to 3,200 in the eight years since the "liberation," and during that time more than 1,900 students had graduated. There are four main faculties in the colleges: clinical medicine, public health, pharmacy, and paediatrics. There were 482 full-time teachers on the staff of the medical school, and this was associated with six hospitals with a total of 1,733 beds.

At Canton all the medical students were put through a general course of medicine, surgery, obstetrics, etc. This medical school was only four years old and resulted from the amalgamation of three previously existing schools. Here there were 2,300 students with 387 teachers. These were divided among 33 teaching and research units, and 10 hospitals were available for clinical teaching. In spite of the large numbers it seemed that an effort was made to give the students individual attention. A number were encouraged to assist with the research work of the various departments, and many were sent to smaller hospitals during the summer vacation.

The medical colleges at Mukden and Tientsin had both similarly expanded their teaching. As the schools were closed for the holiday month it was not possible to form any judgment about the quality of the teaching. One noted, however, that active research work was in progress in many of the departments. When junior staff presented cases on medical rounds, it was obvious that they had been through the usual basic clinical training, and indeed the histories given were well presented and notable for their emphasis on the clinical history and their discriminating use of pathological investigations.

Hospitals

Since the "liberation" eight years ago, according to the official handbook, 860 new hospitals have been built, providing an additional 300,000 hospital beds. Some well-built new hospitals were visited: one of these was the Tung Gen hospital in Peking, built in 1954 to replace an older hospital. There were 591 beds with 120 general medical, 126 surgical, including urology and orthopaedics. There were 90 ophthalmic beds, for this had previously been a popular eye centre, and 80 neurosurgical beds, serving a wide area of the city. There were also 50 paediatric, 80 obstetric and gynaecological, 30 ear and throat, 10 skin, and 5 dental beds. The staff numbered 847, including 130 doctors; in addition there were 40 medical students doing an intern job at the end of their five-year course. The junior medical staff had four years' training rotating in different departments, and at the end of that time were eligible to become assistant senior staff. The hospital was well built with small ward units of three to six beds with nursing stations in the centre of corridors. Halls and corridors and side-rooms were perhaps unnecessarily large: the equipment was adequate but not extravagant. Two notable features were the liberal accommodation in side-rooms for junior medical staff working on the wards and the large medical library. There was a small clinical laboratory to each ward, and a big lecture hall was available for the weekly staff clinical meetings. There was a large out-patient department not yet rebuilt. About half the patients came up on their own and the rest were referred by their doctors working in polyclinics or by traditional doctors working on their own. In Peking there were two new special hospitals, a children's hospital of over 500 beds and chest hospital of 350 beds. As usual, residential facilities were adjacent to the hospital for all the staff. In Canton a first-class new municipal

hospital of 1,000 beds was visited. Here there were 10 private beds, but these were available mainly for high officials and foreigners. In this hospital there was a special gastro-intestinal unit of 90 beds. In the hospitals related to medical schools there was special provision for research laboratories, which were liberally equipped with modern apparatus. Certain departments were clearly well below Western standards. The x-ray equipment was mainly inadequate, and it seemed certain that clinicians received far less help than they would have done from well-equipped departments. Anaesthetics were also less advanced. Relaxant drugs were used, but on a small scale, and much work was done with open ether. Nitrous oxide appeared to be non-existent.

Polyclinics

The doctors trained on Western lines were working in hospitals and polyclinics and public health stations; few were providing a personal general practitioner service, which seemed to be provided by the traditional doctors. In the cities a large number of polyclinics had been developed, providing a general medical and casualty service. Each large factory seemed to have its own medical service for the care not only of the workers but their families as well. The workers were mainly living in flats adjacent to the factory. At the first lathe factory in Mukden there were two medical clinics (one inside and one outside the factory), three health clinics (one inside and one outside the factory), and three health stations. There were 11 full-time doctors concerned with 5,800 workers and their families, approximately 25,000 people. It was stated that an average of only two days a year per person was lost from work through sickness, but perhaps this extremely low figure was maintained by the use of a night sanatorium. At a car factory at Changchun there were 55 whole-time doctors, 170 nurses, and 40 feldshers responsible for the medical care of 18,000 workers and their families. The factory area included a 300-bed hospital.

Medical Research

The over-all pattern of medical research in China is determined by a Central Committee, and the main research institutes adapt themselves to the general plan. It seemed, however, that the individual research worker could follow his own ideas in addition to taking part in co-ordinated work. At the Chinese Academy of Medical Sciences at Peking fundamental work was in progress in many branches of medicine, including nutrition, industrial toxicology, in addition to the usual fields of physiology, biochemistry, pharmacology, and pathology. The library at this research centre took 1,300 medical journals covering world literature.

Pattern of Disease

Quite apart from the tropical diseases the pattern of disease presents a number of interesting contrasts with Western countries. Tuberculosis is very common. In a pilot survey of 1,000 people in Peking 30 active cases were found, and from this and other investigations it seems likely that there is 10 times as much tuberculosis in China as in Great Britain. Undoubtedly the overcrowded living conditions and restricted food supply in the past have been important contributory factors. Under the new regime intensive B.C.G. campaigns to inoculate all infants have been in progress.

Peptic ulcer is a common illness, with about three times as many duodenal ulcers as gastric ulcers—a proportion similar to that in England. Liver diseases are particularly common, and a general hospital of 500 beds will admit 30 or 40 cases of hepatic coma in the year. There are many patients with unexplained hepatic cirrhosis, possibly some of which may be the result of protein-deficiency in infancy leading to fibrotic changes in the liver. In some

regions schistosomiasis was the main cause of cases of cirrhosis. Cancer of the oesophagus was far more common than in Western countries. Radical resections were frequently done, with a mortality of between 5% and 10%. Cancer of the liver was also often seen. In the southern states there were a number of bile-duct carcinomas associated with the presence of *Clonorchis sinensis*, but this infestation is now diminishing since the eating of raw fish has been forbidden. In Canton nasopharyngeal endotheliomata were commonly seen, but much less frequently in the north. Conversely, carcinoma of the penis was a well-recognized condition in Peking but seldom seen in Canton, this being attributed to the better washing facilities in the warm south as compared with the northern regions, where they have a very cold winter. Carcinoma of the bronchus was moderately common all over China. One can discuss impressions only, as unfortunately vital medical statistics are scarce.

Hygiene Campaigns

The problems of tropical medicine were being tackled energetically. It was reported that there were 70,000 people at work on a campaign to control schistosomiasis, mainly by destroying the water-snail which harbours the cercariae. A visit was made to watch some of these field-workers who were using small flame-throwers to burn the banks of the canals. The campaign was assisted by the voluntary efforts of many of the villages, and even the children were said to be picking up the snails with chop-sticks. In a region near Shanghai some 10 million were affected, and the control of schistosomiasis represents a Herculean task. Much research work was in progress in medical centres, and the visit to Hangchow coincided with a conference of research workers concerned with this problem.

The problem of the mosquito may have been less energetically tackled, but considerable work had been done towards the control of filariasis and malaria and the reduction of the dreaded Japanese encephalitis B, which carries a high mortality.

The fall in the prevalence of bacillary dysentery was attributed to the successful campaign against flies. Ascariasis was endemic, and biliary infestation sometimes led to biliary colic liver abscesses and haematemeses. Near Mukden there was a district where the children developed a premature ossification of the epiphyses leading to shortening of fingers and hands and enlargement of the lower end of big bones. This "big-joint disease" also affected the dogs in the locality and was thought to have a nutritional origin.

The New China

The party went as doctors and were treated as doctors, and on no occasion was any attempt made at political indoctrination. One had a natural curiosity to find out about the general political background and its effect on the population in general and on the medical profession. China being a Communist country, the State comes before the individual. For the medical profession this means that all doctors are directed to their posts in any part of the country by the Ministry of Health. It seemed that the wishes of the individual were taken into consideration and there did not appear to be dissatisfaction in the main centres from these official postings, but it was an obvious possible source of dissatisfaction. The doctors one met were probably not a random cross-section of the profession, but one got the impression that they shared the general desire to work hard to build up a new China. For the first time in their lives the country was at peace. They were free from inflation, and indeed food prices had remained stable with rising wages. Life was austere, with little home entertainment, but the tradition had always been to go out occasionally with friends to restaurants and theatres. Only the teachers had a month's holiday. Everyone else, workers and doctors, had six or seven national days a year. They work eight hours a day, six days a week, with three days for a honeymoon and 56 days' maternity leave. The people

clearly appreciated being once more a united country, and one felt that nationalism was their main spur to greater effort. One received no impression of physical cruelty in the regime, although in the first few years after the "liberation" this had undoubtedly been present, but the mental effects may be subtle and difficult to detect.

For the critical person the Chinese regime must often bring about considerable mental frustration. Although criticism has been encouraged, it is clear that those who have been unduly forthright are now labelled "right deviationists" and expected to recant their errors. One hospital visited had a prominent notice denouncing a member of the medical staff as a deviationist. The difficulty must be to know where reasonable criticism ends and "right deviationism" begins. From the Western point of view a serious source of mental stress would be the great lack of privacy. This is due not only to the very considerable overcrowding, but also the system by which every 20 or so families have a leader who keeps himself informed of the lives of those under his care. These leaders in turn form street committees covering some 5,000 of the population. These posts appear to be held by men earning their own living and not by full-time officials. This system enables the Government to bring its policies most effectively to the attention of each individual and enabled the anti-fly campaign, for example, to be so effective. Theoretically it should also allow the Government to become aware of feeling at the periphery, but whether this is so in practice was difficult to ascertain.

Conclusion

Chinese doctors have had little personal contact with Western medicine since the "liberation." Nevertheless they had maintained reasonable contact with world medical literature. Their general plan of campaign has been concentrated on building up a supply of trained doctors, on simple public health preventive measures, building new hospitals, and concentrating research on defined major problems, which seems a very reasonable approach to a fantastically enormous problem. In building up the medical services of New China they have the advantage of the experience of many of the senior doctors who have studied overseas—in England, America, and on the Continent—and these are the doctors who have been able to organize their efficient serum institutes, research laboratories, and administrative services. So far, the younger generation is not getting the opportunity for overseas travel. Without adequate arrangements for sending postgraduates for experience in other countries, it is difficult to see how the initial momentum can be maintained. When postgraduate training overseas is again encouraged by the Chinese, it is to be hoped that Chinese doctors will be welcomed in medical centres throughout the world. Before the last war some of our best overseas postgraduates came from China, and it was particularly gratifying to find how well they had applied their experience. Furthermore, we shall benefit by keeping in touch with the research workers of new China.

At a meeting of the Osler Club on October 4, Dr. ELIOT SLATER read a paper, written in conjunction with Dr. ALFRED MEYER, on "The Psychiatric Illnesses of Handel and Schumann." Handel's paralysis, he claimed, might have been due to cerebral thrombosis, but functional neuralgia could not be excluded. A hyperthymic extrovert, very fond of his food, Handel was definitely not a psychotic. The nature of Schumann's mental illness remains an unsolved problem. Dr. Slater believed it to be an organic psychosis, probably general paresis, and not schizophrenia. Mr. DICKSON WRIGHT discussed the question of Schumann's paralysed hand, caused by his wearing a wooden apparatus of his own design to strengthen his fourth finger, and showed a film depicting his own operation for this purpose. Dr. W. S. C. COPEMAN presided at the meeting, and a lively discussion followed the papers.

A SERIES OF 1,817 PATIENTS SEEN IN A CASUALTY DEPARTMENT

BY

P. MESTITZ, M.B., B.S., B.Sc., M.R.C.P.

Late Casualty Medical Officer, Middlesex Hospital, London

Many patients go to the casualty department of this hospital as they would to their own doctor's surgery. At the same time, the casualty officer has the resources of a large hospital at his disposal. It therefore seemed worth while to analyse complaints, diagnosis, and treatment of a large series of such patients.

Material.—The hospital is situated in Central London, in an area occupied chiefly by tailoring workshops, and very near the polyglot Soho district. The series consists of all patients seen by me between September, 1954, and January, 1955. All patients with obviously "surgical" conditions, such as infected hands and road accidents, are sent to a separate surgical department. Virtually all other patients are seen by one of the two casualty medical officers.

Results

Total attendances in my room during the specified period numbered 1,817. Of these, 975 were by new patients, of roughly equal sex distribution and very mixed nationality. The average age of the new patients was 36.2 years, of the old patients 39.5 years.

Of the 975 new patients, 11 were sent up by their own doctors, 104 by other hospital departments, 23 by a sister or foreman at their place of work, 52 came by ambulance, 43 had no doctor of their own, and 4 said their doctor was not available that day. In answer to the question, "Why didn't you go to your own doctor first?" 38 patients said they were dissatisfied with him. This leaves 700 out of 975 unaccounted for. The great majority of these were not in any sense emergencies. Most of them had no clear explanation of their preference for hospital treatment, though on further questioning certain answers tended to occur frequently. The commonest reply was that it was more convenient to come to the hospital than go to the surgery. A few were genuinely surprised when I told them that the proper course was to consult their own practitioner first. This leaves those patients—quite a considerable number—who, without admitting that they did not trust their own doctor, indicated that they thought that better treatment would be meted out to them in hospital. The two chief factors in this group were the feeling that x-ray examinations were more readily ordered in hospital, and that a hospital doctor would carry out a more thorough examination. Mothers who brought their children often gave this last answer.

The symptoms of the 975 new patients are analysed in Table I, which also shows the final diagnosis in each case. Only the commoner symptoms and diagnoses have been listed in detail. As can be seen, pain is the greatest single problem encountered in this series. Of 327 complaints of pain, no organic cause was thought to be present on 85 occasions (26%). Other complaints, such as feelings of lassitude and transient loss of consciousness, have a much higher incidence of "no organic cause found" (see Table I). Of the 669 complaints analysed, no organic abnormality could be found in 182 cases (27%).

Of the 52 patients who arrived by ambulance, 31 complained of a transient loss of consciousness or of sudden weakness or faintness; of these, six were epileptics and two were suffering from carcinomatosis. Of the 52 patients, 23 had nothing seriously wrong with them, and certainly did not need an ambulance. Nine of the 52 were admitted to hospital.

TABLE I.—Symptoms and Diagnosis

Symptom	Diagnosis	No.
Abdominal pain (142)	No organic cause found Acute indigestion Peptic ulcer Dysmenorrhoea Salpingitis Constipation Acute surgical conditions Urinary disorders Trauma to abdominal wall Others (6 diagnoses)	36 (25.3%) 22 (15.5%) 21 (14.7%) 9 (6.3%) 8 (5.6%) 8 7 7 7 17
Pain in back (44)	Pain of muscular or ligamentous origin (back strain) No organic cause found Others (including 4 cases of lumbar disk prolapse)	15 (34.1%) 11 (25%) 18
Pain in chest (41)	No organic cause found Pain of cardiac origin Bruise Others (8 diagnoses)	15 (39%) 5 (13%) 5 16
Limb pain (35)	No organic cause found Osteoarthritis Lumbar disk prolapse Cervical disk prolapse Others (7 diagnoses)	10 (28.6%) 8 4 4 9
Pain in head (25)	Acute virus infection No organic cause found Others (6 diagnoses)	9 (36%) 6 (24%) 10
Other pains	(no organic cause found)	40 7
Rash (108)	Sensitivity reactions Impetigo Chronic non-allergic eczema Seborrhoeic dermatitis Bites Acne Scabies Others	17 (15.7%) 12 (11.1%) 11 (10.2%) 10 (9.2%) 9 7 6 36
Weakness or faintness of sudden onset (58)	No organic cause found Acute virus infection Carcinomatosis Others (6 diagnoses)	36 (62%) 13 (22.4%) 2 7
Bleeding	(no cause found)	57 18
Cough (50)	Infection of upper respiratory tract No cause found Chronic bronchitis Acute bronchitis Others (5 diagnoses)	19 (38%) 12 (24%) 11 (22%) 3 5
Transient loss of consciousness (26)	No organic cause found Epilepsy Others (5 diagnoses)	13 (50%) 7 6
Dyspnoea (18)	Chronic respiratory insufficiency Bronchial asthma Heart failure No organic cause found Anaemia Others	5 3 3 3 2 2
Chronic lassitude (13)	No organic cause found Anaemia Others	8 2 3
Giddiness (12)	No organic cause found Others	7 5

Investigations.—A total of 334 investigations were ordered for 288 of the new patients—that is, nearly every third new patient: 133 chest x-ray examinations, 71 other plain x-ray examinations, 13 contrast-medium x-ray films, 43 blood tests, and 74 miscellaneous tests. Routine urine tests and faecal occult blood determinations were done by me where indicated, and are not included in these figures.

A record was kept of all prescriptions: 937 were issued for a total of 1,817 attendances; 509 of the prescriptions went to new patients. Table II shows what was prescribed.

TABLE II

Prescription	No.
Local applications	272
Analgesics (mostly codeine and A.P.C.)	238
Indigestion mixtures (mostly antacids)	127
Barbiturates (mostly phenobarbitone for ulcer patients)	93
Iron	36
Antihistamines	36
Sulphonamides	34
Penicillin	24
Others	14

Placebos were prescribed on 53 occasions.

Discussion and Conclusions

The eagerness of patients for "special tests" is well known, and was further confirmed by this series. Our casualty officers also have more time than most general practitioners to examine their patients, and this, together with the whole atmosphere of a busy hospital department, no doubt lured many patients. While every effort was always made to return the patient to the care of his doctor, obviously this could only rarely be done without examining, and often further investigating, the patient first.

This report emphasizes the prime importance of pain as a presenting symptom. The treatment of those in whom no cause can be found for the pain (26% in this series) is difficult and in my experience unsatisfactory. The size of this cult and in my experience unsatisfactory. The size of this particular problem demands more attention than has been given to it so far. Pougher (1955) found that 36.2% of 500 consecutive patients seen by him in his practice were suffering from "neurosis." In the present series no organic cause could be found to account for 27% of 669 symptoms.* Pougher lists 684 symptoms mentioned by his neurotics; there were 213 complaints of pain. Other symptoms, such as weakness, dizziness, and faintness, also figure prominently on his list. It is interesting that in my series far fewer patients came with indefinite complaints such as "depression" or "irritability" than did so in Pougher's series; this may be due to a desire on the part of patients to dramatize their story when attending hospital. Richards (1956) mentions an incidence of 30% for psychogenic disorders in general practice. Analysis of the records from ten general practices over two years (General Practitioners' Records, 1956) shows that approximately 13% of all consultations were sought by patients suffering from frank psychoneurosis.

Analysis of the 52 patients who came by ambulance throws an interesting sidelight on the abuse of this service; 23 of these patients did not need private transport of any sort.

Summary

The source, symptoms, diagnosis, and treatment of 975 consecutive new casualty patients have been analysed: 327 of them complained of pain.

In 27% of all analysed symptoms no definite organic cause could be found.

My thanks are due to Dr. D. G. James for his constant encouragement and criticism. I am also grateful to the Medical Committee of the Middlesex Hospital for permission to publish this article; all opinions expressed in it are naturally my own and not necessarily those of the committee.

THE MOUTH-BREATH

At a meeting of the Section of Paediatrics of the Royal Society of Medicine on October 25 "The Mouth-Breather" was discussed. Members of the Sections of Laryngology and of Odontology were invited to attend.

Mr. E. GWYNNE-EVANS, surgeon in charge of the upper respiratory diseases clinic at the Victoria Hospital for Children, Chelsea, began by noting that nasal breathing depended on both the patency of the nasal passages and the efficiency of the oro-pharyngeal musculature. Failure of the oro-pharyngeal muscles was a commoner cause of mouth-breathing in children than nasal obstruction due to enlargement of the adenoids, and of the various types of nasal obstruction Mr. Gwynne-Evans thought swelling of the anterior nasal mucosa from allergic vasomotor rhinitis also a more frequent cause in children than adenoidal enlargement.

*The difference between this figure and the total number of new patients (975) is made up of those with uncommon symptoms (occurring less than 10 times in the whole series) and those referred for only routine examination.

Significance of the Adenoid Facies

In infants and young children there was a very strong natural instinct towards nasal breathing, and, provided that serious degrees of nasal obstruction were excluded—or corrected—the propensity to nasal breathing tended to overcome failure of the oro-pharyngeal muscles. He was quite certain that in the vast majority of children with the so-called adenoid facies the adenoids were not at fault. These children with long faces, protruding upper teeth and receding chins, and their apparently vacant expressions did not suffer from nasal obstruction, nor were they mentally dull, nor would they develop any permanent nasal, facial, or oral deformities. Their facies was a normal type of natural physiognomy related to hereditary factors rather than to any structural defects.

Professor C. F. BALLARD, professor of orthodontics at the Institute of Dental Surgery, London University, also considered that mouth-breathing never resulted in oral deformities or led to the production of the adenoid facies. His own studies over the past 15 years had convinced him that this facies was a normal phase in the development of a certain type of child and that it was probably an ectomorphic characteristic, possibly related to other features such as asthma and the periodic syndrome. The facies was uninfluenced by any type of remedial exercise or oral appliance—in fact the unnecessary institution of these was very likely to lead to frustration and mental distress in both child and parents.

There was no special morphological type associated with mouth-breathing. Most children with the "open-lip" type of oral posture did not breathe through their mouths, while on the other hand some with a "closed-lip" posture did so. Oral configuration was unrelated to the state of the adenoids, and in his opinion enlargement of the adenoids was never responsible for deformities of the bone structure of the mouth.

In the management of the mouth-breather the first thing was to look for any obvious and definite causes of nasal obstruction and to treat them if present. If there was no obstruction—and there seldom was—then there was no need to embark on any treatment in the young child. Orthodontic treatment might be necessary later, but usually not until around 12 years of age. The majority of children with an adenoid facies would eventually grow out of it.

THYROID HORMONES

At a sectional meeting of the Manchester Medical Society on October 23 Professor N. F. MACLAGAN (Westminster Hospital) reviewed recent work on the thyroid hormones. It was a complex situation, he said. Since the characterization of thyroxine by Dr. (now Sir Charles) Harington in 1926, work inspired by Mrs. R. V. Pitt-Rivers in Britain and by Professor J. Roche in France had led during the last five years to the discovery of four or five other substances which were at present candidates for the position of "the" thyroid hormone. Triiodothyronine had, perhaps, the strongest claim, since it was effective in the smallest dosage, less than 0.1 mg. per day sufficing for the control of human myxoedema. Thyroxine itself was thought to require conversion to some other compound, both because of its relatively long latent period and on account of work with "anti-thyroxine" compounds, which antagonize the metabolic effects of thyroxine by inhibiting its deiodination. 3:3'-Diiodothyronine required consideration, and tetra- and tri-iodothyroacetic acids were more recent competitors for pre-eminence, since they acted with a shorter latent period than the thyronine derivatives. However, larger doses were required, and their rapidity of action was better established in subcellular preparations than in the intact animal or patient.

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Knock-knee in Children

SIR,—It is always gratifying to find what one calls "a clinical impression" confirmed by statistical evidence, and Miss A. J. M. Morley's painstaking research into the aetiology of knock-knee (*Journal*, October 26, p. 976) is a valuable contribution to our knowledge. In the conclusions which the author has drawn from her statistical findings there is, however, one sentence which causes me some dismay. It is an assertion that "apart from operative procedures no effective treatment for knock-knee is known." I personally do not believe that, but my lack of belief is not the reason for my criticism, for none of us can be so bigoted as to resist even the demolition of our established ideas in treatment. In her paper Dr. Morley quotes the use of night splints in one case only. Opinions differ as to the use of night splints, but in any case one has to be quite convinced that the splints are suitably designed, suitably applied, and used consistently. It seems a pity that without any evidence on this particular issue an assertion is made which virtually brands many orthopaedic surgeons as ignorant and extravagant. Economically the withdrawal of all conservative treatment for knock-knee would be a great help to the busy orthopaedic surgeon and to the strained finances of the N.H.S., and I sincerely hope that perhaps the senior staff of the Institute of Orthopaedics, whence this contribution has come, will either endorse Dr. Morley's view that all inoperative treatment is ineffective or will indicate what is really meant by this assertion. It is always difficult to read between the lines of other people's contributions, but perhaps Dr. Morley is suggesting that the psychological trauma of an operation is less than that of wearing splints.—I am, etc.,

London, W.1.

D. F. ELLISON NASH.

SIR,—The most informative investigation on knock-knees in children carried out by Dr. A. J. M. Morley (*Journal*, October 26, p. 976) gives factual proof of the correctness of present teaching—that no treatment is either necessary or curative in the great majority of cases. It must, however, always be borne in mind that, if we take no action at all, it is likely that auntie or grandma will insist that something must be done, and the unfortunate child will be taken the rounds until someone, quack or otherwise, does something definite, with the result that the child may have to endure unending exercises, osteopathic manipulations of the spine, or even irons. It is important, therefore, that as well as explaining matters carefully to the parents some simple and harmless measure such as heel wedges should be prescribed. They may or may not help to improve faulty posture, but they will be good medicine if they help to satisfy anxious relatives and so protect the child from therapeutic onslaughts which can cause real harm, both physical and mental.—I am, etc.,

London, S.E.1.

T. T. STAMM.

Homosexuality

SIR,—In their article on homosexuality (*Journal*, April 6, p. 797) Drs. Desmond Curran and Denis Parr state that they have been unable to find reports of studies of any group of subjects comparable to their own. A recent and as yet unpublished doctorate thesis by myself, entitled "Homosexuality: Results of a Survey as Related to Various Theories," was accepted by the University of the Witwatersrand. It is based on a group of 50 male and 50 female non-institutionalized homosexuals who have never been charged under the laws relating to their activities and who were not seeking psychiatric help. The survey covered

certain biographical information, to see if there were any common background environmental factor which might have some aetiological bearing on the subject of homosexuality; in addition, each case was given the South African version of the Wechsler-Bellevue adult intelligence test to see whether there were any group differences between these and a control group of heterosexuals matched individually for age, education, and type of occupation.

A homosexual was defined as a person who acknowledges his homosexuality, whose sexual life is almost exclusively with a person of the same sex, and whose preference is for sexual relations with a member of the same sex. On Kinsey's rating scale, the subjects were divided as follows:

Kinsey's Rating	Male Subjects	Female Subjects	Total %
6	21	18	39
5	20	27	47
4	9	5	14
	50	50	100

The age range was from 22 years 7 months to 60 years 6 months, with means of 35.8534 and 37.1346 for the males and females respectively. The control subjects were taken from the files of the National Institute for Personnel Research, and were matched individually by age, standard of education, and, where possible, type of occupation. Since no questions on the sex lives of the control group were asked, the criterion for "normality" was marriage. It is emphasized that some of these control subjects, in spite of being married, might have had some homosexual experience during their lives; but it was assumed that by virtue of their marriage their preference or choice, as opposed to that of the test group, was for sexual relations with a member of the opposite sex. Like the group reported on by Drs. Curran and Parr, the education and occupational status of this test group were above the average for the population as a whole, eight males and nine females being university graduates and a further 23 males and 16 females having reached matriculation standard (equivalent to Senior Cambridge Certificate in England) or higher. Occupations among the males ranged from plumber and mechanic to doctor and attorney, and among the females from factory hand (unskilled) and taxi-driver to teacher and medical auxiliary.

Although the homosexual group studied in South Africa was numerically small, four main findings emerged from this survey: (1) No single environmental factor was found to be common to all cases, although one or more cases could be found to fit in with most theories on aetiology. (2) According to group results on the Wechsler-Bellevue scale, the homosexual males showed a tendency towards a schizoid adjustment, and the females towards a mild anxiety state. These trends, however, were well within the bounds of normality and should therefore not be taken as symptoms of neuroses, but rather as personality characteristics indicating types of adjustment which have become integral parts of the character structure. No evidence was found in the homosexual group scattergrams of any trend towards a psychopathic personality. (3) There were some individual subjects who were highly neurotic, but these were found in the control as well as the test groups. (4) The mean I.Q.s of the homosexual groups were significantly higher than those of the control groups in this survey.

	Weighted Score M Males		t	p	Weighted Score M Females		t	p
	Test Group	Control Group			Test Group	Control Group		
Verbal I.Q.	119.90	114.34	2.8460	0.007	117.04	110.14	3.5957	<0.001
Performance I.Q.	116.86	112.92	2.0244	0.05	116.98	111.28	3.0660	0.005
General I.Q.	119.94	114.84	2.9743	0.005	118.38	111.42	3.7631	<0.001

There were no significant differences between the general and performance I.Q.s of the sexes in either group, but the females had a slightly (but significantly) lower score on the verbal I.Q. ($p=0.03$ and 0.04 for the test and control groups respectively). Other facts of interest, which stress the need for further research on non-institutionalized homosexuals, may be summarized as follows: (1) Some psychosomatic and/or psychoneurotic symptoms were present in a large proportion of the homosexual

subjects. (2) Instability in the family was pronounced in only a few cases. (3) Indifference to parents was more prevalent, on the subject's conscious level, than cross-parent fixation. (4) Sixty per cent. of the subjects came from either disrupted or unhappy homes. (5) Seduction was not a prominent factor in the case histories. (6) The homosexual group was as stable as the control group in regard to employment. (7) There was little support for the general contention that all homosexuals are emotionally unreliable and sexually promiscuous; 43% of the group had maintained a relationship with one partner for periods varying from 5 to 30 years. The females were slightly more stable in their relationships than the males. (8) The homosexual group was more inclined than the control group to activities in the artistic sphere, both in interests and occupation. (9) There was nothing in the appearance or build of 93% of these homosexuals to distinguish them from any "normal" group of people. (10) The males had their first overt homosexual experience at an earlier age ($M=16.9$ years) than the females ($M=20.24$ years). (11) The males were less emotionally involved than the females in their first homosexual contacts.

The last two points may be the result of basic sex differences unrelated to homosexuality, whereas numbers 3, 5, 6, 7, and 9 above are contrary to popular belief and warrant further investigation.—I am, etc.,

Johannesburg, S. Africa.

RENÉE LIDDICOAT.

Treatment of Leg Ulcers

SIR,—Drs. Keith Ball and David Phear give me credit in their article (*Journal*, October 12, p. 861) for the importance of sustained pressure in the treatment of chronic ulcers of the leg. I like to achieve this with compression bandages of the adhesive elastic type, combined with the use of "terylene" sponge (this latter is really a heaven-sent help). The whole essence of this treatment was to rescue the treatment of this disease from self-treatment and treatment by nurses, which was almost the rule prior to 1930. It seems a retrograde step to hand it back in 1957 with the addition of the physiotherapist, whose work is much better done by the terylene sponge. This works without effort for twenty-four hours out of twenty-four, whereas the former works with considerable effort for ten minutes twice a week. The boggy of allergy lingers on (it does in every form of therapy), but it is easily overcome by the choice of three different types of adhesive (rubber, diachylon, and glue). A recent extreme case has proved this point, that of a young man (26) recommended to have both legs amputated after five years of ineffectual treatment. Personal treatment by this simple method has healed him and kept him working for the last eighteen months. There are several who could corroborate this particular case. I hope they will continue this correspondence by doing so.—I am, etc.,

London, W.1.

A. DICKSON WRIGHT.

Agranulocytosis due to "Pacatal"

SIR,—In view of the article by Drs. P. H. Mitchell, P. Sykes, and A. King (*Journal*, January 26, p. 204) on the effects of "pacatal," and a question about agranulocytosis from drugs ("Any Questions?" *Journal*, May 18, p. 1195), I should like to report a recent fatal case of agranulocytosis following pacatal therapy.

A housewife, aged 42, was admitted to a mental hospital on April 1 under certificate. She had paranoid delusions and was euphoric and hypomanic. Nothing abnormal was found on physical examination. The cerebrospinal fluid was normal, blood count normal, with haemoglobin 92% and W.B.C. 7,200 per c.mm. Treatment with pacatal was begun on April 17, one tablet three times a day, increasing to two tablets three times a day on April 25. The white cell count was 9,400 per c.mm. and the patient showed definite mental improvement and no longer expressed paranoid ideas. On May 2 the white cell count was 7,100 per c.mm. and on May 7 the dosage of pacatal was increased to four tablets three times a day. On May 15 she had a temperature of 104.6° F. (40.3° C.). Her tonsils were enlarged and inflamed, the white cell count was 800 per c.mm., with 94% lymphocytes and 6% monocytes. The total dose of pacatal up to this date was 6 g. She was transferred to a general hospital with a diagnosis of agranulocytosis and was treated with antibiotics, folic acid, pyridoxine, cortisone, and blood transfusion.

Her haemoglobin was 88% and R.B.C. 4,000,000 per c.mm. The white cell count dropped to 400 per c.mm. on May 17; the platelets were 140,000. Sternal puncture showed a few reticulo-endothelial cells, normoblasts, megakaryocytes, and plasma cells; the rest of the cells were normal lymphocytes and monocytes. No granulocytes were found. A pure culture of yeasts was grown from the ulceration in her mouth. She developed urinary retention and required repeated catheterization. Her abdomen was grossly distended. She died on May 18. Death was due to sepsis and bronchopneumonia associated with acute agranulocytosis.

In their article, Drs. Mitchell, Sykes, and King came to the conclusion that pacatal has proved more toxic than chlorpromazine and that its widespread use is unjustifiable. They conclude that the administration of a drug of the phenothiazine type is advisable only when close supervision of the white cell blood picture is maintained. According to your expert's answer to the question on agranulocytosis from drugs, and all the evidence in the medical literature, the bone marrow depression with drugs appears to come on suddenly, and unless counts are carried out daily there seems to be no point in carrying them out at all. Furthermore, there is no guarantee that the patient can be saved at the time when the fall in the neutrophil count is detected. It seems to me, therefore, that a feeling of false security is created by requesting frequent laboratory examinations, and, moreover, it becomes increasingly difficult for the laboratory to cope with these increasing demands. This applies particularly to mental hospitals where several hundreds of patients are treated with tranquillizing drugs. One can only hope that safer tranquillizing drugs will be developed before they are widely used in general practice.—I am, etc.,

Stafford.

Chlorpromazine in Mittel Angst

SIR,—I thought you might be interested to hear of four patients who developed acute tension and anxiety around the time of ovulation. This tension syndrome considerably inhibited orgasm, and in two cases prevented intercourse at the time when conception was most likely.

The first three patients had all been married for over six years, had made no attempt to prevent pregnancy, and had been carefully investigated by a gynaecologist without his finding any reason why they had not become pregnant. In all three cases the husband's sperm counts were normal. It was therefore decided to try these patients on chlorpromazine, 25 mg. three times a day, starting four days before the expected date of ovulation. Each of these three patients became pregnant and produced normal children, two boys and a girl, after two months' and four months' treatment. The fourth patient had been married only five months and found herself extremely tense around the period of conception. She was put on chlorpromazine 25 mg. three times a day, and has in the last month produced normal twins.

I have not been able to do a comparative series on these patients because of an insufficient number of this type of case being referred to my clinics, but it would appear that the addition of chlorpromazine to the treatment of those on the out-patient fertility waiting-list might well reduce the number of potential in-patients. Since all these five children are normal, it would appear that chlorpromazine in these small doses enhanced conception and did not interfere with ovulation. I would be pleased to hear of any more extensive series of cases.—I am, etc.,

St. Albans.

JOHN H. PRICE.

Description of Cholera Stools

SIR,—In the interesting joint article on the fate of bile pigment in cholera (*Journal*, October 5, p. 803) by three Indian writers from Calcutta, the opening sentence reads: "The rice-water stool of cholera is well known to every student of tropical medicine." I have wondered, in a long experience of cholera both in peace and war, when this totally untrue and ill-fitting description of a cholera stool would disappear. It perplexes those of us who have seen

cholera and rice water how such a false description began. As for its perpetuation, it is only too common an observation that a myth or inaccuracy in a textbook is copied and passed on from one to another.

The stool in cholera is more typically like barley water, and to support my contention I have no less an authority than MacCallum's *Pathology*,¹ and, of course, my own experience in many epidemics in the British Army. MacCallum says: "Rice water must be a poor descriptive phrase, for the stools seem more viscid, turbid, and mucoid than that could be." All through my service, whenever opportunity offered, I never failed to correct this erroneous belief and teaching. One has only to look well at a glass of rice water side by side with one of barley water to appreciate this.—I am, etc.,

London, S.W.19.

B. J. BOUCHÉ.

Influenza Epidemic

SIR,—I am in complete agreement with Drs. A. F. McInnes and J. B. Ross (*Journal*, October 26, p. 998) when they state that the present epidemic of influenza cannot be deemed mild. The epidemic struck this area around September 23 last and reached its peak between October 10 and 15. There is now a slow but steady decrease in the number of cases. While there have been a number of mild cases, this epidemic must surely be regarded as of a somewhat severe nature. The incidence of complications has steadily increased, and includes bronchitis, pneumonia, otitis media, and one case of gross orbital cellulitis, following acute frontal sinusitis. Chest complications have responded to tetracycline with sodium metaphosphate ("achromycin V") in full doses.

I observe that in a national Sunday newspaper it is alleged that the chief of the virus research department at St. Mary's Hospital has stated that this is a mild type of influenza. This is certainly not borne out by our experience in general practice here, and I feel that some enhancement of this "Asian" strain has already taken place: thus the cases now occurring must be treated with due respect.—I am, etc.,

Faversham, Kent.

J. CANTOR.

SIR,—In common with Squadron Leader J. Gilroy (*Journal*, October 26, p. 997) we have met with a number of young adults whose influenza was complicated by staphylococcal pneumonia. We have perhaps been fortunate in not seeing any pneumonias of the type occurring during the 1918-19 pandemic.¹ This may be due to early admission to hospital in our cases, but the observations of Finland *et al.*,² in a more recent influenza outbreak, that most deaths occurred over the age of 60 years, and that fulminating pneumonia predominated in the fifth decade, may still be pertinent.

Culture of the sputum in our patients has shown that most of the *Staph. pyogenes* were penicillin-sensitive, and with one exception the remainder proved sensitive to the tetracyclines. I would therefore enter a plea for the limitation of the use of erythromycin in such pneumonias, first, to patients with severe constitutional upset and progressive pneumonia that threatens life (*Journal*, October 12, p. 872) and, secondly, to those patients in whom the clinical course or bacteriology has shown neither penicillin nor tetracycline therapy to be effective. Only in this way can erythromycin retain its pre-eminence in the treatment of resistant staphylococcal infections.—I am, etc.,

Swindon.

SIR,—During the present influenza epidemic I have been impressed by the impact made upon a large section of the population by the headlines in certain popular newspapers and by advertisements on I.T.V. The several remedies

advertised on the latter medium suggest that the doctor should be called or informed, and on several visits I have been told that that was the sole reason for my visit. Newspaper headlines giving brief details of occasional tragic happenings have added to the state of anxiety of patients and relatives. These factors have, I believe, contributed considerably to the excessive number of calls.

I would like to suggest that, in such times, a few minutes on B.B.C. television by a member of a responsible body, such as the B.M.A., would go a long way towards putting events in their true perspective, allaying anxiety, and suggesting that home remedies should be given a short trial. The concessions made concerning the "first certificate" should also be broadcast, and this alone would save many otherwise unnecessary visits. I know that this latter information has been put in the local press two or more weeks after the epidemic started, but I have yet to meet a patient who has read it. Some sensible advice on the medium that is now almost universal would go a long way towards helping the N.H.S. to function efficiently, even in times of crisis.—I am, etc.,

Walton-on-Thames.

H. V. REEVES.

SIR,—In this area the epidemic had lasted about 40 days. During this time I noticed four times a change in the clinical picture of the disease. The advertised 24 or 48 hour "flu" hardly ever materialized—only a few cases during the first week of the epidemic got better and stayed well almost as soon as they got to bed. During the first 10 days, and indeed among the few sporadic cases preceding the epidemic, the main characteristic was very severe headaches lasting several days, unrelieved by the ordinary mild analgesics, and none of the usual systemic disturbance so typical of the yearly seasonal influenzas. The second 10 days of the epidemic brought a majority of cases which behaved more like ordinary influenza, with the exception that after four days, when one would expect the temperature to drop, a sudden rise took place. During the third 10 days gastric and gastrointestinal disturbances were in the foreground; and during the last 10 days of the epidemic a great number of patients were struck down a second time after they had been quite well in every respect for several days. These cases did not at all resemble those which normally are labelled as "neglected flus" in people who either tried to brave it or else returned to work prematurely before they had completely recovered. The number of complications also rose during that last period.—I am, etc.,

Billingham, Co. Durham.

JOHN ABELS.

Psychopaths

SIR,—The Royal Commission recommends that the term "psychopath" be substituted for the present categories of amentia. I consider that to call all grades of amentia psychopaths is unsatisfactory. The term psychopath is usually applied to the unstable, socially maladjusted individual. The intellectual attainments of many psychopaths are at least average. The intellectual attainments of idiots and imbeciles are nil, and in the case of high grade aments extremely poor. If we must have a change of terminology, perhaps the term "mentally handicapped" would meet the case. It is a term which the lay public can understand and appreciate. The term psychopath is a somewhat ill defined "umbrella" entity.—I am, etc.,

Halifax.

G. C. F. ROE.

Homoeopathy

SIR,—I am glad to learn from Dr. F. W. Campbell's letter (*Journal*, October 12, p. 882) that the attitude to homoeopathy in his department is so liberal. My colleagues and myself in Glasgow Homoeopathic Hospital would be glad to co-operate with him to the limit of our time and capabilities in tests of homoeopathy. Homoeopathy is, however, largely a practical art best taught in the out-patient clinic, and a matter of individualizing each patient, not easily susceptible of statistical analysis. My predecessor, Dr. H. H. Patrick, did make an offer in 1933 to treat diphtheria in

one of the wards of a Glasgow fever hospital to test his claim that homoeopathy would do better than the usual methods. This was refused by the medical officer of health of the day on the grounds that patients could not be experimented upon.

The opportunity for treating numbers of diphtheria cases has now fortunately passed (largely owing to active immunization along homoeopathic lines), but influenza, cholera, poliomyelitis, and many other such diseases that run fairly true to type remain and give ample material for any doctor to try out the method for himself without abandoning procedures of value already in use. But it is necessary to master the main indications for the homoeopathic remedies most often needed in these conditions. With gelsemium, baptisia, bryonia, *Rhus toxicodendron*, arsenic album, lachesis, *Eupatorium perfoliatum*, pulsatilla, and sulphur he could greatly increase his ability to cope with influenza; carbo vegetabilis or antimonium tartrate might save some grave influenza pneumonias; and a knowledge of camphor, cuprum, and *Veratrum album* would vastly improve his results in a cholera epidemic.—I am, etc.,

Glasgow.

T. D. ROSS.

Peptic Ulceration During Prednisolone Therapy

SIR,—Peptic ulceration is one of the well-known complications of cortisone therapy, and the same complication seems to be at least as common with prednisolone. The recent literature on this subject has been reviewed in a case report by Drs. E. V. Hess and M. E. Macpherson (*Journal*, February 2, p. 271). The following two case reports draw attention to the danger of giving prednisolone to patients with a history of previous gastric or duodenal ulceration. If such patients must have prednisolone they should certainly be given prophylactic ulcer therapy at the same time.

