No serious toxic symptoms were observed in any patient. Apart from the two patients who were unable to continue treatment—one on penicillin complaining of burning abdominal pain, the other on oxytetracycline who vomited one hour after taking the capsules—toxic symptoms were reported by five patients on penicillin, eight on oxytetracycline, and four on lactose, nearly all in the first few weeks of treatment. Diarrhoea was the commonest symptom, recorded by 10 patients—three on penicillin, five on oxytetracycline, and two on lactose—while anorexia, nausea, vomiting, flatulence, or epigastric discomfort formed the next group in order of frequency. The only other recorded symptoms were swelling of the foot accompanied by a rash which lasted a week and developed eight weeks after starting penicillin treatment, paraesthesiae of both hands lasting a few weeks 16 weeks after starting oxytetracycline, and joint pain the day after taking lactose capsules, experienced in the early weeks of therapy.

Discussion

It has been shown in trials previously reported that treatment of bronchiectasis with antibiotics, particularly chloramphenicol, can achieve some success in eliminating infection and in reducing the amount and purulence of the sputum. Franklin and Garrod (1953) reported that chloramphenicol was effective in eliminating *Haemophilus influenzae* from the sputum of bronchiectatic children, and in certain instances the drug was used for periods up to five months. Previously Mulder *et al.* (1952) had described comparable results in adult patients, and clinical studies by Wynn-Williams and Moyes (1951) and Harris *et al.* (1952) had also proved satisfactory. More recently Helm, May, and Livingstone (1954, 1956) have shown that there is a place for long-term antibiotic treatment in advanced cases, although only a proportion of these will respond well. Unfortunately the occurrence of blood dyscrasias following long-term chloramphenicol therapy made it necessary to exclude this drug in the present trial.

In the investigation reported here an attempt has been made to assess, by a controlled blind trial, the value of certain long-term antibiotic regimes to the patient with severe bronchiectasis. The symptoms of cough, expectoration, and haemoptyses are interrelated and reflect the state of the bronchial tree. From this standpoint it is clear that oxytetracycline was more effective than was oral penicillin. The lessening of general disability was much more pronounced than that observed in the other two groups. In particular, the reduction by nearly half of the purulent fraction of the sputum was achieved on the average within two weeks, and this change was maintained over the whole year. In the lactose group there was some improvement, but of a degree which could be expected to follow more regular postural drainage. The penicillin group fared a little better, but some of these changes probably reflected the general benefit observed in the lactose group. In all groups there was some indication that the symptoms fluctuated with climatic changes.

During the period of treatment the patients receiving oxytetracycline suffered less severe interference with their lives. The number of days on which patients in this group were confined to bed was less than half the total for those receiving penicillin and only a little over a quarter that for the lactose group. The number of days off work was also substantially less in the oxytetracycline group. On the whole the results by the different methods of assessment are consistent in indicating a definite benefit from the oxytetracycline regime and a probable, but lesser, benefit from oral penicillin. Nevertheless, even in the oxytetracycline group the effect was not dramatic. It is possible that

improvement was limited more by the irreversible changes of bronchitis and emphysema than by failure of the drug to eliminate particular infecting organisms.

It is significant that no serious toxic effect was recorded and that only two patients were unable to continue the trial. It may be concluded that the oxytetracycline regime used is both beneficial in severe cases of bronchiectasis and also safe. It is, however, expensive. A year's treatment on the lines indicated would cost, at the time of writing, at least £60 per patient for oxytetracycline. In regard to the overall problem, it is clear that the response obtained and expense entailed do not justify the widespread use of long-term oxytetracycline therapy in most patients with bronchiectasis. For the relatively few advanced cases it does offer a measure of relief not apparently attainable by oral penicillin in the doses used. The characteristic symptoms of bronchiectasis can be modified and the natural history of the disease influenced whilst oxytetracycline therapy is maintained, but there is no indication that such improvement as may be achieved is permanent, and relapse is almost certain after treatment is stopped.

Summary

In a controlled trial at seven centres 122 patients with bronchiectasis were allocated at random to one of three treatments—38 to penicillin, 44 to oxytetracycline, and 40 to lactose. The drugs were provided as indistinguishable 0.25-g. capsules, two of which were given four times a day on two days each week for a period of a year. Regular visits were paid to the out-patient departments throughout this period, at which measurements were made of the volume of a 24-hour sputum specimen and of the severity of cough, dyspnoea, haemoptysis, and disability since the previous visit.

The three treatment groups were similar in their age distribution, the history of previous respiratory illnesses, and the extent of involvement as determined by a recent bronchogram. During the year's observations three deaths occurred—one in each treatment group. Two patients—one on penicillin and one on oxytetracycline—could not tolerate the capsules and stopped treatment. Four patients—two on oxytetracycline and two on lactose—defaulted before six months' treatment had been completed. One patient given lactose who died subsequent to the year's observation was found to have had fibrocystic disease of the pancreas and was excluded from the analysis.

The records of the remaining 112 patients, 36 on penicillin, 40 on oxytetracycline, and 36 on lactose, were examined to compare the response to the treatments. Each group showed a reduction in sputum volume, during greater for the pus than for the mucus fraction, during the year. The reduction in the oxytetracycline group was rapid, and for pus to about half the pre-treatment level. The reduction in the penicillin and lactose groups was slower, and to about 70% of the original level in each. There was some reduction in each treatment group in the severity of cough and dyspnoea and in the number of episodes of haemoptysis, with a slight advantage shown by those taking oxytetracycline. A more pronounced effect in the oxytetracycline group was observed in the reduction of disability expressed by the number of days off work, in the episodes of fever, and in the number of days confined to bed. No serious toxic effects were observed in any group. Although in general oxytetracycline was beneficial and was more effective than oral penicillin, the limited effect of long-term therapy, having regard to its cost, would not justify its widespread use in most patients with bronchiectasis.

Those taking part in the trial were: Chester: Dr. A. C. C. Hughes (clinician). Edinburgh: Professor J. W. Crofton and Dr. A. R. Somner (clinicians). Glasgow: Drs. T. Anderson, A. W. Lees, and G. Allan (clinicians); Dr. J. B. Landsman (bacteriologist). Leeds: Drs. M. Telling and G. N. Chandler (clinicians). Liverpool: Drs. W. S. Sutton and G. Penrhyn Jones (clinicians); Dr. F. Whitwell (pathologist). Newcastle: Dr. A. G. Ogilvie (clinician). Sheffield: Drs. C. S. Darke and J. E. Middleton (clinicians); Drs. E. H. Gillespie and J. E. M. Whitehead (bacteriologists).

The Subcommittee wishes to express its thanks to those surgeons who allowed their patients to be included in the trial. It is indebted to Messrs. Glaxo (Dr. T. Binns) for the supply of penicillin and to Messrs. Pfizer (Dr. G. Hobby) for the supply of oxytetracycline. Dr. Binns made special studies of the stability of the encapsulated penicillin. The Subcommittee is especially indebted to Dr. Robert Hodgkinson, of Messrs. Parke Davis & Co., for providing special capsules and for encapsulating all the drugs used.

The pathogenesis of chronic bronchitis involves several factors, one of which is believed to be infection (May, 1953a, 1953b; Oswald and Medvei, 1955).

During 1955 in the City of Leeds (population 508,000) 67 persons died of pulmonary tuberculosis, 270 from carcinoma of the lung, and 463 from the effects of bronchitis. The actual incidence of bronchitis in the population is difficult to determine, but Goodman *et al.* (1953) have shown that chronic respiratory disease is an important cause of disability, and accounts for more unemployment than any other physical condition. Similarly