Case 1.—A European man, aged 35, first began to have swelling of his left foot and ankle in 1944. This was diagnosed as gout. Colchicine did not relieve the pain but did produce severe gastric symptoms. He was later treated with probenecid, again unsuccessfully. During the 12 years up to 1956 the diagnosis remained uncertain and the condition progressed. By late 1956 he was only able to hobble about with the aid of two sticks. Both feet and ankles were grossly swollen and distorted, and he was developing a depressive reaction because of his disability. In 1957 the patient developed the typical symptoms of a duodenal ulcer. This was proved radiologically and responded quickly to ulcer. This was proved radiologically and responded quickly to ulcer. This was proved radiologically and responded quickly to ulcer. In late 1956 his doctor put him on oral prednisone therapy for three months, and this seemed to produce a slow improvement in his feet and ankles. He was then changed to oral prednisolone, 10 mg. four times a day, and the improvement became more marked. But within two weeks of starting on prednisolone he began to have vague indigestion which at first he could control with alkalis. Barium meal x-ray again showed a duodenal ulcer. He was admitted to hospital, taken off prednisolone, and treated with diet and alkalis. The peptic symptoms rapidly improved, but his ankles relapsed, becoming very swollen and painful. As soon as his duodenal ulcer was judged to be cured, he was given a course of daily injections of 25 mg. of corticotrophin with tab. colchicin. gr. 1/100 (0.65 mg.) 4-hourly. The feet and ankles rapidly began to improve, and he was discharged. He was then treated as an out-patient on tab. colchicin. gr. 1/50 (1.3 mg.) four times a day, with injections of long-acting corticotrophin gel 40 units twice weekly. Four months later he was seen dancing a polka with careless abandon.

Case 2.—A Eurasian man, aged 43, developed an itchy rash on his trunk, which his doctor treated first with antihistamines without response and then with oral prednisolone, 10 mg. three times a day. The rash rapidly subsided, but after about a week he began to have epigastric pain within 30 minutes of taking food. This pain was relieved by alkalis. A week after the pain began his stools became black and tarry. Three days later he vomited fresh blood and was admitted to hospital. He had been taking prednisolone up to the time of the haemorrhage. On admission the patient was very ill, anaemic, Hb 4.81 g.%, tender in the epigastrium and over the right phrenic nerve, with hyperaesthesia over his right supraclavicular region. He had a leucocytosis, W.B.C. 16,000 per c.mm., 81% neutrophils. It was thought that he had an acute gastric ulcer with a small perforation into the lesser sac. He was transfused, and treated conservatively on a

peptic ulcer regime, oxytetracycline, and intravenous "imferon." He made an uneventful recovery. After admission to hospital the history was obtained of a previous admission for a gastric ulcer in 1945.

Both these patients had a previous history of peptic ulceration. Both developed ulcers again within two weeks of starting prednisolone therapy. There was no other apparent reason for the ulcers beginning at these particular times, and in fact both patients were pleased with the response of their original symptoms to prednisolone. The ulcers both healed very rapidly when the prednisolone was stopped.—I am, etc.,

Singapore.

RONALD WELLS.

Influence of Environment on Surgery

SIR,—It is refreshing when a surgeon of Professor F. A. R. Stammers's eminence reminds us (*Journal*, September 7, p. 555) that the practice of surgery may wear a different guise under primitive circumstances from that with which we are familiar in our larger hospitals. Most of us engaged in surgical work in rural Africa, or anywhere far removed from what is termed civilization, must have repeatedly asked ourselves what we are justified in doing when we plan operative treatment. Is there indeed any justification at all for operating in the country hospital in a world where improved roads, speedy ambulances, and helicopters could carry our patients to centres where are available more skilled aid and better facilities?

There is such justification, I am convinced, but a few rules might be formulated to guide our hands in cases of doubt: (1) That prolonged procedures involving knowledgeable teamwork, both operatively and in the post-operative period, are unjustified in the country unit. This Professor Stammers underlines in his paper. (2) That single-handed surgery without any second person for anaesthetic or resuscitative purposes is perilous, and, except in emergencies, is an unwarranted risk. (3) That even in financially straitened mission hospitals it should be possible to ensure a minimum of working apparatus for the safe conduct of the operation undertaken and for emergency action to be taken in the event of collapse. Which means in practice that two doctors working in the deep country can with predictable safety do most of the "ordinary" surgery, the hernias, caesarean sections, obstructions, skin grafts, and cystoscopies—to which may be added more ambitious procedures which local circumstances have rendered familiar, thyroidectomy in goitre areas, repair of vesico-vaginal fistulae where the home midwifery is below par, cataract in the dusty corners of the Commonwealth.

The country surgeon meets his patients entirely unselected: they have been referred by no one, since there is no one to refer them. Out of the hurly-burly of a dispensary and from among the tuberculous, the sufferers from amoebiasis, the children with whooping-cough, and the women whose pregnancies seem so perpetual, he must select his next week's list, and he must hope for no regular opportunity to pursue any special or narrow field. Those who have come have come not because of any reputation he may have as a surgeon, but in a simple faith that he may help them as he helped their mothers and cousins before. The choice of weapons is wholly with the surgeon: in him is placed a trust which no man ever deserved and which none should ever abuse. This trustful attitude may flatter the individual surgeon to "have a go" (as Professor Stammers puts it) at problems too advanced for his facilities and too great for his skill. But it may also stimulate him to improve both his ability and his scope. He will, it is true, perform operations on Africans which he might not feel justified in performing on Europeans, not, let it be understood, from any disrespect for his African patients, but because he knows that his failure to act with a considered boldness may remove the only hope from his patient's mind.

In all, country surgery is a delicate balance between being a blessing to men and a menace. Men of the size of Schweitzer and Grenfell have attained positions of universal respect and renown: to the smaller surgeon in the bush

come many temptations which only the practice of the virtue of humility and unremitting study of the craft of surgery are likely to overcome.—I am, etc.,

Nqutu, Zululand.

E. A. BARKER.

Public Health Bureaucracy

SIR.—I have just been to the U.S.A. On the outward trip, on account of the weather, our (American) aircraft was diverted to Gander, Newfoundland, in order to refuel. In announcing this change of plan over the internal loud-speaker it was stated that at Gander a nurse would come aboard and inspect our smallpox vaccination certificates—with a rather pointed addendum that such policy was not dictated by the airline in question. Gander was reached around 3 a.m. and the passengers did not disembark during refuelling. We had to wake up, though, and sleepily push the required pieces of paper through apertures in the curtains of our berths to be received by an invisible nurse.

Of what possible use is this measure? It is a source of much irritation to American travellers through a British territory. The smallpox certificates had already been requested for inspection by airline representatives in London. Supposing a passenger had no such certificate on reaching Gander. Presumably he would be considered a risk to the community as a potential spreader of smallpox had he been recently exposed to the disease, for otherwise there would be no point in certification at all. One would expect, therefore, that he would be off-loaded, vaccinated, and possibly detained. This Newfoundland health measure, in the case of airplanes making refuelling stops with the passengers remaining on board, therefore ensures that only potentially dangerous persons set foot in the country—which surely is the very opposite of what is intended. Can somebody please explain?—I am, etc.,

London, W.2.

R. R. WILLCOX.

Detention of Voluntary Patients

SIR.—A coroner is said to have laid down the dictum that such a patient should not be released until the expiry of the 72 hours' notice which he had contracted to give, presumably while arrangements are made for future suitable care.

Dr. W. Lindsay Neustatter (*Journal*, October 19, p. 944) pertinently inquires the legal basis for this, and the consequences of trying to enforce such a line of action. Usually one solves such problems by persuasion of the patient and his relatives. Assuming failure, one considers whether the patient is dangerous to himself, herself, or others. *Felo de se* and infliction of injury on others are criminal offences, and it is the duty of all citizens to prevent crime, and to call in the police, or in these cases the duly authorized officer, who, when convinced of the need, fulfils his function in the routine legal manner. Similar action may be necessary when it is proposed to remove a certified case who is similarly dangerous to himself or others. It is exceptional that such action is necessary, but interesting cases do occur, as anyone with long experience can testify. In this way we safeguard our patients and keep within the law.—I am, etc.,

Ewell, Surrey.

A. A. W. PETRIE.

SIR.—As the superintendent of the hospital referred to in Dr. W. Lindsay Neustatter's letter (*Journal*, October 19, p. 944), may I explain that the matter has been discussed between the coroner and myself, and as a result the suggestion that the law had been broken is now to be regarded as withdrawn. A statement about this appeared in *The Times* for October 24.

In his letter Dr. Neustatter has raised the further question as to what powers of detention, if any, exist during the 72 hours following the patient's notice. As far as I know, there has never been any legal decision on these matters, and presumably there never will be, since the voluntary system as we know it is likely to be superseded by the promised new legislation.—I am, etc.,

Coulsdon, Surrey.

ALEXANDER WALK.

SIR.—Dr. W. L. Neustatter (*Journal*, October 19, p. 944) has raised several interesting questions. I consider we should be spoiling the principle of voluntary status if compulsion were used, be this manual restraint or a locked door, to prevent a voluntary patient from leaving the hospital when he wishes to do so. If the patient who insists on leaving is believed to be a danger to himself or others and certifiably of unsound mind, the duly authorized officer will of course be immediately informed, and the patient would be readmitted under Section 20. A special difficulty is faced when a voluntary patient is considered dangerous but is not certifiable. Recently I had such a patient, who insisted on leaving against medical advice, and stated that he intended to commit suicide. I told him it was my duty to inform the police, but this did not deflect his determination to leave. I therefore rang up the police, who, however, told me that they could not take action until the crime is committed. I had no option but to allow the patient to depart. As far as I know, he did not commit suicide.

I would point out that nowadays, in the great majority of cases, it is not the patient but the medical officer who gives notice of discharge, and we are being faced at times with the opposite problem: the patient refuses to leave after being given 72 hours' notice to do so. In one instance I threatened to call the police with a view to charging the ex-patient with loitering round and trespassing upon Crown property. This proved an efficient stimulus to effect his departure.—I am, etc.,

Basingstoke.

I. ATKIN.

Chemical Boiling Test for Proteinuria

SIR.—Following the article by Drs. D. N. Baron and Celia Oakley (*Journal*, March 16, p. 628) on the salicyl-sulphonic acid tablet test, we have attempted to devise a test which will avoid its drawbacks—namely, relative lack of sensitivity and economy—and which can be used where the standard boiling test is not practical.

1.5 ml. of fresh urine is added to 0.67 g. of citric acid and approximately 0.83 g. sodium hydroxide (three "M. & B." NaOH pellets) in a 6 in. by 1 in. "pyrex" tube and gently agitated. Within 30 seconds a vigorous thermal reaction takes place, causing the urine to boil. When the reaction has ceased and froth has cleared the urine is examined for turbidity or presence of particles in the usual manner. Sodium citrate formed in the reaction crystallizes out of the solution only on prolonged standing and does not interfere with the interpretation of the test, neither do phosphates if present, as it is thought that they combine with excess caustic soda to form sodium phosphate and calcium and magnesium hydroxide, which are soluble in the alkaline medium. The test can therefore be used regardless of the original pH of the specimen.

The reagents should be put together just before the test, and it has been found convenient to have the citric acid (fine crystals being preferable) weighed out into tubes and to add three sodium hydroxide pellets when required. A permanent mark is made on the tube to show the required urine level. As both reagents are 'highly deliquescent' in powder form it is distinctly dangerous to attempt to pulverize and mix them, and for the same reason it is not possible to incorporate them into one tablet or two tablets and store under ordinary conditions. The test is sensitive to a protein concentration of 0.01%, and if materials are obtained in bulk about six tests can be done for one penny.—We are, etc.,

Cost of a New Car

SIR.—The Earl's Court Motor Show, and its attendant influx of mototrophic hormone to the blood stream, has stimulated me to embark on a modest analysis of the price list of cars currently available in the U.K., as published weekly in our principal motoring magazines. The results

are enlightening, and I offer them without further preamble as a list of categories. I have not taken three-wheelers into account.

(1) Cars which I might purchase for ready cash by a cheque on my current account—0. (2) Cars which I might acquire by trading in my present car, without additional cash adjustment—12. (3) Trade in, plus a maximum cash contribution from my available resources—12. (4) Trade in, plus cash contribution, plus a prudent degree of hire purchase—42. (5) Trade in, plus cash, plus the absolute limit of hire purchase short of sheer folly—31. (6) Cars in the price range between the maximum of category five and twice that figure—100. (7) Cars from price twice category five to four times category five—90. (8) Cars from price four times category five to eight times category five—36.

The most significant points are that, of the three hundred odd cars listed, two-thirds are completely out of my reach, and, of these, one-half covers a price range from twice to eight times the maximum figure which I can contemplate. Most important of all, perhaps, the type of car which is necessary for my requirements is not to be found below category five—i.e., at a price which compels my incurring the heaviest hire-purchase commitments. The picture is a bleak one, and one is bound to ask if this is a just presentation of the status in the community which is properly due to those like myself who bear the responsibilities of consultant rank. Might we not aspire to category six?—I am, etc.,

South Shields.

D. M. McCLURE.

Press Publicity

SIR.—I write, as one of many members of our profession, with a genuine sense of grievance. Can nothing be done to stop the less reputable lay press lifting papers from medical journals, rewriting them (in a form suggesting an interview) in language calculated to appeal to the less educated, garbling the facts and even mentioning the author by name with his or her professional appointments? Is there no legal redress for this unwelcome and unwholesome publicity? If not, it is time there was.—I am, etc.,

Crediton, Devon.

MARGARET HADLEY JACKSON.

Mass B.C.G. Vaccination

SIR.—I wish to support the views of Dr. E. F. James (*Journal*, August 17, p. 410) in which he opposes the use of mass B.C.G. vaccination in schoolchildren. Countries, particularly those with a relatively low incidence of tuberculosis, which continue mass B.C.G. vaccination in age groups such as 10 and 12 may rue the day that they are confronted with a Mantoux-positive instead of a Mantoux-negative population. It must surely be obvious that, as the prevalence of tuberculosis diminishes, the value of the Mantoux test becomes greater and greater.

There is one factor, however, which lends support to continued B.C.G. vaccination, particularly in infants and adolescents of tuberculous families—that is, the increasing numbers of people being infected with drug-resistant tubercle bacilli. There is no doubt that such an infection is most serious and has often been brought about by the inadequate treatment and supervision of tuberculous sufferers by physicians themselves. How many times do we see newly diagnosed or even chronic cases of tuberculosis being treated with isoniazid plus P.A.S. or even isoniazid alone, without any efforts being made to determine the sensitivity of the particular tubercle bacilli to these agents? There is also a belief that chemotherapy is unable to kill tubercle bacilli, and, as if to prove their point, many physicians prescribe tiny inadequate doses of the various anti-tuberculous drugs available, often hiding behind a plea of avoidance of toxicity to justify such empirical therapy. Again one often sees patients continuing to receive a chemotherapy regime which is failing to convert sputum or clear tuberculous infection, even after many months.

The key to the successful eradication of tuberculosis lies in the hands of every physician, who must realize that each patient suffering from tuberculosis under his care must be rid of his tubercle bacilli by every means at his command. Recalcitrant sufferers wherever possible must also be prevented from mingling with the population, but, even more important, they must be prevented from receiving inadequate and non-specific chemotherapy when they are finally persuaded to receive treatment. If this problem is rigorously tackled from the bedside, then mass B.C.G. vaccination would very soon become unnecessary. It is paradoxical that physicians, on the one hand, are urging the more widespread use of B.C.G. vaccination, and on the other hand, as a result of indecisive treatment, are themselves actually creating a greater need for its use.—I am, etc.,

Northfield, S. Australia.

R. MUNRO FORD.

G.P. Responsibility in Gynaecology

SIR.—We should like to reply to some of the points raised by correspondents following our article on general practitioner responsibility in gynaecology (*Journal*, September 7, p. 558).

Unlike Dr. W. G. Dawson (*Journal*, September 21, p. 711), we find trichomonas and monilial vaginitis difficult to treat successfully. Such short courses of treatment as he describes have not, in our experience, given more than temporary relief. In particular this applies to trichomonas infection, where the initial course of pessary treatment should last at least eight weeks. It is not unusual for the discharge to recur at period times, and we advise, under these circumstances, that pessaries be used for two or three days before and during periods for a few months. Similarly, a failure to identify and treat physical lesions in the genital tract is likely to result in the reappearance of the discharge sooner or later. In our original communication we reported that 16 of 21 patients with vaginal discharge (including cases of trichomonas and monilial vaginitis) had underlying physical lesions in the genital tract. We believe that there is a greater chance of permanent relief from such secondary infections as trichomonas and monilia if these cervical erosions, polypi, etc., are treated. When so many women with vaginal discharge have physical lesions in the genital tract it seems, for this reason alone, very reasonable to refer these patients for a gynaecological opinion.

Dr. J. D. C. Cook (*Journal*, September 28, p. 767) has suggested that the family doctor should be prepared, without reference to a gynaecologist, to fit a ring pessary for these patients with prolapse who do not wish to have surgical treatment. Ring pessaries when worn over a number of years can lead to much trouble and discomfort, and these women may, in old age, present themselves for surgical treatment. We think that it is in the patients' best interests to be given the opportunity of discussing treatment with the gynaecologist. We know very well how difficult it is for the general practitioner to decide which cases should remain under his care and which should be referred for a specialist opinion. In our year's study we found ourselves constantly asking the question, "What would be done if this patient were a close relative?" We found this approach most realistic and helpful.—We are, etc.,

Maternal Anaesthetic Deaths

SIR.—The recent Report on Confidential Inquiries into Maternal Deaths in England and Wales for the three years 1952-4 by the Ministry of Health¹ was made the subject of an admirable leading article in the *Journal* (August 3, p. 280). This pointed out certain grave defects in the working of the obstetric service, particularly in regard to the division of responsibility in the antenatal period, which in many cases was obviously a contributory factor in cases of maternal death.

The especial object of this letter is to draw attention to that section in the report which deals with deaths due to complications of anaesthesia. These are classified in the report as "Deaths Due to Therapeutic Misadventure," which presumably means that for the most part they were avoidable. The most disturbing feature in the report comes under the heading "Inhalation of Stomach Contents." This was by far the commonest cause of death associated with anaesthesia and accounted for no fewer than 32 out of the 49 deaths. The report points out that "it is generally believed that the emptying of the stomach is commonly unduly delayed during labour, and even if the patient has taken nothing by the mouth for many hours the stomach during labour may contain a large amount of fluid." In slightly over half these cases death occurred during the induction of the anaesthetic. Attention is drawn to such points as the skill of the anaesthetist, the depth of anaesthesia, the pre-operative evacuation of the stomach, and the position of the patient during anaesthesia and while awaiting delivery of the placenta. Unfortunately little or no evidence is produced as to the relative importance of these factors, but on one point the report is clear—in 42 out of the 49 cases the anaesthetic was administered in hospital. This confirms Dr. R. B. Parker's conclusion (*Journal*, July 7, 1956, p. 16), and gives rise to the suspicion that, if forceps delivery becomes necessary under general anaesthesia, the patient is considerably safer in her own home.

In regard to the 25 deaths from aspiration of vomit in forceps delivery, it is almost certain that none of the deaths would have occurred if the patients had been anaesthetized and delivered in the lateral position. Is it not obvious that with the possibility of vomiting always present in these cases the lithotomy position is the worst possible position for the patient and invites the risk of inhalation of vomit? I have repeatedly, in this *Journal*, challenged anyone to produce records of even one single death from aspiration of vomit when the patient has been anaesthetized and delivered in the lateral position, and no such evidence has been forthcoming.

There is little doubt that simple, open methods of anaesthesia are adequate and safer for patients in labour than elaborate and closed methods. It is a striking fact that no death is recorded in the report which was associated with the use of open ether. These deaths from aspiration of vomit constitute a reproach to obstetricians and ought never to occur. Those responsible for the teaching of obstetrics in this country will bear a heavy weight of responsibility if they continue to teach the lithotomy position for forceps delivery under general anaesthesia. For if and when death from aspiration of vomit occurs they cannot justly blame the anaesthetist, and they must surely, if they have any imagination, feel some sense of joint responsibility with the students they have taught when they, in their turn, may be faced with what must always be regarded as a calamity of the first order.—I am, etc.,

London, N.W.7.

A. H. MORLEY.

Hormones and Behaviour Pattern

SIR,—Dr. S. Leonard Simpson's paper (*Journal*, October 12, p. 839) is, as usual, amusing, erudite, most scholarly, based on personal experience, and elegantly written. I would like, therefore, the following remarks to be regarded not as criticism but perhaps as an addition to his paper, as obviously it is not possible for anybody to overlook the complete field of any branch of medicine nowadays.

Hormones and Behaviour is the title of a book written by Frank A. Beach, professor of psychology, Yale University.¹ It was based on his studies mainly of animal behaviour of over 10 years' experimental work. On another occasion, I quoted from the book that "male puppies lifted one hind leg during micturition at eight weeks after being injected with androgen, in contrast to the 19 weeks of the normal dog, and a complete lack of such behaviour after

early castration." Similarly, that "girls who were learning to walk a tight-wire showed a deceleration of the learning curve during menstrual periods" (page 126).

Of particular importance, however, is the fact that pioneers in the field of endocrinology and constitution who are still alive and active should not be forgotten; especially as their most recent books and publications are available to the English-speaking world. I am referring to Professor Julius Bauer, of Los Angeles, California, who was 70 last August. You, Sir, stressed the value of his work in a leading article in April, 1943,² on the occasion of the publication of the first edition of his book *Constitution and Disease*.³ The last book written by him, and published in 1956, is called *The Person Behind the Disease*,⁴ but the earliest book on the subject, which he wrote when he was professor of medicine at the University of Vienna, was published in 1921.⁵ A great deal of Dr. Simpson's lucid and admirable ideas put forward in his paper are already contained in Bauer's earliest writings.

Two more remarks of minor importance: Starr⁶ is quoted as having in 1952 made a special study of personality changes in Cushing's syndrome. Dattner and Professor E. Stengel made similar studies in 1933 and 1934 with similar results (personal communications). Next, Dr. Simpson's question, "Do endocrine disorders, in major and minor forms, occur in families?" has been answered in an excellent paper by B. Aschner.⁷—I am, etc.,

London, S.W.3.

Use and Abuse of Blood

SIR,—“Where does the milk come from, Mummy?” “From the bottle, Johnny.” “Where does the blood come from, doctor?” “From the blood bank, Johnny.” Both are half-truths. The way to get blood used properly is surely this: When a man is appointed to a job which is concerned with transfusing blood, bleed him. And every now and again, waste a man's blood, and let him know it is wasted. Offhand, I can think of no single act that annoyed me more than when some of my good, red, Rhesus-negative blood was spilt on the floor. In this way, hospital staff develop a good hatred of anyone who wastes blood, and will be reminded of the primary source of the blood. Secondly, tell donors what has happened to their blood. I believe this is already done somewhere in the south. About a week after a donor is bled he gets a card saying, “Your blood was given to a man who had a prostate operation (for example) and he is now recovering.” This gives the donors something to gossip about—and medical gossip is always good value. After all, a donor is a person who believes in personal service. So let it be personal, not impersonal.—I am, etc.,

Middlesbrough, Yorks.

JOHN EARLE.

Urea

SIR,—The interesting article by Drs. Cornelio Papp and K. Shirley Smith (*Journal*, October 19, p. 906) on “Urea, the Forgotten Diuretic” prompts me to draw attention to yet another of its forgotten actions.

Some years ago a patient of mine, upon whom I had performed an abdominal hysterotomy for a massive hydatidiform mole, developed a *Bacillus proteus* septicaemia. For the best part of a month the unfortunate woman ran a steeple-chart temperature and was at death's door. None of my colleagues who saw her with me in consultation had the slightest suggestion to offer. Blood transfusion, penicillin, and the sulphonamides were obviously doing her no good. It seemed only a matter of time for her to

develop symptoms of an abscess in the brain, lungs, liver, or elsewhere. In desperation I mentioned the problem to yet another pathologist colleague, Dr. Hirta Schwabacher. She suggested that it might be worth while trying urea, which she remembered as having an inhibitory effect from some experimental work on the *Bacillus proteus* many years before. Then, at the suggestion of the hospital pharmacist, who had had recent experience with urea formic iodide in the treatment of *B. proteus* cystitis, I consulted the makers, Southon Laboratories. Although never used intravenously, so far as they knew, except in animal experiments, they assured me that it should be perfectly safe. As to dosage, they suggested 120 gr. (7.8 g.) four-hourly.

That afternoon I inserted both intravenous and intra-uterine cannulae, and proceeded to administer the solution. Within 24 hours her temperature had fallen to 99° F. (37.2° C.), and after 48 hours the change in her condition was quite dramatic. I continued the intrauterine drip for four days, when I stopped it because of the local irritation resulting from the constant trickling of urea. The intravenous drip was continued for eight days. After 36 hours of intravenous and intrauterine medication with urea formic iodide her temperature remained perfectly normal. In spite of a uterine haemorrhage a fortnight later she made a complete recovery. On the same day that the haemorrhage occurred I received the first negative Aschheim-Zondek report on the urine. I have little doubt that medication with urea formic iodide was entirely responsible for saving this patient's life.—I am, etc.,

Prah Sands, Cornwall.

D. G. WILSON CLYNE.

Misnamed Stethoscope

SIR,—Bravo, Dr. F. R. Langmaid (*Journal*, October 19, p. 943). By all means let us have stethophone instead of stethoscope. At the same time, could we not revert to flutterby instead of the erroneous butterfly? But first things first: could not surgeons please use the correct term appendectomy instead of persisting in calling it appendicectomy? It is not the inflammation they are excising. It is the appendix itself.—I am, etc.,

Romford, Essex.

LÉON M. SHIRLAW.

Subcutaneous Emphysema after Labour

SIR,—The medical memorandum by Dr. J. Llewellyn Skinner on subcutaneous emphysema occurring after labour (*Journal*, August 17, p. 394) prompts me to report the following case.

The patient, a primigravida aged 18 years, first attended the antenatal clinic of the North Middlesex Hospital on January 30. Her last menstrual period was on October 18, 1956, and the expected date of delivery July 25, 1957. On examination no physical abnormality was noted; she gave a history of pneumonia in 1941, but other than this there was no previous respiratory disorder; her blood pressure was 120/60; chest x-ray was reported as satisfactory. Her pregnancy was uneventful.

The patient was admitted on July 23 at 3.45 p.m. She had had backache since 7 a.m. that morning and on arrival was distressed. On examination the foetus was presenting as a vertex in the left occipito-anterior position, with the head engaged; on rectal examination the cervix was found to be two fingers dilated; the membranes were intact; no contractions were felt. She was given 100 mg. pethidine intramuscularly at 3.55 p.m. Following this she rested well. At 6 p.m. she was having good contractions 1:7. Another 50 mg. pethidine was given at 6.15 p.m., following which she continued to rest well between contractions. At 10 p.m. contractions were strong at 1:5 and the previous dose of pethidine was repeated. The membranes ruptured spontaneously at 11.55 p.m., and the cervix was fully dilated at 12.15 a.m. on July 24. She was given gas and air analgesia during the second stage, which proceeded normally although the patient was very apprehensive throughout. She was delivered spontaneously of a living 7 lb. 4 oz. (3.3 kg.) male infant at 1.5 a.m. The placenta and membranes were

delivered intact at 1.10 a.m. Total duration of labour was 18 hours 10 minutes: first stage—17 hours 15 minutes; second stage—50 minutes; third stage—5 minutes. Later that morning the patient complained of a feeling of stiffness of the right side of the face and neck, and across the upper chest anteriorly. On examination a marked crepitus was felt in these regions, but there was no visible swelling or oedema. This did not give rise to any respiratory embarrassment or other symptoms. Clinical examination of the chest was negative. This subcutaneous emphysema gradually subsided and had disappeared completely by the eighth day.

I wish to thank Mr. K. A. K. Hudson, senior obstetric surgeon, for his permission to report this case.—I am, etc.,
J. G. FRANCIS.

London, N.18.

Diet and Dental Caries

SIR,—The paper by Lady Mellanby and her colleagues (*Journal*, August 10, p. 318) on the teeth of London school-children contains much valuable material. The interpretation, however, can be disputed. How would Lady Mellanby explain the virtual absence of caries in children in Indian districts with gross nutritional deficiencies, including vitamin D, with prevalent obvious rickets and common osteomalacia, this on diets high in fermentable carbohydrates? Under the poor, inadequate dietary regime of the Mayan Indians of Guatemala, again we see a very low decay rate, while the children's teeth in New York are about as poor as those found in London; their milk consumption is high, the milk is fortified with vitamin D, their diet is well balanced, at least in the first few years of their lives, and ample supplements are given during pregnancies; rickets in New York has vanished. How does Lady Mellanby explain this paradox? Dental caries is surely due to a dietary factor, but from our experience it is not linked to the biochemical balance and nutritional adequacy of the diet.—I am, etc.,

New York.

H. H. NEUMANN.

POINTS FROM LETTERS

Influenza Publicity

Dr. J. H. MILLEN (Birmingham, 28) writes: I heartily endorse the comments made by Drs. G. E. R. Hamilton and G. Fielding on influenza publicity (*Journal*, September 28, p. 763). The time is long overdue when the British Medical Association should make some attempt to curtail the hysterical outpouring of nonsense which appears in all the daily papers and women's magazines and television on medical matters. . . . If the doctor of the future is to keep in step with the general public, he had better give up reading *Gray's Anatomy* and Samson Wright and peruse the women's magazines, *Family Doctor*, and watch the television programmes instead.

Diagnosis of Poliomyelitis

Dr. GWENDA M. LEWIS (Vellore, S. India) writes: The difficulty of diagnosing early poliomyelitis was discussed in a leading article recently (*Journal*, August 31, p. 513). Is it correct to say that “in the minor illness of poliomyelitis there are no specific signs or symptoms”? Having missed the significance of the presenting symptom of girdle paraesthesia in myself, I cannot help thinking that early symptoms which should immediately suggest the possibility of poliomyelitis may be missed in others.

Homoeopathy

Dr. M. D. MCCREADY (London, S.W.3) writes: I would like to congratulate Dr. F. W. Campbell (October 12, p. 882) on his fair-minded approach to a subject which has, unfortunately, for too long been taboo. It will be to everyone's advantage when it is more widely known that, in particular cases, homoeopathy can be a most valuable addition to the medicinal armamentarium.

Vive le Sport

Dr. H. H. SLACK (Sedgley, Staffs.) writes: For several weeks my waiting-room has been packed with countless numbers of victims of Asian influenza and other incapacitating maladies. One evening our local football team, the Wolverhampton Wanderers, were playing at home against a visiting Spanish team, the game being televised. To my surprise, amusement, and pleasure, I found my waiting-room empty, and was able to sit at my desk reading the *B.M.J.* “Vive le sport.”

Obituary

G. H. COLT, M.B., F.R.C.S.

Mr. G. H. Colt, who, before returning to London in the mid-thirties, was lecturer in clinical surgery in Aberdeen University for a quarter of a century, died at his home at Chilworth, near Guildford, Surrey, on October 26. He was 79 years of age.

George Herbert Colt was born at Hampstead in 1878, the third son of a barrister and bencher of Inner Temple. From Tonbridge School he entered Sidney Sussex College, Cambridge, of which he became a scholar. He took a first-class in the Natural Sciences Tripos in 1900 and, after receiving his medical training at St. Bartholomew's Hospital, where he was awarded a prize, obtained the degrees of M.B., B.Chir. in 1904. Four years later he was admitted a Fellow of the Royal College of Surgeons of England. In the *Lancet* of September 19, 1903, Mr. (later Sir) D'Arcy Power reported a case of aneurysm of the abdominal aorta treated by the introduction of silver wire, with a description of instruments invented and constructed by Colt to facilitate the introduction of wire into aneurysms. At that time Colt had yet to take his medical degrees.

After graduation Colt held the appointments of house-surgeon and junior and senior resident anaesthetist at St. Bartholomew's. Then, following a senior house-surgeoncy at the Derbyshire Royal Infirmary, he was appointed assistant surgeon at Aberdeen Royal Infirmary in 1910. On the outbreak of the first world war in 1914 he was mobilized with the 1st Scottish General Hospital, and two years later went to Salonika in charge of the surgical division of the 43rd General Hospital. From November, 1918, to September, 1919, he was officer in command of the surgical division of the 82nd General Hospital at Constantinople. On demobilization he returned to Aberdeen, and in 1923 became full surgeon at the Royal Infirmary. From 1910 until 1934, when he left Aberdeen, he was also assistant to the professor of surgery in the university. When the British Medical Association, of which he was a member for nearly fifty years, held its Annual Meeting at Aberdeen in 1914 he acted as one of the honorary secretaries of the Section of Surgery.

On his return to London Colt became a consultant in surgery, in which capacity he served the Gravesend and North Kent Hospital for many years. A man of wide culture, he brought to the instruction of students at Aberdeen critical experience and a mind enriched by a study of the history of his subject. As an examiner in surgery for Glasgow University he was thorough and fair. For a time he also examined in surgery for the General Nursing Council of England and Wales. On leaving Aberdeen he was appointed honorary consulting surgeon to the Royal Infirmary. Colt was twice married. His first wife, formerly Miss Henrietta Dick, who was a sister at St. Bartholomew's Hospital, died in 1950, and his second wife in July of this year. He is survived by a daughter of his first marriage.

DAVID LANDSBOROUGH, M.D.

Dr. David Landsborough, who was a pioneer medical missionary in Central Formosa, died on October 11, never having recovered from injuries received in a road accident on September 3. He was 87 years of age.

David Landsborough, who was born on August 3, 1870, was a classical scholar at Kilmarnock Academy. He graduated M.A. at Glasgow University at the age of 20, and then, with his brother, went to Edinburgh to study medicine. The two brothers lived in the traditionally Spartan conditions which were typical of Scottish student life in those days. Early on, a prize for physics of £50 won by David eased their financial difficulties. In his last year at the university he became a member of the Edinburgh Medical Missionary Society. He then took his part in the district medical work

as a "Coogate" doctor in the slums that were then the shame of the city and the field of opportunity for the students attached to the Cowgate Dispensary. After graduating M.B., C.M. in 1895 he was offered the post of house-surgeon to Mr. Alexander Miller at the Royal Infirmary. However, he was persuaded by Professor Hugh Barbour, who took an active interest in the medical missionary work of the English Presbyterian church in Formosa, to respond to an urgent call for a medical man. The young, inexperienced graduate had been led to believe that the only medical missionary in Southern Formosa would initiate him into the craftsmanship of operative surgery, but on arrival he found that conditions in the hospital were very primitive and that his senior colleague did very little surgery.

R. H. M. writes: When I became a colleague of David Landsborough's many years after his arrival in Formosa I soon realized that he had become a most competent all-round surgeon, and was obtaining results comparable with those in home hospitals. Over the years the lone surgeon—for he soon left the south of the island—had taught himself new techniques, keeping himself up to date with the new editions of standard textbooks. His thesis on vesico-vaginal fistula was accepted for the M.D. degree of Edinburgh University in 1925. After acquiring a working knowledge of Chinese, Landsborough began medical work in the small market town of Chiang-hoa, in Central Formosa. At first much of his time was spent travelling in the district, on foot or bicycle, and he saw huge numbers of patients in the villages and small towns. At length, by adding, and adapting, one room and then another to the old native house in which he had started, a hospital came into being. There were no female nurses for many years, and the staff, who ranked as "students," were trained by the missionary. Later, when graduates from the Japanese medical school became available, it was possible to discontinue the student system. Old students told afterwards how at the end of a long day, during which perhaps 400 patients had been attended to, their chief would struggle to keep awake as he conducted evening classes.

Frequent attacks of malaria and dysentery threatened to end his career in Formosa, but an exceptionally tough constitution triumphed and he was able to complete 41 years' service before he retired in 1936. During the years his Chinese name "Lan i-Seng" attained phenomenal renown over the island, particularly in the central part in which he pioneered Western medicine and established confidence in operative surgery in the face of deeply ingrained prejudice. But his memory will be honoured—it is already becoming legendary—for what he was in himself, a beloved doctor who "never lost his temper" and who diffused kindness as well as performing a prodigious number of good deeds. As a medical missionary he was a supreme example of Christianity in action. Dr. Landsborough is survived by his widow and son. He had the joy of seeing his son succeed him in the hospital, now largely rebuilt and modernized, he had founded sixty years ago.

HAROLD THWAITE, M.B., B.S.

Dr. Harold Thwaite, for many years a consultant physician at Birmingham, died on October 26 at his home at Lower Kingswood, Surrey, where he had been living in retirement. He was 74 years of age.

Harold Thwaite was born at Birmingham on January 19, 1883, and was educated at Arden House, Henley-in-Arden, and at Cheltenham College. He studied medicine at the Birmingham and London universities, qualifying by taking the London Conjoint diploma in 1910 and the London degrees of M.B., B.S. in the following year. He then entered general practice at Hampton-in-Arden, where he became also the medical officer to the local auxiliary hospital during the first world war. After the war he returned to Birmingham, where he established himself as a consultant interested in diseases of children and of the heart. From 1915 to 1919 he was acting physician and in 1921-2 physician to out-patients

at the Children's Hospital, Birmingham. During the second world war he was asked to organize the blood transfusion service in the Midlands. As a director of companies he brought to this task a business training which helped considerably in the establishment of a service which was regarded as being one of the best of the early centres. In 1952 he was appointed a life member of the court of governors of Birmingham University.

Outside his profession Thwaite had a deep and abiding passion for cricket. In 1909 he joined the Warwickshire county club, of which for over forty years he was a pillar of strength. He became honorary treasurer of the club in 1930 and its chairman nine years later. From 1942 to 1955 he was president of the club, to which, among other things, he presented two scoreboards. New main gates to the club's headquarters at Edgbaston, erected by public subscription in 1952, were named after him. In the previous year he had the great satisfaction of seeing Warwickshire finish the season as county champions. He was twice married. First, in 1907 to Miss Mabel T. Cheshire, who died in 1946, and by whom he had a son and a daughter, and secondly, in 1955, to Mrs. Evelyn D. Goodway, who survives him.

NORMAN LUMB, O.B.E., M.S., F.R.C.S.

Mr. Norman Lumb, formerly consulting surgeon to the Portsmouth Group of Hospitals, died at St. Richard's Hospital, Chichester, on September 6. He was 66 years of age.

Norman Peace Lacy Lumb was born in London on July 26, 1891, and was educated at Emanuel School, Wandsworth Common. Receiving his medical training at St. Thomas's Hospital, he qualified M.R.C.S., L.R.C.P. in 1914. After a short spell as casualty officer and resident anaesthetist at St. Thomas's, he joined the R.A.M.C. and served throughout the first world war, attaining the rank of temporary major. He was twice mentioned in dispatches and in 1916 was appointed O.B.E. He graduated M.B., B.S. from London University in 1920, was admitted a Fellow of the Royal College of Surgeons of England in 1922, and proceeded to the M.S. in 1929. He was house-surgeon at All Saints' Hospital for Genito-Urinary Diseases and clinical assistant at St. Peter's Hospital for Stone. Having settled at Portsmouth in 1926, he held appointments of honorary surgeon to the Royal Portsmouth Hospital, Gosport Hospital, and the Havant War Memorial Hospital, and was visiting surgeon to St. Mary's Hospital and consultant surgeon to the Ministry of Pensions Hospital, Cosham. His special interest was in urology. With the advent of the National Health Service he became one of the senior consultant surgeons in the Portsmouth group of hospitals, but had to retire because of ill-health in 1952. A member of the British Medical Association for over thirty years, he was honorary secretary of the Southern Branch from 1927 to 1930, and served for one session (1928-9) on the Central Council of the Association.

Mr. Lumb was much loved and respected by all his colleagues and was sadly missed when he had to retire. He was one of the most patient of men, and the courage with which he took his almost complete loss of sight, first in one eye and then in the other, aroused the greatest admiration in all who knew him. The sincere sympathy of all his colleagues goes to his widow and two children.—R. S. M.

JAMES A. LAVERY, L.R.C.P.&S.Ed., D.P.H.

The death of Dr. James A. Lavery at King George Hospital, Ilford, on September 29 is a great loss to his family, his many friends, and his patients. He was 55 years of age.

Born on May 3, 1902, at Swindon, James Aloysius Lavery was one of the four sons of Dr. Charles Lavery, who carried on general practice in Swindon for fifty years. James Lavery took the Scottish triple qualification in 1926, and in 1933 the Glasgow D.P.H. While holding a house post at Charing Cross Hospital he was summoned to Swindon by his father

to help out during an epidemic. He stayed on in general practice, with the exception of the period of the second world war, when he was a major in the R.A.M.C., and, for six years, deputy assistant director of hygiene in Cyrenaica. On his return from the Army he devoted himself to his practice in the Chadwell Heath area of Essex. He was friend and adviser to his patients, not only in medical matters but in all their troubles. His own ill-health was his last consideration. Dr. Lavery is survived by a widow, two daughters and two sons, both of whom are students at Oxford.—T. B. M.

C. G. STRACHAN, M.C., M.B., F.R.C.P.Ed.

Dr. C. G. Strachan, who was in general practice at Cheam, Surrey, for some thirty years and, more recently, resident medical officer at Crieff Hydro, died at Bridge of Earn Hospital, Perthshire, on October 13. He was 66 years of age.

Charles Gordon Strachan was born on September 24, 1891, and studied medicine at Durham University, graduating M.B., B.S. in 1915. He then served in the R.A.M.C. for the remainder of the first world war, being awarded the Military Cross in 1919 for conspicuous gallantry and devotion to duty while in charge of stretcher-bearers in Salonika: the successful evacuation of all wounded during this action, which took place during the night of September 1-2, 1918, was largely due to his personal conduct. After the war he held the appointment of house-physician at the Edinburgh Royal Infirmary and at Chalmers' Hospital before going into general practice in Edinburgh. He became also senior anaesthetist at Craigleith Pensions Hospital and tutor in medicine at Edinburgh University. In 1925 he moved south to join Dr. Charles Corben in practice at Cheam. A little over two years ago he returned to Scotland to become resident medical officer at Crieff Hydro.

C. C. writes: The death of Dr. Strachan came as a great shock to his many friends. At Cheam he soon became one of the most popular doctors in the district. When the National Health Service came in he joined, but quickly realized it was impossible for him to give the attention to his patients which he had been accustomed to give. He therefore resigned and carried on his private practice till March, 1955, when he went to Crieff. He was beloved by his patients, never sparing himself, and showing infinite patience and kindness combined with skilful treatment and charm of manner. He leaves a widow and four children to mourn his loss.

W. F. MINDHAM, M.B., Ch.B., B.Sc.

Dr. W. F. Mindham, who died at his home at Thorne, Doncaster, on October 13, had achieved success in two careers—the Colonial Service and medicine. He was 66 years of age.

William Frederick Mindham was born on January 30, 1891. About forty-five years ago he took an honours degree in mathematics at the then young University of Sheffield. He intended to become a teacher, but instead joined the Colonial Service and was posted to Nigeria, where eventually he became director of ordnance survey. During the first world war he served as a soldier in East Africa. He retired from the Colonial Service in 1932, and started the study of medicine at his old university.

R. C. writes: It was in our first lecture in zoology that I met W. F. Mindham. After passing the second M.B. he decided to continue his studies at Guy's Hospital, and in 1938 obtained the Conjoint diploma and in 1939 his university degree. He then worked as a houseman, demonstrated in anatomy at his university, worked in the pathology department at the Sheffield Royal Infirmary, and also did a little general practice. During the second world war he offered his services to the Colonial Office but was not accepted. He joined the Home Guard, and, as he smilingly told me, was

at once posted for a course in map reading. A few years after the war he had a severe coronary thrombosis which prevented his taking any further active part in medical work. He had another attack a few years later while on holiday in London. Since then his strength had gradually decreased, and he told me a year ago that he had almost ceased to write letters and rarely went about without an escort. "W. F.," as he was known to me, was a most likable man with a very happy and generous disposition. His interests were many; including anthropology, geography, music, languages, and, of course, mathematics. He never married, and our sympathies go to the brothers and sisters who survive him. I shall miss a kind and generous friend.

J. B. DUNLOP, O.B.E., M.B., B.Chir.

Dr. J. B. Dunlop, who had been in practice at Bradford for fifty years, died at Bradford Royal Infirmary on October 15. He was 82 years of age.

John Beattie Dunlop was born at Bradford in March, 1875, the son of Dr. John Dunlop. From Bradford Grammar School he entered Sidney Sussex College, Cambridge, taking a first-class in Part I of the Natural Sciences Tripos in 1897. He was a scholar of the college. From Cambridge he went on to Edinburgh to complete his medical training, qualifying M.R.C.S., L.R.C.P. in 1901. Three years later he took the degrees of M.B., B.Chir. After qualification he held the appointments of house-surgeon at Swansea General Hospital and resident medical officer at the Royal United Hospital and the Royal Mineral Water Hospital, Bath. In 1906 he returned to Bradford to join his father in practice, and was appointed honorary assistant physician at the Royal Infirmary, becoming full physician ten years later. He held this appointment until the introduction of the National Health Service in 1948. He was also medical officer to the Post Office at Bradford, and it was chiefly for his forty-six years' service in this capacity that he was appointed O.B.E. in the 1945 New Year Honours. A member of the British Medical Association for over fifty years, he was honorary secretary of the Bradford Division from 1909 to 1913 and again from 1915 to 1919. In 1920 he was elected vice-chairman of the Division. He also served as one of the honorary secretaries of the Section of Dermatology when the Association held its Annual Meeting at Bradford in 1924. A great reader, he had a special knowledge of heraldry and of many of the titled families in England and Scotland. A bachelor, he lived with his sister, who kept house for him within 100 yards of the house where he was born.—W. A.

W. W. FORSYTH, M.B., Ch.B.

Dr. Walter Forsyth died suddenly at his home at Darlington on October 16. He was 61 years of age.

A native of Airdrie, Lanarkshire, where he was born on March 27, 1896, Walter Watson Forsyth graduated M.B., Ch.B. at Glasgow University in 1917, and then served as a surgeon lieutenant in the Royal Navy for the remainder of the first world war. After demobilization he was in general practice in Scotland until 1921, when he joined Dr. Walter Petter in Darlington, assuming control of the practice on Dr. Petter's death in 1923. His was a life of distinguished and devoted service to his patients and to the town of his adoption. Ten years ago he was joined in partnership by Dr. J. W. Cathcart. Dr. Forsyth held many local appointments, and was vice-chairman of the Darlington Executive Council and a co-opted member of the borough's health committee. His services to the British Medical Association, particularly as honorary secretary of the Darlington Division from 1925 to 1933, culminated in his chairmanship of the Division from 1933 to 1937 and, later, his presidency of the Tees-side Branch in 1952-3. He presided at meetings with characteristic courteousness and charm. He was an enthusiastic freemason and a past president of the Darlington Burns Association. A man with many and varied hobbies, he was keenly interested in physical fitness, playing a useful

game of tennis and golf. He leaves a widow, a son who is a doctor, and a married daughter.

W. G. A. writes: The sudden and unexpected death of Dr. Walter Forsyth has removed from our midst one who, by persistent personal endeavour, self-sacrifice, and a very particular charm of manner, had become a beloved and respected personality in the town of Darlington and in the north-east of England. He exemplified the highest traditions of general practice and social service, and beneath his somewhat stern Scottish exterior there lay a wealth of human understanding. Going to the town in 1930 as a young consultant, I shall never forget the genuine kindness and assistance which he so readily extended to me. Walter impressed me as one who early in life had acquired that elusive gift the art of living. His chief aims were to put more into life than he took out, and to create happiness for those around him and those to follow. To all who had the privilege and pleasure of knowing him, whether as a patient, as a colleague, or in his wide circle of friends, his death is nothing short of a tragedy; but the memory of one who possessed, to such a marked degree, high Christian principles will ever live among us as an example and a stimulus to the highest efforts. To his widow, son, and daughter we extend our sincerest sympathy.

R. E. T. TATLOW, M.D., F.R.C.S.

Mr. Evelyn Tatlow, who had been in practice at Porlock, Somerset, for thirty-seven years, died there on October 16. He was 71 years of age.

Robert Evelyn Tislington Tatlow was born on August 1, 1886, and received his medical education at Trinity College, Dublin, graduating M.B., B.Ch. from Dublin University in 1911 and proceeding immediately to the M.D. While at Dublin he was awarded the Hudson Prize of the Adelaide Hospital. He was admitted a Fellow of the Royal College of Surgeons of England in 1919. After graduation he held the appointment of house-surgeon at the General Infirmary at Leeds, and for some time was surgical assistant to Lord Moynihan. As a result of this experience he acquired all the qualifications needed by a surgeon of the highest class. After serving as a surgical specialist in the R.A.M.C. throughout the first world war, he joined an old-established firm of general practitioners at Porlock. Soon afterwards he was appointed surgeon to the Minehead and West Somerset Hospital, and it was in that capacity that his skill and great talents became manifest. During the second world war, with consequent depletion of hospital staff, all the surgical work devolved upon him: at all times, however, he was both anxious and willing to give of his best.

A. V. B. writes: Both before and during the years of the second world war I must have administered many hundreds of anaesthetics for Mr. Evelyn Tatlow. I am therefore in a position to testify that his cool, calm, and collected demeanour in the operating theatre was an inspiration to all of us. In addition to his manifold duties at the hospital, he was able to perform the necessary tasks of a general practitioner in Porlock, where he was greatly admired and respected by all his patients. His resignation, owing to ill-health, was deeply felt by all and sundry. In his earlier days at Porlock his chief recreation was hunting, which afforded him many happy hours with the Devon and Somerset Stag-hounds.

H. C. ROLLIN, M.B., B.S.

Dr. H. C. Rollin, who was in practice for many years at Esh Winning, Co. Durham, died at Chesterfield on October 21. He was 79 years of age.

Henry Charles Rollin was born at Durham on February 12, 1878, and was educated at Durham School, where he was a King's scholar. He served throughout the first world war, enlisting as a private and finishing with the rank of captain in the East Yorkshire Regiment. After demobilization he studied medicine at Durham University, where he graduated M.B., B.S. in 1923. In the following year he took over the

practice of the late Dr. J. J. French at Esh Winning and remained there until his retirement in 1950. He was a keen member of the British Medical Association, and from 1940 to 1946 was chairman of the Durham Division and of the local medical war committee, to which he gave valuable service. For some years he was a member of the disablement advisory committee. He was medical officer at Ushaw College for twenty-two years, and his long service to the St. John Ambulance Association was recognized by his appointment as a Serving Brother in the Venerable Order of St. John of Jerusalem. He was a sound general practitioner, with a special interest in the welfare of the elderly, and although it is seven years since he retired and moved to Chesterfield he is remembered by them with respect and affection as a kindly doctor and gentleman. Our sympathy goes out to his sister, who nursed him so devotedly in his long illness.—J. W. D.

ADOLPH HIRSCH, M.D.

Dr. A. Hirsch died at Kingston Hospital on October 23 at the age of 64.

Born at Munich of a Continental family distinguished in medicine, Adolph Hirsch studied in Vienna and Munich, graduating M.D. (Munich) in 1922. He was on the staff of the cardiological department of the German University in Prague, and later was in practice in Munich. When the Nazis seized power in 1933 he was put in "protective custody," but eventually was able to come over with his family to this country, obtaining the triple qualification in Scotland in 1937. He settled in general practice at Surbiton in the same year, becoming later a member of the staff of Surbiton Hospital. Before graduation in Munich, he served in the Austrian Army in the first world war, and was awarded the gold medal for bravery. Although retaining his first love for cardiology, he had varied medical interests and was very conscientious in all his work, and this, coupled with a sense of humour, made him much liked and respected as a medical practitioner. A cello player in his younger days, he was also expert chess player and a keen philatelist. He leaves a widow and two sons, the elder of whom is also in the medical profession.—R. G. S.

Medical Notes in Parliament

Medical Appeal Tribunals

The Government's intentions on giving effect to the recommendations made by the Franks Committee on Administrative Tribunals and Inquiries (Cmd. Paper 218) were indicated to the House of Commons on October 31 by the Home Secretary. In brief, as the Attorney-General summed up the conclusions, 71 of the 95 have been accepted completely or broadly, eight have been accepted in part, four rejected, and 12 reserved wholly or in part for further consideration.

The Committee recommended that there should be a right to legal representation before tribunals, save in the most exceptional circumstances; but that in tribunals relating to national insurance and industrial injuries the consent of the tribunal should be first obtained. The Government accept the recommendation, but the Home Secretary added the safeguarding phrase that further consideration would need to be given to the numerous local service committees under the Health Service. The proposal that legal aid should be provided was rejected "at present," since it had not yet been possible to extend the Legal Aid and Advice Act, 1949, to all litigation in the ordinary courts.

Sir FRANK SOSKICE, speaking for the Opposition, thought that one of the most important changes proposed in the Franks Report was that all proceedings before the Health Service Medical Appeal Tribunal should be published, with one exception. At present, he said, when a local service committee had recommended a punishment, and the execu-

tive had imposed a punishment less than dismissal from the Health Service, the doctor had a right of appeal to the Minister. No publicity attached to the appeal, and if the punishment was confirmed there was no public disclosure of the doctor's name. The Report recommended that even if the penalty proposed was less than dismissal appeal from it should lie not to the Minister but to the Appeal Tribunal, and that all proceedings should be in public in the fullest sense. That meant, he took it, that the evidence should be deployed in public, the arguments reported, and so on. He had some hesitation about whether it was altogether fair on the doctor that the matter should be discussed openly in all cases brought before the Appeal Tribunal. Was it fair, for example, that that should be done when the charge was dismissed, when the appeal was successful? Was it not enough to provide that only when the charge was sustained and the penalty—whether dismissal, or less than dismissal—was upheld and imposed should the result, with the name of the doctor, be published? It must be said, on the other hand, that the Disciplinary Committee of the G.M.C. normally, though not always, conducted its proceedings in public; and further, that when a case came before the Appeal Tribunal it must already be one in which the appropriate service committee had found that there was a strong prima facie case against the doctor which in the view of that committee merited punishment. He also asked this question: Was it reasonable that, with regard to their own disciplinary proceedings and the publicity attendant thereon, doctors should stand in a different position from other professions—the law, accountancy, and others? He put these questions to the Government, and asked for its views on them.

Doctors' Pay Claim

Sir JOCELYN LUCAS (Portsmouth, South, Con.) asked the Minister of Health on October 29 to state the average payment made to doctors in general practice under the 10% interim grant for the first two-monthly period pending a final settlement of their claims. Mr. D. WALKER-SMITH stated that the interim adjustment for general medical practitioners was 5% (not 10%) from May 1, 1957. The average additional payment resulting, before deduction of superannuation contributions, was estimated to be about £21 for the months of May and June.

Radioactive Fall-out

The PRIME MINISTER, replying to questions about measurement of strontium-90 and other radioactive substances in various parts of the country, stated that measurements of the extent to which soil, herbage, farm animals, and milk and other foodstuffs had been contaminated by radioactive fall-out were made regularly at a number of localities in Great Britain.

To ensure that the fullest possible precautions were taken, some reorganization of the machinery for monitoring fall-out, and of the responsibility for its operation, was introduced last summer. The Agricultural Research Council had accepted responsibility for monitoring soil, herbage, farm animals, and milk and other foodstuffs, while the Atomic Energy Research Establishment would remain responsible for monitoring air and rain-water and for analysing the radioactivity present in samples of human bone.

The Joint Committee of the Agricultural and Medical Research Councils and the Development Commission on Biological (Non-Medical) Problems of Nuclear Physics, of which Lord Rothschild was chairman, had been charged with the responsibility for the oversight of this monitoring. To assist it in this task the joint committee had set up a special subcommittee under the chairmanship of Dr. LOURIE, director of the Medical Research Council Radiobiological Research Unit.

Dr. D. W. WADE (Huddersfield, West, Lib.) suggested that information collected in 1955 and 1956 might not be accurate now in view of the continuing hydrogen bomb tests. He asked if figures could be published from time to time, and if they could be accompanied by comment from

the Medical Research Council. Mr. MACMILLAN said that a great deal of analysis by experts was necessary to see that the figures were correctly interpreted, but he would bear the point in mind. •

Windscale Inquiry

The PRIME MINISTER told the House on October 29 that the report of the inquiry conducted under the direction of Sir William Penney into the accident at the Windscale atomic energy reactor, and the measures taken to deal with it and its consequences, had been presented, and that he would make a full statement when the report had been assessed. At the suggestion of the Atomic Energy Authority he was asking the Medical Research Council to give their own independent views on the information collected so far as it affected public health.

Sewage Pollution

Mr. R. RUSSELL (Wembley, South, Con.) asked the Minister of Housing and Local Government what steps were being taken to reduce the pollution of beaches round the coasts by sewage. Mr. H. BROOKE stated that, provided that the siting and design of the outfalls were such as to ensure that the sewage was carried out to the open sea and not along the coast, the discharge of sewage into the sea was not necessarily objectionable, and indeed was often an efficient and economical method of disposal. Where nuisance was caused, as had happened with some of the older outfalls, it was for the local authorities concerned to provide a remedy. They were well aware of their responsibilities in this matter, and a number of schemes in coastal areas had been carried out in recent years, or were in preparation, to improve outfalls or to provide preliminary treatment or both. He was keeping a close watch on the position.

Discharge from Trains

Mr. D. LEWELLYN (Cardiff, North, Con.) asked the Minister of Health to what extent effluent discharged from trains was contributing to the spread of poliomyelitis or other infections; and whether he would consult with the British Transport Commission to ensure that British Railways included in their modernization plans better processes for dealing with effluent. Mr. D. WALKER-SMITH said he was advised that study of the location and environmental circumstances of notified cases of poliomyelitis afforded no support for the view that effluent from railway trains was a determining factor in the incidence or transmission of the disease, and that there was no evidence of other infection being attributable to this cause. He did not therefore feel it appropriate to pursue this matter further in the way suggested.

Tonic Alcohol

Sir ALFRED BOSSOM (Maidstone, Con.) asked the Minister of Health, in view of his policy that medical practitioners were in a position to judge in particular cases the relative merits of medication and dietary measures, to what extent dietary measures could be paid for under the Health Service scheme; and whether this included payments in respect of diets involving moderate amounts of alcohol for tonic purposes. Mr. WALKER-SMITH replied that the hospital service met the cost of feeding patients, including alcoholic beverages if they were prescribed individually on medical grounds. Foods could not be provided under the general practitioner service, but local health authorities might provide them as part of their arrangements for the care and aftercare of sick persons. They might recover reasonable charges, having regard to the means of the persons concerned. Any arrangements made by local authorities would, however, be very unlikely to include the provision of foods containing alcohol.

Hospital Building

In the plans for restricting capital investment in the public sector, announced by the Chancellor of the Exchequer on October 29, it was stated that £23m. would be spent on the hospital programme next year (as already announced), and in the year after it was planned to spend £25m. This

should allow some increase in the amount of work in 1959-60, Mr. THORNEYCROFT said, but how much would depend on the movement of building costs. He emphasized that the limits imposed on all investment programmes were expressed in money terms. If costs rose the amount of work would have to be reduced so that the expenditure limits would not be exceeded.

Medico-Legal

TRANQUILLIZERS AND DIVORCE

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Some legal implications of the use, or abuse, of "tranquillizers" were discussed in the Court of Appeal¹ in the course of the hearing of a divorce appeal which was described by Lord Justice Morris as being made to seem like some kind of crude contest in which success or failure was to depend on the astuteness or defects of rival pleas in a bitter battle of wits.

The circumstances were that Mrs. Alva Denise Benton, of Tunbridge Wells, was respondent to a divorce petition by her husband, Lieut.-Commander Anthony Fabian Benton, of the Royal Canadian Navy. The husband's case was that some time after the marriage in 1944, and the birth of their children in 1945 and 1946, his wife had become an alcohol addict. As a result of this her behaviour had brought him to the verge of a nervous breakdown, and he had left home in 1956. He relied on his wife's conduct as cruelty, and the Commissioner before whom the case was heard had found in his favour on this.

The wife's case was that if her conduct amounted to cruelty it had been condoned because during the course of the divorce proceedings they had had marital intercourse. She also cross-petitioned for divorce, alleging cruelty, sodomy, and adultery on the part of her husband, but the Commissioner rejected this part of her case. The principal question on appeal was whether the wife's cruelty had been condoned, and the husband admitted that on one occasion during the currency of the proceedings he had had intercourse with her, but denied that it amounted to condonation, because it had taken place under the influence of an overdose of "largactil."

After the separation he used to visit his wife frequently in order to see the children and spent a good deal of time in her company, not always with the children present. He had been told by his doctor to take largactil in doses of two tablets three times a day, and he said that on May 27, 1956, when he was on a visit to his wife she persuaded him to take five tablets in one dose, that the effect was to produce a sense of diminished responsibility comparable to a drunken condition, and that his wife had seduced him shortly after while he was under the influence of the drug.

In his judgment, reversing the finding of the Commissioner that this did not amount to condonation, Lord Justice Hodson said that the husband did not allege that the act of intercourse with his wife had not been a voluntary act. His comparison with drunkenness was apt in view of his charges against his wife that she drank so much that her behaviour amounted to cruelty. The husband did not say that because she was drunk she was not responsible. He had said in evidence that he knew what he was doing, and he described in detail the events on that evening up to the time he left her caravan. The doctor's evidence had been that the drug, although described as a "tranquillizer," if taken in large doses would produce an effect comparable to drunkenness by removing the emotional inhibitions of people of normal sensitivity. The doctor had not suggested that reasoning power or knowledge of conduct or memory would be affected, and the husband's evidence had been that they were not. On the evidence it had plainly been a voluntary act of intercourse, and therefore in the absence of any suggestion that his consent to the act had been

¹ The Times, October 24, 1957.

induced by fraud it was conclusive against him on the issue of condonation.

Lord Justice Hodson went on to deal with the question whether the wife's cross-petition falsely alleging cruelty and sodomy would revive her original cruelty in spite of the condonation. Had the husband been an ordinary man the effect of such charges on him would be such as to revive the cruelty. In this case, however, he went on seeing his wife after he must have known that these charges had been made, and the evidence was that the making of them had no disastrous effect on his feelings. Her condoned cruelty was therefore not revived.

Lord Justice Morris said that on the facts of the case there was an air of complete artificiality about the point on revival.

The wife's appeal was accordingly allowed, and the parties remain bound by their marriage tie.

DRIVING AND MENTAL DISORDER

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

The Road Traffic Act of 1930 requires applicants for driving licences to state on their application forms if they are suffering from any disease or physical disability specified in the form, or any other disease or physical disability which would be likely to cause the driving by them of a motor vehicle to be dangerous to the public. Section 5 (2) of the Act forbids the licensing authority to issue a licence if it appears from the application for the grant or renewal of the licence that the applicant is suffering from such a disease or physical disability. In most cases if the authority would otherwise refuse a licence the applicant has the right to have his fitness or ability to drive tested, and if he proves his fitness to drive on test the licence is not to be refused so long as he is not otherwise disqualified.

There is, however, no right to a test, and a licence must always be refused, when the applicant is suffering from the conditions specified in Regulation 5 of the Motor Vehicles (Driving Licences) Regulations, 1950. These include epilepsy and mental disorders or mental defects as a result of which either the applicant is certified or duly ascertained as subject to be placed under statutory supervision, or his estate is in the hands of a receiver, *curator bonis*, or judicial factor. These sensible provisions and their implications are of course well in the minds of those who have to deal with mental illness. The possibilities are illustrated, happily without tragic results, by a case heard before the Cardiff magistrates recently.¹

Trevor Henry Bastin had for 20 years been a certified mental defective in Hensol Castle Mental Hospital, Bridgend. His conduct in hospital was so good that the hospital officials found it extremely difficult to refuse him a day off when he asked for one. When out on a privilege pass Bastin, while under the influence of drink, helped himself to somebody's car, ran into a traffic sign, bounced over a roundabout and hit another car, and then reversed into another traffic sign. He pleaded guilty to driving while under the influence of drink, taking a car away without the owner's consent, driving dangerously, and driving without insurance. Chief Inspector Jones then told the Court that he had been there twelve times before, mostly on larceny charges. A hospital official said that Bastin knew perfectly well what he was doing, but that every now and then when out on pass he broke down and committed these offences.

Sentencing Bastin to be detained for one day and to the statutory 12 months' disqualification from driving, the chairman of the magistrates said he hoped the hospital authority would keep firm control of him and limit his visits away from the hospital, as he might have caused a serious accident.

There was no provision for the withdrawal of a driving licence during its currency, but the fact that a new declaration of fitness to drive has to be made with each annual application for a licence has at least limited the period during which people whose disability has come on during the year have been licensed to drive when unfit to do so. Now that

¹ The Times, October 15, 1957.

driving licences are to be issued for three-year periods, it is time to consider whether provision should be made for their compulsory surrender when the holder becomes unfit, and whether entry into a mental hospital as a voluntary patient should not also be a disqualification.

DAMAGES FOR WEIGHT INCREASE

Claiming personal injury damages at Chester Assizes before Mr. Justice Finnmere on October 21, a former bus conductress, Miss Betty Badger, aged 35, of Crewe, said that since her injury nearly four years ago she had put on 35 lb. (16 kg.) in weight. Miss Badger was awarded £2,125 damages against her former employers, Crosville Motor Services Ltd., of Chester. She fractured her right leg when the bus in which she was working was struck by another bus and she was thrown to the floor.

The accident happened on December 10, 1953. Miss Badger was taken to Crewe Hospital and afterwards to the Orthopaedic Hospital at Oswestry, where it was found that a fractured tibia and fibula had not mended, that a fractured tibia and fibula had not mended, and a bone graft was taken from her thigh. She attended at hospitals until last year, and still had a limp. Formerly weighing 8½ stone (54 kg.), she was now 11 stone (70 kg.). Miss Badger said that her weight had been as much as 11 stone 7 lb. (73 kg.), but dieting had reduced it to 11 stone.

Making the award, the judge said that Miss Badger had not yet returned to work. There would be appreciable limitation to her walking and activities for the enjoyment of life. She had put on a great deal of weight since the accident, but he was not very concerned whether it was due to a deep-seated upset of her glandular system, or because for four years she had been inactive. She had had advice from her doctor and had been put on a diet.

DAMAGES FOR ANKLE INJURY INCREASED

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On September 19, 1956, Mrs. Margot Winifred Wilson, aged 21, of Chertsey, was struck by a motor-cycle while crossing Kingston Road, Staines. She sustained an irregular dirty wound which entered her right ankle-joint, and a few pieces of the external malleolus and part of the external lateral ligament were torn off. She made a very satisfactory recovery, and was expected to regain full function within a matter of months, but the prognosis was that she was always likely to have some discomfort in the right ankle in cold or wet weather.

Mrs. Wilson duly brought an action for damages against the rider of the motor-cycle in the Kingston-on-Thames County Court. The judge held that the rider had been negligent but that she was also at fault for not having looked properly before crossing the road, and he apportioned the responsibility for the accident between them equally. He assessed the damages for her injury at £75.

Mrs. Wilson appealed to the Court of Appeal against the decision on damages. In his judgment¹ increasing the figure from £75 to £200, the Master of the Rolls, with whom Lord Justice Romer and Lord Justice Ormerod agreed, emphasized that interference by the Court of Appeal with an award of damages made by a trial judge must be a rare occurrence, and even more rare in the relatively small cases tried in the county courts. It must be established plainly that the judge had proceeded on a wholly erroneous basis.

In this case they had come to the conclusion that, judging by modern standards in the same type of case, he had done so. Mrs. Wilson's injury could not be called a slight or minor injury, and £75 damages to-day would be appropriate only in cases which, if not trifling, might properly be regarded as slight and not likely to have any permanent after-effect. In so far as the variety and nature of cases permitted, it was desirable that there should be conformity in the kind of award made, and this was a case in which the damages should be increased.

¹ The Times, October 23, 1957.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending October 19 (No. 42) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
§ Includes puerperal pyrexia.

Vital Statistics

Influenza

The epidemic has continued to decline in most parts of Great Britain, and the numbers of deaths from pneumonia and influenza have also dropped sharply. In the week ending October 26 deaths from influenza reported from the great towns were as follows, with the figures for the previous week in parentheses: England and Wales 396 (600), Scotland 31 (39), Northern Ireland 16 (26), and Eire 13 (6). Towns with 10 or more deaths from influenza were as follows: London 51, Glasgow 14, Belfast 10, Liverpool 18, Birmingham 22, Stoke-on-Trent 17, Wolverhampton 10. The total of new National Insurance claims again fell, being about 393,000 in the week ended October 22, as compared with about 521,000 in the previous week and 159,000 in the corresponding week last year.

The accompanying graph shows numbers of deaths in the 160 great towns of England and Wales from early September to the latest date for which figures are available.

The following table shows the age distribution of deaths from influenza in the 160 great towns of England and Wales:

Week Ending	0-	1-	15-	25-	45-	65+
Sept. 14	1	9	3	4	14	16
" 21	2	18	8	17	39	37
" 28	3	25	22	47	102	83
Oct. 5	2	36	28	57	159	160
" 12	4	36	32	58	213	248
" 19	5	22	22	54	189	308
" 26	4	11	17	32	114	218
Total: Deaths	21	157	132	269	830	1,070
%	1	6	5	11	33	43

The maps show the number of deaths from influenza plus pneumonia as a percentage of the total deaths. These are deaths reported from the great towns in the latest two weeks for which figures are available.

England and Wales in September Quarter

Live births numbered 179,925, giving a rate of 15.9 per thousand population, the highest rate for a September quarter since 1949, when the figures were 183,221 and 16.6, respectively. 110,070 deaths were registered, giving a rate of 9.7 per thousand population. This is the highest rate for a September quarter since 1944, when the rate was 10.1 (107,254 deaths); the rates in 1956 and 1955 were 9.3 and 9.1, respectively. Deaths of children under 1 year of age numbered 3,853, giving a rate of 21.4 per thousand related live births. The rates in the September quarters of 1956 and 1955 were 20.1 and 21.6, respectively. There were 4,104 stillbirths.

Nov. 9, 1957

VITAL STATISTICS

giving a rate of 22.3 per thousand live and still births; in the corresponding quarter of 1956 the figures were 3,948 and 22.2, respectively.

Deaths from influenza plus pneumonia as percentage of deaths from all causes in week ending October 19.

Deaths from influenza plus pneumonia as percentage of deaths from all causes in week ending October 26.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years

1948-56 (influenza, 1952-6) are shown thus - - - - - the figures for 1957 thus ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

Only small fluctuations were recorded in the trend of the notifications of infectious diseases in England and Wales during the week ending October 19. The largest increases in the numbers of notifications were 93 for measles, from 1,217 to 1,310, and 46 for scarlet fever, from 336 to 382; the largest decrease was 35 for dysentery, from 210 to 175.

The largest variations in the local trends of measles were a fall of 62 in Lancashire, from 198 to 136, and rise of 46 in Norfolk, from 77 to 123. The notifications of whooping-cough numbered 318, being 1 more than in the preceding week. Only small changes were recorded in the local returns of both whooping-cough and scarlet fever. Only 1 case of diphtheria was notified, being the same number as in the preceding week; this case was returned from Plymouth C.B., where 1 case has been notified for three consecutive weeks. The large rise in the incidence of acute pneumonia has been halted, and the 2,280 notifications were 5 more than in the preceding week. The number of notifications of acute pneumonia has decreased in the north and risen in the south; in the combined area of Lancashire, Cheshire, Yorkshire, and the four northern counties the notifications fell by 286, from 996 to 710, and in London and south-eastern counties they rose by 155, from 298 to 453.

Five of the 7 cases of paratyphoid fever were notified in Lancashire, Swinton and Pendlebury M.B.

80 cases of acute poliomyelitis were notified, and these were 4 fewer for paralytic and 10 fewer for non-paralytic cases than in the preceding week. The largest returns were Yorkshire West Riding 11 (Leeds C.B. 2, Baildon U.D. 2), London 5 (Hackney 2), Essex 5 (Brentwood U.D. 2), and Nottinghamshire 5 (Nottingham C.B. 2).

The chief centres of dysentery were Lancashire 44 (Liverpool C.B. 20), Yorkshire West Riding 36 (Huddersfield C.B. 12), and Durham 17.

Week Ending October 26

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 399, whooping-cough 349, diphtheria 3, measles 1,414, acute pneumonia 1,897, acute poliomyelitis 66, dysentery 197, paratyphoid fever 1, typhoid fever 4.

Scotland in Second Quarter

The birth rate in Scotland during the second quarter of 1957 was 19.5 per 1,000 of the population, being the same as the rate for the preceding June quarter and 0.6 above the average of the five preceding second quarters. The infant mortality rate was 27 and the neonatal mortality rate was 20 per 1,000 registered live births; these rates were, respectively, 1 and 3 above the rates for the second quarter of 1956. Maternal mortality was 0.3 per 1,000 births; this rate was only half the rate for the corresponding quarter of 1956 and 0.4 below the five years' average. The general death rate was 11.2 per 1,000 population and was 0.2 below the average of the five preceding June quarters.

The deaths from the principal epidemic diseases numbered 24 and included 12 from influenza, 6 from measles, 4 from meningococcal infections, and 2 from whooping-cough. No deaths were recorded from diphtheria, scarlet fever, or typhoid fever. The death rate from all forms of tuberculosis was 12 per 100,000 and that from respiratory tuberculosis was 11; these rates were, respectively, 9 and 8 below the five years' average. The 2,743 deaths from malignant diseases gave a rate of 214 per 100,000, and this was 5 above the rate for the preceding second quarter and 16 above the average of the five preceding second quarters. Deaths from road accidents numbered 126, and 514 deaths were attributed to other forms of violence. These deaths were, respectively, 20 below and 38 above the numbers recorded in the June quarter of 1956.

Medical News

Nobel Prize for Chemistry.—Sir ALEXANDER TODD, F.R.S., has been awarded this year's Nobel Prize for chemistry (worth about £14,400). The award is for his work on nucleotides and nucleotide co-enzymes. Sir Alexander, who is aged 50, has been professor of organic chemistry at Cambridge since 1944. He is a son-in-law of Sir Henry Dale. Although not medically qualified, much of Sir Alexander's research has had to do with medicine, and his current research programme is described as being on substances of physiological importance. Before going to Manchester University as professor of chemistry and director of the chemical laboratories there (1938–44) and thence to Oxford, he had been on the staff of the Lister Institute and reader in biochemistry at London University. On the basis of his own chemical studies, x-ray crystallographic analysis by Mrs. D. M. Hodgkin, and work elsewhere, he proposed the structural formula of vitamin B₁₂ (cyanocobalamin). His formula for the vitamin made it a nucleotide with its basic structure resembling that of haemoglobin and the porphyrins (*Journal*, September 3, 1955, p. 610).

[Planet News]

Sir Simon Marks's Benefaction to R.C.S.—At the Hunterian Festival Dinner last February the then president of the Royal College of Surgeons, Sir HARRY PLATT, said that the College's rebuilding programme would come to a halt in the autumn for lack of funds. Phase IIIa, comprising research laboratories and lecture rooms, would be completed, but only as a hollow shell (*Journal*, February 23, p. 455). Now, following a personal appeal from Sir JAMES PATERSON ROSS, the present president, Sir SIMON MARKS, chairman of Marks & Spencer, Ltd., and a patron of the College, has ensured that the work can proceed. Sir Simon Marks has made an immediate personal contribution of £75,000, and has increased his earlier 7-year covenanted donation of £7,500 a year (*Journal*, July 21, 1956, p. 185) to £10,000 a year. In addition the firm of Marks & Spencer, Ltd., has covenanted to give £10,000 a year for seven years towards the costs of either the College's building programme or the maintenance of its scientific departments. In his letter to Sir Simon, the president estimates that the completion of Phase IIIa of the building will cost about £250,000. A further sum of the same magnitude will be needed to complete the entire rebuilding of the College, which would then be linked with the laboratories of the Imperial Cancer Research Fund and to the new College of General Practitioners, both of which are being built alongside. The letter continues: "The profound influence which this unique combination of minds and knowledge will have upon teaching and research in medicine cannot be sufficiently stressed." In addition, to take full advantage of these new developments, the College's annual income will need to be increased by £150,000.

Medical Women at Dinner.—There were only nine women doctors on the *British Medical Register* in 1879, when an association of registered medical women was formed. All nine joined it. This was the forerunner of the now flourishing Medical Women's Federation, formed 40 years ago. At its annual dinner last week, with Dr. MARY HELLIER in the chair, Dr. ANNIS GILLIE proposed the health of the guests in a characteristically charming speech. In response Mr. VALENTINE LOGUE paid a tribute to the late Miss DIANA BECK, whom he had succeeded as neurosurgeon at the Middlesex Hospital. So far as he knew, Miss Beck had been the only woman neurosurgeon in Europe or the U.S.A. The toast, "The Medical Women's Federation," was proposed by Dr. G. F. ABERCROMBIE and the response was made by the president of the Federation, Dr. JEAN MCINTOSH.

Poliomyelitis Vaccine.—Burroughs Wellcome and Co. have now released their first supplies of poliomyelitis vaccine. This means that there are now two manufacturers in Britain making the vaccine, the other being Glaxo Laboratories Ltd. The three consecutive batches of Burroughs Wellcome vaccine comprising this first consignment have successfully passed the Medical Research Council's stringent safety tests. According to the Ministry of Health the consignment is enough for about 117,000 doses. In a letter to M.O.H.s, Sir JOHN CHARLES, chief medical officer to the Ministry of Health, states that the composition of the Glaxo and the Burroughs Wellcome vaccines is identical and that the two vaccines can be used without distinction.

New Buildings at Radiochemical Centre.—The Atomic Energy Authority's Radiochemical Centre at Amersham now deals annually with some 18,000 consignments of radioisotopes, whose sales value exceeds £400,000. Over 70% of this total is exported, and the products go to some

50 different countries throughout the world, including those behind the iron curtain. To meet demands which have more than trebled in the last three years, a new laboratory and an office block have been built, and these were opened on November 1 by the MARQUIS OF SALISBURY. The new laboratory is the second part of a group of buildings specially designed for the separation of pure radioactive isotopes from materials irradiated in the Authority's reactors, the synthesis of labelled compounds for research, and the manufacture of radiation sources for industrial and medical use. A group of "hot cells" is under construction which will allow handling of isotopes, such as radiocaesium, emitting penetrating radiation of up to 1,000 curies of activity. The cells are totally enclosed, shielded by some 300 tons of high density concrete, and equipped with the latest master-slave manipulators of British manufacture. Since the four smaller laboratories were opened by Sir Henry Dale in April, 1954, the scale of production in simple form of basic isotopes such as iodine-131, phosphorus-32, sulphur-35, and carbon-14 has generally increased to between two and three times and the

quality of the products has been substantially improved: the best carbon-14 made recently has been nearly 50% "isotopic abundance" compared with under 2% three years ago. The demand for some of the less common isotopes, particularly labelled compounds, has grown sufficiently to warrant the constantly changing demand make safe and economic the housing of these processes a difficult problem. A system of standard boxes for working with fixed gloves or tongs has been installed (see illustration). The boxes are transportable, interchangeable, and can be connected to form larger units; when in use they are tethered to the service mains by flexible connexions. A buoyant demand is reported for compounds labelled with carbon-14, particularly from biochemists. As all these compounds have to be derived from radioactive carbon dioxide—the primary source of carbon-14—much effort is devoted to chemical synthesis. Biosynthesis is also being increasingly used in making labelled compounds. Recently available labelled compounds include steroids (cholesterol, testosterone, progesterone, oestrone), the carcinogens dibenzanthracene and benzanthrane, specifically labelled sugars, and several amino-acids. Human serum albumin iodinated with iodine-131 has been in regular production at Amersham since January, 1955, and another compound is vitamin B₁₂ (cyanocobalamin) labelled with one or other of the cobalt isotopes—cobalt-56, cobalt-58, or cobalt-60.

Royal College of Physicians.—At a quarterly comitia on October 31 Dr. W. P. H. SHELDON, Professor R. E. TUNBRIDGE, Dr. W. N. MANN, and Dr. J. S. RICHARDSON were elected councillors. Dr. ROBERT PLATT, the president, Sir HAROLD BOLDERO, Sir ALLEN DALEY, Dr. R. R. BOMFORD, and Dr. S. R. F. WHITTAKER were elected members of the Standing Joint Committee of the three Royal Colleges. Dr. A. R. SOUTHWOOD was appointed Milroy Lecturer for 1959. The following, having satisfied the Censors, were elected M.R.C.P.:

S. Bank, R. G. Bannister, C. Fraser Brockington, J. J. Brown, T. M. Dauncey, C. J. Edmonds, B. J. Fairhurst, M. L. Gladstone, M. R. P. Hall, E. B. D. Hamilton, M. Hill, C. K. Hudson, E. E. F. Keal, G. A. J. Lomax, J. B. McGuinness, J. Richmond, N. R. Rowell, D. M. Shaw, A. B. Shearer, P. Sleight, G. R. Sparrow, and D. A. H. Yates.

Warning to Diabetics.—On October 30 the Ministry of Health issued a public warning to diabetics that some 80-unit vials of soluble insulin from batch No. 1212 had been reported by their makers to have lost potency since issue. "Diabetics who have received vials from this batch," stated the Ministry, "are advised not to use any more of it, but to return it to their chemist, who will replace it." We understand that the batch consisted of several thousand vials and that a warning of this nature about insulin is most unusual.

Windscale Accident.—On the Medical Research Council's advice, the MINISTER OF AGRICULTURE, FISHERIES AND FOOD permitted the resumption of milk distribution from farms in the Lancashire sector of the restricted area around Windscale on November 4. The ban remained, however, on farms in the Cumberland sector. Farmers were warned to clean their milking machinery and utensils thoroughly before resuming milk distribution.

Royal College of Physicians of Ireland.—At the annual meeting on October 18 (St. Luke's Day), Dr. F. J. O'DONNELL and Dr. R. B. PRINGLE were re-elected respectively president and vice-president.

Association of Clinical Biochemists.—At the annual general meeting in September Professor E. J. KING, Dr. R. GADDIE, and Dr. A. L. TARNOKY were re-elected president, chairman, and hon. secretary respectively. Dr. J. H. WILKINSON was elected hon. treasurer.

Lord Cohen of Birkenhead has accepted nomination as president of the Royal Society of Health in place of Lord PERCY OF NEWCASTLE, who has decided to retire for health reasons. Lord Cohen's election will take place at the Society's annual meeting in May, 1958.

COMING EVENTS

James Mackenzie Lecture.—Dr. D. M. HUGHES will lecture before the College of General Practitioners at 11.30 a.m. on November 16 at B.M.A. House, London, on "Twenty-five Years in Country Practice."

London Medical Exhibition.—November 18–22, at the New Hall of the Royal Horticultural Society, Greycoat Street, London, S.W.1. Open from 11 a.m. to 6.30 p.m. (7.30 p.m. on November 21).

Doctors' Hobbies Exhibition.—November 18–22, 10 a.m.–7 p.m. daily (November 18, 2.30–7 p.m.), at the Royal Society of Health, Buckingham Palace Road, London, S.W.1. Sponsored by Benger Laboratories Ltd.; open to doctors and their friends.

Carcinoma of the Lung.—Symposium arranged by the National Association for the Prevention of Tuberculosis, November 22, 3.30–6.30 p.m. at B.M.A. House. Admission by ticket (price 10s.) from N.A.P.T., Tavistock House North, Tavistock Square, London, W.C.1.

William Meredith Fletcher Shaw Memorial Lecture.—Dr. BETHEL SOLOMONS will lecture at 5 p.m. on November 22 at the Royal College of Obstetricians and Gynaecologists on "The History of Infant Welfare." Admission by ticket only, obtainable from the secretary of the College.

Tuberculosis Control.—Joint meeting of the British Tuberculosis Association and the Society of Medical Officers of Health, at 5.30 p.m. on November 29 at the London School of Hygiene and Tropical Medicine.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, November 11

GUY'S HOSPITAL.—At Physiology Theatre, 4.45 p.m., Endocrine Demonstration by Dr. P. M. F. Bishop: Addison's Disease.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Professor A. Kekwick: Obesity.
UNIVERSITY COLLEGE, LONDON.—At Anatomy Theatre, Gower Street, W.C., 5.30 p.m., inaugural lecture by Professor D. Lewis, F.R.S.: Experimental Approach to Life.

Tuesday, November 12

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, W.C., 5.30 p.m., Dr. D. L. Mollin: Metabolism of Anemia.
CHELSEA CLINICAL SOCIETY.—At Rembrandt Hotel, S.W., 8.30 p.m., discussion to be opened by Lieutenant-Colonel E. L. O. Hood, R.A.M.C.: Doctor and Nuclear Warfare.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. E. J. Moynahan: Hair Growth.
MANCHESTER MEDICAL SOCIETY.—(1) At Large Anatomy Theatre, Manchester University, 4 for 4.30 p.m., University Lecture on the History of Medicine by Professor Fraser Brockington: Epidemiologists of the Privy Council, 1858–1870. (2) SECTION OF SURGERY.—At Small Theatre, Clinical Sciences Building, Manchester, 7.30 for 8 p.m., Mr. K. V. Bailey: Stress Incontinence with Uterine Prolapse (Part II).
MANCHESTER REGIONAL DERMATOLOGICAL ASSOCIATION.—At Clinical Sciences Building, York Place, 8.30 p.m., in conjunction with North-west England Faculty of College of General Practitioners. Lecture for general practitioners. Dr. R. H. Seville: General Medicine in Dermatology; Dr. L. Wertheim: Dermatological Problems in General Practice.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Professor C. G. Rob: Surgical Treatment of Atherosclerosis.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Langdon-Brown Lecture by Dr. R. Bodley Scott: Chemotherapy of Malignant Disease.
ST. MARY'S HOSPITAL MEDICAL SCHOOL (WRIGHT-FLEMING INSTITUTE THEATRE).—5 p.m., Mr. C. W. F. Burnett: Postpartum Collapse.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Mr. J. Minton: Ocular Manifestations in Clinical Neurology, Part II.

Wednesday, November 13

● **BRITISH COUNCIL FOR THE WELFARE OF SPASTICS.**—At B.M.A. House, Tavistock Square, W.C., 4.30 p.m., Professor Alan Moncrieff: Cerebral Palsy To-day.
● **INSTITUTE FOR THE STUDY AND TREATMENT OF DELINQUENCY.**—At St. George's Institute, 7.30 p.m., Miss Pearl Jephcott, M.A.: Changing Social Background.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Virus Diseases.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. F. H. Scadding: Delayed Resolution in Pneumonia.
● **INSTITUTE OF NEUROLOGY.**—5.30 p.m., Dr. M. Kremer: Metabolic and Toxic Disorders.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. G. F. Murnaghan: Hydro-nephrosis.
LONDON AMATEUR BOXING ASSOCIATION.—At Great Northern Hotel, King's Cross, N., 8 p.m., meeting of London A.B.A. Medical Advisory Panel.
LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.15 p.m., Professor T. F. Hatch (Pittsburgh University): Environmental Stress and Man's Health.

MANCHESTER MEDICAL SOCIETY: SECTION OF PATHOLOGY.—At Large Anatomy Theatre, Manchester University, 4 for 4.30 p.m., Dr. L. Goldberg and Dr. J. P. Smith: Iron—Food for Thought.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. E. Lester-Smith: Biochemistry of Vitamin B₁₂.
ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Finlayson Lecture by Dr. E. F. Scowen: Endocrine Influences on Breast Cancer.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—4 p.m., Mr. Harold Dodd: Varicose Veins and Ulcers of the Leg (illustrated).
ROYAL SOCIETY OF HEALTH.—At Baths Assembly Hall, Thimble Mill Road, Bearwood, Smethwick, 10 a.m., Symposium on the Health of the Worker, with reference to the Control of Dust and Other Respiratory Diseases. Mr. W. B. Lawrie: Control of Dust Hazards; Dr. W. Jefferies Lloyd: Problem of Pneumoconiosis and Silicosis; Dr. J. P. W. Hughes: The Worker with Chronic Chest Disease; Dr. C. R. Lowe: Tuberculosis in Industry.

Thursday, November 14

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, W.C., 5.30 p.m., Dr. H. O. Schild: Mechanism of Anaphylaxis.
HILL END HOSPITAL MEDICAL SOCIETY.—8.45 p.m., Sir Clement Price Thomas: Carcinoma of the Lung.
HONYMAN GILLESPIE LECTURES.—At University New Buildings, Teviot Place, Edinburgh, 5 p.m., Dr. J. B. Stanton: Recent Approaches to Disorders of Speech and Language.
INSTITUTE OF DERMATOLOGY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. H. O. Schild: Mechanism of Anaphylaxis.
● **INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.**—3 p.m., Dr. T. N. MacGregor: Endocrine Problems in Gynaecology.
LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Florence Blair-Bell Memorial Lecture by Professor T. N. A. Jeffcoate: Cancer Research.
LONDON UNIVERSITY.—At The Swanley Hall, Wye College, 3 p.m., Amos Memorial Lecture by Mr. F. C. Bawden: Viruses and Virus Diseases.
NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, 8.30 p.m., Professor A. K. Saha: Flail Hip: Its Treatment by Abdominal Muscle Transfer.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Thomas Vicary Lecture by Sir Cecil Wakeley, Bt.: Surgeons and the Navy.
ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.—At Royal Society of Medicine, 2 p.m., 32nd Maudsley Lecture by Sir Wilfrid Le Gros Clark, F.R.S.: Sensory Experience and Brain Structure.
ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION: CHILD PSYCHIATRY SECTION.—At 11, Chandos Street, W., 6 p.m., Mr. G. A. Lyward, M.A.: Residential Care in the Treatment of Disturbed Adolescents.
ROYAL SOCIETY.—10.30 a.m., discussion to be opened by Professor J. D. Bernal, F.R.S.: Physics and Chemistry of Water.

Friday, November 15

BIOCHEMICAL SOCIETY.—At Westminster Medical School, Horseferry Road, S.W., 2.15 p.m., 367th meeting.
COLLEGE OF GENERAL PRACTITIONERS: MIDLAND FACULTY.—At Board Room, Worcester Royal Infirmary, 3 for 3.15 p.m., Dr. P. Hopkins and Mr. C. M. Gwillim: Management of the Climacteric.
● **INSTITUTE OF DERMATOLOGY.**—5.30 p.m., Dr. G. B. Mitchell-Heags: Clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. Smart: Clinical demonstration.
INSTITUTE OF LARYNGOLOGY AND OTOLARYNGOLOGY.—5.30 p.m., Mr. S. E. Birdsall: Demonstration of Laryngeal Cases.
● **INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.**—4.30 p.m., Mr. P. Mahpas: Utero-Vaginal Prolapse and its Treatment.
PLYMOUTH MEDICAL SOCIETY.—At Freedom Fields, 8.30 p.m., Mr. J. D. S. Postgraduate Medical School of London.—10 a.m., Professor Brodie Hughes: Indirect Injuries of the Optic Nerves and Chiasma. 4 p.m., Dr. W. J. Card: Gastro-Secretory Function.
ROYAL MEDICAL SOCIETY, EDINBURGH.—8 p.m., address by Professor G. J. Romanes: Some Problems in Development.
ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—At Royal Faculty of Physicians and Surgeons of Glasgow, 8.30 p.m., combined meeting with Southern Medical Society. Professor W. C. W. Nixon: Use and Abuse of Oxytocic Drugs in Obstetrics and Gynaecology.

Saturday, November 16

● **COLLEGE OF GENERAL PRACTITIONERS.**—At Great Hall, B.M.A. House, W.C., 11.30 a.m., 4th James Mackenzie Lecture by Dr. D. M. Hughes: Twenty-five Years in Country Practice.

Sunday, November 17

MANCHESTER UNIVERSITY: FACULTY OF MEDICINE.—At Theatre 1, Clinical Sciences Building, York Place, 11 a.m., in conjunction with North-west England Faculty of College of General Practitioners. Lecture-demonstration for general practitioners. Dr. N. J. de V. Mather and Dr. D. Sumner: Suicide.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS
Anderson.—On October 20, 1957, to W. Ainslie Anderson, M.B., Ch.B., F.R.C.S., F.R.C.S.Ed., and Eileen Anderson (formerly Davis), M.B., Ch.B., D.A., of 332, Queen's Road, Aberdeen, a son—William George Baird.
Baird.—On October 17, 1957, at Jessop Hospital, Sheffield, Yorks, to Ivy, wife of Ian McLean Baird, M.D., M.R.C.P., a brother for Fiona—John Neil Rose.

DEATHS
Benson.—On October 14, 1957, in hospital, Oxford, Eric John Benson, L.R.C.P.S.I. & L.M., of 59, Riverbank, Staines, Middx.
Carton.—On October 12, 1957, Cecil Carton, L.R.C.P.S.I. & L.M., of 40, Crown Lane Gardens, London, S.W.
Clare.—On October 2, 1957, at Lincoln City Isolation Hospital, Harold Frederick Clare, M.R.C.S., L.R.C.P., of 20, Manwood Avenue, Canterbury, Kent, aged 33.
Cowan.—On October 12, 1957, at 11, Abercorn Terrace, Portobello, Edinburgh, William George Cowan, M.B., Ch.B.
Strachan.—On October 13, 1957, at Bridge of Earn Hospital, Perthshire, Charles Gordon Strachan, M.C., M.B., F.R.C.P.Ed., of Crieff, Perthshire, late of Cheam, Surrey.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Eczema of the Nipple

Q.—A young married woman, when four months pregnant with her first baby last year, developed a small swelling on the areola of the left breast, which rapidly became eczematous. All treatment, including cortisone ointment, failed to relieve it and the baby could not be suckled. She is now pregnant again. The area shows cracks from which clear serum oozes; there is no evidence of bacterial infection. The condition is painful and prevents sleep. What treatment is advised?

A.—Eczema of the nipple can be extremely resistant to treatment. In some cases there is an underlying benign papilloma of the duct with which may be associated some degree of low-grade infection. In the case mentioned the presence of a swelling on the areola and a discharge of clear serum suggest that a papilloma may be present. If it is, surgical exploration of the swelling and removal of the papilloma are probably essential to recovery. If there is no underlying disease of the ducts, the most reliable treatments are the application of ointments containing tar and stilboestrol, and superficial radiotherapy.

Dysphagia after Polio

Q.—What exercises are recommended for a woman with weakness of the muscles of respiration and slight dysphagia following poliomyelitis? Her biggest trouble is bringing up sputum when she has only a slight cold, and, unless she concentrates when swallowing, her food is apt to enter the larynx. She has no other paralysis.

A.—It would be helpful here to take an x-ray cinematograph record of her swallowing. If this patient is frequently inhaling a little food, then the dangers of infection are considerable. It is of course essential that she should be taught the positions for postural drainage of the lung, which she should assume to assist coughing and to clear her trachea. This is specially valuable if the diaphragm is working well, as the weight of the abdominal viscera assists expiration in such cases. The principal coughing muscles are those of the abdominal wall, and it is not stated whether or not these are paralysed. The chief problem here is not really exercises, but mechanical and postural aids to protect the air passages from inhalation. The patient should concentrate intently and without distraction on the task of swallowing, and she may find that certain positions of the head or neck assist the process.

Piles and Rectal Prolapse During Pregnancy

Q.—A multipara who is now at a fairly advanced stage of pregnancy has a rectal prolapse and prolapsed piles. Suppositories and ointments have proved useless. What palliative treatment is advised until after delivery? What is the likely prognosis after delivery, and what would be the indications for surgical treatment?

A.—This problem may, of course, be one of prolapsed piles, in which case every effort should be made by firm digital pressure to replace them properly after defaecation. For this purpose pressure should be made with dry gauze or cotton-wool on the finger, and after replacement the patient should rest in the recumbent position for half an hour. It seems not unlikely, however, that part if not all of the external swelling may be due to thrombosis of the external haemorrhoidal plexus, perhaps with some oedema, and inspection will at once show if the "piles" are covered by skin. If this proves to be the case a spirit lead lotion

compress should be applied every four hours and especially at bed-time, the dressing being kept in position by a sanitary towel or T-bandage. It has already been noted by the questioner that ointments have proved useless, as might be expected, and suppositories would only be indicated perhaps if the patient was extremely constipated.

It would be impossible to make any prognosis until some time after delivery, when routine proctoscopy and sigmoidoscopy, say three to six months after delivery, would enable an accurate assessment of the case to be made. The chief indication for operation would be if the patient was proved to have third-degree haemorrhoids, but other factors would need to be taken into consideration, particularly her age, and in general it might be said that the younger the patient the greater would be the indication for injection treatment in the hope of giving symptomatic relief.

Lung Cancer in Non-smokers

Q.—Can you tell me the number of cases of lung cancer in non-smokers in any group where the incidence of the disease has been investigated? In 1900, the Registrar-General informs me, there were returned 161 male cases of lung cancer and 112 female cases. These latter would have been young women in, say, the 1860's. In the nineteenth century respectable women, with few exceptions, did not smoke, and this 112 would certainly have been mostly non-smokers, which is an interesting reflexion at the present time.

A.—The proportions of non-smokers reported in different series of patients with lung cancer vary somewhat, depending on the definition of a non-smoker used in the study and the care with which the definition was applied. In the study by Doll and Hill¹ there were found to be 7 non-smokers among 1,357 men with lung cancer (0.5%) and 40 among 108 women with lung cancer (37%). This study was limited to patients under 75 years of age, and if patients of all ages had been examined the proportions would probably have been slightly higher. It has been estimated from Doll and Hill's data that the number of cases of lung cancer which would have occurred in the absence of smoking among persons under 75 years in England and Wales in 1950 would have been 1,246 men and 1,003 women. To some extent the difference between these numbers and the numbers of deaths recorded in 1900 can be explained by changes in the size and age structure of the population. Whether the rest can be attributed to improved diagnosis is an open question. It is clear from what is now known about the relative effects of smoking cigarettes, pipes, and cigars that the form of smoking which was current among men before 1900 is unlikely to have caused many cases of lung cancer at that period, and it is striking that the sex ratio at that time was, in fact, only a little greater than 1 to 1.

Permissible Activities for Young Diabetics

Q.—Should the activities of a young diabetic who is well controlled by insulin and diet be restricted in any way? I have in mind such things as swimming, bicycling, mountaineering, diving, or flying, where loss of consciousness might be disastrous.

A.—As a general rule young diabetics, provided that the disease is well controlled, should be encouraged to partake in almost all the activities of a normal life. Clearly the necessity of taking insulin by injection and keeping to a diet must impose some slight restrictions in this respect, but, in the absence of defective vision, the only important limiting factor is the danger of hypoglycaemia. This can be effectively guarded against in the majority of cases by proper and suitable treatment with buffer feeds at appropriate times, such as mid-morning and at bed-time, and the avoidance of large, single, morning injections of delayed-action insulins; two smaller injections of soluble insulin are often both safer and more satisfactory for the control

of the active young diabetic. There is, however, a small minority of patients in whom it is impossible, by any practicable method of treatment, to avoid wide fluctuations in blood sugar level; in these circumstances there is always some risk of hypoglycaemia, especially in the event of severe and unaccustomed exercise. In this relatively small group, activities liable to expose the patient or those with him to serious danger, such as swimming, mountaineering, and driving, are better avoided altogether, or indulged in only at times when it is certain, from experience, that the blood sugar is raised and the action of the insulin is on the wane. For the majority, provided that the rules regarding diet and insulin are obeyed and due allowance is made, either by reducing the dosage of insulin or better by adding extra carbohydrate food, for the lowering effect of exercise on the blood sugar, there need be no restrictions.

The rules in respect of car-driving were described in a letter by Lawrence,¹ and flying, except as a passenger, is prohibited by regulation. It is a wise precaution for any diabetic before swimming or diving to take about 20 g. glucose, while prolonged exercise such as cycling and golf usually calls for considerable increase in carbohydrate food.

NOTES AND COMMENTS

Clicking Jaw.—Mr. N. L. ROWE, F.D.S.R.C.S. (Basingstoke), writes: Your expert has stated ("Any Questions?" October 5, p. 838) that a girl of 16 with a persistent and audible clicking emanating from the region of the right temporo-mandibular joint "would be well advised not to seek treatment," and furthermore suggested that it is very likely that the "click will disappear in time." The only treatment envisaged was limited to meniscotomy or manipulation under anaesthesia, and, while I would agree that operative interference is very rarely indicated in such cases, it would seem that your expert is unaware of the aetiology and correct treatment of at least 75% of those with derangement of temporo-mandibular joint function. Only a relatively small proportion of such cases are caused by acute trauma, which may result from external violence or internal dislocation—i.e., yawning too widely, acute or chronic infection of the joint, or neoplastic change in the anatomical structure of the joint surfaces. The majority of cases are due to some abnormality in the occlusion of the teeth, whether these are natural or artificial, and there is a very reasonable expectation of cure when these abnormalities have been corrected. Removal of the meniscus under such circumstances is merely treating the symptom while ignoring the causal factors which are responsible for the signs produced, and may lead to chronic traumatic degenerative changes in later years.

Any factor which disturbs the stream of proprioceptive impulses from the periodontal membranes or the muscle spindles will interfere with the carefully co-ordinated pattern of muscular contraction in mastication. Deviation of individual teeth from their correct position in the dental arches can be brought about by premature loss of teeth through caries and drifting of adjacent teeth into the gap thus created; or overcrowding of the teeth may cause a reverse bucco-lingual relationship of opposing teeth with the production of severe cuspal interference during occlusion of the jaws, and abnormal tilting of wisdom teeth can also have a similar effect. The abnormal proprioceptive impulses thus created produce a subconscious deviation of the mandible from its true centric position, a condition associated with interference with resting tone of the muscle fibres and often severe contractile spasm. The patient may indulge in bruxism, or nocturnal grinding of the teeth, which may be an attempt to eliminate the cuspal interference. During closure of the jaws the external pterygoid fails to relax synchronously with the contraction of the elevator muscles, and the disk is held forward and does not return with the condylar head. During the opening movement the disk tends to slip forwards and laterally in advance of the condylar head, which eventually catches up with the disk with the production of an audible click. A vicious circle is set up, which results in laxity of the attachments of the disk to the lateral poles of the condylar head, so that a "bucket handle" type of movement takes place when the external pterygoid muscle is contracted. In some cases an orthodontic deformity of the teeth and jaws may be responsible.

Further discussion of this extensive subject is prevented by lack of space, but I trust that sufficient has been said to justify my opinion that the patient in question should be advised to seek immediate investigation and treatment of her problem,

preferably from a consultant dental surgeon experienced in such conditions. Those who have to deal with a large number of these cases annually know that relief is often dramatically obtained by the correction of occlusal imbalance, and that, if neglected, "so trivial a symptom as a click" can progress inexorably to locking of the joint, severe limitation of movement, and pain, which in one case referred to me was so intense as to require continual sedation with pethidine by the patient's general practitioner.

Mr. P. GILLET, F.D.S.R.C.S. (Hove), writes: This symptom has been the subject of much study by oral surgeons all over the world for some years. It is now generally accepted that, in the absence of any bony changes within the joint, it is due to detachment of the meniscus from the posterior part of the joint capsule—with the result that the condyle "clicks" off and on the meniscus. This detachment is probably brought about by imbalance of the muscles of mastication—notably the lateral pterygoid which is inserted into the anterior aspect of the disk. The imbalance may be due, especially in the adolescent, to muscle tension arising from mental tension, or reflexly from an erupting or misplaced lower wisdom tooth or carious tooth—which themselves are symptomless. Another factor may be the derangement of occlusion from loss of teeth. The subject is a large one, but I do feel these factors should be mentioned so that they may be investigated and, if necessary, dealt with.

Oxytocin Infusion in Postmaturity.—Mr. G. W. THEOBALD (Bradford) writes: In an answer in "Any Questions?" (October 19, p. 953) it was stated that the use of the oxytocin drip in the induction of labour in postmature patients is attended with the danger of "uterine contractions so violent as to embarrass an already inefficient placenta and thus cause fatal asphyxia." It is further warned that in such cases the margin of safety is so narrow that "the obstetrician must himself be prepared to stay with the patient constantly, observing the behaviour of the foetal heart after each contraction, and not delegate this responsibility to someone less experienced."

May I be permitted to state that if not more than 0.5 unit of either pitocin or "syntocinon" is added to the drip bottle (540 ml.) and the drip is started at 16 drops and not allowed to run faster than 40 drops a minute, there need be no fear of violent uterine contractions. Very occasionally strong contractions may occur when the drip is running at 16 drops a minute, and in such circumstances it is desirable to put up another bottle containing not more than 0.25 unit of oxytocin. If on the other hand efficient uterine contractions do not result, one unit can be added to the next bottle. If it is safe for a woman to go into labour, it is safe for her to have an oxytocin drip, provided it is given in physiological and not pharmacological amounts. It is not only unnecessary but undesirable for the obstetrician or anybody else to sit by the patient all the labour, and counting the foetal heart after each contraction is surely liable to cause so much anxiety to the patient as to induce incoördinate uterine action. These remarks are based on the experience of more than 2,000 oxytocin drips given after rupture of the membranes (of which many scores were given to postmature patients) and are only made because the oxytocin drip will fall into disrepute and achieve only limited usefulness if the distinction between physiological and pharmacological quantities is not fully recognized.

OUR EXPERT replies: Mr. Theobald is not quite fair in taking quotations out of their context. A relevant sentence in the original reply, which he has omitted, reads: "This risk is slight if the concentration of oxytocin is small, if the rate of drip is kept slow, and if the effect is continually observed by an expert." Since Mr. Theobald agrees that the reaction of any uterus to the standard concentration and drip rate of an oxytocin infusion is variable, it follows that clinical observation is necessary in order to decide whether the dosage should be altered as he suggests. On further consideration, and bearing in mind the variable conditions and standards of supervision under which this treatment might be administered, I still consider that the note of caution which characterized the original reply to the question was wise.

PREDNISOLONE IN THE TREATMENT OF PULMONARY TUBERCULOSIS: A CONTROLLED TRIAL

A PRELIMINARY REPORT BY THE RESEARCH COMMITTEE OF THE TUBERCULOSIS SOCIETY OF SCOTLAND*

The climate of opinion regarding the safety of the use of corticosteroids in tuberculosis has altered greatly in recent years. Early clinical reports (Freeman *et al.*, 1950) and studies in experimental animals (Hart and Rees, 1950) stressed the enhancing effect of steroid hormones on tuberculosis. Gradually, however, it began to be realized that, so long as adequate antituberculous chemotherapy was given, corticosteroid therapy might well have a place in treatment (Cochran, 1954; Houghton, 1954). The evidence accumulated over this period is admirably reviewed by Johnson and Davey (1954). These authors concluded that the use of combined corticotrophin or cortisone and antimicrobials in the treatment of certain types of tuberculosis was probably still to be considered an experimental procedure to be performed only under controlled conditions.

It was against this background that the Research Committee of the Tuberculosis Society of Scotland embarked upon an attempt, by means of a controlled trial, to assess whether corticosteroid therapy was able to hasten the rate of improvement attainable by chemotherapy in the treatment of pulmonary tuberculosis, and to try to answer some of the important related questions. The investigation began in February, 1956, and there are now over 200 cases in the trial. This is a preliminary report on the first 110 cases that had completed six months' treatment by the end of April, 1957. The report was prepared by Dr. N. W. Horne and Dr. D. T. Kay.

The physicians participating in the trial were as follows. Aberdeen: Drs. Douglas Bell and Robert Fraser. Bangour: Drs. G. J. Summers, K. Murray, G. G. Robertson, and J. H. R. Ramsay. Dundee: Drs. D. H. Smith, R. N. Johnston, W. Lockhart, and R. T. Ritchie. East Fortune: Drs. W. A. Murray, A. P. Littlewood, and Rose Donaldson. Edinburgh: Professor J. W. Crofton, Drs. I. W. B. Grant, N. W. Horne, H. M. MacLeod, A. L. Pines, J. D. Ross, J. McD. Simpson, A. R. Somner, and J. Williamson. Glasgow: Drs. W. M. Borthwick, G. B. Marshall Clarke, J. E. Geddes, G. Johnson, Helen S. Kennedy, R. S. Kennedy, J. S. Marshall, and W. G. Wimsatt. Lochmaben: Drs. C. Clayson, J. A. Cameron, J. B. Cochran, and B. R. Hillis.

The trial was co-ordinated by Dr. D. T. Kay, Royal Victoria Hospital Tuberculosis Trust Research Fellow.

Plan of Investigation

Cases for admission to the trial were selected by physicians at the seven centres, provided that such cases conformed to

*The members of the Research Committee of the Tuberculosis Society of Scotland were Dr. Christopher Clayson (chairman), Dr. W. M. Borthwick, Dr. L. G. Bruce, Professor J. W. Crofton, Dr. J. Cuthbert, Dr. Agnes R. Macgregor, Dr. W. A. Murray, Dr. G. J. Summers, and Dr. N. W. Horne (secretary, City Hospital, Edinburgh).

certain defined criteria. The criteria were as follows: (1) It should be expected that the patient would co-operate to the extent of remaining in hospital for six months. (2) No surgical treatment or collapse therapy should be envisaged for six months from the beginning of treatment. (3) Patients would not be suitable for admission to the trial under the following circumstances: (a) if they had received previous collapse therapy or previous chemotherapy; (b) if they had tubercle bacilli known to be resistant to streptomycin, para-aminosalicylic acid (P.A.S.), or isoniazid; (c) if they were less than 15 years of age; (d) if active extrapulmonary disease was present; (e) if they were pregnant or within three months of parturition; (f) if they suffered from any condition—for example, peptic ulcer, hypertension, cardiac failure, etc.—known to be adversely affected by corticosteroid therapy.

Previous chemotherapy of up to one month's duration was permissible, but it was highly desirable that chemotherapy should be begun only after acceptance into the trial. This latter provision was almost invariably observed.

The patient was allocated by the physician to one of three subgroups: (1) *Acute*: where the disease was judged on clinical and radiological grounds to have been present less than two years. (2) *Chronic*: where the disease was judged on clinical and radiological grounds to have been present for more than two years. (3) *Chronic Disease with Acute Spread*.

The physician, being satisfied that the necessary criteria were adhered to, and having allocated the patient to one of the subgroups of disease type, submitted the name of the patient to the co-ordinator. The patient was allocated centrally to one of two treatment groups from prearranged lists based upon random sampling numbers, the physician in charge of the case thus being entirely unaware of the likelihood of allocation to any specific group.

Treatment Groups

In each group, patients were required to remain on bed-rest for three months and to remain in hospital for six months.

Control Group (Chemotherapy Only).—Two categories, varying according to age, were designed to try to minimize the development of ototoxicity following streptomycin therapy. (i) Patients aged 40 years or under:—Streptomycin sulphate (or "dimycin"), 1 g. daily; isoniazid, 100 mg. twice daily. (ii) Patients over 40 years:—Streptomycin sulphate (or dimycin), 1 g. thrice weekly; P.A.S., 5 g. twice daily; isoniazid, 100 mg. twice daily.

Prednisolone Group (Chemotherapy plus Prednisolone).—(i) Chemotherapy as in control group. (ii) Prednisolone, 5 mg. four times daily for three months, plus A.C.T.H. gel 30 units I.M. on two successive days every fortnight during prednisolone therapy. (iii) Potassium citrate, 2 g. twice daily during prednisolone therapy. Throughout the trial, prednisolone was administered in the form of "delta-cortril."

The following observations were recorded prior to commencement of treatment and at monthly intervals during the

trial. (1) General condition. (2) Weight. (3) Radiograph of chest. (4) E.S.R. (Westergren). (5) Sputum or gastric lavage or laryngeal swabs for culture and sensitivity tests to streptomycin, P.A.S., and isoniazid. (6) Tuberculin test. (7) Blood pressure. (8) Urine for albumin and sugar. (9) Serum electrolytes (sodium, potassium, and chlorides).

Withdrawals from Analysis

As previously stated, this report is concerned with an analysis of the first 110 cases admitted to the trial. It was found necessary to withdraw 20 cases from analysis—8 in

TABLE I.—Withdrawals from Analysis

Reasons	Control (54 Cases)	Prednisolone (56 Cases)
Primary drug resistance	2	3
Failure to conform to protocol	1	3
Patients leaving hospital against advice	4	5
Co-existing bronchial carcinoma	1	0
Non-tuberculous	0	1
Total withdrawals	8	12

the control group and 12 in the prednisolone group—for reasons shown in Table I. Thus 90 cases remained for analysis—46 in the control group and 44 in the prednisolone group.

Composition and Comparability of Groups

The two treatment groups have been compared according to age and sex; type of disease; extent of disease—unilateral or bilateral and number of zones involved; presence of cavities and presence of tubercle bacilli in pulmonary secretions at beginning of treatment.

Age and Sex.—The age of the patients ranged from 15 to 64 years, the age distribution in the two groups being closely comparable. Of the patients 54% were male and 46% female.

Type of Disease.—The proportion of acute disease (93.2%) was rather higher in the prednisolone group than in the control group (78.3%). Correspondingly, there was only 6.8% of chronic disease with recent spread in the prednisolone group compared with 21.7% in the control group. No cases of chronic type were submitted.

Extent of Disease.—The proportion of cases having bilateral disease was approximately the same—80.4% in the control group and 72.7% in the prednisolone group. Similarity also existed in the number of zones involved, except that the prednisolone group contained a rather higher proportion of patients with extensive disease (involvement of five or six zones)—31.9% compared with 19.5% in the control group. Four-fifths of the cases in each group had three or more zones involved.

Cavitation.—There were 50 cavities recorded in each group, cavitation being present in approximately 70% in each.

Bacteriological State on Admission to Trial.—Tubercle bacilli were present in pulmonary secretions in 98% of the control group and 88% of the prednisolone group.

It will be seen that the control group and the prednisolone group are comparable in all respects.

Results

General Condition and Weight Gain.—In general, the clinical condition of patients in the prednisolone group improved more rapidly than those in the control group in respect of subsidence of fever, improvement in appetite, and weight gain. The amount of average weight gain is shown in Fig. 1. It will be seen that patients receiving prednisolone gained weight more rapidly than those in the control group, and the weight gain in the prednisolone group flattened out abruptly at the third month. No fall in weight was recorded following the cessation of prednisolone therapy,

suggesting that there had not been any significant amount of fluid retention in this group. The difference in weight gain is statistically significant in favour of the prednisolone group ($P < 0.01$) only in the first month of treatment.

Erythrocyte Sedimentation Rate.—There was a rapid fall in the average E.S.R. to within normal limits in the prednisolone group within the first month (Fig. 2), contrasting with the more leisurely fall in the control group. A small rise in the E.S.R. occurred in the prednisolone group following withdrawal of corticosteroid therapy, this rise persisting to the sixth month.

Radiological Changes.—All radiographs were assessed by a panel of clinicians experienced in the reading of radiographs of the chest and radiologists who were unaware of the treatment group to which the patient belonged. Each series of radiographs was assessed on two separate occasions. The radiographs were assessed as showing improvement, no change, or deterioration. The degree of improvement, if any, was categorized as slight, moderate, or considerable. The results of the analysis of radiological improvement are shown in Table II. The degree of improvement or deterioration is expressed in comparison with the radiographic appearances at the beginning of treatment. By the end of the first month the proportion of cases showing moderate or considerable radiological improvement was greater in the prednisolone group than in the control group, and this trend continued throughout the six months, the difference in favour of the group treated with prednisolone being statistically significant ($P < 0.01$). Though the trend over the six months was statistically significant, when the difference between the two groups is assessed at each month separately it is only at the second month that a highly significant difference ($P < 0.01$) is observed. The difference in favour of the prednisolone group was, however, significant at the 1 in 20 level ($P < 0.05$) at the end of the first month.

In two cases, one in each group, radiological deterioration in comparison with the initial radiograph was recorded. The patient in the control group showed an area of segmental atelectasis between the second and third months which disappeared between the third and fourth months. The patient in the prednisolone group showed radiographic deterioration between the third and fourth months and no improvement had subsequently occurred up to the end of six months. (This patient's radiograph improved subsequently.)

The cumulative analysis shown in Table II, however, fails to demonstrate a phenomenon which occurred in the prednisolone group between the third and fourth months of treatment—that is, immediately subsequent to the withdrawal of prednisolone. Radiological deterioration occurred between the third and fourth months in seven patients (16.6%) in the prednisolone group, the deterioration being of moderate degree in one patient and slight

in six patients. No similar deterioration was observed in the control group at this period, or in either group at any other stage of the investigation. All but one of the patients showing radiographic deterioration subsequently improved, the exception being detailed above.

Cavity Closure.—There were 50 cavities in each group. The percentage of cavities closed at each month is shown in Table III. At the end of six months' treatment 85% of

TABLE III.—Analysis of Cavity Closure

	Control	Prednisolone
1	12	17
2	30	37
3	40	56
4	58	71
5	68	71
6	72	85

cavities were closed in the prednisolone group and 72% in the control group. The trend of cavity closure was not significantly higher in the prednisolone group.

Sputum Conversion.—The rate of sputum conversion is shown in Table IV. The rate was higher in the prednisolone group throughout up to the fifth month, but the difference is not statistically significant. All 83 patients who were positive at the beginning of treatment had become negative at the end of six months.

5	93	98
6	100	100

Toxic Effects

Chemotherapy.—84% of the patients in the control group and 89% of those in the prednisolone group showed no toxic effects from chemotherapy. Four cases in the control group and two in the prednisolone group showed evidence of vestibular dysfunction from streptomycin therapy. Mild gastro-intestinal symptoms were recorded in three of the patients in the prednisolone group, but no such symptoms occurred in the control cases. Transient rashes were recorded in the first three months in three patients in the control group and in two patients treated with prednisolone.

Prednisolone Therapy.—In only two instances (4.6%) was it considered necessary to stop prednisolone therapy prematurely, this being due to the development of hypertension. Further details are given below. **Mooning** of the face was recorded in 46% of cases. Skin rashes subsequent to withdrawal of prednisolone were recorded in 17 patients (40%). In 11 of these patients (25%) the rash appeared within two weeks of cessation of the prednisolone therapy; in several this occurred within a few days. The face and trunk were especially involved, and the rash was described as mainly

erythematous, though occasionally a papular element was recorded. In most cases the rash was itchy and was followed by scaling. In the other six patients the rash developed more than a month after cessation of treatment with prednisolone, and was described as eczematous or acneiform. Any direct relationship between prednisolone therapy and the skin lesions in the latter group must remain very dubious. **Effect on Blood Pressure.**—In 18 cases (41%) the diastolic pressure persistently exceeded 100 mm. during prednisolone therapy, chiefly in the latter six weeks of treatment. In two cases the diastolic pressure rose to 115 at seven weeks, and to 140 at eight weeks respectively, and the prednisolone was stopped on this account. In all but one of the 18 cases the diastolic pressure had returned to pre-treatment levels three months after stopping prednisolone. The phenomenon of a rise in diastolic pressure occurred in all age groups. No similar alterations in blood pressure occurred in the control group. No significant disturbance of the serum electrolytes was observed.

Discussion

This investigation was designed to try to assess whether corticosteroid therapy was able to hasten improvement in pulmonary tuberculosis treated by chemotherapy. It would seem that the main questions to which a controlled investigation of this nature might give an answer were these: Is prednisolone ever hazardous so long as adequate antituberculous chemotherapy is given concurrently? Does corticosteroid therapy enhance the rate of clinical progress, radiological improvement, cavity closure, and sputum conversion? Do the serious hazards of corticosteroid therapy outweigh the advantages? At a later date further information of value may accrue from a study of the relapse rate in the two groups.

Corticosteroid therapy in tuberculosis is fraught with considerable danger when given without adequate chemotherapy cover. This is made abundantly clear in the report of Des Autels *et al.* (1956). In the present investigation every precaution was taken to ensure that adequate chemotherapy cover was given. In only one patient out of 44 was any persistent radiological deterioration seen, and this occurred after withdrawal of prednisolone. The subsequent progress of this patient is reported as very satisfactory. It would seem, therefore, fairly conclusive that pulmonary tuberculosis should no longer be considered a contraindication when corticosteroid therapy is clearly required, provided there is adequate chemotherapy cover.

The anti-inflammatory action of the corticosteroids might well be expected to reduce the toxic effects of tuberculosis in acutely ill patients. This phenomenon has already been described by Houghton (1954) and others, and was confirmed in this trial. The anti-inflammatory action of corticosteroids seems also to be reflected in the rapid fall in the erythrocyte sedimentation rate in the patients treated with prednisolone. Weight gain in the patients treated by prednisolone was, on the average, more pronounced than in the control group, this gain being significantly greater in the first month of treatment. That the gain in weight in the prednisolone group was not in fact due to fluid retention is suggested by the absence of the fall in weight when prednisolone was stopped.

So far as the degree of radiological improvement is concerned, the results of this investigation reveal that in cases

of pulmonary tuberculosis of the type described—patients with acute disease or chronic disease with acute spread—the trend of radiological improvement over a period of six months is favourably influenced by prednisolone to a significant degree. This difference exists from the commencement of treatment and is of highly significant degree during the second month of therapy. The difference between the groups becomes less obvious in successive months thereafter. Of considerable interest is the fact that almost one-sixth of the patients in the prednisolone group showed radiographic deterioration between the third and fourth months. This so-called "rebound" phenomenon is presumably due to a recrudescence of inflammatory response which had been suppressed by corticosteroid therapy. In all but one of the seven patients so affected the "rebound" phenomenon was of no permanent significance, the changes being reversed by the time the radiograph was taken at the fifth month. It is also of interest to observe that of the 90 patients in the trial five-sixths had shown a degree of improvement of moderate or considerable extent by the end of six months. Only one patient had shown no change in the radiological appearances.

Perhaps of greater practical importance than the question of general radiological improvement is the question of cavity closure. As Ross and Kay (1956) remark, cavitation in pulmonary tuberculosis has long been regarded as a feature of grave import, and even although sterilization of cavities may rob the lung cavity of its terrors, cavity closure remains an important objective in therapy. In a series of 138 patients these authors estimated that the true frequency of cavity closure on chemotherapy alone lay between 50 and 79%, and probably nearer the latter figure. In this series the cavity-closure rate at six months in patients treated by chemotherapy alone was 72%, and in those treated by prednisolone plus chemotherapy 85%. Although this superior rate of cavity closure in the prednisolone group is not statistically significant, the high rate of closure in the prednisolone group cannot be completely discounted at this stage in the investigation.

The rate of sputum conversion is also of much practical importance. It is known that cortisone aggravates tuberculosis in mice (Hart and Rees, 1950) and that corticosteroids are capable of producing a much greater census of tubercle bacilli in the lungs and spleen in fatal infections in mice than in control animals (McCune *et al.*, 1956). It was possible, therefore, that the absence of cellular response in patients treated with prednisolone might retard sputum conversion or, alternatively, that this phenomenon might allow the more ready destruction of bacilli by chemotherapy, many antimicrobials being most effective against actively multiplying organisms. Recent work by Pagel and Treip (1956) has suggested that in the experimental animal cortisone does not prevent, though it slightly delays, the disposal of tubercle bacilli, and that the removal of bacilli is by a humoral rather than a cellular mechanism. In this series the rate of sputum conversion in the two groups was not statistically significant, though the patients in the prednisolone group had a slightly higher rate of conversion up to the end of the fifth month. It is of interest also to observe that, with the form of chemotherapy used, all the 83 patients who were positive at the beginning of treatment had become negative on culture at the end of six months, irrespective of whether prednisolone was given or not.

Long-term corticosteroid therapy has obvious serious hazards, and it is important to assess the nature of the side-effects observed in this series. Fortunately none of the serious side-effects were encountered. Mooning was observed in almost half the patients, and a transient mild degree of hypertension developed in 41% of cases. In two instances prednisolone was stopped prematurely on this account. No significant disturbance of electrolyte balance was observed. Of interest was the occurrence of skin rashes in 25% of patients within two weeks of withdrawal of prednisolone. The rashes were described as being mainly erythematous, though some were papular in character, and in most

cases the rash was itchy and was followed by scaling. It may be that prednisolone administered concurrently with chemotherapy from the beginning of treatment may interfere with the natural processes of drug desensitization and that those rashes represented a mild drug-hypersensitivity reaction shortly after the withdrawal of prednisolone. It is of interest that two patients not among those recorded in this report have developed severe hypersensitivity to P.A.S. five days after completing a three-months course of prednisolone, thus suggesting that the concurrent administration of prednisolone may not completely suppress hypersensitivity reactions.

The preliminary results of this investigation suggest, therefore, that, provided adequate chemotherapy cover is given, patients with active pulmonary tuberculosis can safely be treated with prednisolone, and that prednisolone therapy in such patients produces more rapid remission of toxic symptoms. The desire for a rapid abatement of symptoms in severely ill patients may indeed warrant the use of corticosteroid therapy. Prednisolone also causes significantly more rapid improvement radiologically, especially in the first two months of treatment, and slightly more rapid cavity closure and sputum conversion. Whether the latter advantages are of practical importance and whether they outweigh the known serious hazards of corticosteroid therapy—which so far we have escaped—is a matter for further research and study.

Summary

Preliminary results of treatment in a controlled trial are reported in which 46 patients were treated with chemotherapy alone and 44 with identical chemotherapy plus prednisolone.

Clinical improvement was more rapid, especially in those acutely ill, in those treated by prednisolone, and there was a more rapid fall in the erythrocyte sedimentation rate in this group.

Radiological improvement was significantly hastened by prednisolone over a six-months period, most of the significant difference occurring in the first two months. Cavity closure and sputum conversion were slightly hastened by prednisolone, but not to a significant degree.

No patients receiving prednisolone showed any significant evidence of deterioration, though a temporary "rebound" phenomenon was observed radiologically in one-sixth of cases. No serious side-effects were recorded.

The significance of these results is discussed.

The Research Committee of the Tuberculosis Society of Scotland wishes to express its gratitude to the physicians, bacteriologists, and nursing staffs of the hospitals concerned for the excellence of their co-operation; to Miss Patricia McGuinness, Mrs. Joan Valentine, Miss Laureen Jackson, and Miss Joyce Thornton for secretarial assistance and to the Royal Victoria Hospital Tuberculosis Trust for generous financial aid. The Committee is also greatly indebted to Pfizer Ltd., and especially to Dr. A. Brunton, for the generous donation of the large amount of dactacortil used in this investigation. Our thanks are also due to the clinicians who assisted in the assessment of radiographs, and to Dr. N. Thomson for his help in this regard.

ENHANCEMENT OF MANTOUX REACTION COINCIDENT WITH TREATMENT WITH CORTISONE AND PREDNISOLONE

BY

LESLIE H. TRUELOVE, B.M., M.R.C.P.

Medical Registrar, Stoke Mandeville Hospital,
Aylesbury, Bucks

Patients with advanced pulmonary or miliary tuberculosis may show a low or absent hypersensitive reaction to intradermal injections of tuberculin (Happ and Casparis, 1922; Hart, 1932). Such patients often show excessive pigmentation of the skin with a distribution reminiscent of that seen in suprarenal insufficiency, and there is some support for this clinical observation in the work of Clarke *et al.* (1954), who showed a correlation between the severity of the disease in patients suffering from pulmonary tuberculosis and the urinary 17-ketosteroid excretion. In their series of 109 patients, those with the more frankly exudative disease had the lowest excretion of 17-ketosteroids. Of the patients classified as suffering from far-advanced disease, 86% had a low 17-ketosteroid excretion, and in 37% the excretion was less than 50% of the normal. If other factors can be excluded the question arises whether there is any relation between the loss of tuberculin hypersensitivity and insufficiency of suprarenal function.

The investigation of a patient with Addison's disease afforded an opportunity of testing this rather speculative idea. The patient was a 40-year-old woman presenting in pregnancy with hypoglycaemic manifestations of Addison's disease probably secondary to hypopituitarism, and has been reported in detail elsewhere (McFarlane and Truelove, 1957). Two weeks post partum the Mantoux reaction was negative at a dilution of 1/100, and treatment with cortisone was begun as there were definite signs of impending Addisonian crisis. Thirty-seven days later, when the patient was on a maintenance dose of 50 mg. of cortisone daily, the Mantoux reaction had become positive at 1/1,000. This result prompted the observation of the tuberculin sensitivity in patients suffering from various conditions before and during treatment with corticosteroids.

Summary of 20 Cases in which "Conversion" occurred

Case No.	Sex and Age	Diagnosis	Mantoux Before Treatment	Treatment Dosage/Day	Mantoux During Treatment	Time Interval Between Tests

C. = Cortisone. P. = Prednisolone.

Material and Methods

The results from 24 patients are analysed. They were mostly acute admissions to two general medical wards, and were mostly elderly, although younger ages were represented. Patients who were likely to need steroid treatment were Mantoux-tested routinely, those showing positive reactions to the dilutions employed being excluded. The series includes all patients fulfilling these criteria who were admitted to two wards in a 15-months period, together with three other patients kindly referred to me from elsewhere.

Mantoux tests were performed in the usual way by injecting 0.1 ml. of old tuberculin (Evans) intradermally into the volar surface of the forearm, the reactions being confirmed by independent observers. Time did not always allow the use of serial dilutions, but 1/1,000 was the weakest used. Reactions were classified as positive only if there was definite induration at 48 hours.

During the times concerned the patients received diet, fluid intake, and drugs appropriate to their condition, and there was no constant factor likely to have influenced the results.

Results

Mantoux-testing was done as opportunity offered, and it must be emphasized that the times at which conversion was observed were not necessarily the earliest at which it actually occurred. Late development of reaction at the site of earlier, negative, tests was observed after steroid treatment was started in two cases (Nos. 16 and 17).

The results of 20 cases in which "conversion" occurred are summarized in the Table. It will be noted that three of them changed from negative at 1/100 to positive 1/1,000. The tests recorded in the table as "before treatment" were the lowest dilutions tried, and those "after treatment" were the highest dilutions tried.

On the whole the patients improved in general condition during the period under review, but this was pronounced in only six (Cases 1, 2, 4, 5, 16, and 17). In six (Cases 8, 10, 11, 12, 15, and 19) there was no change; three (Cases 11, 12, and 16) were severely ill and subsequently died; three (Cases 8, 10, and 15) were not very ill. The skin was of normal texture in 10 cases, but in 10 it was dry or showing a senile atrophy. None of the cases converting from 1/100 negative to 1/1,000 positive were among these 10, and only one (Case 5) was among those showing marked clinical improvement. In five cases it was possible to repeat the Mantoux test after steroid treatment was stopped. Three of these became negative to the dilutions which previously gave a positive reaction (Case 2 in three weeks, Case 4 in six days, and Case 11 in eight days), and Case 7 reverted from positive to 1/1,000 to negative at 1/100 in 10 days. Case 13 was still positive

at the previous dilution of 1/100 18 days after treatment was stopped.

Four of the cases showed definite signs of suprarenal cortical insufficiency (Nos. 1, 4, 5, and 16). Cases 4 and 5 had 24-hour urinary 17-ketosteroid excretion of 1 and 2 mg. respectively (both women: Case 1 had clinical evidence, together with lack of eosinophil responses to corticotrophin 100 units daily; and Case 16 had electrolyte changes and pigmentation).

With the exception of the Addisonian Cases 4 and 5 there were only four patients under 60 years of age in this series; one (Case 11) was severely ill, and another (Case 3) was moderately ill but made a fair recovery. Nevertheless, the return of tuberculin hypersensitivity in association with recovery of suprarenal function may occur in a young person undergoing a severe illness, as the following case history shows.

A man aged 35, previously well and with no relevant past history, was admitted as an emergency case of pneumonia following an upper respiratory infection. Five days after admission there were frank signs of a pleural effusion and he subsequently developed an empyema. Mantoux 1/1,000 was negative on admission, and 1/100 was negative 16 days after admission. At this stage he was still severely ill with swinging fever. Urinary 17-ketosteroids were 7.6 mg./24 hours on admission, but by the time of the second negative Mantoux test they had risen to 19 mg./24 hours. Clinical signs of suprarenal insufficiency in the form of hyperpigmentation, including the palmar creases, and fall in blood pressure became evident 10 days after admission, and were still present at the time of the second Mantoux test, although the 17-ketosteroid excretion had risen. The clinical picture, however, was suggestive enough for the decision to be made to give cortisone if there was any further deterioration. Clinical recovery dated from this time. Mantoux 1/100 was still negative 44 days after admission, when the 17-ketosteroid excretion was 16.3 mg./24 hours; but the Mantoux reaction became positive at 1/100 eight days later, and positive at 1/1,000 when tested after a further one month's convalescence.

In addition to the cases described above, there were four which showed no tuberculin hypersensitivity change at any time.

Case 21.—A woman of 74 with carcinoma of the stomach and rheumatoid arthritis proved negative to 1/100, and was treated with prednisolone 60 mg. daily. Repeated testing showed no reaction whatever.

Case 22.—A woman of 65 with rheumatoid arthritis and fixed joints treated with prednisolone 20 mg. daily and negative to 1/1,000. Further testing with 1/1,000 showed no reaction after seven days.

Case 23.—A man of 72 with chronic bronchitis and emphysema, negative to 1/100, was treated with prednisolone 20 mg. daily. Repeated tests at all dilutions remained negative.

Case 24.—A man of 40 with long-standing bronchial asthma, negative to 1/100 and treated with prednisolone 20 mg. daily. Further testing after eight days showed no reaction.

Case 24 was interesting in that, although this patient showed no reaction to intradermal tuberculin, scratch-testing with standard allergens (Bencard), which were all negative on admission, showed a definite sensitivity to certain of the pollen preparations after seven days' treatment, suggesting that the treatment may have some influence on this form of hypersensitivity also.

Discussion

The results suggest that the Mantoux reaction may be suppressed in certain severe conditions and also that the reaction may return with recovery. This agrees with previous work (Plicher, 1930; Schwartz and Heise 1931). Most patients in the series were elderly, but the phenomenon was observed in some younger patients and has also been described by Taylor, Smith, and Vollum (1953) in younger people with tuberculous meningitis.

The wide variety of conditions investigated and the variations in their clinical states demand a very large control series if the effects of steroid therapy on the Mantoux reaction are to be separated without question from changes merely associated with clinical recovery. Such a control

series was not possible under the conditions of the present investigation, but the results do not suggest a necessary correlation between the return of a suppressed reaction and clinical improvement. Thus six of the cases showed no clinical improvement during the period under review, and the rapidity of the conversion observed in some cases is against any such correlation.

Wasting and dehydration are commonly accepted as simple causes of lack of skin reactivity which may result in a negative tuberculin reaction. There is no evidence that these factors influenced the present series, as there were mostly no changes in the condition of the skin during the relevant times. Finally, the mere performance of tuberculin-testing may enhance a previous reaction (O'Grady, 1957), but there is no evidence that this was a significant factor in this series, and, as described, four cases became negative again in spite of repeated testing. In one case (No. 17) a reaction, previously negative, became rapidly positive following administration of prednisolone, without further injection of tuberculin.

It is generally accepted that cortisone may, in therapeutic dosage, suppress the Mantoux reaction (Long and Favour, 1950; LeMaistre *et al.*, 1951; Long and Spensley, 1954; Houghton and Davies, 1954); and the anti-inflammatory action of cortisone is established. However, Coste *et al.* (1951) treated 15 patients with arthritic or rheumatic conditions with enhancement of the tuberculin reaction in 10; and Sulzberger *et al.* (1951) reported that of three patients with negative reactions two became positive after treatment with corticotrophin. The effect of treatment with small doses of steroid hormones on the Mantoux reaction has not been previously described.

In certain circumstances the addition of small quantities of cortisone to the tuberculin extract may result in the enhancement of the reaction or at least result in a diminution of the usual inhibitory effect. Citron and Scadding (1957) have shown a direct relationship between the degree of inhibition of the response by local cortisone and the degree of hypersensitivity present. They also confirm earlier work (Pyke and Scadding, 1952), in which it was shown that a negative tuberculin response in sarcoidosis may become positive with cortisone treatment or if cortisone is added to the tuberculin reagent. They postulate that these effects may be due to retention of the tuberculin at the injection site for a longer period than usual.

The treatment of pulmonary tuberculosis with steroid hormones in addition to antibiotics is rapidly becoming established (Houghton, 1954; Rose and Jauffret, 1956; Favez and Aguet, 1956), and the advantages have been assumed to be related to suppression of the hypersensitive reaction. However, Even *et al.* (1955), while supporting this method of treatment, recommend the use of more "physiological" doses than those reported as causing spread of infection. The reactivation of chronic tuberculous lesions in men over 65 has recently received attention (Wilkins, 1956), and this, together with the results of Clarke *et al.* (1954), who found low 17-ketosteroid excretion especially in elderly patients, suggests that in certain cases the advantages gained by steroid treatment in small dosage may be due to the correction of the effect of suprarenal insufficiency rather than to the suppression of a hypersensitive response. If this is so it may be expected that other severe infections apart from tuberculosis would respond, especially in the elderly, to the addition of steroid hormones in small dosage to standard antibiotic treatment. Such treatment was used in Case 2, in which the primary disorder was a severe pyogenic bronchopneumonia, and the response was clinically dramatic. This patient also had two relapses of his chest infection in the following year. On each occasion the relapse closely followed the reduction or stoppage of cortisone, and both times recovery was rapid when the drug was recommenced.

The small number of cases in this series and the lack of adequate controls make the results inconclusive, but the implications seem to justify publication as a preliminary report.

Summary

The cases are presented of 24 patients with various diseases who had negative tuberculin reactions. Whilst treated with cortisone or prednisolone in moderate or low dosage the tuberculin reaction became positive at the same or higher dilutions in 20 of the cases.

The patients were mostly elderly, or showed frank signs of suprarenal cortical suppression.

The suggestion is made that steroid treatment, although able to suppress a positive tuberculin reaction when given in high dosage, may, given in lower dosage, actually restore a reaction which has been suppressed by age, infection, or suprarenal deficiency.

The implications of these findings and their possible application to the treatment of severe infections, especially in the elderly, are discussed.

I thank the physicians of the Aylesbury Hospitals for permission to investigate their patients, and in particular Dr. Wilfred Stokes and Dr. M. Saxty Good for much valuable advice and criticism. I also thank Dr. L. Nunn for the biochemical investigations and the nursing staff for assistance with the tuberculin reactions.

Speaking at a conference on mental deficiency at Manchester on November 7 and 8, Mr. RICHARD THOMPSON, Parliamentary Secretary to the Ministry of Health, said that the theme of the Royal Commission's proposals was based on the success of non-residential training and a growing tolerance of the public towards the mentally handicapped. To obtain results a closer co-ordination between health, welfare, and education services was essential, because the needs of defectives were chronic but not constant. If community care was to work public opinion must accept it, which meant abandoning some of the controls and restraints of present procedures. "We should develop a new outlook towards mental defectives not as hopeless outcasts, as has so often been the case hitherto, but more as we consider, for instance, blind people." Great progress had been made since the start of the Health Service in the organization for training mental defectives at occupation centres. In 1948 100 centres existed; to-day over 300. In 1951 just over 4,000 boys and girls under 16 were receiving training; to-day well over 9,000. Because most resources had been applied to mentally handicapped children, the more complicated problems of adult defectives had not yet been properly studied. With full employment and economic stringency it was difficult to provide staff and buildings, but this need not prevent a start being made. The conference was arranged by the National Association for Mental Health.

THE BINDING OF HAEMOGLOBIN BY PLASMA PROTEINS (HAPTOGLOBINS)

ITS BEARING ON THE "RENAL THRESHOLD"
FOR HAEMOGLOBIN AND THE AETIOLOGY
OF HAEMOGLOBINURIA

BY

Metabolism, Department of Biochemistry, University of
Oxford

Jayle and his colleagues (Jayle, 1939, *et seq.*, see Jayle and Boussier, 1955) have carried out an extensive series of investigations on serum proteins that have the striking property of combining with haemoglobin. These proteins have been termed haptoglobins, from the Greek root *ἅπτειν*, meaning "to hold fast." The haptoglobin migrates with the α_2 fraction on electrophoresis in the Tiselius apparatus and on filter paper, but when haemoglobin is added the haptohaemoglobin complex has a mobility corresponding to that of β_1 -globulin (Jayle, Boussier, and Badin, 1952). This observation has been confirmed by Wieme (1953), Tuttle (1955), and Reich (1956). Tuttle failed to find the haptoglobin in umbilical cord blood, although it was present in the blood of older children.

In an interesting series of experiments, Smithies (1955a, 1955b) observed that when mixtures of haemoglobin and serum are submitted to electrophoresis in starch gels the resulting patterns differ from subject to subject in a manner described fully below. Since the haptoglobins appear to be the only serum proteins that combine with haemoglobin, there is little doubt that Smithies was describing individual differences in haptoglobins. Smithies reported that the haptoglobins form a complex with about 125 mg. of haemoglobin per 100 ml. of plasma, any excess of haemoglobin above this figure remaining uncombined. Smithies, like Tuttle, was unable to find any haptoglobins in umbilical cord blood.

We have been able to confirm and extend the findings of Smithies and have obtained evidence that the binding of haemoglobin by plasma proteins has a bearing on the circumstances under which methaemalbumin is formed, on the problem of the so-called "renal threshold" for haemoglobin, and on the aetiology of haemoglobinuria.

Material and Methods of Investigation

Serum specimens from 12 normal subjects and 7 patients with haemoglobinuria have been studied. About 5 ml. of blood was allowed to run down the side of a centrifuge tube. The clot was allowed to form and retract for six hours at room temperature, and serum was removed after centrifugation. The serum proteins were submitted to electrophoresis in starch gels in borate buffer, pH 8.48, using the technique of Smithies (1955b). After electrophoresis the gels were sliced horizontally into two parts, one of which was stained with amidoschwartz B (Gurr) while the other was stained for haem proteins by benzidine (Franklin and Quastel, 1949) or

orthotolidine (O'Kelly and Kohn, 1955). Both the latter, especially the benzidine technique, are extremely useful, since they show quite clearly haem-protein bands that are scarcely visible or quite invisible when not specifically stained. Their application has enabled us to extend the observations of Smithies on the binding of haemoglobin by plasma proteins in normal subjects and to correct his description in some points of detail.

Oxyhaemoglobin solutions were prepared by collecting erythrocytes in 3% sodium citrate, and washing them three times in 0.9% sodium chloride. To each volume of packed cells two volumes of distilled water were added. The mixture was frozen twice to facilitate complete lysis of the cells, and the preparation was centrifuged at 10,000 *g* for 1 hour to sediment the erythrocyte stroma. The concentration of oxyhaemoglobin in the supernatant was measured in a Unicam SP.600 spectrophotometer at 539 *mμ* (*Emm*=59.6). Methaemoglobin was prepared by treating this oxyhaemoglobin solution with an equal volume of a 0.5% solution of $K_3Fe(CN)_6$ for two hours at room temperature. The excess ferricyanide was removed by dialysis and the concentration of methaemoglobin measured by the absolute extinction at 500 *mμ* (*Emm*=38.2). Methaemalbumin was prepared by the method of Fairley (1941). Purified haematin (B.D.H.) was dissolved in 0.01N NaOH (1 mg. per ml.), and one volume of this solution added to five volumes of serum to give a clear brown methaemalbumin solution. Absolute extinction values of all haem-proteins were obtained from iron analyses carried out by the method of Paul (1948).

Binding of Haemoglobin by Haptoglobins in Different Subjects

Varying quantities of oxyhaemoglobin (from 25 to 200 mg. per 100 ml.) were added to sera from different subjects and submitted to electrophoresis. The great majority of subjects fall into one of three groups with respect to the patterns obtained. For these groups the revised terminology of Smithies and Walker (1956) is used.

Subjects in group 1-1 have only one haptoglobin. In the absence of haemoglobin, this protein migrates in the fast α_2 position (Fig. 1 A). When small quantities of oxyhaemoglobin have been added, two haemoglobin-containing bands appear (Fig. 1, B). One of these bands is intermediate in mobility between the fast α_2 - and β -globulins while the other corresponds in mobility to β -globulin. When the quantity of added oxyhaemoglobin is raised, the first band disappears and the second band is intensified (Fig. 1, C). The interpretation of this observation will be discussed in detail elsewhere, but our tentative conclusion can be summarized here. Jayle, Boussier, and Tonnelat (1956) have produced evidence that each molecule of haptoglobin₁ (the type commonly observed in the blood) can combine with two molecules of haemoglobin. This suggests that the haptoglobin molecule might form a complex with either one or two molecules of haemoglobin, according to the equation:

where *Hp* stands for haptoglobin and HbO_2 for oxyhaemoglobin. We have concluded that the first band described above represents $Hp(HbO_2)$ and the second $Hp(HbO_2)_2$. As the quantity of added oxyhaemoglobin is raised, the second band increases at the expense of the first according to the phase rule.

When the quantity of added oxyhaemoglobin exceeds 135 mg. per 100 ml. another band appears (Fig. 1, D). This seems to represent uncombined oxyhaemoglobin, since it lies between the β - and the slow α_2 -globulins, which is the

position taken by oxyhaemoglobin when submitted to electrophoresis alone under comparable conditions. Smithies (1955b) states that the free oxyhaemoglobin band is intermediate between the β - and fast α_2 -globulins, but in all our experiments it has been in the position described, between the slow α_2 and β bands.

Subjects belonging to group 2-2 have three haptoglobin bands in the $\alpha\beta$ region (Fig. 2, A). When small quantities

FIG. 1.—Serum from a subject belonging to group 1-1. In A all the serum proteins are shown in the absence of haemoglobin. The protein bands are, in order from the origin (O): slow α_2 , post- β , β , fast α_2 , post-albumin, and albumin. The pre- α bands are not included in the photograph. When 50 mg. of oxyhaemoglobin is added per 100 ml. of serum, two haptoglobins (B) are shown by staining with benzidine. The faster-moving band appears to be $Hp(HbO_2)$ and the slower-moving $Hp(HbO_2)_2$. When the concentration of oxyhaemoglobin is raised to 135 mg. per 100 ml. the former disappears (C). When the concentration of oxyhaemoglobin exceeds 135 mg. free oxyhaemoglobin appears behind the haptoglobins band (D).

FIG. 2.—Serum from a subject belonging to group 2-2. In A all the serum proteins are shown in the absence of haemoglobin. They are, in order from the origin (O): slow α_2 , three $\alpha\beta$ bands, β , fast α_2 , and albumin. When 100 mg. of oxyhaemoglobin per 100 ml. of serum is added, three haptoglobins (B) are observed. C shows serum from a subject belonging to group 1-2. The three $\alpha\beta$ -haptoglobin bands have migrated further than in the serum from a group 2-2 subject. When 135 mg. of oxyhaemoglobin is added to a group 2-2 subject, four haptoglobins (D) are observed by staining with benzidine.

of oxyhaemoglobin are added, three rather faint benzidine-staining bands, all showing slightly slower mobility than the uncombined haptoglobin bands, are observed; these may represent complexes of $Hp(HbO_2)$. When the added oxyhaemoglobin is increased, three benzidine-staining bands, with a still lower mobility, are observed (Fig. 2, B). The slowest moving band is rather faint, so that it is difficult to see without specific staining, but the other two are more intense. It is believed that these represent the three $Hp(HbO_2)_2$ complexes. In addition, a fourth, rather faint, band with a slightly greater mobility is usually observed; this may represent $Hp(HbO_2)$. When the concentration of this may represent $Hp(HbO_2)$. When the concentration of added oxyhaemoglobin exceeds 100 to 120 mg. (the exact level varying from subject to subject), an uncombined oxyhaemoglobin band appears in the usual position.

In the third group of subjects (group 1-2), all four haptoglobins are present (Fig. 2, C). Three of the haptoglobins lie in the $\alpha\beta$ position, although their mobility is slightly greater than that of the haptoglobins of subjects belonging to group 2-2. The fourth haptoglobin (which was overlooked by Smithies) migrates with the fast α_2 -globulin and corresponds to the haptoglobin in subjects belonging to group 1-1. On to the haptoglobin in subjects belonging to group 1-1. On addition of oxyhaemoglobin patterns are obtained which resemble a combination of those previously described in group 1-1 and 2-2 sera (Fig. 2, D); however, the $\alpha\beta$ -haptoglobin complexes in group 1-2 subjects always show a somewhat greater mobility than those of group 2-2 subjects. Oxyhaemoglobin added in excess of 135 mg. per 100 ml. remains uncombined.

As pointed out by Tuttle and by Smithies, serum from umbilical-cord blood lacks haptoglobins altogether. A few older children and adults, apparently in good health, have been observed who have no demonstrable haptoglobins or who have only a single haptoglobin band in the $\alpha\beta$ region. Nevertheless, it can be concluded that the great majority of human subjects have proteins in their plasma (haptoglobins) that are capable of combining firmly with oxyhaemoglobin in concentrations up to 100 to 135 mg. per 100 ml. The electrophoretic mobility of the haptoglobins varies from subject to subject and allows the identification of three main groups of subjects. There is no doubt that these groups are genetically determined. The pattern of inheritance usually follows that postulated by Smithies and Walker (1955); the common haptoglobin types (1-1, 2-2, and 2-1) could be the three phenotypes expected in subjects homozygous and heterozygous for a single pair of allelomorphous genes. However, the existence of individuals showing other haptoglobin patterns, together with some of the findings in family studies, suggests that the mode of inheritance is more complex. This aspect of the problem will be discussed in detail elsewhere.

Methaemalbumin Formation

It has already been pointed out that when oxyhaemoglobin is added to serum in concentrations up to 100 mg. per 100 ml. in some subjects and 135 mg. per 100 ml. in others, all the haem-protein present, as shown by the benzidine and orthotolidine reactions, is in the form of the haptoglobin and orthotolidine reactions, is in the form of the haptoglobin complex. As soon as oxyhaemoglobin is added in excess of the combining power of the haptoglobins, however, material staining with benzidine and orthotolidine appears in the albumin region as well as in the position of free oxyhaemoglobin (Fig. 3, A and B). The haem-protein in the albumin region is in all probability methaemalbumin, since it corresponds in electrophoretic mobility to methaemalbumin prepared artificially.

In addition to the large and dense methaemalbumin band, a rather faint haem-protein band in the position of the fast α_2 -globulins is usually observed. This band has a mobility quite different from methaemoglobin, and may represent a complex of haem and globulin. The concentration appears to be usually about 5% of that of methaemalbumin.

The identification of methaemalbumin by benzidine staining of serum proteins after filter-paper electrophoresis has been reported by Hensley and Blackburn (1952). This is a sensitive method for detecting the compound, but staining of starch gels, which contain more protein, further increases the sensitivity. Quantities of methaemalbumin of the order of one-hundredth of those detectable spectroscopically can be identified in this way. Methaemalbumin was observed in all our subjects when the added oxyhaemoglobin concentration was 150 mg. or higher. Fairley (1940) was able to

FIG. 3.—Serum from Case 1 with paroxysmal nocturnal haemoglobinuria (A) and from Case 6 with recurrent cold haemoglobinuria (B), stained with benzidine. Only uncombined oxyhaemoglobin (HbO_2) and methaemalbumin (*Mhalb.*) are visible.

recognize methaemalbumin spectroscopically after oxyhaemoglobin injections in human subjects when the concentration in the plasma exceeded 200 mg. per 100 ml.

In none of our experiments was methaemoglobin observed after addition of oxyhaemoglobin to serum. The electrophoretic mobility of methaemoglobin was determined by adding the compound to serum shortly before electrophoresis. Free methaemoglobin was found to have a mobility less than that of oxyhaemoglobin and slightly greater than that of the slow α_2 -globulins. Some of the methaemoglobin was bound by haptoglobins and some transformed into methaemalbumin.

These observations suggest that oxyhaemoglobin forms a relatively stable complex with haptoglobin. Free oxyhaemoglobin, on the other hand, is unstable and breaks down to liberate haem groups which are immediately oxidized and combine with albumin to form methaemalbumin. If methaemoglobin is an intermediary in the reaction, it must disappear rapidly, since it cannot normally be detected at all. Thus methaemalbumin is formed only when the concentration of oxyhaemoglobin in the plasma is greater than that which can be bound by haptoglobins.

Relationship of the Binding of Haemoglobin by Haptoglobins to the "Renal Threshold" for Haemoglobin

A great deal of experimental work on dogs and on human subjects has established that when the concentration of haemoglobin in the plasma is below a threshold level no haemoglobin can be detected in the urine. In dogs the haemoglobin threshold varies from 80 to 150 mg. per 100 ml. plasma (Lichty, Havill, and Whipple, 1932; Monke and Yuile, 1932; Yuile, 1942) and in man it varies from 100 to 140 mg. per 100 ml., being in the majority of subjects about 135 mg. per 100 ml. (Ottenberg and Fox, 1938; Gilligan, Altschule, and Katersky, 1941; Blackburn, Hensley, Kerr Grant, and Wright, 1954). Once overt haemoglobinuria is established, however, in both dog and man it continues until the level of haemoglobin in the plasma falls to about 50 mg. per 100 ml., less than one-half of the original threshold level.

The explanation of Lichty *et al.* for the renal threshold is that haemoglobin passes through the glomeruli even at low plasma concentrations, only to be reabsorbed by the renal tubules. If the plasma concentration exceeds the threshold level the concentration of haemoglobin in the glomerular

filtrate exceeds the capacity of the renal tubules for reabsorption and haemoglobinuria occurs. This explanation has been generally accepted (Yuile, 1942; Smith, 1951; Dacie, 1954).

It has also been shown that shortly after haemoglobin injections above threshold levels the epithelial cells of the convoluted tubules of the kidney contain minute brown granules. These do not at first give the Prussian-blue reaction for iron, but can be stained by various methods which are more or less specific for haemoglobin (Fukuda and Oliver, 1923; Köster, 1937; Lison, 1938). After a few days the granules appear larger and stain readily for iron (Bogniard and Whipple, 1932). In chronic haemoglobinurias in man this process leads to a striking degree of siderosis of the kidneys (see Dacie, 1954). Even after very large injections of haemoglobin only part of the haemoglobin injected appears in the urine. There is thus no doubt that the convoluted tubules of the kidney can reabsorb and degrade haemoglobin.

However, a number of observations on record are difficult to reconcile with this explanation of the renal threshold for haemoglobin. In the first place, after repeated subthreshold injections of haemoglobin in dogs no deposits of iron-containing material can be observed in the kidney tubules (Bogniard and Whipple, 1932); at least some iron should be visible if haemoglobin had passed through into the glomerular filtrate and been reabsorbed. Second, the threshold level is reduced to less than one-half its original value by haemoglobinuria or repeated diminishing daily injections of haemoglobin into dogs (Lichty *et al.*, 1932). The lowering of the threshold has been explained by assuming that the tubular epithelial cells become filled up with haemoglobin and its degradation products to such an extent that their capacity to reabsorb haemoglobin is diminished. However, experimental results fail to support this view. Yuile *et al.* (1941) studied iron retention in the kidneys of dogs after injection of haemoglobin labelled with radioactive iron. Large injections, sufficient to raise the plasma concentration of haemoglobin to about 700 mg. per 100 ml., were given to dogs that had not previously received any haemoglobin and to others in which the threshold had been markedly lowered by repeated injections. When the perfused kidneys were analysed, only about 16% of the injected iron was present in the kidneys of the normal animals, in contrast with well over 20% in the kidneys of comparable animals with lowered thresholds.

Moreover, in both dogs and man the rate of haemoglobin excretion is proportional to the concentration of haemoglobin above the threshold level in the plasma up to very high concentrations (1,300 mg. per 100 ml.—see Yuile, 1942). It is difficult to reconcile this finding with an injury phenomenon increasing glomerular permeability or a process of tubular saturation leading to diminished reabsorption.

We have been led to an alternative explanation of the threshold for haemoglobin from consideration of the remarkable coincidence between the haemoglobin-combining power of the haptoglobins and the threshold level of haemoglobin in the plasma. We suggest that haemoglobin bound to haptoglobin does not appear in the glomerular filtrate at all. Jayle *et al.* (1956) have concluded that the common haptoglobin in plasma has a molecular weight of the order of 175,000 and that it does not appear in the urine of patients with renal disease. It is thus even less likely that the haptoglobin-haemoglobin complex (the molecular weight of which is about 310,000) would traverse the glomerular filter. Free oxyhaemoglobin, on the other hand, seems to pass into the glomerular filtrate relatively easily, which accounts for the proportionality between the rate of haemoglobin excretion and the concentration of haemoglobin above threshold level in the plasma.

The same observation implies that a nearly constant proportion of the haemoglobin present in the glomerular filtrate is reabsorbed in the renal tubules.

On this hypothesis, haemoglobinuria would be expected whenever the level of oxyhaemoglobin in the plasma exceeds the haemoglobin-combining power of the haptoglobins, which is in fact the case. Furthermore, haemoglobin injected to subthreshold concentrations would all be bound by haptoglobins, so that none would appear in the glomerular filtrate and be reabsorbed by the renal tubules. As stated above, no iron can be demonstrated in the renal tubules in these circumstances. The diminished threshold after repeated injections of haemoglobin would be due to the removal of haptoglobin from the plasma at a rate greater than the rate of replacement of haptoglobin. Hence, in animals receiving injections of haemoglobin after previous injections of the compound, less haemoglobin would be bound by haptoglobin and more would escape into the glomerular filtrate than in animals receiving a single haemoglobin injection. This would explain the comparatively high concentration of labelled iron found by Yuile *et al.* (1941) in the kidneys of animals receiving repeated haemoglobin injections.

Haptoglobins in Patients with Chronic Haemoglobinurias

It follows from this explanation of the "renal threshold" for haemoglobin that haemoglobinuria would be expected clinically in two circumstances. The first would be when an episode of severe acute intravascular haemolysis liberates enough haemoglobin to raise the concentration in the plasma above 135 mg. per 100 ml. Haemolysis of less than 1% of the circulating erythrocytes would be sufficient to achieve acute haemoglobinuria of this type, which might occur, for instance, in transfusion reactions or blackwater fever. Second, haemoglobinuria might occur in the presence of less severe intravascular haemolysis if for any reason the concentration of haptoglobin was much lower than usual.

For this reason it seemed worth testing the sera of patients with chronic haemoglobinuria for haptoglobins. Through the courtesy of Professor J. V. Dacie, Professor L. J. Witts, and Dr. Sheila Callender sera were obtained from four patients with paroxysmal nocturnal haemoglobinuria, one with paroxysmal cold haemoglobinuria, and two with acute cold haemoglobinuria.

Paroxysmal Nocturnal Haemoglobinuria

Paroxysmal nocturnal haemoglobinuria can be defined as a chronic haemolytic anaemia accompanied by attacks of haemoglobinuria occurring chiefly at night, associated with a characteristic defect in the erythrocytes. The abnormality of the erythrocytes is manifested by an increased susceptibility to haemolysis in acidified serum. This can be demonstrated conveniently by Ham's (1937) test. A description of the findings in four typical cases of paroxysmal nocturnal haemoglobinuria follows.

Case 1.—A female laundry worker, now aged 29, was admitted to the Radcliffe Infirmary, Oxford, in 1950, under the care of Professor L. J. Witts. She had a three-month history of lassitude, breathlessness on exertion, and increasing pallor. On examination she was strikingly pale, with a slight yellow tinge to the skin. There were no physical abnormalities; the liver and spleen were palpable. The erythrocyte count was 860,000 per c.mm., the haemoglobin level 3.0 g. per 100 ml., and the reticulocyte count 10%. The peripheral blood film showed only polychromasia, with slight macrocytosis and anisocytosis. The bone-marrow film showed erythroid hyperplasia. The direct antiglobulin (Coombs), Wassermann, and Kahn tests were negative. The urine at this time showed only increased urobilinogen. Vitamin B₁₂ and folic acid were given for a fortnight without response, and she was then slowly transfused with the packed cells from 9 pints (5.1 litres) of blood.

Following discharge from hospital, the patient was well for two months, after which she had a shivering attack with

pain in the loins. The urine passed in the early morning was almost black, but it was paler during the rest of the day. This continued for five days, after which she was readmitted to the Radcliffe Infirmary. The erythrocyte count had fallen to 2,300,000 per c.mm. and the haemoglobin to 7.5 g. per 100 ml. The reticulocyte count was 6.4%. The plasma bilirubin concentration was 2.2 mg. per 100 ml., and spectroscopic examination of the plasma showed the presence of methaemalbumin. The urine contained urobilinogen in excess of normal, together with oxyhaemoglobin and excess of normal, together with oxyhaemoglobin and excess of normal, together with oxyhaemoglobin. No cells were seen on microscopical examination of the urine. Ham's test produced gross haemolysis, but Donath and Landsteiner's test for cold haemolysis (see below) was negative. Paroxysmal nocturnal haemoglobinuria was diagnosed and the patient was transferred to the Postgraduate Medical School under Professor J. V. Dacie, who confirmed the laboratory findings and diagnosis.

During the past seven years the patient has had 12 relapses with similar symptoms and has been admitted to hospital for transfusion with packed erythrocytes.

A serum specimen was obtained from the patient when she was visiting the out-patient department during a period of remission, when she had had no attack for three months and was feeling well. The haemoglobin was 11.9 g. per 100 ml. and the reticulocyte count 0.6%. The serum obtained was coloured faintly red and was submitted to electrophoresis without added oxyhaemoglobin. The resulting pattern is shown in Fig. 3, A. There was no evidence of haemoglobin binding by haptoglobin. On staining with benzidine, distinct free oxyhaemoglobin and methaemalbumin bands were evident.

Case 2.—A 55-year-old storeman had a nine years' history of pallor and weakness, aggravated at intervals when there was haemoglobinuria and slight jaundice. The condition was diagnosed in 1951, the patient being admitted to the Radcliffe Infirmary under Professor Witts. Two days before admission he had an acute febrile episode with pallor, slight jaundice, and dark urine. On admission he was found to have an erythrocyte count of 3,740,000 per c.mm. The plasma contained 2.5 mg. of bilirubin per 100 ml., and also oxyhaemoglobin and methaemalbumin. Haemoglobin and moderate amounts of albumin were found in the urine. The serum contained no demonstrable haemolysins or agglutinins, a finding confirmed by Professor J. V. Dacie. The diagnosis was paroxysmal nocturnal haemoglobinuria, and the patient was transfused with the packed erythrocytes of 3½ pints (2 litres) of blood. On four subsequent occasions the patient was readmitted to hospital with similar symptoms and treated by transfusions with packed cells. On the last two attendances at the out-patient clinic, when he had been symptom-free for 9 and 11 months, respectively, blood specimens were collected. The haemoglobin at these visits was 13.0 and 13.4 g. per 100 ml. respectively, and the reticulocyte count 1% on the latter occasion. The sera were faintly red and were submitted to electrophoresis in starch gels without added haemoglobin. On both occasions the results were very similar to those shown in Case 1. The oxyhaemoglobin migrated in the free position, with no sign of a haptoglobin-haemoglobin complex, and dense methaemalbumin bands were present.

Case 3.—This is a case of severe nocturnal haemoglobinuria in a man now aged 51. The history is described by Dacie (1954) in his report of Case 32 on page 442. The serum was distinctly red and was found on electrophoresis to contain moderate amounts of free oxyhaemoglobin and methaemalbumin but no bound haemoglobin.

Case 4.—The history is given by Dacie (1954) in his description of Case 33 on page 442. It is that of a typical, moderately severe case of paroxysmal nocturnal haemoglobinuria of 17 years' duration in a single woman now aged 52. The serum was faintly red, and was found on electrophoresis to contain free oxyhaemoglobin and methaemalbumin only.

Case 5.—This patient, now aged 37, is described by Dacie (1954) as Case 35, on page 445. He had been treated for (aplastic ?) anaemia in childhood. In 1939 his blood was observed to undergo rapid spontaneous haemolysis, and this led to the discovery that his erythrocytes behaved *in vitro* in exactly the same way as paroxysmal nocturnal haemoglobinuria erythrocytes. However, he never had haemoglobinuria. Laboratory tests for the paroxysmal nocturnal haemoglobinuria abnormality were positive in 1942 but are now negative. The serum was clear, and 135 mg. of oxyhaemoglobin per 100 ml. was added before electrophoresis. All the haemoglobin was bound by haptoglobins, the pattern being typical of subjects belonging to group 1-2.

Paroxysmal Cold Haemoglobinuria

This is a haemolytic syndrome characterized by repeated episodes of haemoglobinuria following local or general exposure to cold. In 1904 Donath and Landsteiner showed that the haemoglobinuria is due to sudden intravascular haemolysis resulting from the action of a cold haemolysin present in the patient's blood. The haemolysin is absorbed by erythrocytes only at low temperatures, and haemolysis ensues when the cells are warmed and take up complement.

A description of the findings in a case of this type and in two cases in which there was a single episode of cold haemoglobinuria follows.

Case 6.—This is Case 3 of Ferriman, Dacie, Keele, and Fullerton (1951). The patient, a married woman aged 73, had chronic Raynaud's phenomena, haemolytic anaemia, and cold haemoglobinuria. High-titre cold haemolysins were present in her serum. Before electrophoresis 135 mg. of oxyhaemoglobin per 100 ml. was added to the serum. No binding of haemoglobin by haptoglobins was observed. The only haem-proteins present were free oxyhaemoglobin and methaemalbumin (Fig. 3, B).

Case 7.—The history is described by Dacie (1954) as Case 18, on page 288. The patient, a girl now aged 7, had two attacks of cold haemoglobinuria following measles. She was found to have in her serum a potent cold haemolysin of the Donath-Landsteiner type, which was active against normal erythrocytes as well as her own erythrocytes up to at least 25° C. The disappearance of the haemolysin over a period of three months coincided with her complete recovery, and there has been no recurrence of symptoms or abnormal laboratory findings. The serum specimen obtained was free from haemoglobin, and 100 mg. of oxyhaemoglobin per 100 ml. was added before starch gel electrophoresis. None of the haemoglobin was bound by haptoglobin, most of it migrating as free oxyhaemoglobin. A relatively small band of methaemalbumin was also present.

Case 8.—This is Dacie's (1954) Case 17, page 287. An 18-year-old soldier while undergoing military training in very cold conditions passed a specimen of urine which was dark red in colour. The haemoglobinuria lasted for about half the next day. He had never had this symptom before, nor has there been any recurrence. One month after this episode Dacie demonstrated the presence of a cold haemolysin of the Donath-Landsteiner type in the patient's serum; its activity *in vitro* slowly declined, but the antibody was still present three and a half years after the initial and only attack of haemoglobinuria. A recent specimen of serum contained no visible haemoglobin, and 100 mg. of oxyhaemoglobin per 100 ml. was added before electrophoresis. All the haemoglobin was present in the form of a complex with haptoglobin, the pattern being typical of that in subjects belonging to group 1-2.

Serum specimens from two other patients with haemolytic anaemias and high-titre cold haemolysins, but with no history of haemoglobinuria, were analysed. Both contained haptoglobins, the one belonging to group 1-2 and the other to group 2-2.

March Haemoglobinuria

A third recognized type of haemoglobinuria, march haemoglobinuria, is observed in a small proportion of subjects after severe exercise—for example, route marches or marathon races. The serum of one subject with this syndrome was available for analysis.

Case 9.—This subject, seen through the courtesy of Drs. R. G. Macfarlane and M. Shields, of Radcliffe Infirmary, Oxford, was a 22-year-old undergraduate. He was well until two years ago, when after running five miles in a marathon race he developed lower abdominal pain and nausea. A specimen of urine passed shortly afterwards was bright orange-red. These symptoms have recurred on two subsequent occasions. He can play ordinary games without difficulty.

No physical abnormalities were found on examination. The haemoglobin was 16 g. per 100 ml. and the white-cell count 5,700 per 100 ml. The blood film was normal, without increased polychromasia. The erythrocyte sedimentation rate (Westergren) was 6 mm. per hour. A specimen of serum was free from haemoglobin. The patient returned to the laboratory after running five miles. He had lower abdominal pain and nausea, and passed a specimen of urine distinctly red in colour. The characteristic absorption bands of oxyhaemoglobin at 540 and 570 m μ were found, and the benzidine test was strongly positive. The urine contained 300 mg. of protein per 100 ml. and only occasional red and white cells and hyaline casts. A second specimen of serum removed at this time was coloured distinctly red, and on electrophoresis showed an unusual pattern. Small bands of combined haemoglobin were present in the slow α_2 and β positions, and a third band of free oxyhaemoglobin was present between the two. A similar picture was obtained when 50 mg. of oxyhaemoglobin per 100 ml. was added to the specimen of serum obtained before exercise. When 100 mg. of oxyhaemoglobin was added to this serum a similar pattern was obtained but the band of uncombined haemoglobin was intensified and a distinct methaemalbumin band was observed. It can therefore be concluded that the haptoglobins in this subject are unusual in that only a single $\alpha\beta$ is present along with a small fast α_2 component, and that both can combine with less than 50 mg. of oxyhaemoglobin per 100 ml. as compared with the usual value of 120 mg. or more.

Comment

Thus in all four patients with paroxysmal nocturnal haemoglobinuria studied, and two of the three patients with cold haemoglobinuria, the haptoglobins were absent or present only in quantities too small to be detected. In the single case of march haemoglobinuria studied the haptoglobin concentration was less than half the normal value. It is inferred that the susceptibility of these subjects to haemoglobinuria may be related to the low level of haptoglobins in the plasma, which would be expected to reduce the "renal threshold" for haemoglobin.

There are two obvious explanations for the low level of the haptoglobins in these subjects: first, that the rate of formation or liberation into plasma is markedly reduced, for genetic or other reasons; or second, that because of continuous intravascular haemolysis the haptoglobins combine with oxyhaemoglobin as soon as they are released into the plasma and are then rapidly removed, so that their concentration at any time is low. It is not possible to decide between these alternatives on the available evidence. In paroxysmal nocturnal haemoglobinuria the well-known defect in the erythrocytes would seem to be the primary abnormality, and the low plasma haptoglobin level may be secondary. To suppose that a coincidence of defective erythrocytes and congenital absence of haptoglobins is required for full development of the haemoglobinuric syndrome does not seem to be an economical hypothesis. However, this is not impossible, since cases are known—for example, Case 5—in which the typical erythrocyte defect

was present without haemoglobinuria and in which the haptoglobin level was high when tested later.

In cold haemoglobinuria low plasma haptoglobin may be one of the primary aetiological factors. Many subjects show haemolysis both *in vivo* and *in vitro* in the presence of cold antibodies in high titre without any signs of haemoglobinuria (Dacie, 1954). In the two such subjects tested by us haptoglobins were present, as they were in two subjects with severe acquired haemolytic anaemias with warm antibodies. Haemoglobinuria might be expected when the intravascular haemolysis was so severe that enough oxyhaemoglobin would be released to exceed the combining power of the haptoglobins, as in the single episode of haemoglobinuria in Case 9, whose serum was later shown to have normal haptoglobins. Less severe intravascular haemolysis would produce haemoglobinuria if the haptoglobin level was already low. This may be the explanation of the absence of haptoglobins in Case 7 long after the patient ceased to show signs of intravascular haemolysis. A similar mechanism presumably operates in march haemoglobinuria. After severe exercise some subjects show well-marked haemoglobinuria (Gilligan, Altschule, and Katersky, 1943). Haemoglobinuria might occur in a small proportion of these if the concentration of liberated oxyhaemoglobin in the blood rose above the normal combining power of the haptoglobins or if the concentration of haptoglobin in the plasma was originally low, as in Case 9.

These observations provide a clue to the physiological and genetical significance of the haptoglobins. For the binding of haemoglobin in the plasma prevents the loss of this substance from the body through the kidneys and must play a part in iron retention, upon which the critical iron balance depends.

Summary

Proteins (haptoglobins) exist in human plasma that combine specifically with oxyhaemoglobin when the concentration of the latter is up to about 135 mg. per 100 ml. Four distinct haptoglobins, occurring in three common and a number of rare combinations, have been distinguished by electrophoretic analysis by previous workers and the authors.

The complex of oxyhaemoglobin with haptoglobin is relatively stable. When the concentration of oxyhaemoglobin in serum or plasma exceeds the combining power of the haptoglobins, however, the uncombined oxyhaemoglobin is rapidly broken down, with the formation of methaemalbumin.

The haptohaemoglobin complex probably does not pass into the glomerular filtrate, which free oxyhaemoglobin does readily. Hence haemoglobinuria is observed only when the level of oxyhaemoglobin in the plasma exceeds the combining power of the haptoglobins. In the sera of four cases of paroxysmal nocturnal haemoglobinuria and two out of three cases of cold haemoglobinuria studied, no haptoglobins could be demonstrated. In one case of march haemoglobinuria the concentration of haptoglobin was considerably below half the normal value. It is concluded that the susceptibility of these subjects to haemoglobinuria is related to the low level or absence of haptoglobins in the plasma.

Specimens of serum from patients with haemoglobinuria and haemolytic anaemia were obtained through the courtesy of Professor J. V. Dacie, of the Postgraduate Medical School, London, and Professor L. J. Witts, Dr. S. Callender, Dr. R. G. Macfarlane, and Dr. M. Shields, of the Radcliffe Infirmary, Oxford. We are indebted to Professor H. A. Krebs, Professor Dacie, and Dr. Macfarlane for reading and commenting on the typescript of this paper.

ADDENDUM.—After this paper was submitted for publication a paper by C. B. Laurell and M. Nyman has appeared

(*Blood*, 1957, 12, 493) suggesting that haptoglobins determine the renal threshold for haemoglobin. However, no observations were made on patients with haemoglobinurias.

SOME PAEDIATRIC PROBLEMS OF
UGANDA

BY

JOSEPH LUDER, M.D., M.R.C.P., D.C.H.
Senior Registrar, the Hospital for Sick Children,
Great Ormond Street, London, seconded to Uganda
Medical Service, 1954-6

This paper deals specifically with problems of paediatrics that were met with during my experience in Uganda from 1954 to 1956 as the first liaison registrar to go there from Great Ormond Street. Many of these problems, however, are common to other parts of the tropics and subtropics. It is often overlooked that a majority of the children in the world are living in these underdeveloped regions, and that the bulk of the childhood mortality and morbidity is occurring there.

Whilst the diseases of temperate climates are largely present, indeed in florid form, many of the problems are conditioned by different genetic backgrounds, environments, food habits, customs, superstitions, and disease vectors, and the result is not merely a number of unfamiliar "tropical" diseases, but a pattern of child life, health, and disease which differs greatly from that of temperate areas. The whole subject of tropical paediatrics has been largely neglected in medical practice and teaching in these regions and even more so in the advanced countries. It is with the object of casting some light upon these problems that this paper is presented.

Background

Uganda is a somewhat under-populated country taken as a whole, supporting some five million people. With

a good average rainfall and mainly fertile soil, it could undoubtedly support far more. Sir Harry Johnston as early as 1900 considered twenty millions as a reasonable figure. The effects of disease and deprivation, however, have kept the population static, and until recently it was declining, owing to the combined effects of relative infertility and premature adult death.

There are some ten major tribes and many smaller ones, but from their way of life they can be divided into two main groups—those living mainly by settled cultivation of plantains (non-sweet bananas), cassava (tapioca), sweet potato, millet, and maize, and those living off their herds of cattle, of which the blood and milk are taken but rarely the meat. The agricultural peoples have a largely carbohydrate diet, with little protein and fat, and protein malnutrition is rife. The herdsmen have the protein at hand, but the children may still suffer through ignorance. In many areas cash incomes are very low, and there is a large population of immigrants from Ruanda-Urundi working for very low wages, so that very few Africans can afford to buy foods such as meat or milk.

Numerous customs, superstitions, and taboos exist in these peoples, many of them connected with ill-health. The subject must be approached with caution, since, as Jelliffe (1955) emphasizes, not all are harmful, and some may be beneficial, as, for instance, the widespread practice of prolonged breast-feeding in many parts of the tropics where cow's milk is not available. Others, however, such as female circumcision and many native remedies, are harmful. Medical practice is hampered by the great suspicion of blood transfusion and of taking blood samples.

Vital statistics are most unreliable owing to lack of trained personnel, inaccessibility of dwelling-places, lack of proper machinery, concealment of information, etc. The proportion of children is undoubtedly much higher than in more advanced countries because of the greatly reduced expectation of life. The infant mortality figure can only be guessed at, but most observers think it is well over 100 per 1,000 live births, and may reach 300 in places. Furthermore, the infant mortality does not give a good indication of the total child wastage, as many deaths occur in the early years of childhood. The main causes of child death are malnutrition of all forms, malaria, respiratory disease, gastro-enteritis, and sickle-cell anaemia. There is often a fatalistic acceptance of death in childhood which militates against cases being brought early for advice. It is probable that half the children die before reaching adolescence.

Medical Services

When the Uganda Medical Service was instituted the two major diseases to be faced appeared to be syphilis and sleeping sickness. The first proved to be less formidable than expected, but trypanosomiasis caused vast epidemics around Lake Victoria some fifty years ago, and a major achievement has been its reduction to the occasional clinical curiosity or diagnostic puzzle. Pathological services have been largely conditioned by the prevalent diseases, malaria and helminthiasis, except in the main centres.

The majority of sick persons, adult and children, are seen first or entirely by African personnel called medical assistants who have done a three-year course in elementary medicine and nursing. Some of these invaluable persons are in sole charge of rural dispensaries with up to 30 or 40 in-patient beds, with only monthly visits by a doctor.

Paediatrics has been virtually non-existent outside the main hospital, Mulago Hospital. Welfare clinics are in their infancy and there is no distribution of welfare foods, apart from cheap dried skimmed milk at a few centres. The medical budget has been about £1½ million for a population of five millions, which contrasts with almost £700 million for Great Britain with fifty million people—that is, about one-fiftieth.

Problems of Diagnosis

Histories, when obtained through possibly three interpreters, must be approached with caution. Pain in the abdomen, chest, and head are prominent symptoms at all ages. Questions must be leading, and answers often vague, especially as to time. The recognized intervals, days, weeks, and months, deeply impressed on the English mind, become a continuous blur in that of the African, who seldom thinks back more than a few weeks. Ages are rarely known. In the first year the "standard deviation" may be four months, in the first five years it may be two years, and after that it rises progressively.

Pigmentation of the skin is less of a barrier to diagnosis than might be imagined. Most rashes can soon be distinguished, though measles may be difficult at first, and scarlet fever would probably elude the eye. The normal vascularity of the cheeks and hands adds to the depth of colour of the pigmented skin, so that anaemia of any severity can be detected by a lighter muddy tint. For confirmation there are always the conjunctivae, insides of the lips, tongue, and palms. Jaundice is apt to be confused with areas of subconjunctival fat which are prominent in the African eye, and cyanosis can be very difficult to recognize, since the best areas for seeing it, the lips, ears, and nails, are slightly pigmented and tend to mask it. A reliable form of oximetry would be very valuable in Africa.

Multiple diagnoses are the rule rather than the exception; a typical "syndrome" might be kwashiorkor, hookworm, malaria, and sickle-cell trait. A number of tropical diseases are encountered and must be recognized, such as onchocerciasis, the protean lesions of leprosy, localized yaws, the "ground-itch" skin lesions of ankylostomiasis, the appearance of scabies when chronically infected, the skull and bone lesions of sickle-cell anaemia, and many others. Consideration of these, however, must not lead to the neglect of the "temperate" diseases, which are largely represented, often in florid form.

Investigations and Treatment

Facilities are few outside the main centres. Whilst many tests, such as the search for malarial parasites, *Treponema recurrentis*, or trypanosomes in the blood, are accurately done, others, such as most biochemical tests, are open to suspicion. Practice in the tropics thus engenders the habit of economy in laboratory requests, of healthy suspicion of the results offered, and of discrimination in what is asked for in a particular hospital. The idea of necropsies is abhorrent to many African minds, and permission for necropsies on children is rarely given. This greatly impedes the advance in medical knowledge in the tropics.

Where there is a shortage of most drugs, the cheapest effective drugs, minimum effective dose, and length of course all have to be considered. Unnecessary multiple therapy is avoided. For out-patient use the great need is for effective one-dose therapy because of the difficulty of follow-up or return visits. Very long-acting penicillins find their main use here in infective conditions, and one dose of 400 mg. of chloroquine base will cure many mild degrees of malarial parasitaemia in the partially immune child.

Intravenous therapy offers special problems of its own, as pyrogen reactions are frequent, and the quantities infused are often vaguely reported. Blood transfusion is the object of much suspicion and superstitious fear, though this is slowly being overcome. Blood is mainly obtained from relatives of transfused persons, from the staffs and students of schools, or from the police. Pyrogen reactions can often

closely resemble an incompatible blood reaction, and the decision to continue or not is often very difficult. The transference of malaria by transfused blood occurs occasionally, but is not a very serious matter. I have also seen a *Staphylococcus albus* septicaemia occur in this way, and other diseases such as syphilis, relapsing fever, trypanosomiasis, filariasis, etc., could be, and probably are, sometimes transferred by fresh blood transfusions.

The Neonates

Labour among the more primitive African tribes is not always as easy as might be supposed. In some Uganda tribes, for example, the women tend to have small pelves; this seems to be a racial characteristic and results in a relatively high proportion of obstructed labour, ruptured uterus, and caesarean sections. There is correspondingly a higher stillbirth rate, though figures are not available. Birth weights are significantly lower than in more advanced countries, particularly among the poorer strata of the population, suggesting that maternal malnutrition may be a factor (Jelliffe, 1952a).

The incidence of prematurity probably differs little from that elsewhere—maternal infections, anaemia, and obstetric abnormalities being important causes. Toxaemia of pregnancy is, however, virtually unknown. Weight for weight the African premature baby seems more vigorous than its European counterpart, and often feeds surprisingly well, even sucking the breast when still well under 4 lb. (1,800 g.).

Neonatal infections occur in both the premature and the full-term infant, particularly pneumonia and umbilical sepsis, though the penicillin-resistant staphylococcus is not in evidence. The incidence is probably related largely to the environmental circumstances. Icterus gravis is extremely rare in Africans, whether due to rhesus or ABO isoimmunization. In South Africans, Zoutendyk (1947) has shown that some 5% of Bantu are rhesus-negative, and it is probable that this figure holds good for Uganda. Other neonatal conditions that are rarely seen are haemorrhagic disease and pyloric stenosis, though it must be admitted that conditions in most tropical clinics are not conducive to the palpation of a pyloric tumour. I have in fact described a typical case in an African child (Luder, 1956).

Infant Feeding

In most tropical regions, breast-feeding is the only available method of rearing infants, and in the vast majority of cases it is successful. Necessity is a powerful stimulus to success. Such breast complications as cracked or inverted nipples are rarely seen, for which the lack of tight brassières is probably to be thanked. Nor is breast engorgement or infection at all common. The milk often comes in at about the third day, by which time the mother is likely to be up and away. It is well known that breast-feeding may be continued for long periods—for example, two years or more—unless interrupted by another pregnancy. The further from civilization the longer the period as a rule. The advantages of prolonged breast-feeding are, firstly, that it provides some protein, however little, to supplement the largely non-protein weaning diet, and, in some areas at least, sexual continence is the rule during lactation, thus forming a natural birth-control method. On the other hand, there is no doubt that the quantity often falls away after the first year (Jelliffe, 1952a), so that the breast then provides little but comfort. It may be actually harmful if it seems to exclude cow's milk, and should then be discouraged. Feeds are, of course, entirely on "demand," a feasible method where the infant accompanies the mother everywhere. In older infants it seems that a "demand habit" can be set up so that short feeds are loudly and frequently cried for, and the result in a hospital ward is often more noise rather than less.

Where breast-feeding is not possible—for example, owing to the death or flight of the mother—the infant's chances

of survival are slender unless another woman can be found to wet-nurse it. There is sometimes prejudice against this, but practice varies. Away from the towns, cow's milk is often not obtainable or is very expensive, and facilities for artificial feeding are very poor; death from marasmus or gastro-enteritis follows. It is remarkable how even a small dose of civilization powerfully affects the incidence and success of breast-feeding. In and near Kampala, where dried milks were advertised and cow's milk could be bought, artificial feeding has become something of a desideratum, and breast-feeding often fails, probably because of the subconscious knowledge that an alternative is available. Artificial feeding is, however, often deplorable, feeds being small, dilute, infrequent, and infected. In these circumstances it is extremely difficult to decide whether it is best to educate mothers more widely in how to carry out artificial feeding properly, thus saving some infant lives, but inevitably striking a further blow at breast-feeding, or to leave mothers in ignorance about artificial feeding in the hope of preventing the decline of breast-feeding.

Malnutrition

Three main types of malnutrition can be distinguished, though there is, of course, considerable overlap. These are marasmus, kwashiorkor, and vitamin deficiencies.

Marasmus.—This may operate from the early weeks of life, mainly in the artificially fed infant who is given a grossly insufficient or dilute feed. It is curious how the bottle-fed baby may only be fed three times a day, while the breast-fed baby may be fed three times in an hour. The result is a total calorie deficiency, giving the well-known picture of gross wasting, absence of subcutaneous fat, alertness, hunger, "starvation" stools, and a great deal of screaming in the early stages. Treatment is often more difficult than would appear at first. Although these babies take feeds avidly, those that have barely exceeded their birth weight by 6 months of age or more, a frequent occurrence, seem to have passed a "point of no return." No matter how large the calorie intake, many will not gain weight significantly, and frequently die, after a long battle, of a secondary infection. Although the stools usually look outwardly normal, further research is clearly needed into possible failure of absorption.

Kwashiorkor (Fig. 1).—This is one of the most widespread nutritional diseases in the world, though it is not at all certain that more children do not die of simple calorie

deficiency, or marasmus. Kwashiorkor is typically seen after about 9 months of age, and in Uganda important factors in the causation are sudden weaning from breast milk on to an almost entirely carbohydrate diet, and maternal deprivation when the child is then "boarded out" with a grandmother. These points are well described by Welbourn (1955). A full description of the condition is provided by Trowell, Davies, and Dean (1954). There is no doubt that certain cases may have marasmic features also, and may be complicated by infections, worm infestations, malaria, etc., which may all be "silent" and easily overlooked. Cancrum oris forms an infrequent but most dangerous complication (Jelliffe, 1952b) (Fig. 2).

A great deal remains to be discovered concerning the eventual prognosis regarding weight and height, relapses, permanent liver damage, degree of pancreatic recovery, cause of sudden death, and many other problems. Blankhart (1953) thinks that kwashiorkor often results in cirrhosis of the liver (Fig. 3), as an end-result of the fatty infiltration in the acute stage. Some of the sudden deaths are due to unsuspected bronchopneumonia, but many remain a mystery. Suprarenal deficiency may explain some. I have seen two cases of collapse in kwashiorkor with low blood pressure, tachycardia, low serum sodium level, and high serum potassium level, which responded to treatment with deoxycortone acetate. It is well recognized that the suprarenals show atrophic changes (Trowell *et al.*, 1954).

Vitamin Deficiencies.—Few overt vitamin deficiencies were seen in Uganda. The commonest was xerophthalmia, which is encountered mainly in the poorest sections of the people, more often in adults and older children. Only three cases of rickets were seen—in children aged 1, 4, and 6 years. The latter two responded rapidly to vitamin-D treatment, and must therefore have been cases of vitamin-D deficiency, presumably of long standing. Scurvy is prevented by the commendable habit of feeding mashed paw-paws to babies from the early months. Much argument has raged over whether the dermatosis of kwashiorkor is pellagrous in type; but in Uganda this seems unlikely, as healing was rapid without extra doses of nicotinic acid.

Malaria

In a hyperendemic zone such as much of Uganda the severest effects of malaria fall upon young children, of whom the great majority have had repeated infections before the first birthday. Since malaria is continuous in hyper-

FIG. 1.—Kwashiorkor showing oedema and severe skin changes.

FIG. 2.—Cancrum oris in a child with kwashiorkor.

FIG. 3.—Cirrhosis of liver with gross ascites.

endemic zones, immunity is not allowed to wane as it does in areas of seasonal incidence, and therefore affords considerable protection in older children and adults, in whom clinical attacks are uncommon and usually mild. Any loss of immunity—for example, through temporary absence—can be serious.

Death in young children is due to cerebral malaria or malarial anaemia. Both are emergencies, as the latter may be rapidly progressive. Cerebral malaria is probably best treated with intramuscular chloroquine (1–2 ml.). Sequelae seem to be extremely uncommon, though long-term studies are naturally lacking. Intramuscular mepacrine, however, is very toxic and may cause death or cerebral damage. In acute malarial anaemia, drug treatment is followed by a further dangerous fall in haemoglobin levels, so that blood transfusion should precede it.

In a hyperendemic zone malaria prophylaxis on a wide scale is fraught with the grave danger that anything short of complete success will make matters much worse by interrupting slowly acquired immunity, and it is difficult to foresee any practicable scheme for the indigenous population in the near future. There may be a case, however, for attempting prophylaxis in children under 2, though the practical difficulties would still be enormous.

Helminth Infestations

Hookworm has a very wide distribution over the tropics and subtropics, and is a major public health problem, albeit a relatively tractable one.

Several interesting problems arise in connexion with hookworm anaemia. Since it is very slow in developing, extremely low haemoglobin levels can be endured—for example, below 20%. There is little doubt that the degree

FIG. 4.—Severe anaemia and oedema due to hookworm infestation.

of anaemia is not proportional to the worm load, and that oedema is out of proportion to the anaemia (Fig. 4). Protein loss in an already albumin-deficient child is presumably a factor. Severe melaena has been seen in a few patients, two of whom had low prothrombin levels, though whether this was a result of chronic liver disease or a possible toxic product of the ankylostoma is not known. Treatment is often very difficult. Blood transfusion may be poorly tolerated because of the fatty state of the heart, and the value of anthelmintics is limited by their toxicity. The most widely used for ankylostomiasis are still tetrachlorethylene and oil of chenopodium, but the most that can be achieved as a rule is a considerable reduction of the worm load by three or four treatments. I saw several cases of aplastic anaemia which were probably due to these anthelmintics. Clearly the problem is one that must be solved by prevention and not by mass treatment.

Onchocerciasis is another helminthic infection of considerable importance. This disease, caused by *Onchocerca volvulus*, is transmitted by the biting fly *Simulium damnosum*, which does not belie its name. The main effects are skin irritation due to numerous microfilariae in the deeper layers, leading to dryness, wrinkling and atrophy, unsightly

swellings, and blindness. Fortunately, the disease is relatively localized, and progress has been made in eliminating the insect vector.

Other helminths are much less serious. Roundworm can occasionally be responsible for a curious intestinal "toxaemia," with pain, poor appetite, and vomiting. Occasional cases of intestinal obstruction due to a mass of worms are also met with.

Specific Fevers

Of the specific fevers, measles, whooping-cough, diphtheria, mumps, chicken-pox, and smallpox all occur, the first two being extremely common and diphtheria relatively so. One doubtful case of scarlet fever was seen, and this must be very rare. Others, such as rubella and roseola infantum, are probably missed.

The specific fevers present special problems in the tropics. They are often more severe than in temperate zones, with a high incidence of complications, especially bronchopneumonia, a cause of heavy mortality. Isolation facilities barely exist, and only too often cases have to be sent home, to infect others. Whooping-cough immunization would save many lives, though it must be recognized that the endemicity of poliomyelitis would be a danger.

Other Infections

Typhoid.—This is endemic in all areas, and should be thought of first in all cases of "P.U.O." The response to chloramphenicol is extremely good, and I did not see a death out of possibly 25–30 cases. One of these was that of a grossly wasted girl of about 8, found in a hut starving and weighing only 28 lb. (12.7 kg.). Soon after admission her temperature rose and typhoid was confirmed, but she made as rapid and full a recovery as a well-nourished child.

Diarrhoea and Vomiting.—Diarrhoea in the tropics, with or without vomiting, is a somewhat different disease from that seen in temperate areas. It is usually a fairly sudden and short-lived illness, with a much shorter course and fewer sequelae than temperate "infantile gastro-enteritis." In Uganda, at any rate, bacterial causes probably account for half the cases, the commonest organism being *Shigella flexneri*. The atypical *E. coli* is a very uncommon cause (Wilson and Luder, 1957). The presence of pus cells in a fresh stool is a good indication of a lower intestinal infection, and a return to this simple procedure may be valuable even in non-tropical countries. Severe malaria can cause diarrhoea and vomiting, and parenteral infections cause a smaller proportion than in temperate areas. Diarrhoea of all types differs greatly in severity in different tropical countries. Mortality from bacillary dysentery is appreciable in Kenya but very low in Uganda, and much less diarrhoea is seen in kwashiorkor cases in Uganda than in South Africa, Central America, Jamaica, etc. It may be that the cooked banana, which forms the staple diet in Uganda, is "antidiarrhoeal" as compared with maize or rice, and thus resembles the cooked apple, long known for its value in gastro-enteritis.

Meningitis.—The main forms of meningitis seen were influenza and pneumococcal, the former being the commoner. Both types were treated with oral chloramphenicol in large doses—that is, 75 mg./lb./day (165 mg./kg./day) for at least two weeks. This is accepted treatment for the influenza type, but not generally so for the pneumococcal. It was given a trial after disappointing results with intrathecal and intramuscular penicillin and sulphonamides, and the results improved considerably. One child who had been in coma for a week in spite of combined penicillin therapy made a full recovery with chloramphenicol. Thereafter the majority of the cases recovered without sequelae. Meningococcal meningitis is very rare in Uganda, but is commoner in drier parts of Africa.

Congenital Syphilis.—The incidence of this disease has probably been exaggerated in the past. All the cases seen presented with tender swellings of the forearm or lower leg due to osteitis, sometimes with dactylitis of hands and feet

(Fig. 5). The babies were in general well nourished and fit, and the swellings subsided with a short intensive course of penicillin. Follow-up unfortunately was not possible.

Tetanus.—This is seen at all ages, though neonatal cases are fortunately not common. The mortality is still 50–60% in spite of advances in treatment. Prolonged sedation gives disappointing results, as spasms seem to return unless the

FIG. 5.—Dactylitis due to congenital syphilis.

patient is maintained virtually in an unconscious state, which has its own obvious dangers. Some severe cases were treated with intramuscular gallamine triethiodide, with artificial positive-pressure respiration carried out via a tracheotomy, using a cuffed tube, and promising results were obtained.

Poliomyelitis.—Acute poliomyelitis presents a picture in the tropics similar to that seen many years ago in more advanced countries. The main incidence is in infants and young children, in whom the disease occurs in endemic form. Epidemics are rare and small. The mortality is low, though the sum total of paralysis is high and distressing. New-comers to the tropics from countries of high sanitary standards are thus in a peculiarly susceptible state and may contract severe or fatal attacks. As living standards slowly improve, there is a danger that the indigenous populations may go through periods of severe epidemicity, occurring at gradually higher ages, unless the gap can be bridged by widespread immunization.

Mental Deficiency.—It is impossible to give a reliable estimate of the incidence of mental deficiency in Uganda. Though in a two-years stay most of the common types were met with, including microcephaly, mongolism, simple primary amentia, those associated with cerebral palsy, etc. For many reasons mental defect is not a noticeable problem in tropical countries. Many mild degrees are unrecognized, and are compatible with a useful life in an unsophisticated community. Low-grade defectives are kept within the family circle, but probably suffer a heavy mortality in conditions of competition with normal children—for example, for food. Defectives are rarely seen in the few mental hospitals in tropical Africa. It is probable that in some backward tribes these children are neglected or abandoned. The real problem will come in the future when more of these children survive, tribal community feeling diminishes, and their care becomes a State responsibility, out of limited resources.

FIG. 6.—Skull bossing due to sickle-cell anaemia.

Anaemia.—A low haemoglobin is almost universal among the population of all ages. The common causes are well known, and are well described by Trowell (1956).

These are malaria, helminthiasis, especially hookworm, and malnutrition. In children, sickle-cell anaemia must be considered (Fig. 6), and in certain areas of the tropics schistosomiasis, sprue, and kala-azar are important.

The anaemias of malnutrition include iron-deficiency, nutritional megaloblastic, calorie-deficiency, and protein malnutrition types, of which the last is the most baffling and most resistant to treatment. It is seen in young children with kwashiorkor and in pregnant and lactating mothers when protein requirements may outstrip supply (Woodruff, 1955). It is typically of moderate severity, and the cells are broad and flat, with increased diameters, normal cell volumes, and slightly reduced haemoglobin concentration. There is a moderate reticulocytosis reflecting a hyperactive and slightly megaloblastic bone marrow (Trowell, 1956), but none of the accepted signs of haemolysis is present. There is no response to iron, liver, vitamin B₁₂, folic acid, vitamin C, or other "haematinics," and only a slight rise may occur after months of protein feeding. The effect of blood transfusion is variable. The rise of haemoglobin may be held, but in some cases the level falls again slowly or rapidly. In a few cases the level falls again to its previous low level within one week without any signs of haemolysis, but with some enlargement of the spleen. It seems possible that there is a true "hypersplenism" in these cases, and a syndrome of moderate anaemia of similar haematological type with gross splenomegaly is seen in older children and adults. It is difficult to avoid speculating that in these anaemias there is a deficiency of an unknown factor.

Geographical Paediatrics

A study of the global distribution of disease forms one of the more fascinating and growing by-ways of medicine. In many conditions, especially those forming the classical "tropical diseases," the reasons for this differential distribution are not too obscure. These include those dependent on localized vectors (trypanosomiasis, bilharziasis, malaria); those dependent on different environmental backgrounds (malnutrition, brucellosis, scabies, diseases of heat or cold); and those dependent on genetic differences (haemoglobinopathies, rhesus disease). Even in these groups all is not fully clear; thus malaria does not occur in all the areas where its vectors are to be found, and even if introduced—for example, by immigration—does not necessarily flourish.

It is, however, the great mass of other unexplained observations that provide the greatest interest. Only a few can be mentioned here, apart from those considered earlier. Pathogenic bacteria seem to behave in a somewhat different way in the tropics. One of the commoner staphylococcal lesions is pyomyositis, a condition in which multiple muscle abscesses arise consecutively in any muscle over a period of many weeks, yet no pyaemic metastasis occurs to internal organs. The haemolytic streptococcus, though present, is relatively avirulent. Tonsillitis and rheumatic fever are rare, and acute nephritis is extremely rare. In this connexion it might be added that nephritis in children is almost entirely nephrotic in type, largely due to amyloidosis of the kidney, though not of other organs. The almost universally high gamma-globulin levels due to malaria may explain this. Pneumococcal diseases are acute and severe, and include meningitis, peritonitis, pericarditis, and occasionally osteomyelitis.

Malignant disease in children is much less often seen than in more advanced countries. This can only partly be due to an increased death rate from more acute causes, since the types of malignant disease seen are different. Acute leukaemia was not seen in a Uganda African child, but is seen in Indian children in the same areas, and retinoblastoma seems to be commoner than neuroblastoma. No reticulososes have been diagnosed. The name "Kaposi" indicates, not a varicelliform eruption, but a curious spreading tumour of blood vessels of subcutaneous tissue, eventually becoming highly malignant. In adults these tumours far outnumber tumours of the stomach, colon, rectum, lung, and brain combined.

"Silent" and puzzling cases of heart failure have been ascribed to endomyocardial fibrosis (Ball, Williams, and Davies, 1954), a condition almost confined to tropical Africa. This takes the place of coronary disease as the prime cause of cardiac death in adults, and the aetiology is quite unknown.

The distribution of coeliac disease and fibrocystic disease provides some unsolved puzzles. Coeliac disease is said not to occur in parts of the world where wheat is not a regular item of diet (Sheldon, 1955). In Uganda, however, bread is eaten occasionally in large parts of the country, but one wonders how the disease would be recognized when fat is virtually absent from the diet. Possibly some cases are being missed. The diagnosis of fibrocystic disease is made difficult because the pancreatic enzymes are absent in acute kwashiorkor and slowly return with improvement. One possible case was seen but could not be followed up.

These few scattered examples can only hint at a subject of great importance and interest, the study of which will undoubtedly provide valuable clues to the aetiology of disease, both temperate and tropical.

Summary

An attempt has been made to describe some common and urgent tropical paediatric problems as they were encountered during a two-year attachment to the Uganda Medical Service, together with some of the ethnographical, economic, and human background. Even for this very limited purpose, two years is but a fleeting acquaintance, and there will undoubtedly be omissions and distortions.

Infant mortality is very high and there is a high death rate throughout childhood, the main causes being malnutrition, malaria, respiratory disease, gastro-enteritis, helminthiasis, and sickle-cell anaemia. Medical work is hampered largely by financial stringency, and to a less extent by superstition and suspicion on the part of patients.

The conception of a tropical branch of paediatrics is justified by the different pattern of child life and disease, both temperate and specifically tropical, and the subject has received little prominence in medical teaching, considering the huge child populations of the tropics and subtropics.

A study of the differential geographical distribution of disease will undoubtedly throw much light upon aetiology, and is worthy of greater effort.

It is a pleasure to express my thanks to the Board of Governors of the Hospital for Sick Children, Great Ormond Street, for having made possible the experience underlying this paper. I wish also to thank Dr. Hugh Trowell for his constant help and encouragement in Uganda, and Professor Alan Moncrieff and Dr. Wilfrid Sheldon, who kindly offered comments on and criticisms of this paper.

THE NATURAL HISTORY OF POLYARTERITIS*

BY

GEOFFREY A. ROSE,† B.M., M.R.C.P.

Senior Medical Registrar, St. Mary's Hospital and
Paddington General Hospital, London

In 1952 the Collagen Diseases and Hypersensitivity Panel of the Medical Research Council began a clinical trial of cortisone in polyarteritis nodosa. It was clearly unjustifiable to have concurrent untreated controls, and so some form of retrospective control was necessary. Cases reported in the literature are unsuitable because they are a selected group and are often inadequately followed up. It was thus necessary to collect a new body of data from an unselected and consecutive series of cases studied specially for this purpose. Such a study presented an opportunity not only to learn the prognosis and duration of the disease but also to make a comprehensive survey of its natural history and pathology. Some of the special aspects of this investigation have been reported already (Rose, 1956, 1957; Rose and Spencer, 1957); in the present paper the whole of the results are presented in summary form. The complete report and the case histories are lodged with the Medical Research Council, from whom a copy may be borrowed on request.

The survey was based on all histologically proved cases of polyarteritis under care at nine teaching centres during the period 1946 to mid-1953; 111 cases were obtained. Of these, 90 were located from diagnostic indices, and the remaining 21 by a search of all the necropsy reports (and sometimes the sections also) for the period in question. In any possible cases of polyarteritis all the available sections were studied by one or other member of the panel of pathologists set up for this purpose by the Medical Research Council.† Doubtful cases were seen by the whole panel. Full reports were provided on all approved cases, and these form the basis of the histological analysis in the present report. The panel did not, however, take responsibility for the analysis.

There was evidence that the number of cases diagnosed was tending to increase during the period of the survey, particularly among the elderly. This may well have represented a true increase in the incidence of the disease; but the limitations of a retrospective survey prevent any firm conclusions. Unfortunately no trend was apparent towards either earlier diagnosis or more frequent ante-mortem diagnosis.

Classification

In a preliminary survey of data it appeared that some classification might usefully be based on the presence or absence of pulmonary involvement. Unfortunately adequate histological material from the lungs was not always available, and the assignment of patients to one or other group was therefore based in addition on other features which were

*A summary of a report to the Collagen Diseases and Hypersensitivity Panel of the Medical Research Council.

†A Research Fellow of the Medical Research Council at the time of this investigation.

‡Professor G. Payling Wright (chairman), Professor C. V. Harrison, Dr. A. H. T. Robb-Smith, and Dr. H. Spencer. The greater part of this work was undertaken by Dr. Spencer.

found to be characteristic of cases with demonstrable pulmonary polyarteritis. By this means a group of cases was obtained distinguished by the presence in each case of at least three (usually more) of the following features: a characteristic respiratory illness preceding the onset of systemic polyarteritis; high blood eosinophilia (1,500 or more per c.mm.); numerous eosinophils in acute polyarteritic lesions; giant pulmonary polyarteritis; granulomatous polyarteritis; giant cells in polyarteritic lesions; and the presence in viscera of necrotizing or granulomatous lesions not demonstrably related to arteries. The term "polyarteritis nodosa with lung involvement" is suggested for this group, which comprised one-third of the cases.

From a study of previous reports it appears that similar cases have been given a variety of names, including polyarteritis nodosa, periarteritis nodosa, Wegener's granuloma arteritis nodosa, after Wegener, 1936, Loeffler's (Godman and Churg, 1954, after Wegener, 1936), Loeffler's syndrome (Buckles and Lawless, 1950), Harkavy's syndrome (after Harkavy, 1941), "giant-cell granuloma associated with lesions resembling polyarteritis nodosa" (Howells and Friedmann, 1950), "periarteritis nodosa in granuloma of unknown aetiology" (Weinberg, 1946), "necrotizing granulomatous angiitis" (Fienberg, 1953), "diffuse eosinophilic arteritis" (Lumb, 1950), "allergic granulomatosis, allergic arteritis, and periarteritis nodosa" (Churg and Strauss, 1951), etc.

The reasons for adding yet another name to this list are, first, that a newly defined group of cases is being described, and, secondly, that the terms listed above are mostly too cumbersome for general use. The term "polyarteritis nodosa with lung involvement" is suggested because it stresses what appears to be the chief criterion of the syndrome, and it does not imply any particular aetiology.

The characteristic features of the group with lung involvement were all either completely absent or rare in the other groups. Microscopically, however, the majority of lesions in the two groups were often indistinguishable; that is to say, the characteristic lesions in cases with lung involvement were often small in number. It is not clear whether these were often small in number, or merely variants; but two syndromes are distinct diseases or merely variants; but it is suggested that this is the most valid classification so far proposed, and that it is of practical value in clarifying the natural history of the disease. Unfortunately it appears that steroid treatment makes it more difficult to discover at necropsy the characteristic lesions associated with lung involvement.

In six cases the available evidence was suggestive of lung involvement, but not conclusive. These cases are described separately, as also are seven other cases which differed greatly from both the two main groups.

Polyarteritis Nodosa Without Lung Involvement

There were 66 patients in this group (41 males and 25 females); 55 of them died and 54 came to necropsy. The age incidence showed a steady rise throughout life to a maximum in the seventh decade. The onset of the disease most often fell in the winter months. No special trends were apparent with regard to the patients' occupations or smoking habits.

At the time of onset of the disease 18 patients (27%) had chronic respiratory infections (bronchiectasis, chronic bronchitis, or suppurative otitis media), and another 12 (18%) had had recent acute upper respiratory infections (attributable to at least eight to haemolytic streptococci); at least three of the patients with recent acute infections had not received any drugs. In six patients (9%) there was active or quiescent polyarthritides indistinguishable from rheumatoid arthritis.

A constitutional illness (with loss of weight, fever, and tachycardia) was prominent at some stage of the disease in nearly all patients. Erythrocyte sedimentation rates were almost always high, and anaemia and leucocytosis were very common; slight or moderate eosinophilia (>400 per c.mm.)

was noted at some stage in 30% of patients. Measurement of the serum protein usually showed increased globulin and lowered albumin levels.

There was evidence of coronary polyarteritis in 32 patients (48%). The commonest clinical manifestations were cardiac failure and enlargement; cardiac pain was uncommon, although necropsy often revealed infarcts (usually microscopic).

Pulmonary manifestations in this group of patients were all attributable to infections or heart failure; there was no evidence of any specific lesions.

Renal involvement occurred at some stage in 52 patients (79%). The commonest lesion was renal polyarteritis, present as the only renal lesion at necropsy in 39 cases. Clinically this was associated in nearly all cases with proteinuria and microscopic haematuria, and sometimes also with a few granular and hyaline casts; 10 of these patients died of renal failure, and at necropsy they showed infarcts (often extensive) in the renal cortex.

A specific form of glomerulitis was present as the only renal lesion at necropsy in 16 cases. This was characterized in its initial phase by capillary microthrombi, focal fibrinoid necroses, polymorph infiltration, and capsular proliferation (often with crescent formation); clinically such cases showed macroscopic or heavy microscopic haematuria and early renal failure. Hypertension was not a feature of this initial phase. The three patients who survived this stage developed progressive hypertension and uraemia, and died within a year; at necropsy the microscopical appearances resembled those of ordinary chronic glomerulonephritis. In six additional cases the typical acute glomerulitis was associated with renal polyarteritis.

Significance of Raised Blood Pressure

In assessing the significance of an elevated blood pressure, the average normal pressure for each patient's age and sex was calculated from the tables compiled by Hamilton, Pickering, Roberts, and Sowry (1954). If the systolic or diastolic pressure exceeded these values by 30 or 20 mm. Hg respectively, the patient is referred to as having hypertension. Alternatively, where during the period of observation the systolic or diastolic pressure rose by 30 or 20 mm. (or more) respectively above the initial value the patient is said to have developed hypertension.

Valid records of arterial blood pressure were available in 55 cases. In 24 the pressure was normal on all occasions; at necropsy in these cases recent arterial and glomerular lesions were common, whereas healed lesions with associated ischaemic changes were seen only once. In 15 cases hypertension was observed to develop during the course of the disease; urinary evidence of renal lesions preceded any rise in pressure in all cases where data were adequate. At necropsy 12 of them had either healed renal polyarteritis or chronic glomerulitis; the other three had ischaemic changes in the kidneys not attributable to arteriosclerosis, but without positive evidence of polyarteritis. In 16 cases the blood pressure was raised at the initial measurement; but in 14 of these this measurement was made several months after the onset of the disease, and only in the other two was there definite evidence that hypertension preceded polyarteritis nodosa. Furthermore, in eight cases in this group the hypertension was found to be advancing rapidly during the period of observation, and at necropsy all but 2 of the 16 cases had healed renal polyarteritis. It is concluded that hypertension in polyarteritis nodosa is in almost all cases a sequel of renal polyarteritis or glomerulitis, but that the pressure rises only during the healing or healed stages of these lesions. Once initiated, hypertension is progressive; it terminated in the malignant phase in at least 11 patients in this series (10 males and 1 female). At necropsy the severity and extent of polyarteritic lesions were approximately the same in cases with normal and cases with high blood pressure; healed lesions were more frequent in the latter.

Symptoms and Signs

There was evidence of gastro-intestinal polyarteritis in 46 patients (70%). The commonest symptom was poorly localized pain; haemorrhage was common, and sometimes severe. Physical signs were usually slight or absent. At necropsy submucous haemorrhages and superficial ulcers were frequent. Polyarteritic lesions were usually confined to the terminal branches of the mesenteric arteries.

The liver was involved in at least 29 out of 54 necropsy cases (54%), but clinical evidence was usually lacking. Pathologically, the lesions appeared to excite more surrounding fibrosis than in other organs. In two patients necropsy showed diffuse hepatitis; neither had demonstrable hepatic polyarteritis.

Muscle pain and tenderness were frequent (often initial) manifestations of the disease, but the presence of nodules was recorded only once. Muscle was taken for biopsy on 26 occasions, on 12 (46%) of which polyarteritic lesions were demonstrated; in several of the negative cases the amount of muscle removed was very small. The impression was gained that the pectoral muscles were probably the site of choice for biopsy.

Arthritis arose during the course of the disease in 18 patients (27%). In six of these the changes were acute and transient (sometimes migratory, as in rheumatic fever). In eight others they were chronic and more closely resembled a rheumatoid type. Hypertrophic osteoarthropathy developed in two patients, one of whom had no pulmonary lesions of any sort.

The spleen became palpable in eight patients (in two of whom sections taken at necropsy did not show any splenic polyarteritis). Splenic polyarteritis (usually in arterioles or small trabecular arteries) was seen in 16 of the 39 cases from which sections were available.

There was clinical evidence of peripheral nerve lesions in 24 patients (36%). Combined sensory and motor loss was usually present. In seven patients there was clear evidence of lesions of isolated peripheral nerve trunks; in the remainder the signs were those of a more widespread (but still asymmetrical) peripheral neuritis. Sections of nerve were available from 12 of these cases, in seven of which polyarteritis was seen in the vasa nervorum. It is suggested that all peripheral nerve lesions in polyarteritis nodosa are due to local polyarteritis.

Lesions of the central nervous system were in most cases attributable to hypertension or atheroma. Microscopical proof of cerebral polyarteritis was found in only two cases; but in nine others there was no clear explanation for the clinical evidence of cerebral damage, and local polyarteritis cannot be excluded as a possible cause.

Focal indurated skin lesions, probably all due to local polyarteritis, occurred in 18 patients (27%). These ranged from subcutaneous nodules to superficial papules, often with haemorrhage and ulceration. A characteristic surrounding purple reticulation was a common sequel. Biopsy of the lesions was undertaken on 15 occasions, on 10 of which there was demonstrable local polyarteritis; in the negative sections the presence of infarction or infection usually made interpretation impossible. Other skin lesions included purpuric rashes, painful subcutaneous oedema, and (in one case) scleroderma.

At necropsy complete absence of any active lesions was found in nine cases (in three of which cortisone had been given). In 29 cases polyarteritic lesions were visible to the naked eye; aneurysms (usually few in number) occurred in 10 cases. It was not possible to base any distinct classification on the size of artery involved.

A correct clinical diagnosis was reached in 31 patients (47%), but was frequently delayed; 22 of these were proved by biopsy. In retrospect it appears that a correct clinical diagnosis could have been achieved on the basis of the recorded data in 47 patients (71%). Thus, despite its varied clinical manifestations, polyarteritis nodosa does, nevertheless, produce recognizable clinical patterns in most cases.

Prognosis

Of the 66 patients in this group, 12 were treated with cortisone or corticotrophin. Of the remaining 54, 51 died (one-third within three months and two-thirds within six months); three cases remitted fully, in two of which the lesions appeared to be confined to the skin and joints. Renal lesions were the cause of death in 65% of cases; the immediate cause was uraemia in those who died early, but hypertension in the majority of late deaths. In the remaining cases death was due mainly to coronary or gastro-intestinal polyarteritis. The severe constitutional illness contributed to death in most instances.

These figures on the prognosis of the disease are heavily weighted by cases that were first diagnosed at necropsy. A true assessment of the prognosis of the untreated disease needs to be based on cases proved in life (by biopsy) during the pre-cortisone era. In order to increase the small number of such cases available, the survey was extended to five additional teaching hospitals, covering the period 1941 to mid-1950—that is, prior to the introduction of cortisone and corticotrophin. In all, 16 cases were obtained; these have been described in detail elsewhere (Medical Research Council, 1957). Of the 16, 11 died (all but one within a year), in two the disease was still active (8 and 11½ years respectively from the onset), and three remitted. Of the latter, only one had evidence (based on macroscopic haematuria) of visceral lesions; this case remitted after three months. In the other two cases lesions were apparently confined to skin and joints, and remission occurred after five and seven years. The period of follow-up was three, three, and five years respectively from the date of remission.

Polyarteritis Nodosa with Lung Involvement

There were 32 cases in this group (16 males and 16 females). In eight patients (25%) there was a long history of respiratory infection preceding (so far as could be ascertained) the onset of polyarteritis. A past history of rheumatic fever was obtained from five patients, and one other was found at necropsy to have mitral stenosis (a total of 19%). One patient had rheumatoid arthritis.

Loss of weight, fever, and tachycardia were prominent features. Eosinophilia was observed in 69% of the cases from which data were available; it exceeded 1,500 per c.mm. at some stage in 50%, but was often intermittent. In 36% the highest count was 5,000 per c.mm. or more.

A respiratory illness occurred in all patients, and in all but one it preceded the onset of systemic polyarteritis (usually by less than one year, but occasionally by up to seven years). The evidence suggests that this phase of the illness was associated with the presence of specific pulmonary lesions.

Clinically the main features (Rose, 1957; Rose and Spencer, 1957) were those of asthma, pneumonia, or chronic bronchitis. The asthma appeared to be distinct from ordinary allergic asthma in that there was no family history, symptoms started at any age, extremely high eosinophilia was frequent, and necropsy usually revealed necrotizing lesions and polyarteritis in the lungs. The pneumonia ranged in clinical severity from transient symptomless infiltrations to large chronic abscesses; there was no response to antibiotics.

Haemolytic streptococci were isolated at some stage from 23% of those patients whose sputum was cultured; tubercle bacilli were never found. Radiological examination revealed a very variable pattern of consolidation. At necropsy (Spencer, 1957) severe lung damage was present in nearly all cases. The commonest change observed (50% of cases) was the presence of nodular or caseous lesions, often resembling tuberculosis (but with a complete absence of tubercle bacilli). Other lesions included haemorrhagic pneumonia, cavities, infarcts, fibrosis, and bronchiectasis. Microscopy showed characteristic necrotizing or granulomatous lesions in 61% of cases, and pulmonary polyarteritis

in 14 of the 20 cases from which adequate sections were available; diffuse and focal eosinophil infiltration was frequent.

In five cases granulomatous lesions occurred in the nose or middle ear. This lesion seems to be confined to cases with lung involvement.

The incidence of polyarteritis in other organs and the accompanying clinical manifestations were in the main similar to those seen in cases without lung involvement. Hypertension was less frequent; this appeared to be related to the shorter survival of cases with lung involvement once to the systemic polyarteritis was established. In the alimentary tract superficial ulceration (at all levels, from mouth to colon) tended to be more frequent and extensive than in cases without lung involvement. Necrotizing or granulomatous lesions not demonstrably related to arteries were encountered in the liver, kidneys, spleen, lymph nodes, and heart. Foci of collagen necrosis were seen very occasionally in the splenic capsule and trabeculae, and in the endocardium. In patients who had a high blood eosinophilia at the time of death there was usually a widespread diffuse and focal infiltration of interstitial tissues with eosinophils.

Of the 32 cases, eight received cortisone or corticotrophin. Only one patient (a cortisone-treated case) survives. The mean total duration of the disease was rather longer than in patients in whom the lungs were spared, but the period of survival from the onset of systemic polyarteritis was of less. The various characteristic forms of pulmonary disease accounted for 42% of all deaths; another 26% were due to renal lesions (mostly acute).

Only four cases were obtained that had been proved by biopsy in the pre-cortisone era. Three of these patients died (2, 8, and 18 months respectively from the onset of the disease); in the surviving case the disease was still slightly active 16 years from its onset.

Aetiology

The aetiology of the disease remains obscure. The most likely clue is the relation to preceding chronic and acute respiratory infections (especially those due to haemolytic streptococci). One of the chief problems is to distinguish whether the significant association is with the infections or with their treatment. The evidence from the present survey favours the incrimination of the infection itself, although no definite conclusions are justified (Rose, 1956; Rose and Spencer, 1957). The important observations are the association of some cases with haemolytic streptococcal infections not treated by any drugs, the association of the other cases with rheumatic fever, and the prolonged course of the disease with exacerbations and partial remissions seemingly unrelated to any drug therapy.

Other Examples of Polyarteritis

Six patients showed two of the features listed above as characteristic of polyarteritis nodosa with lung involvement, but this was considered insufficient evidence to warrant their inclusion as definite examples of the syndrome. It is possible that their classification would have been simpler if more adequate data had been available. One of these cases was of special interest because of its association with acute rheumatic fever.

Seven other cases were classified separately because they differed markedly from both of the two main groups. They have been regarded (with the possible exception of the first two cases described below) as examples of separate diseases which happen to show a similar histological lesion. They were:

1. A case of typical disseminated lupus erythematosus with terminal polyarteritis of mesenteric and perirenal arteries and a vas nervi. An association between these two diseases has been reported previously by Karani (1953).
2. A case of dermatomyositis in which necropsy revealed localized polyarteritis in voluntary muscle and in the oesophagus.
3. A case of scleroderma with cystic lung changes in which polyarteritis was confined to the areas of damaged lung.

4. A case of fibrosarcomatosis with terminal polyarteritis in skin and voluntary muscle.

5. and 6. Two cases of polyarteritis confined to branches of the pulmonary artery, occurring in patients with pulmonary hypertension (due in one case to mitral stenosis and in the other to emphysema). At least 10 cases of this sort have been described previously (Jones, 1942; Old and Russell, 1950; McKeown, 1952; Symmers, 1952; Hicks, 1953; Wade and Ball, 1957), and Parker and Weiss (1936) described five cases of mitral stenosis in which there was necrosis of pulmonary arterioles without any inflammatory reaction. The condition seems in some respects comparable to the systemic arteriolar necroses of malignant hypertension.

7. An infant who died at the age of 4 months, in whom necropsy revealed multiple aneurysms on the aorta and its branches and on the coronary arteries. Histologically the process seemed to have started as a necrotizing endarteritis. There was no clinical or pathological evidence of bacterial or mycotic infection.

Conclusions

This investigation offered a unique opportunity to assemble information on a large and unselected series of cases of polyarteritis. Certain features have emerged from it which are new or which now receive more detailed support.

1. The suggested classification into two groups, according to the presence or absence of lung involvement, appears to be the most reasonable so far available. It stresses the peculiar importance of lung involvement in the disease: for it is remarkable that lung lesions, if they occur at all, almost always precede lesions in other organs (sometimes by years), and that they are commonly associated with characteristic lesions in other organs of a type not seen in cases without lung involvement. These characteristic lesions may be few in number, and it is not certain whether these two syndromes represent distinct diseases or merely variants of the same condition.

2. The relation between the onset of the disease and preceding respiratory infections has been noted before—for example, Grant (1940) and Miller and Daley (1946)—but it now receives further support. An association with rheumatoid arthritis and with rheumatic fever is also apparent.

3. It has been suggested by Knowles, Zeek, and Blankenhorn (1953) that hypertension is a common cause of polyarteritis nodosa. The more detailed evidence now available shows that hypertension in polyarteritis nodosa is almost always a result of renal involvement (either arterial or glomerular). It is of interest that the arterial pressure is normal during the acute stage of these lesions, and begins to rise only when healing and fibrosis occur.

4. The existence is confirmed of a characteristic form of glomerulitis peculiar to cases of polyarteritis nodosa, as described by Davison, Ball, and Platt (1948). It is shown that some patients with this lesion survive into a chronic phase, in which they develop hypertension and renal failure.

5. Only 20 cases were located which had been proved by biopsy in the pre-cortisone era. But, although small, this group provides the largest consecutive series so far available for the assessment of the course and prognosis of the untreated disease.

Summary

The clinical and pathological findings are presented from a series of 111 proved cases of polyarteritis collected in nine teaching hospitals from the period 1946 to mid-1953. A classification is suggested and some evidence relating to the aetiology is discussed.

I am indebted to Professor P. R. H. Lovell and Professor Sir George Pickering, who gave invaluable advice at every stage of the work; also to Professor G. Payling Wright, Professor C. V. Harrison, and Dr. A. H. T. Robb-Smith. I thank Dr. H. Spencer, who undertook the greater part of the extensive histological work.

This survey was made possible only through the generous and unstinted co-operation of the clinicians, pathologists, and records officers at the various hospitals concerned. The survey was carried out at the following hospitals: Canadian Red Cross Memorial Hospital, Taplow (Special Unit for Juvenile Rheum-

alism); Guy's Hospital; Hammersmith Hospital and Postgraduate Medical School of London; London Hospital; Radcliffe Infirmary, Oxford; Royal Infirmary, Edinburgh, and the hospitals served by the Edinburgh University Department of Pathology; Royal Infirmary, Manchester; St. Mary's Hospital; St. Thomas's Hospital. The following hospitals co-operated in a limited extension of the survey to include more cases proved by biopsy: Middlesex Hospital; Royal Victoria Infirmary, Newcastle upon Tyne; St. Bartholomew's Hospital; University College Hospital; Westminster Hospital.

NEUROPSYCHIATRIC SEQUELAE OF LIGHTNING STROKE

BY

DAVID SHAW, M.D., M.R.C.P.

Medical Administrator, Belmont Hospital, Sutton, Surrey

AND

M. E. YORK-MOORE, M.B., D.P.M.

*Senior Registrar, Horton Hospital, Epsom; Lately
Psychiatric Registrar, Belmont Hospital, Sutton, Surrey*

On July 14, 1955, lightning struck the racecourse at Ascot, killing two people and injuring a number of others. 51 were taken to various casualty centres in the vicinity, the majority suffering apparently from a minor degree of shock only; 31 were not detained. Twelve persons were rendered unconscious for more than a few moments, and two of these died from head injuries. The immediate effects, apart from shock, were in the nature of burns, temporary paralyses of the limbs, paraesthesiae, tremors, transient deafness and dysphasia, numbness, and headache (Arden *et al.*, 1956).

Injury or death from lightning is not a rarity in this country. It causes about five to ten deaths annually in England and Wales according to Hughes (1956), the victims usually being the unfortunate individual, or small group, trying in vain to shelter from the storm. Luckily, incidents on the scale of the one at Ascot occur very rarely. There was the well-known Koenigsberg disaster in 1925, which was fully reported by Panse (1925). Much more recently a lightning incident occurred at Aldershot.

Much of the relevant medical literature is concerned with the immediate effects of lightning injury. Neuropsychiatric sequelae are occasionally mentioned, but it is difficult to get a clear idea of their incidence. Psychiatric effects are recorded by Critchley (1932), the

principal ones being paranoid states and chronic psychoneurotic illnesses. Arden *et al.* reported that a few of the patients struck at Ascot had residual emotional disturbances, but no details were given. Hysterical manifestations after injury by lightning were also noted by Critchley (1932), particularly functional blindness, deafness, and loss of speech, and Langworthy (1936) mentioned hysterical aphonia as an occasional late sequel of injury by electricity. Hysterical symptoms were found by Critchley (1934) to be more common in lightning than in electrical injury. He also described a heterogeneous group of neuropsychiatric sequelae, which included transient pains, vasomotor disturbances, and spasms occurring in the limbs. A case of arterial spasm in the right arm and leg with transient paralysis has been reported by Currens (1945).

In the frequent references in the literature to paraesthesiae and loss of power in the limbs as the result of lightning stroke, opinions differ concerning the aetiology, although most authors emphasize a possible organic cause (Critchley, 1932; Cambier, 1953). Bach (1950) claimed to have demonstrated the organic nature of so-called neurotic symptoms following trauma by lightning. In one of his cases a demonstrable left-sided internal hydrocephalus was regarded as responsible for a fairly typical picture of post-traumatic neurosis, which had supervened in a man aged 38 who had been unconscious for two hours as a result of lightning stroke, and had later developed a temporary paralysis and dysphagia. A second man who showed symptoms of cerebral irritation became depressed, paranoid, and hypochondriacal, and later committed suicide. Haemorrhages in the occipital cortex were seen and reference was made to other similar cases in the German literature, and also to the findings described by Hassin in the brains of electrocuted criminals. Among the more clearly defined neurological sequelae are several references to cases of paralysis of both upper and lower motor neurone types (Critchley, 1934; Langworthy, 1936), and cases presenting as amyotrophic lateral sclerosis are described (Leys, 1942; Woods, 1952). Sphincter disturbance appears to be uncommon. A variety of ocular changes have been reported by Critchley and others, of which cataract seems to be the most common. Abnormal E.E.G. recordings have been noted; Cambier has reported minor changes in the theta rhythm.

The Inquiry

In view of the diversity of neuropsychiatric sequelae described, as well as their uncertain incidence, it seemed desirable, as Panse (1925) urged long ago, to inquire further into the consequences of lightning stroke. In describing the Koenigsberg incident of 1925, when three were killed and 26 injured as a result of lightning stroke, Panse referred to four cases (16%) as having reacted "psychopathically" to the trauma. Fear and anxiety were the common immediate effects. In no case did a traumatic neurosis ensue.

In the recent Aldershot incident a party of men were struck by lightning, and one man was killed. There were five other casualties, and medical reports were received relating to four of them. A month after the incident two men were still disabled by psychiatric symptoms. One, who had earlier displayed signs of cerebral irritation, had developed a mild anxiety state with loss of weight, poor appetite and sleep, tremors, apprehension, and dizzy spells; and the second, who was a close friend of the man killed in the incident, has continued to complain of weakness of the legs, dizzy spells, and headache, symptoms which are regarded as hysterical in nature.

An opportunity presented itself for an inquiry into the late effects of the Ascot incident. A questionnaire was sent to 50 patients who were treated at various hospitals and casualty departments as a result of the incident. The following questions were asked: (1) What were the immediate after-effects in your case? (2) Did you develop any further symptoms subsequently? (3) Are you now in good health? (4) If not, what symptoms do you now have? There were 28 replies, as shown in Table I.

TABLE I

Total number of cases admitted to hospital	..	19
Number replying to questionnaire	..	14 (74%)
Total number of cases not detained in hospital	..	31
Number replying to questionnaire	..	14 (45%)

TABLE II

Type of Symptom	Early*	Late†
Headache	11 (34%)	3 (11%)
Paraesthesiae	10 (31%)	3 (11%)
Loss of consciousness	8 (25%)	1 (4%)
Paralysis	7 (22%)	3 (11%)
Anxiety or hysterical states	6 (19%)	0
Fatigue	4 (12%)	2 (7%)
Limb or neck pains	4 (12%)	1 (4%)
Deafness	3 (9%)	0
Dysphasia	2 (6%)	1
Depression	1 (3%)	2 (7%)
Ocular	1 (3%)	1 (4%)

* Ascot and Aldershot. † Ascot only.

Neuropsychiatric sequelae present after six months (referred to as "late" sequelae in this article) occurred in 11 cases (39%). The total number of early sequelae in the Ascot and Aldershot cases was found to be 30 (94%). An analysis of the symptomatology of the cases studied is shown in Table II.

The following cases illustrate some of the neuropsychiatric sequelae found.

Illustrative Cases

A boy aged 10 was apparently blinded by the flash of lightning for several days. He had told his mother that he was watching the lightning dancing along the rails of the racecourse. He complained of acute pain in the eyes and had photophobia, and both eyes were reported to be mildly injected. There were peripheral opacities in the left eye, and vision in this eye rapidly deteriorated. Two months after the incident the left eye became acutely inflamed and oedema of the macula was reported. Nine months later a rosette cataract was present, and the macular changes were confirmed.

A woman of 57 became quite deaf following the incident, and a year later some degree of deafness was still present.

A man of 63 said he shook all over for three hours after the lightning. Giddiness and paraesthesiae in the arms were present. A year later he was reported in poor health. He had numbness of the fingers, he dropped objects, and his wife had to do his buttons up. He still complained of persistent paraesthesiae in the right arm and also of dizziness, although he had never lost consciousness. He was always, so it appeared, of a restless, nervous disposition and had done very little regular work. Most of his time was spent in helping bookmakers on racecourses. Since the Ascot incident he had become depressed, was afraid to go into busy thoroughfares, and had done practically no work at all.

A man of 65, knocked unconscious for a short period by the stroke, subsequently had a transient aphasia. He complained of severe headaches, stiffness of the neck, and on admission to hospital was regarded as suffering from a post-convulsional state. He reported a year later an intensification of headache of a migrainous type.

A woman of 63 who had not been rendered unconscious by the stroke said she had developed fears and had become very excitable since the accident.

The mother, aged 38, of the lad of 10 referred to above was dazed as a result of the stroke. She has had bouts of

depression since, and has complained that she has been unable to go to the cinema or watch television, and seemed to feel "the vibration of electricity very strongly."

Case Showing Unusual Features

A single woman of 46 developed an hysterical ataxia. There were unusual details in this case which merit further description. This patient, an assistant nurse, was admitted to hospital in November, 1955, complaining of difficulty in walking. She had formerly been in domestic service and had volunteered for the Civil Nursing Reserve at the outbreak of the war. At the age of 12 she had sustained an injury to the left leg in a road accident. Seven years before admission to hospital she was "coshed" on the head and sexually assaulted in the grounds of her own hospital. She was badly shocked and sustained a large laceration of the scalp as well as injuries to the vulva. Her assailant was captured and there followed the ordeal of identification and the prolonged trial proceedings. She became very depressed and tremulous, and for several days her legs were weak. "My legs just would not go," she said. Troublesome headache and insomnia followed and persisted, and she was referred to a psychiatrist and given barbiturates. She had returned to light duties at her hospital and gradually improved, although she remained moody and was irritable at times.

She attended Ascot with a party, and was struck by lightning. She was rendered unconscious for an hour and sustained several burns on the scalp and on the left shoulder, elbow, and thigh. There was apparently very little retrograde amnesia, but the post-traumatic amnesia and confusion extended to about 36 hours. On admission to hospital after the accident, she was reported to have been conscious but incoherent. There was paralysis of the fifth, seventh, and ninth nerves on the right side, all deep reflexes were very much diminished, and the plantar reflexes were equivocal. Deafness, greater on the left side, was present, and lasted about two weeks. There were no sphincter disturbances. She was out of bed and had practically left her wheelchair at the end of two weeks after admission, but complained persistently of numbness and shakiness of her legs. Her gait was jerky and ataxic, and she clung to an assistant for support. Physiotherapy produced little improvement, and she was referred to a neurologist, who considered the gait hysterical. She left hospital after three weeks to return to her lodgings, but continued to have difficulty in walking. She also complained of showers of paraesthesiae, especially in the left arm, which on effort tended to become tremulous. She was practically confined to the house, but in spite of this stated that she felt much brighter and more cheerful since the Ascot incident than she was before.

Her complaint on admission to the neurosis centre four months after the disaster was that her legs just would not go and that there was no feeling in them. She also complained of shakiness and pins-and-needles in her left arm and leg, particularly on exertion or change of posture.

She was of short stature and pyknic build. There were healed burns of the left shoulder, elbow, and thigh, and a dry scab over the scalp burn. The cranial nerves were normal, apart from a slight degree of deafness on the left side. There was no wasting, and active movements in the lower limbs were full, apart from slight impairment of flexion and extension of the left knee and of dorsiflexion and plantar flexion of the left foot. Tone and co-ordination were normal and all tendon reflexes were brisk and symmetrical. Plantar reflexes were flexor. Anaesthesia of glove and stocking distribution was present, somewhat more extensive on the left side. The gait was a series of tremulous jerky steps. With encouragement she walked slowly in this fashion, like a clockwork toy, and complained of the great effort it required and the severe fatigue it caused. She was mildly euphoric and appeared more concerned with her paraesthesiae and burn scars than with her stiff awkward gait. She was quite certain that she had no neurotic illness,

and, although she was co-operative enough and was prepared to undergo investigation and treatment, she was rather passive, aloof, and incredulous. Her own explanation for her symptoms was that a nerve was being pressed on in her spine.

Well-meaning friends had told her that just after the lightning stroke her face was blue and set like one dead, and she was also told that her spine was affected, causing a partial paralysis, and that the resulting disturbance of gait would take at least six months to clear up. She regarded herself as a "living miracle," but wondered why she had been singled out for such trauma. There was a purpose behind it all, she supposed, and she was at least instrumental in placing a dangerous sadist behind bars. Now she would give anything to walk normally again, so that she could return to nursing. The E.S.R. was 4 mm. in one hour (Wintrobe). The E.E.G. was within normal limits. Blood W.R. and Meinicke test were both negative.

The disturbance of gait which had been present since admission was regarded as hysterical. The opinion of the consulting neurologist was that there had been an organic effect on the spinal cord, but it had practically cleared up.

Strong suggestion given under intravenous sodium amyl-barbitone produced an excellent response. She walked easily and even briskly with no jerkiness, and on her first weekend leave managed to climb the stairs. She held on to her opinion that the symptoms were organically determined. Removal of the hysterical gait had been followed by a complaint of more pain, particularly over the old lightning burns on the leg and in both hands, although the actual numbness was beginning to clear up. Physiotherapy and walking exercises were instituted concurrently and the improvement was maintained. When discharged in mid-January she walked quite normally, but still had some anaesthesia of the typical glove and stocking type. She said that until recently she felt that she was owed some suffering; it had been uncanny and quite past her understanding why she had not suffered more after such a severe shock. Now she realized that she had been through a serious illness and was making a complete recovery. A follow-up 12 months later showed that she had maintained the improvement, and had resumed full nursing duties, which included night duty.

Other Effects

Critchley (1932) has noted the apparently beneficial effects of lightning on the course of intercurrent disease. Two women in our series, aged 52 and 57, both reported that their rheumatism had noticeably improved since the Ascot incident. In contrast, however, a man who had sustained multiple burns in the accident stated that he had subsequently developed pains in his elbows and hands, and added that he had since been under treatment for early arthritis.

A woman of 36 was thrown to the ground and rendered unconscious; she sustained burns on the head and arms, and subsequently complained of headache and dizziness. She was discharged after four days in hospital. Eight years previously she had been admitted to a mental hospital on certificate, and was reported as being suspicious, antagonistic, and at times mute and inaccessible. She had made three attempts at suicide. She was given E.C.T. and then deep insulin therapy, in the course of which she had an irreversible coma. On recovery she admitted that earlier she had been hallucinated, and had heard spiritualistappings. She was discharged as recovered after five months in hospital. Her husband had rigid and narrow views, and was no great support apparently. Her subsequent history was more like that of a manic-depressive. She had periods of elation followed by bouts of depression, for which outpatient E.C.T. was given. A year before the lightning incident she was severely depressed and retarded for several months, and had once more attempted suicide. In hospital E.C.T. was again given, and in the course of treatment she went abruptly into a state of elation. This persisted for two months, and at the time of her discharge, only eight months before the lightning incident, she was still a little

hypomaniac. A year after the incident she was in good nervous and physical health. She had made an unexpectedly rapid recovery from the effects of the lightning stroke, which in her case may have acted as an E.C.T.

A freak effect occurred in the case of a man aged 39, who complained of frequency of micturition for about three days after the incident. He stated that he was wearing a pair of trousers with a metal zip-fastener at the time of the accident, and added, "That's where it seemed to hit me."

Discussion

In both the Ascot and the Aldershot cases headaches and paraesthesiae were found to be the most common early after-effects. Second only to these in frequency were cases presenting transient paralyses of the limbs. Dysphasia was noticed twice in this series, and in both cases was mild and temporary. There are frequent references in the literature (Critchley, 1932; Langworthy, 1936; Cambier, 1953) to spinal atrophic paralysis as a not uncommon sequel of lightning stroke, but not a single example was found in any of our cases. We did not encounter an example of a post-traumatic syndrome of any appreciable duration, nor, with the possible exception of one case, was there an instance of a post-traumatic personality change. These findings are in keeping with Panse's experience in the Koenigsberg disaster. In contrast, although the trauma is not strictly comparable, Denny-Brown (1945) found in 200 cases of closed head-injury in military personnel (53% resulting from traffic accidents) that psychiatric symptoms occurred in 70 (35%) and the post-concussion syndrome in 30 (15%). Headache was the commonest sequel, as with the lightning cases in our series.

It is tempting to speculate on the virtual absence of traumatic neurosis as a sequel of lightning stroke. The nature of the traumatic experience could be shattering enough. Several of the victims at Ascot did not lose consciousness, but were rendered helpless, were badly shocked, and had their clothing burnt off them. Through torrential rain they could hear the cries of terrified children and the groans of the stricken victims. Nevertheless, this traumatic experience has tended to be regarded as a true "act of God," and passively accepted as such, with mingled feelings of thankfulness and relief, not only by an Evangelist victim of the Ascot incident, but, one sensed from the replies, by many other victims too. The nature and circumstances of the trauma were such, therefore, that the psychopathological factor of guilt and the closely related factor of compensation would not be expected to play any considerable part.

A prolonged neurotic disability could be said to have occurred in only two cases. One of these, that of the man of 63, briefly reported above as having become depressed, phobic, and practically unemployable, had, it is noted, a poor previous work record and was possibly of inadequate psychopathic make-up. In the second case, which is the one more fully reported, the ataxia was undoubtedly hysterical. This particular patient had suffered much trauma in the past, and on previous occasions under stress had developed hysterical weakness of the legs. The lightning stroke had in this instance released a similar pattern of neurotic symptoms. She felt in some way singled out for some special attention, and she made an oblique reference to herself as having some special role as a victim of God's mysterious ways.

Summary

A review of neuropsychiatric sequelae of lightning stroke has been made in the light of the literature on the subject, and with special reference to cases occurring as a result of the incidents at Ascot in 1955 and at Aldershot in 1956. The incidence and nature of such sequelae are described, and one case which shows special features is more fully reported. The incidence of early after-effects was high, although prolonged sequelae occurred in only two cases.

We would like to acknowledge permission and help given in this inquiry by Dr. L. Minski, physician-superintendent, Belmont Hospital and Dr. C. Kenton, regional psychiatrist, N.W. Metropolitan Regional Hospital Board. We thank Miss E. S. Rogers, psychiatric social worker, for help in the investigation.

A CASE OF PODOPHYLLUM POISONING WITH INVOLVEMENT OF THE NERVOUS SYSTEM

BY

A. N. G. CLARK, M.D.

Lately Registrar

AND

MAURICE J. PARSONAGE, M.B., B.Sc.
M.R.C.P., D.C.H.

Assistant Physician

Neurological Department, the General Infirmary at Leeds

There are a number of toxic substances which, after absorption via one route or another, may lead to the development of a disturbance of function in the nervous system with or without ensuing structural damage. Quite often the peripheral nerves appear to be principally involved, this resulting in the production of a more or less symmetrical type of peripheral neuropathy; moreover, in such cases there may be severe structural changes, with the result that recovery of function, although tending ultimately to be complete, may be long delayed. There may also be involvement of the central nervous system by the toxic action of the ingested substance, and, although the exact *modus operandi* may not be known, it seems likely that in many such cases the upset of function in the nervous system may well be the result of interference with various enzyme systems.

The following case report is of a patient who developed a fairly severe disturbance of central and peripheral nervous function after taking an overdose of a podophyllum extract by mouth. We have not been able to find a similar case in the literature. For this reason, and also because the effects of this substance upon living tissue have recently been the subject of investigation, we felt that the case should be placed on record.

Case History

A married woman aged 25, believing herself to be pregnant, drank 1 fl. oz. (28.4 ml.) of a proprietary concentrated alcoholic extract of American podophyllum root

(*P. peltatum*) one evening on the advice of a friend. There were apparently no immediate ill effects, but the next day she began to vomit repeatedly, becoming confused and finally comatose within 24 hours. The same evening vaginal haemorrhage also supervened and she was transferred to hospital as a gynaecological emergency. On admission she was found to be confused, noisy, and restless, hiccupping, yawning, and retching in turn. A bruise was present over the right eye, but her colour was good and her tongue moist and clean. The ocular fundi and pupils were normal, the knee-jerks were present and equal, but the abdominal reflexes were absent and the plantar responses extensor. The pulse rate was 60 a minute, the temperature 97.8° F. (36.6° C.), and the blood pressure 120/80 mm. Hg. On clinical examination no abnormalities could be detected in the cardiovascular, respiratory, or gastro-intestinal systems, and, although a gynaecological examination revealed the presence of a blood-stained watery discharge from the vagina, the cervix and vagina itself were normal in appearance, there being no evidence of enlargement or abnormality of the uterus.

A provisional diagnosis of poisoning was made in view of the clinical history, and gastric lavage was performed shortly afterwards. From the time of admission the patient was able to take fluids by mouth, and a marked lessening in the severity of her confusional state had occurred two days after admission. It was recorded at this stage that the tendon reflexes had become sluggish, while a lumbar puncture revealed a clear cerebrospinal fluid at a pressure of 210 mm. of water; it contained: protein, 45 mg. per 100 ml.; chlorides, 680 mg. per 100 ml.; sugar normal in amount; and about 3,000 red blood cells per c.mm.; the latter was probably the result of accidental contamination.

The patient was first seen by one of us (M. J. P.) eight days after her admission to hospital. She was then mildly confused and somewhat restless, and uninhibited in her behaviour. Neurological examination revealed no abnormalities of the cranial nerves apart from a sluggish reaction of the pupils to light and an inconstant horizontal nystagmus on conjugate lateral deviation of the eyes. There was, however, a fairly severe degree of general weakness of the limbs, which were hypotonic and exhibited gross incoordination with associated pseudo-athetotic movements of the outstretched hands and fingers. The plantar responses were flexor in type, but the tendon-jerks were either extremely sluggish or absent, and there was impairment distally in the limbs of all modalities of sensation, postural sense being lost in the digits. A further lumbar puncture next day showed a spinal fluid pressure of 105 mm. of water; the fluid contained: protein, 200 mg. per 100 ml.; chlorides, 620 mg. per 100 ml.; sugar within normal limits; cells, nil. At this stage the blood pyruvate level was 0.85 mg. per 100 ml., the serum alkaline phosphatase level 11 units (King-Armstrong), the serum bilirubin 0.4 mg. per 100 ml., and thymol turbidity 0.9 unit, the thymol flocculation test being negative.

On the eleventh day of her illness the patient was transferred to a neurological unit for rehabilitative treatment. By this time her mental state had become almost normal. Examination of the cranial nerves disclosed that there was still an inconstant horizontal nystagmus on conjugate lateral deviation of the eyes to the right, together with sluggish responses of the pupils to light. The weakness, hypotonia, and incoordination of the limbs were unchanged. The tendon reflexes had remained virtually absent and the previously observed sensory changes were still demonstrable.

Progressive improvement in the symptoms and signs ensued during the course of the next three weeks, at the end of which a further lumbar puncture was performed. The fluid was under a resting pressure of 35 mm. of water, and the Queckenstedt test was negative; it contained two cells per c.mm. (one polymorphonuclear leucocyte and one lymphocyte) and had a protein content of 60 mg. per 100 ml.; the Pandy test for globulin was weakly positive, but the sugar content was within normal limits (47 mg. per 100 ml.). Both the Lange gold curve and W.R. were negative. No abnormalities were found in the urine, spectroscopic examination

and the Waldenström test being negative; a heavy growth of coliform organisms was, however, obtained on culture. The latter finding may well have accounted for the moderately raised E.S.R. (34 mm. in the first hour) which was observed at this time. The results of a full blood count were essentially normal. An E.E.G. examination carried out a month after admission showed normal cortical electrical activity.

At the end of a month of rehabilitative treatment the patient was able to stand without support, but her balance was impaired and she could not walk unaided. After a further two months she was able to walk without help, although her gait remained ataxic and widespread weakness of the limb musculature was still present. There was pronounced tenderness of the calf muscles. The tendon reflexes had not returned and there was still some impairment of all sensory modalities in the limbs, postural sense remaining considerably impaired in the digits. The patient was, nevertheless, considered fit enough to be allowed to return home at this stage.

When examined as an out-patient seven months after the onset of illness her condition had improved considerably; motor functions and the tendon reflexes were then found to be normal in the arms. There was still, however, some weakness of dorsiflexion of the feet and of the great toes, and the knee- and ankle-jerks remained absent. Vibration and postural sense were virtually normal in the arms but were still slightly impaired in the toes.

A final examination was made 16 months after the commencement of the illness. At this time the patient was walking normally and complained only of slight tenderness and occasional cramps in the calves. Her mental functions appeared to be quite normal, and full neurological examination revealed only sluggishness of the knee-jerks, absence of the ankle-jerks, some impairment of vibration sense in the legs, and minimal impairment of postural sense in the left hallux.

Discussion

Subsequent analysis of a sample of the podophyllum extract ingested by this patient revealed that it had been prepared from American podophyllum root (*P. peltatum*) and that it contained 9.96% of podophyllin resin in 75% alcohol. It is estimated that she must have taken 2.8 g. of the resin by mouth, this amount being approximately 44 times the maximum stated B.P. dose of the resin. Furthermore, the fatal dose of the resin is stated to range from 0.3 to 0.6 g. (Gonzales *et al.*, 1954), and the patient had in fact ingested more than four times this amount. However, a probable important mitigating factor arises from the fact that the resin has the physical property of becoming precipitated from strong alcoholic solution into dense curds in water and in acid fluids such as stomach contents; vomiting therefore might possibly have resulted in the removal of some of the resin.

Podophyllin is a resin mixture obtained from the dried rhizome and roots of *P. peltatum* (May apple). Its purgative action was accidentally discovered 120 years ago (Zakon, 1952), and it has long been a popular lay remedy for constipation and the "sluggish liver." Its principal use in recent years has been in the treatment of genital warts, as it possesses the power of arresting epidermal mitoses (Sullivan, 1949). On account of its anticarcinogenic properties its possible toxicological effects have been carefully studied recently. Experimental overdosage with this substance in rats has been found to result in the development of abnormalities of gait, muscular flaccidity, and coma (Sullivan *et al.*, 1951); furthermore, in the cat, weakness and incoordination of the posterior extremities have been found to occur (Ormsbee *et al.*, 1947). In addition, Miller *et al.* (1949) have shown experimentally that podophyllotoxin, one of the constituents of the resin, inhibits respiration *in vitro* in various cellular organs, including the brain.

The occurrence of fatal systemic poisoning following podophyllin treatment of a large condyloma acuminatum of the vulva in a negro girl of 18 was reported by Ward *et al.*

(1954). The local lesion had been cleansed with an antiseptic soap, after which multiple biopsy specimens were taken. Within 24 hours of the local application of a 25% podophyllin ointment the patient lapsed into a state of deepening coma with associated nitrogen retention, and died at the end of a week. At necropsy congestion of all the organs was found; in addition, the brain exhibited rarefaction of the cortex, fragmentation and swelling of the white matter, which contained many capillaries with wide perivascular spaces, and increase of the glial elements. These authors concluded that failure to remove the podophyllin ointment was probably the principal reason for the poisoning; they also thought that its application to the site from which multiple biopsy specimens had been taken may have resulted in more rapid absorption than would have occurred from an intact surface. They were unable to find any record in the literature of a similar type of occurrence, but drew attention to a fatal case quoted by Peterson *et al.* (1923) in which the podophyllin had been taken orally. This concerned a woman who became comatose and died just over 30 hours after taking by mouth 5 gr. (0.35 g.) of the resinoid podophyllin.

The only really comparable example of poisoning of a human subject that we have been able to discover in the literature concerns a case of colocynth poisoning recorded by Kroll (1938). This author recorded the clinical findings in a female patient who developed a flaccid paralysis of the legs with muscular atrophy and a reaction of degeneration, with considerable improvement after two months and complete recovery at the end of four months. The cause of this syndrome was ascribed to the effects of a laxative which the patient had been taking for over a year and which on analysis was found to be an essence of colocynth with an alcohol content of 35 vol.%. Other possible causes of the condition—infection, organic poisons, etc.—were regarded as excluded, and the author points out that it has been shown experimentally that the administration of colocynth to dogs, cats, and rabbits can produce a fatal polyneuritis. Although podophyllin and colocynth are unrelated chemically, they are both powerful intestinal cathartics, and it would appear, therefore, that the administration of alcoholic extracts in the cases described by Kroll and ourselves produced similar sequelae.

In our patient the ingestion of the podophyllum extract resulted in a severe disturbance of nervous function, although the effects were not observed until the following day. There then ensued a state of mental confusion leading to coma within the next 24 hours. The patient did not, however, remain long in a comatose state, and at a later stage a detailed neurological examination revealed that she had developed a severe peripheral type of neuropathy, the spinal fluid protein content having by this time risen to 200 mg. per 100 ml. A variable nystagmus had also been observed, and by the eleventh day the patient's mental state had still not returned to normal. Recovery proved to be a slow process and was still incomplete at the end of six months. We consider, therefore, that there must have been a disturbance of both central and peripheral nervous function, and in the light of the experimental evidence it seems to us likely that this occurred as a result of interference by the podophyllin with the metabolism of the nervous system. The disturbance of brain function which occurred was of far shorter duration than that which developed in the peripheral nerves, and the slow recovery indicates that in the case of the latter comparatively severe degenerative changes must have taken place.

It could also be argued that the alcohol content (75%) might have played some part in the production of the syndrome, since it was the only other constituent of the extract that might conceivably have been important as an aetiological agent. The amount of alcohol present was the equivalent of 21 ml. of absolute alcohol ($\frac{1}{4}$ oz.), and it seems unlikely that so small an amount could itself have been of any consequence. Whether the podophyllin or colocynth in combination with alcohol is apt to be more toxic than either of these agents alone is perhaps rather less certain.

Summary

A case of poisoning as a result of the ingestion of an alcoholic podophyllum extract is described.

The resulting toxic effects comprised an initial severe disturbance of consciousness followed by a state of confusion, and a fairly severe type of peripheral neuropathy.

A substantial amount of recovery of function had occurred at the end of six months after ingestion of the podophyllin, but a residual neurological deficit was still evident at the end of 16 months.

The mode of action and probable effects of the podophyllum extract are discussed briefly.

We thank Mr. J. B. Farquhar, consulting gynaecologist and obstetrician, who originally referred the patient to us, and Dr. G. A. Nelson, department of pharmacology, University of Leeds, who kindly analysed and reported upon the podophyllum extract.

ANKYLOSING SPONDYLITIS AND CHRONIC INFLAMMATORY LESIONS OF THE INTESTINES

BY

V. L. STEINBERG, M.B., M.R.C.P.Ed.
Senior Registrar, Department of Physical Medicine,
London Hospital

AND

GEOFFREY STOREY, M.D., M.R.C.P.
D.Phys.Med.

Consultant in Physical Medicine, Hackney and Central
Group

This paper describes six cases in which ankylosing spondylitis was associated with chronic non-specific inflammatory lesions of the intestines. Four of these cases had chronic ulcerative colitis, one had Crohn's disease, and one had ulcerative colitis and Crohn's disease. The aetiology of ulcerative colitis and Crohn's disease is uncertain. Although it seems unlikely that they represent different manifestations of the same diseases, nevertheless there appears to be enough similarity between them to make differentiation difficult at times (Butler, 1953; Crohn, Garlock, and Yarnis, 1947), and we may be justified in considering them together. The diagnosis of Crohn's disease was made at operation in both our cases, while radiology with a barium-filled colon was relied on for the diagnosis of ulcerative colitis.

The English literature has few references to the association of ankylosing spondylitis and ulcerative colitis. West (1949) makes no mention of the two conditions in his discussions of the aetiology of ankylosing spondylitis, and Hart (1955), reviewing 184 cases of ankylosing spondylitis, does not mention ulcerative colitis or Crohn's disease (although he refers to other diseases of the intestines). However, Romanus (1953) describes three

cases of ulcerative colitis associated with ankylosing spondylitis, and, indeed, French authors have always believed that ankylosing spondylitis might be related to disorders of the intestines. Forestier (1939) stated that the primary focus in ankylosing spondylitis lay in the genito-urinary system or in the lower bowel. Further, dysentery and post-dysentery syndromes have always, since Reiter's (1916) original description, been recognized as aetiological factors in Reiter's syndrome, and it is recognized that involvement of the sacro-iliac joints may be a part of this syndrome (Marche, 1950; Ford, 1953). We have been unable to find any reference to the association of ankylosing spondylitis and Crohn's disease.

Case Reports

Case 1.—A man aged 42 was first admitted to the London Hospital in 1938 with an acute attack of diarrhoea and blood in his stools. Sigmoidoscopy revealed changes typical of ulcerative colitis. Following treatment he was much improved. Since that time he has been readmitted five times for recurrences of ulcerative colitis, and on the last occasion a barium enema showed changes of advanced ulcerative colitis throughout the whole of the large intestine, and possibly some involvement of the small gut. Three years after the diagnosis of ulcerative colitis was made he complained of pain in the lumbar region lasting for three months. In 1945 he had a recurrence of low back pain, associated with aching pain and stiffness in his neck. At that time he began to develop a stoop. The ulcerative colitis was still active. Examination showed an upper dorsal kyphosis and rigidity throughout the spine. Chest expansion was limited to $\frac{1}{2}$ in. (1.3 cm.). The right temporo-mandibular joint was also affected. X-ray examination showed obliteration of the sacro-iliac joints and calcification of the anterior longitudinal ligaments. These changes were regarded as typical of ankylosing spondylitis. Radiotherapy was given, but had to be discontinued as severe diarrhoea developed after a few treatments. In 1949 the symptoms of ankylosing spondylitis became more severe, and he was given a course of radiotherapy, with marked relief.

Case 2.—A man aged 50 began in 1949 to have diarrhoea with blood in his stools. This improved with treatment, and for several years he had little trouble. In 1954 he complained of pain in the right knee, followed by pain in the back. Examination showed rigidity of the thoracic and lumbar spines, and limitation of movement of the cervical spine. There was an effusion in the right knee. X-ray examination showed typical changes of ankylosing spondylitis, with obliteration of the sacro-iliac joints and calcification of the spinal ligaments. Erythrocyte sedimentation rate was 20 mm. in one hour. He was treated by physical methods, with improvement. One month before this was written he had a further relapse of diarrhoea, with blood, and a barium enema showed a loss of haustration involving the descending and pelvic colon. For some years this man had had diffuse psoriasis.

Case 3.—A man aged 48 complained in 1937 of diarrhoea and bloody stools. He was admitted to hospital, and ulcerative colitis was diagnosed. In 1942, while in hospital with a further attack, he first noted stiffness of his spine. Since then he has had intermittent attacks of ulcerative colitis. He also found that his neck was bending forward, and that he was unable to look up. In 1949 a diagnosis of ankylosing spondylitis was made. He was treated with deep x-ray therapy. Following this he developed his first attack of iridocyclitis, affecting the left eye. In 1950 he experienced a severe attack, affecting the right eye. X-ray examination revealed obliteration of both sacro-iliac joints, typical of ankylosing spondylitis.

Case 4.—A married woman aged 49 developed umbilical pain and vomiting eight years ago. She attended the London Hospital for investigation. A barium-meal examination revealed a filling defect in the colon. Laparotomy was performed, and a right hemicolectomy, with removal of 3 ft.

(90 cm.) of terminal ileum, and end-to-end ileocolostomy were carried out. Histological examination of the specimen showed the changes of Crohn's disease. After the operation she first complained of low back pain, which continued and became more severe. The following year x-ray examination revealed sclerosis around both sacro-iliac joints, typical of ankylosing spondylitis. Radiotherapy gave some improvement. More recent x-ray films show irregularity of the margins of both sacro-iliac joints, with increased sclerosis. They also show the presence of sclerosis around the symphysis pubis, with irregularity of the bony margins and squaring of the vertebral bodies. Six years ago she was investigated for persistent diarrhoea, but the results were negative. They were suggestive, however, of early ulcerative colitis. Two years ago she was readmitted, with diarrhoea, blood in the stools, marked weight loss, and pyrexia. Sigmoidoscopy showed typical changes of ulcerative colitis in the rectal mucosa, and a barium enema revealed changes of advanced ulcerative colitis throughout the large gut.

Case 5.—A man aged 49 first suffered from blood-stained diarrhoea in 1943. After one attack he was free of symptoms until 1951, when he had a recurrence of symptoms. Radiological examination with barium showed typical ulcerative colitis, the smooth appearance involving the whole colon. Two years later he began to suffer from pain and stiffness of the back and pains in the limbs. On examination nine months later (January, 1954) the movements of the cervical and thoracic spines were greatly limited. The lumbar spine was also limited in its movements, but it was not rigid. Chest movement was limited. X-ray examination of the lumbar spine and sacro-iliac joints showed nothing abnormal, but calcification of the interspinous ligaments in the cervical and lower dorsal region, and bony bridging between vertebrae L 1 and 2 were present. The erythrocyte sedimentation rate was 62 mm. in one hour. A course of deep x-ray therapy improved the mobility of the spine, and the patient has remained symptom-free for the past two years.

Case 6.—A man aged 42 first complained of diarrhoea and vomiting 16 years ago, when in the Army. The following year an appendicectomy was performed, but two weeks later an abscess developed in the right groin, with slight flexion contracture of the right hip. At first a diagnosis of a tuberculous hip-joint was made. He was admitted to an orthopaedic hospital, and, as his vomiting continued, a barium-meal examination was performed; this showed the appearances of Crohn's disease. Following this, three operations were performed on his gut. The exact nature of these is uncertain. Seven years ago he first noticed that his neck and back were becoming stiff. Later the same year a diagnosis of ankylosing spondylitis was made. X-ray films showed typical changes of ankylosing spondylitis in the sacro-iliac joints. Deep x-ray therapy brought marked improvement.

Discussion

The course of events in these six cases was very similar. The onset of backache followed the beginning of bowel symptoms, usually in a few years, but the diagnosis of ankylosing spondylitis was delayed for several more years. In Case 4 the spondylitis followed the development of Crohn's disease but preceded the demonstration of involvement of the colon. Five of these cases were classical ankylosing spondylitis. In Case 6 only the sacro-iliac joints showed radiological abnormality. Case 4 had erosions of the sacro-iliac joints and the symphysis pubis, while Cases 1, 2, and 3 had involvement of the sacro-iliac joints, with uniform calcification of spinal ligaments. Case 5 was atypical in that the cervical spine and lower dorsal spine were mainly affected, the sacro-iliac joints being spared. This, however, is recognized as occurring in 14% of cases of ankylosing spondylitis (Oppenheimer, 1943). Case 3 also suffered from psoriasis, which has been associated with ankylosing spondylitis (Fletcher and Rose, 1955).

In all these cases, however, the main emphasis of the arthritis centred on the spine, and, although other joints

were involved, these appeared to be secondary phenomena. This feature differentiates this group of cases from that in which the peripheral joints are involved in ulcerative colitis. The peripheral type of arthritis is well recognized, and has been reported in from 4 to 8% of cases (Kirsner, Palmer, Maimon, and Ricketts, 1948). It occurs in severe late cases of ulcerative colitis, although it may occur early in right-sided colitis (Butler, 1952). It involves one or more of the larger joints, and waxes and wanes with exacerbations of the colitis. There are no reports of changes in the spine in these cases, and spinal involvement has been absent in those cases which we have had the opportunity of examining.

It seems unlikely that the cases reported here represent chance associations of intestinal disease with ankylosing spondylitis. The four cases of ulcerative colitis occurred among 399 cases of ankylosing spondylitis admitted to the London Hospital for the period 1937–55, an incidence of 1%. West (1949) states that the incidence of ankylosing spondylitis in the general population is 1 in 2,000, so that the association seems to be more than one of chance. From a review of the literature also there seems to be an association between intestinal disorders and spinal disease. The association of bacillary dysentery with Reiter's syndrome, in which sacro-iliac involvement is sometimes a feature, has already been mentioned. In brucellosis infections, where the portal of entry is the intestinal tract, there is also a predilection for the spine. As a rule, according to Benassi (1952), the pathological changes in this condition are those of a low-grade localized osteomyelitis in which hypertrophy of bone is well marked (as distinct from the osteoporosis of tuberculosis), so that in a late stage two adjoining vertebrae become invested with hypertrophic bone. In some cases the sacro-iliac joints are affected, but here again the changes are usually unilateral and represent a low-grade osteomyelitis (Steinberg, 1948). Nevertheless, it seems that typical ankylosing spondylitis occurs in some cases; for Goldfain (1943) reported five cases of ankylosing spondylitis with positive serological tests for brucellosis, and Steinberg (1948) reported one case, although he believed that brucellosis was not a factor in ankylosing spondylitis.

Typhoid fever has similar effects. Generally the process is a low-grade osteomyelitis, affecting the intervertebral disk region (Silver, 1907) in the lower dorsal and lumbar vertebrae, producing irregular density of adjacent vertebrae and ossification of perispinal ligaments. The prognosis is good (Swart, 1938). Sometimes, however, ankylosing spondylitis occurs, and Romanus (1953) reported one such case.

Oppenheimer (1938) has described a type of hypertrophic spondylo-arthritis which he differentiates from osteoarthritis and from ankylosing spondylitis, and which he believes was related to amoebic dysentery, as 13 out of 14 patients had *Entamoeba histolytica* in their stools. However, he did not publish x-ray films to allow an opinion on whether the condition simulated brucellosis and typhoid fever.

It seems that ankylosing spondylitis may represent a non-specific reaction to diseases of the intestinal tract. Brucellosis and typhoid fever as a rule produce a low-grade osteomyelitis. Bacillary dysentery is associated with Reiter's syndrome, and ulcerative colitis with a type of arthritis confined to one or two large joints, but all of these conditions and Crohn's disease are sometimes associated with typical ankylosing spondylitis.

The reason for the association of spinal disorders and diseases of the intestines has been suggested by Romanus (1953). He believes that the connexion is via the system of veins which has been demonstrated by Batson (1942). These connect the pelvic veins to the vertebral veins. Batson was interested in the spread of secondary carcinoma of the prostate, but Romanus considers that infection from the prostatic bed may spread in this way. The rectal veins form part of the pelvic system. However, it is less easy to account for the association of Crohn's disease with ankylosing spondylitis in this way, and, indeed, until the aetiology of ulcerative colitis and of ankylosing spondylitis is known, it seems premature to speculate about the channels of spread.

Summary and Conclusions

Of the six cases described, four had ulcerative colitis and ankylosing spondylitis, one had Crohn's disease and ankylosing spondylitis, and one had ulcerative colitis, Crohn's disease, and ankylosing spondylitis.

It is believed that these associations are more than those of chance.

There seems to be a definite relationship between diseases of the intestines and spinal disorders.

Ankylosing spondylitis can be a non-specific reaction to diseases of the intestinal tract.

We thank Dr. W. S. Tegner for his advice and criticism, and Dr. A. Freedman for Case 2.

MICROSPORUM CANIS—AN INTENSIVE OUTBREAK

BY

G. T. N. LAWSON, M.B., D.P.H.

Assistant Divisional Medical Officer, County Down

AND

W. J. McLEOD, M.D., D.P.H.

Senior Medical Officer, Belfast County Borough

Cases of ringworm diagnosed at the Royal Victoria Hospital, Belfast, and the Royal Belfast Hospital for Sick Children are notified to the medical officer of health of the area in which the patient resides. On January 15, 1957, one such notification reported *Microsporum canis* infection in three adults, two dogs, and a Persian kitten—this comprising all the individuals living in one household. The diagnosis had been confirmed by examination of the animals under Wood's light (ultra-violet light screened with nickel oxide glass), when the typical bright pale-green fluorescence was obtained. The kitten was noted to be most heavily infected, and, as it had been acquired on December 17, 1956, it was believed to be the source of the infection. It had been obtained from a local breeder of Persian cats.

All 12 of the animals in the breeder's cattery were examined under Wood's light, and two tom-cats showed typical fluorescence. Confirmation of the diagnosis was obtained by sending affected hairs to the laboratory, where *M. canis* was cultured.

Two litters had been born in September, and the first two kittens were sold in October, but the breeder then

noticed bald patches on the face of the remaining kitten and deferred selling them until this condition improved. Further sales took place from November 25 to December 17, 1956, and, in all, 10 kittens had been sold in the period October 24 to December 17.

Summary of Contacts

Kitten	Date of Purchase	Human Contacts		Animal Contacts in Home	
		Infected	Not Infected	Infected	Not Infected
No. 1	24/10/56	2 children (1 M, 1 F), 1 adult (F)	1 adult (M)	0	0
.. 2	25/10/56	2 children (1 M, 1 F), 1 adult (F)	1 adult (M)	0	0
.. 3	11/12/56	2 children (2 F)	2 adults (1 M, 1 F)	0	0
.. 4	12/12/56	1 child (F), 1 adult (F)	1 adult (M)	0	0
.. 5	13/12/56	1 adult (F)	1 adult (M)	0	0
.. 6	13/12/56	4 children (4 F)	2 adults (1 F, 1 M)	0	0
.. 7*	13/12/56	3 adults (1 M, 2 F)		2 dogs	0
.. 8	17/12/56	1 adult (F)	1 child (F), 1 adult (M)	1 cat	0
.. 9†	17/12/56	3 children (2 M, 1 F)	10 adults (5 M, 5 F)	3 cats	3 cats
Total		22 (5 M, 17 F)	20 (12 M, 8 F)	6	3

* This kitten was responsible for the infections which started the investigation.

† This kitten had passed through four households before it was finally located.

The addresses to which the kittens had been sold were obtained and visited (see Table). We were, however, unable to complete the investigations in respect of a kitten sold on November 25.

Of persons exposed to infection from the kittens 14 of 15 children (93%) and 8 of 27 adults (30%) are known to have been infected.

The common sites for lesions were the face, neck, forearm, and backs of hands. In only two cases were the scalp and the hair affected. The most extensive infection was in a girl of 8, whose neck, face, trunk, and scalp were involved.

The sex distribution of the cases was predominantly female (17 F., 5 M.), perhaps because many of the kittens were bought as pets for girls. Only one adult male was affected.

Investigation in Retrospect

The breeder recalled that all kittens born after the purchase of a tom-cat from Leeds in February, 1955, had shown patchy alopecia of the face. The tom-cat itself had suffered from a skin condition on arrival, and, although the breeder and her two children developed ringworm with three weeks after its arrival, no one had thought of blaming the newly acquired tom-cat. Three kittens born on the breeder's premises before the arrival of the Leeds tom-cat were traced and no cases of ringworm were reported from these three households.

All the kittens born between February, 1955, and September, 1956, could not be traced, but visits to six households receiving kittens during this period revealed that three of these kittens had given rise to four cases of ringworm; the other three kittens produced no cases, but there were 1 children in these last households.

It was confirmed that *M. canis* infections have been endemic among cats in Leeds in recent years (La Touch personal communication).

Examination under Wood's light of cats belonging to neighbours of the breeder and of several pedigree Persians elsewhere showed no infection. The case against the tom-cat was considered proved.

One other interesting point emerged from these investigations which had stimulated an animal-lover to report that she had visited the breeder's premises on one occasion and had fondled the cats. She then developed a patch of ringworm on her thigh 17 days later, and a second patch appeared near the original site in a further five days. This gives an incubation period of 17 to 22 days. The affected part of the thigh was that area where a finger-nail would rub when adjusting a stocking suspender.

Comment

The high infectivity rate is notable—93% of children and 30% of adults exposed being affected. It was considered that the degree of exposure was responsible, as the kittens would be frequently fondled by the children, while their mothers performed the daily combing of the long hairy coat.

The fact that scalp lesions due to *M. canis* regress at puberty (Kligman and Anderson, 1951), "albeit slowly," has given rise to the impression that adults are relatively resistant to this type of ringworm. The present outbreak does not lend support to this view, as both adult humans and cats were infected, and it would appear that the degree of exposure might be the factor responsible for the difference in age incidence. Most of the lesions occurred on the glabrous skin, whereas a high percentage of *M. canis* infections seen in hospital practice occur on the scalp. This would suggest that the real incidence of this infection is generally greatly underestimated, as the body lesions, being easily treated, never reach hospital clinics.

The circumstances of the outbreak produced an excess of females over males infected, in contrast to previous outbreaks described (Beare and Cheeseman, 1953), where boys were more commonly affected than girls (ratio 2:1). However, in these cases stray cats were usually traced as the source of the infection. The sex incidence of scalp infection shows a higher percentage of boys, because the long hair of girls protects the epidermis of the scalp.

All the cases occurred within a few weeks of the arrival of the kitten in the household, and were obvious kitten-to-child transmissions. No case of child-to-child transmission was noted, and no further cases occurred after the infected kittens and cats had been destroyed. This would suggest that child-to-child transfer may be an even less important factor in the spread of the infection than noted by Duncan (1945) and that the main source of infection is the infected kitten or dog. General practitioners, while generally adept at diagnosing the ringworm infection, were unwilling to point suspicion at the recently acquired expensive kitten—perhaps the name *M. canis* is misleading. Some of the new owners, however, suspected the kittens and brought them to experienced veterinary surgeons. As the kittens all appeared clinically free from any infection they were returned to their owners, who were reassured. This confirms the advice given by La Touche (1952) that all kittens and cats associated with human cases of *M. canis* should be examined under Wood's light, as generally there are no obvious clinical lesions. In dogs and puppies, and sometimes with short-haired cats, the condition is more apparent, as depilated or desquamated areas are frequently present.

The necessity for close co-operation between the health department and local veterinary surgeons when cases of *M. canis* infection arise is stressed so that no affected animals are missed. As frequent false types of fluorescence are seen, anybody using Wood's light should be familiar with the typical pale-green fluorescence which is given by hairs affected with the microsporum fungus.

We realize that the condition often undergoes a spontaneous cure, but are unaware of any proved treatment for the infection in cats and dogs. As the fungus can remain dormant in the spore stage for up to a year, special difficulties arise when the condition occurs in breeding catteries or pet shops, and it then becomes a special problem for the local health authorities.

Summary

An outbreak of ringworm due to *Microsporum canis*, giving a high infectivity rate (93% children and 30% adults affected) and unusual sex distribution (M./F. 1/3.4), is described.

Epidemiological investigations revealed the source of the outbreak.

An opportunity to confirm the incubation period (17–22 days) is noted.

The necessity of ascertaining and dealing with the animal reservoir as the essential factor in controlling this infection is stressed.

The role of a cattery in spreading infection throughout a community is noted.

Our thanks are due to Dr. J. Martin Beare (who referred the original case) for his assistance in compiling this report; Dr. V. D. Allison and the staff of the Northern Ireland Public Health Laboratory for isolating and culturing the fungus; local general practitioners and veterinary surgeons for their close co-operation; and Dr. J. B. McKinney, Dr. W. G. Swann, and Dr. S. Hayes for permission to publish this report.

Medical Memorandum

Traumatic Aneurysm Treated by Excision, and the Effect of Chlorpromazine

The following two cases are recorded in view of the increasing interest in the surgery of aneurysms. Both, moreover, were unusual in site. One followed a trivial commonplace injury, and the other presented interesting anastomotic features. The most satisfactory treatment for aneurysm is excision, preferably with arterial replacement, for which a prepared artery or plastic tube is required. If excision is impracticable then an obliterative operation may be attempted or the aneurysm ligated proximally or distally. Excision alone seemed to be indicated in our cases, neither stored arteries nor suitable plastic material being available for replacement.

In the treatment of subclavian aneurysms the record in the past has been a poor one and history has recently been summarized by Moloney (1955). The greatest dangers lay in operative blood loss and in the effects of sepsis. Proximal ligation alone resulted in considerable mortality. Excision was practised on occasion. Saigo (1906) was the first to excise an aneurysm of the subclavian artery successfully, and Herzen (1910) recorded a further case. Von Haberer (1915), Braithwaite (1920), and Moloney (1955) each excised an aneurysm at this site with recovery of the patient.

CASE I: ANEURYSM OF THE SECOND PART OF THE RIGHT SUBCLAVIAN ARTERY

On January 12, 1956, a 30-year-old married Chinese was involved in a fight during which a penknife was plunged into his neck above his right clavicle. He was admitted to hospital suffering from haemorrhage from this wound, where it was noted that the posterior triangle on the injured side of the neck was tense with blood clot. A little blood still oozed from the wound. The right radial pulse was palpable but feeble. He was transfused, a pressure dressing was applied above the right clavicle, and he made a steady recovery. The skin wound was not sutured.

During the course of the next three weeks the skin wound healed, and the swelling in his neck became firmer, smaller, and pulsatile. A bruit was detectable over it. Compensated mitral stenosis was also noted. A saccular aneurysm of the subclavian artery was diagnosed. On February 6 the aneurysm slowly began to increase in size. The right radial pulse remained palpable though diminished in force, and there was no interference with brachial-nerve conduction. The aneurysm was explored on February 11.

Operative Details.—Anaesthetic (Captain Boyes): chlorpromazine hydrochloride 50 mg., promethazine 50 mg., pethidine 100 mg. (all three given fifteen minutes pre-operatively), thiopentone 0.4 g. Endotracheal tube used and N₂O + O₂ given throughout. Pethidine was given intermittently. A large drip cannula was inserted into the left cephalic vein at the shoulder and two pints (1.14 l.) of

Diagram showing the aneurysm, the costo-cervical trunk opening into it posteriorly, and the transverse cervical artery preserved as the only anastomotic vessel before excision of the sac. The points of main vessel ligation are also shown.

blood was given at varying speed during the operation. The root of the neck was exposed on the right side by Henry's incision and method, the clavicle and sternomastoid muscle being divided and the shoulder allowed to fall outwards. The aneurysm of the second part of the subclavian artery was confined by the scalenus anterior muscle and surrounded by thickened inflammatory tissue; it was saccular in type (see Diagram). The sac was then opened and a considerable resulting haemorrhage was checked by packing the sac with gauze. Intravenous blood was administered under pressure. The distal end of the main artery was then closed from within, using thread sutures on a needle, but bleeding continued from the costo-cervical trunk, the mouth of which opened into the sac. This was similarly dealt with. The field was now quite dry and it was a simple matter to remove the aneurysmal sac.

The patient's progress was uneventful and he left hospital five weeks later. When examined two months later he complained of pain at the site of division of the clavicle. The right arm and hand were normal, and a faint pulsation could be detected in the radial artery at the wrist.

CASE II: ANEURYSM OF LEFT SUPERFICIAL TEMPORAL ARTERY

A Welch Fusilier was admitted to the Military Hospital, Kluang, on March 26, 1956. He had been on a jungle patrol when a branch of a tree swung back and hit him heavily on the left temple. He was "dazed" but not concussed, and later that evening he noticed a painful lump on the side of his head.

On examination he had a lump the size of a glass marble just in front of and above his left ear. This lump showed expansile pulsation but could not be made to collapse by occluding any surrounding vessel. A skull x-ray film was negative. Otherwise he was quite normal. A diagnosis was made of aneurysm of the superficial temporal artery.

Operation (April 4).—The swelling was encircled by an incision, and the resulting scalp flap retracted backwards. A saccular aneurysm of the superficial temporal artery was uncovered. The temporal vein was intact but was stretched over the aneurysm. The tumour was excised after ligation of both the artery and the vein above and below it. The scalp was then closed. He made an uninterrupted recovery.

COMMENT

We have been unable to trace references to traumatic saccular aneurysm of the superficial temporal artery, and it seems surprising that this lesion does not occur more often at that exposed site. The resemblance of this type of aneurysm to a sebaceous cyst may be a trap for the unwary—with dangerous consequences.

The result following excision of the subclavian aneurysm was gratifying, considering that the transverse cervical artery and minute thoracic vessels alone provided the collateral circulation in the shoulder region. It is likely that this meagre collateral supply was opened to its utmost by the four-weeks delay between wounding and formal operation. Few available collaterals had been damaged by the injury, and the virtues of a waiting policy in this type of lesion are generally accepted. It should be added that Henry's exposure proved very suitable for the large vessels at the root of the neck, but that division of the clavicle gave rise to a good deal of post-operative pain.

Thanks are due to Colonel R. Stephen, Consultant Surgeon FARELF, and to Lieutenant-Colonel J. Irvine, O.B.E., for permission to record these cases, and to the Sisters and Malay orderlies who assisted in their care.

The seventeenth congress of the International Society of Surgery was held in Mexico City from October 20 to 27, under the presidency of Professor WOLFGANG DENK, of Vienna. Over 300 surgeons from 22 countries, including a delegation of 21 from Soviet Russia, attended. Those from Britain included Professor LAMBERT ROGERS (Cardiff) and Mr. G. H. McNAB and Mr. M. H. HARMER (London). The main theme of discussion was cancer. An outstanding contribution was that by Dr. E. L. WYNDER (New York), who, in tribute to the late Dr. Evarts Graham, of St. Louis, dealt with the epidemiology. Dr. Wynder believed that many lives could be saved if attention were paid to what he regards as now well-established facts: for instance, reduction in cigarette smoking would reduce the incidence of lung cancer, and circumcision of infants that of cancer of the uterine cervix. Mr. Harmer reported on the results of adrenalectomy in breast cancer at the Royal Marsden Hospital and on the value of combined surgery and radiotherapy on cancer of the mouth; Professor Lambert Rogers on malignant tumours of the spine and spinal cord; and Mr. McNAB on cancer in childhood and on hypophysectomy combined with radiotherapy in metastatic cancer of the breast.

Reviews

TEXTBOOK OF PSYCHIATRY

A Textbook of Psychiatry for Students and Practitioners. By Sir David Henderson, M.D., F.R.F.P.S., F.R.C.P., and the late R. D. Gillespie, with the assistance of Ivor R. C. Batchelor, M.B., F.R.C.P.Ed., D.P.M. Eighth edition. (Pp. 746 + xii. 35s.) London, New York, Toronto: Oxford University Press. 1956.

This famous textbook of psychiatry has now reached its eighth edition, and all British psychiatrists will wish to congratulate the senior author on this great record and on the contribution he and his co-authors have made to psychiatric education. It is not too much to say that the British approach to clinical psychiatry has been dominated by this work, which has made the influence of the Edinburgh School more important than any other. The vitality that still lies in the Meyerian approach as exemplified and diffused by Sir David Henderson still maintains itself. Among the most interesting features of the book are the contributions of Sir David himself, his views on psychopathic personality, and on the independence of the paranoid syndromes which most psychiatrists would not distinguish from paranoid schizophrenia. It would be an ungrateful task to criticize the book in detail but for the hope that new editions will continue to appear and that the Scottish School will continue to make its influence felt.

The present edition has been rearranged and rewritten, but the authors have not been ruthless enough in discarding portions of the old. There are many items which might be considered for omission, such as the discussion of focal infection, the classification of the various insanities according to the physical disease (diabetic insanity, gouty insanity, etc.), and a great part of the over-long case histories. One of the most interesting and valuable features of the work which are peculiar to it is the first chapter of historical review. This is so good that it should be made factually perfect. I think I am justified, therefore, in suggesting the following corrections, which have been brought to my attention by Dr. Richard A. Hunter. The "sacred disease" of Hippocrates was not epilepsy only, but included all abnormal mental states of sudden onset. Helkiah Crooke (not "Crookes") was appointed Keeper and Physician (not Governor) to Bethlem in 1618, not 1632; indeed, he was dismissed in 1634 because he absconded with the funds. The treatment meted out to George III did not cause great indignation, but rather caused a widespread interest in insanity and the insane and so led to reforms. A committee to inquire into the King's treatment was appointed not by the House of Lords only but also by the House of Commons. Daquin (not Daguin) is associated with humane reform in France, not Italy. Conolly, the great exponent and champion of non-restraint, and who introduced the term, spelt his name with one "n," not two. Pinel was appointed physician to the Bicêtre Hospital in 1793, so that he could not have been given a free hand by the revolutionary Commune in 1792. Dr. Munro was physician to Bethlem, not superintendent. The first Bill appointing Commissioners to visit homes in which the insane were detained was not passed in 1828, but in 1774; what happened in 1828 was that the College of Physicians relinquished their authority for appointing visitors in the London area to the newly constituted Metropolitan Commissioners. The first teacher of psychiatry in Great Britain was not Morison in 1823 but William Battie, who was giving clinical instruction to students at St. Luke's in 1753. These are small points, but as this is an important standard textbook, of which further editions will certainly be called for, they are worth pointing out. Perhaps also, in a future edition, some system might be introduced into the giving of references; these vary from a full reference to "A recent investigation . . . in a Scottish city showed . . ."

ELIOT SLATER.

CONGENITAL VISCERAL ANOMALIES

Congenital Anomalies of the Viscera: Their Embryological Basis. By J. Lewis Bremer, M.D. (Pp. 202+ix; illustrated. 40s.) Cambridge, Mass.: Harvard University Press. London: Oxford University Press. 1957.

This book is written mainly to supply the needs of the paediatrician, pathologist, or surgeon who requires a more detailed description of the commoner abnormalities in development than is to be found in the usual textbooks of embryology. As the author points out, many of the recognizable abnormalities can be traced to arrest of development followed by a halting resumption of growth or to disturbances of growth sequences. He points out that many abnormalities or anomalies may be caused by chemical or hormonal agencies or by maternal disease as well as by genetic factors. Many of the hitherto unexplained abnormalities can now be traced to their embryological source. The book is divided into eleven chapters each dealing with one or more of the main organ systems. In each chapter the normal development is briefly reviewed, and this is followed by a description of the commoner abnormalities found. The book is well written and presents lucidly the results of many years of research. It can be recommended to those who wish to have a concise account of congenital anomalies.

W. J. HAMILTON.

OPHTHALMOLOGY FOR THE G.P.

The Eye in General Practice. By C. R. S. Jackson, M.A., B.M., B.Ch., D.O.M.S., F.R.C.S.Ed. (Pp. 152+vii; illustrated. 21s.) Edinburgh and London: E. and S. Livingstone Ltd. 1957.

This is a book of 150 pages. Part I is devoted to diseases of the eye and takes up two-thirds of the space available; Part II describes ocular manifestations of cardiovascular, intracranial, endocrine, and systemic disease; and Part III consists of two short chapters—on the welfare of the blind and on the ophthalmic aspects of the National Health Service. It is a book which is welcome because it is right in length and weight for the busy general practitioner or for the interested undergraduate. It is well written, compact without being terse, well balanced with no serious omissions, and seemingly unhurried in its composition. That is not to say that all the author has written is generally accepted. Surgery is usually regarded as the treatment of choice for rodent ulcer rather than radiotherapy, and band-shaped opacity of the cornea is treated much more satisfactorily with sodium calciumedetate than by the curette. With regard to convergent concomitant squint, many cases begin before the age of 3 years, and it is worth stressing that, if strabismus is treated as an emergency, occlusion and orthoptic re-education may be reduced to a minimum. Early surgery is becoming standard treatment, and the general practitioner should know about this tendency so that he can obtain the parents' co-operation. Glaucoma is regarded as a mystery by the author, but this attitude of mind is surely out of date. When we consider much commoner diseases such as peptic ulcer or disseminated sclerosis, glaucoma is an open book by comparison. Most surgeons believe that medical therapy has no place in the treatment of infantile glaucoma and that closed-angle glaucoma should be treated surgically if catastrophe is to be ultimately avoided. To teach that homatropine to dilate pupils is always an absolutely safe procedure (p. 6) is quite inexcusable. In the presence of shallow anterior chambers its use may precipitate a bilateral acute attack of glaucoma requiring surgical intervention. This would be particularly unfortunate if the patient was on the list of "a single-handed general practice some distance from a town and from an eye specialist," as mentioned in the preface. Eserine should be added to the list of drugs on page 29 which can give rise to an allergic and florid conjunctivitis of a most troublesome kind in patients with chronic glaucoma. On page 74 retrolental fibroplasia is discussed and recognition is given to Terry for first describing the disease in the United States.

TUMOURS OF NERVOUS SYSTEM

Atlas of Tumors of the Nervous System. By H. M. Zimmerman, M.D., Martin G. Netsky, M.D., and Leo M. Davidoff, M.D. (Pp. 191; illustrated. £9.) London: Henry Kimpton. 1957.

1957.

The authors in their preface reveal their intention that this book should be a reference atlas for neuropathologists and neurosurgeons, but it is difficult to believe that in this country many individuals could afford the luxury of its purchase. For the neuropathologist the inspection of reproductions of microscopic preparations can never take the place of practical experience and personal tuition under the guidance of an expert; while the neurosurgeon would do better not to attempt for himself the art of neuropathological diagnosis (except as a hobby)—he has his time fully occupied with other matters. The illustrations are lavish, mainly coloured, and include many histological preparations, for the most part of high quality, and photographs and drawings of specimens at operation and at necropsy. The quality of the reproductions of macroscopic specimens varies a great deal, but for a book of this price too many are poor and would have been better omitted. A section on the effects on the brain of raised intracranial pressure has been included, with particular reference to internal herniations. But this important subject has been dealt with in a cursory and inadequate manner: of five illustrations of brains with herniations, the causative tumour is mentioned in only one; and in one illustration what are described as medial herniations of the occipital lobes through the central incisura appear rather to be posterior hippocampal herniations. There is no picture of calcarine infarction. The statement that terminal pontine haemorrhages and occipital haemorrhagic necrosis are of venous origin is not acceptable in Britain. Reproductions of radiographs of the skull, ventriculograms, an angiogram, and a myelogram are out of place. There are a number of pages entirely blank and others only partially used. With careful editing the authors could have achieved their aim at a lower price. Wasted space could have been avoided, and greater emphasis placed on histological preparations, omitting illustrations which merely irritate because they do not demonstrate, and reducing the text, which includes "clinical features" so elementary that they are the minimum requirements for an undergraduate. The book is beautifully produced and on excellent paper. D. W. C. NORTHFIELD.

EXTRASENSORY PERCEPTION

Healing the Mind: How Extra-sensory Perception Can be Used in the Investigation and Treatment of Psychological Disorders. By R. Connell, M.D., F.R.C.P.I., and Geraldine Cummins. (Pp. 190. 12s. 6d.) London: The Aquarian Press, 1957.

Press, 1957.

This book presents problems of reviewing which are insuperable. Briefly, the authors claim therapeutic success by means of extrasensory perception (E.S.P.), making use of a medium. A number of case histories illustrate the method used, and there can be no doubting the striking nature of these reports. In view of the impressive work of Rhine, Soal, and others, I would not wish to doubt the reality of some E.S.P. phenomena. However, those reported here transcend by a long way the experimentally ascertainable facts. The case histories are too short to allow one to judge the adequacy of the precautions taken to avoid the well-known pitfalls of this type of work, and the fact that the main author is writing anonymously does not even permit one an opportunity of checking his competence in this field by reference to his past experience and publications. The book cannot, therefore, be regarded as anything but a curiosity, but as such may appeal to those who are unwilling to rule out the improbable completely.

H. J. EYSENCK.

MEN WHO MADE SURGERY

Scalpel: Men Who Made Surgery. By Agatha Young. (Pp. 311+viii; illustrated. 21s.) London: Robert Hale Ltd. 1957.

This is a readable but rather selective book about a number of famous men who have, directly or indirectly, advanced the art of surgery. There is a thin thread of surgical history running through the book, for the biographies are chosen to show the progress of control over haemorrhage, pain, infection, and shock.

The author at one time did nursing and at another time taught at the Yale School of the Drama. It is therefore not surprising that the lives of her heroes are dramatized. Concerning Vesalius and his liking for dissecting small animals we are told: "The mangled corpses he so painstakingly dismembered had for him a strange sort of beauty, and their physical mechanisms absorbed him." We are told of the occasion on which Cushing laid down his instrument, walked to the side of the operating table, leaned over the conscious man, who was, without knowing it, rapidly bleeding to death, and said, "You must not worry now. In a very few minutes you are going to feel better." A great many useful facts are put before the reader, but there is not sufficient indication of the relative value of the facts, and there are many minor inaccuracies which will annoy the medical historian. By an unfortunate misprint on page 168 Lister instead of Syme is made out to be a quarrelsome fellow. There are some good epigrams—for example, "In surgery the only changeless thing is change"; and again, "If Lister had a vice, it was excess of virtue." There is a felicitous reference to "the tangled skein of personalities, antagonisms, jealousies, ambitions, coincidences, hates and simple stupidity which is the story of anaesthesia." Finally, the absence of central heating in some English hospitals is driven home—"In many a ward in England to-day there can still be seen a double row of patients with blankets up to their chins, their breath turning into little columns of white vapour." As the reader will have divined, there are few dull pages in this book, but surgeons will not be satisfied with it.

ZACHARY COPE

ZACHARY COPE.

The Oxford Handbooks for Medical Auxiliaries are a new series of textbooks designed primarily for the training of auxiliaries in the Tropics, the first of which, *Surgery: A Guide to Surgical Diagnosis and Treatment Including Tropical Surgery*, by W. G. Kerr, has recently been published (Oxford University Press, Amen House, Warwick Square, London, E.C.4; pp. 410 + viii; 25s.). The book explains the types of injury or disease requiring surgical measures and describes the treatment which an auxiliary could give or maintain. Necessary technical terms are explained, and such anatomy or physiology as is needed has been included. As well as those for whom it is designed, the book should also prove of use as an introduction to surgery for medical students, and to lay persons whose work requires some knowledge of general medicine and surgery.

To smoke or not to smoke being the question of the day, Sir Compton Mackenzie's latest book, *Sublime Tobacco* (Chatto and Windus; 21s.), may well be regarded as the apologia of a lifelong addict. It has been written, the author says, "as a token of gratitude for the immense benefit I have received from tobacco and in complete certainty that I have not derived from it the slightest harm." This is a well-documented and illustrated history of tobacco, tobacco-smoking, and the tobacco trade from its introduction into Europe from America to its present position as an important source of revenue, both public and private. The text contains many quotations, ranging from James I's *Counterblaste to Tobacco* of 1604 to eighteenth-century rhymed advertisements and the anti-tobacco campaign of Dr. Solly in 1857. As a prologue Sir Compton relates the history of his own smoking life, from his first cigarette at the age of 4½, through a variety of pipes, cigarettes, and cigars, to his present unrepentant addiction.

Synthetic Polypeptides, by C. H. Bamford, A. Elliott, and W. E. Hanby, is a comprehensive survey of the preparation, structure, and properties of these compounds. It is published by the Academic Press, Inc., 111, Fifth Avenue, New York, 3, price \$10.

BINDING OF HAEMOGLOBIN

Proteins which combine with haemoglobin in plasma or serum are called haptoglobins. They have been studied on the Continent for some years.¹ On electrophoresis in a Tiselius apparatus or on filter paper the haptoglobins separate with the α_2 globulins. According to M. F. Jayle and colleagues² each molecule of haptoglobin can combine with one or two molecules of haemoglobin. The molecular weight of haptoglobin has been estimated to be about 175,000 and that of the complex (with two molecules of haemoglobin) 310,000.

Recently O. Smithies^{3,4} has shown that when electrophoresis of serum is carried out on starch gels several different patterns of haemoglobin-haptoglobin complexes can be distinguished. He concluded that healthy people could in fact be separated into three hereditary groups according to the number and mobility of the complexes so formed. Smithies also reported that the haptoglobins could normally bind about 125 mg. of haemoglobin per 100 ml. of plasma and that any haemoglobin in excess of this remained uncombined. The bearing of these interesting new developments on the renal threshold for haemoglobin and the occurrence of haemoglobinuria in haemolytic syndromes has been the subject of two recent publications.

C. B. Laurell and M. Nyman,⁵ of Malmö, injected haemoglobin intravenously into normal subjects in an amount calculated to saturate the plasma haptoglobins; they found that the haemoglobin-haptoglobin complex as a whole disappeared steadily at a rate of about 13 mg. per 100 ml. per hour, and that it took up to a week for the haptoglobins to be fully regenerated. They concluded that free haemoglobin would not be found in the plasma unless the binding capacity of the plasma was fully saturated, and that the minimum amount of haemoglobin injected intravenously which would result in haemoglobinuria would vary with the amount of circulating haptoglobin. Laurell

and Nyman estimate that the amount of haemoglobin which may be bound by the plasma of normal subjects varies from 50 to 140 mg. per 100 ml. The renal threshold for haemoglobin therefore depends, according to these Swedish workers, on the ability of the plasma to bind haemoglobin (that is, on its haptoglobin content) as well as on the ability of the renal tubular cells to reabsorb haemoglobin from the glomerular filtrate. The reduction in renal threshold first observed experimentally by J. A. Lichty and co-workers⁶ in dogs given repeated injections of haemoglobin could therefore be attributed, at least in part, to the slow regeneration of plasma haptoglobin. Laurell and Nyman mention, though without giving details, that sera from some patients with acquired haemolytic anaemia or untreated pernicious anaemia showed no demonstrable haptoglobin, and they refer to the early and forgotten work of A. W. Sellards and G. R. Minot.⁷ These workers, observing that a smaller amount of intravenously administered haemoglobin was required to produce haemoglobinuria in patients with pernicious anaemia or haemolytic anaemia than in health, concluded that there was a relationship between tolerance of haemoglobin and destruction of blood.

In the *Journal* this week Dr. A. C. Allison and Mr. W. ap Rees (p. 1137) publish further observations on the relationship between the plasma haptoglobins, renal threshold, and haemoglobinuria. Using the starch-block technique of electrophoresis, they have confirmed that the great majority of subjects fall into one of three groups: 1-1, with only one haptoglobin migrating in the fast α_2 position; 2-2, with three haptoglobins migrating as three distinct bands in the $\alpha\beta$ region; and 1-2, with four haptoglobins, three migrating slightly faster than those of group 2-2 plus one which is apparently the same as that of group 1-1. Umbilical cord blood is distinctive in not containing demonstrable haptoglobin, and Allison and Rees also state that a few older children and adults have sera lacking haptoglobin or at the most a single component giving a band in the $\alpha\beta$ region. They then describe interesting experiments on the effect of adding oxyhaemoglobin to serum *in vitro*. When more than 100-135 mg. per 100 ml. are added, free oxyhaemoglobin can be demonstrated, migrating as a band distinct from the haemoglobin-haptoglobin complexes, as well as methaemalbumin, which migrates in the albumin region. Like Laurell and Nyman, they conclude that the renal threshold for haemoglobin depends primarily on the haptoglobin level of the plasma. Finally, they report observations on the sera of patients suffering from intravascular haemolysis. In four patients with paroxysmal nocturnal haemo-

globinuria and in two of three patients with paroxysmal cold haemoglobinuria haptoglobins were absent or present in quantities too small to be detected, and in one case of march haemoglobinuria the concentration of haptoglobin was less than half the normal value. In one possible case of paroxysmal nocturnal haemoglobinuria, examined at least eight years after apparent complete recovery, the haptoglobins were normal, as they were also in a patient with paroxysmal cold haemoglobinuria who had had a single attack several years previously. Allison and Rees point out that the low levels of haptoglobin could be the result of one of two mechanisms: (1) diminished formation, for genetic or other reasons; or (2) rapid removal from the blood stream as the result of the continuing intravascular haemolysis. The second hypothesis seems the more likely on the available evidence. However, the suggestion that march haemoglobinuria might be the consequence of an originally low plasma haptoglobin level is attractive and merits further study.

MAN ON THE MOON

Any moment now, it is rumoured, the Russians will follow up their latest satellite with a rocket directed at the moon, where a successful hit on the target should be recognizable through a telescope, according to report, as a splodge of red powder. Eventually, man is expected to follow in its wake; but, if the same method were used, he, in turn, would finish up in a state not far different from powder.

A manned rocket to the moon will have to carry not only enough fuel to get its passenger there, but further fuel for braking his descent (by reversing the rocket so that the gases are fired forwards), and again for starting him on the return journey. In addition, this extra fuel will need still more fuel—many times as much—for lifting it off the earth into space. All this adds up to such a gigantic take-off weight for a direct voyage from earth to moon and back that the astronomical experts envisage making a preliminary journey up to a sort of staging point in a satellite orbit, and there, so to speak, changing ships in mid-stream. For example, Wernher von Braun,¹ who designed the wartime V2 rocket, has worked out a detailed plan for taking 50 men in two vehicles from a satellite station to the moon and back. The ships would be built at the satellite station, and hundreds

of ferry rockets would be needed to bring the building materials, fuel, and passengers up from the earth. Each ship, according to his calculation, would leave the satellite weighing 4,370 tons, reach the moon weighing 350 tons, take off again weighing 333 tons, and finally draw alongside the satellite station weighing only 39 tons. Food, oxygen, and water for each party of 25 men would weigh 1.4 tons. It is not quite correct to describe these figures as "weights," for the objects would have to come down to earth to weigh that much. At the satellite station these materials would weigh virtually nothing, and even on the moon they would have only one-sixth of their earthly weight.

Arthur C. Clarke, in a fancifully prophetic book,² imagines the moon as a new kind of health resort where people who, from cardiac insufficiency or other causes, find difficulty in moving their weight about can discard five-sixths of it and so prolong their lives into a comfortable old age. More active people would adapt their recreations to lunar standards: but here we are warned to distinguish between weight and mass. In spite of reduced gravity, it does not follow that a man can jump vertically up from the ground six times as fast on the moon as on the earth; it is mass that he has to accelerate, not weight, and mass is the same on both worlds. However, though a man could jump no faster, the weak gravity would take six times as long to bring his vertical ascent to a stop, and again six times as long to pull him back to the ground. Nor would an athlete who can do a 6 ft. (1.8 m.) high-jump on the earth manage 36 ft. (11 m.) on the moon, for, though the soles of his feet rise through that distance, his centre of mass goes up hardly more than 4 ft. (1.2 m.) as he lifts it over the cross-bar. Still, a high-jump of something over 25 ft. (7.5 m.) should be an impressive sight. The same distinction between mass and weight, Clarke points out, would apply to games: bowls and billiards should be hardly affected, as all the motion is horizontal, but tennis, cricket, and baseball could be awkward, and a golfer might well lose his ball after every drive. But why indulge in games and athletics on the moon? The answer is, to prevent muscular atrophy; because people will need little more than a baby's muscle-power to carry on normal activities.

However, the inconveniences of reduced weight are as nothing compared to the problem of living on an airless world, and, moreover, one whose temperature at the surface can range from +220° F. (105° C.) at mid-"day" to -240° F. (-151° C.) at "night." That the moon is virtually airless was long ago proved by watching it pass in front of a star; the star maintains its brightness, with no sign of dimming, right up to the moon's edge and then vanishes instantaneously.

Nevertheless, in spite of this observation, the moon has been thought to possess a tenuous atmosphere of about the same density as that of the earth at the level where meteors are destroyed by friction, although the density at this height is less than one-millionth of that at sea level.³ Some optical evidence suggests that the moon's atmosphere is about as dense as this, in which case any visitors to its surface would at least be free from celestial bombardment, whatever other difficulties they might have to cope with. But even that hope now seems to have gone, for radio astronomers at Cambridge⁴ have concluded, from watching a celestial radio source being eclipsed by the moon, that its atmospheric density cannot be more than one million-millionth of that at sea level on the earth; and this would stop no meteors.

In any case, the first arrivals on the moon will have to go about in space suits until they can put up some sort of airtight shelter. Space-suit designs vary between two extremes. On the one hand we have those often depicted in illustrated science fiction, which fit the female form so closely that essential "vital statistics" are in no way concealed. Unfortunately, experience has shown that, when this kind of suit is adequately inflated, the four limbs tend to become splayed out at right angles to each other so rigidly that no effort can move them. On the other hand, we have the opinion of F. Haber, of the Space Medicine Department of the U.S. Air Force, who believes that, "If humans want to work in the vacuum outside their space ships, they must do it in solid-walled cylinders, each provided with elaborate air-conditioning apparatus. If they want to walk on the surface of the moon, they will have to do the work with metal arms and hands like the remotely controlled manipulators used by atomic scientists."⁵ As to airtight living quarters, it has been suggested⁶ that oxygen to fill them could be extracted from iron or aluminium oxides in the moon's crust. A municipal engineer,⁷ who proposed rigid buildings with a double roof as protection against extremes of temperature, was criticized on the ground that a sort of plastic balloon, kept rigid by internal pressure and placed in a cave to guard against meteors, would be as effective; but he replied that he liked his game of darts and would hate having to dive for a space suit whenever he missed the board.

Many are the motives for wanting to go to the moon. The geologists would like to settle the age-long controversy whether all those innumerable craters were formed by meteoric bombardment or by volcanic action; the astronomers want to set up their telescopes where no atmospheric unsteadiness will blur

their optical images; the meteorologists want to watch the earth's weather in their never-ending search for some method of accurate forecasting; Sir John Hunt has heard that the lunar mountains rise to 40,000 feet, and is anxious to have a go.⁸ And finally there are the nationalists whose object is to plant their country's flag there, forgetting that a flag is a severely functional piece of apparatus designed for "waving proudly in the breeze." On the moon they will find no breeze for it to wave in.

THE WILLINK REPORT

It was stated in Monday's newspapers that the Willink Committee report will be published by the end of this week, but it had not reached this *Journal* by the time we went to press. A correspondent in the *Sunday Times* of November 10 appears to know what is in the report, for he began his letter thus, "How disturbing to members of professions to learn that the Willink Committee has recommended restricting future entry into medical schools. Will the rot spread?" According to the Political Correspondent of *The Times*,¹ "It is expected that the report will make recommendations for the control of the entry of student doctors into the medical schools, on the basis of long-term estimates of the number of medical practitioners who will be needed in Britain and the Commonwealth." If these forecasts are correct, then the recommendation of the Willink Committee will be contrary to the views of the medical profession as expressed in the evidence given by the B.M.A. and by its Scottish Committee, summaries of which are published in this week's *Supplement*. If it is true that the Willink Committee is advocating a numerical limit on the entry of medical students on the basis of predicting something which is almost unpredictable—that is, the future medical needs of this country—one possible explanation would be that such a recommendation is related not so much to medical needs as to the cost of the Service.

ACCIDENT AT WINDSCALE

A report on the accident at Windscale,² published as a White Paper³ last week, shows that no harm to anyone's health is to be expected, though it points to certain shortcomings in organization. An operation for the controlled release of Wigner energy, which is a routine procedure in uranium-graphite piles, was being carried

out at the time the accident occurred. A standard pile consists of a large block of graphite somewhat larger than a house, with hundreds of cylindrical holes passing from one side to the other, parallel to the ground. Cartridges composed of uranium and uranium oxide contained in a case of aluminium or zirconium alloy are inserted into the centre of the pile through the holes at one side, and, when expended, are pushed out from the other by fresh cartridges similarly inserted. The surrounding graphite is known as the moderator and slows down the neutron emission from the uranium to a suitable level. This results in some of the atoms of carbon becoming displaced from stable to unstable positions, thus increasing the internal energy of the graphite. E. P. Wigner⁴ postulated that this would occur, and the phenomenon is known as the Wigner effect. The Wigner effect is progressive and can result in a spontaneous release of energy. This occurred in the Windscale pile in 1952. Artificial heating of the graphite under controlled conditions causes a reversal of the Wigner effect, and this operation, which had been successfully accomplished on eight previous occasions, was in progress when the accident occurred.

Controlled release of stored Wigner energy is accomplished by shutting off the air cooling systems which are normally in operation and allowing the temperature of the pile to rise. The progress of the operation is assessed by observation of the temperatures which are recorded by thermocouples, but on this occasion, owing partly to the lack of adequate knowledge of the Wigner effect at the time the pile was built, unduly high temperatures were being attained at points in the graphite where thermocouples were not installed. The physicist in charge of the operation, handicapped by insufficient data and inadequate instructions for the procedure, repeated the heating process too soon and too quickly, causing failure of the uranium cartridges and oxidation of the uranium. On October 9 it was realized that the graphite temperature readings were unusually high, and the cooler fans were turned on intermittently. Early on the next day, meters in the chimney recorded increased radioactivity, but the levels were considered to be within normal limits. The fans were turned on again, and again the measured radioactivity increased. As a result of these observations the operators concluded that one or more uranium cartridges had failed. Special apparatus is installed to assist in the detection of burst cartridges, but on this occasion the scanning gear was found to be jammed, although it had been recently repaired. It was necessary therefore to arrange for visual inspection through the pile face, and four channels revealed cartridges at red heat. Because the cartridges were distorted by the heat it was not possible to eject them in the normal way through the opposite face of the graphite pile, and the fire was therefore localized by removing a number of neighbour-
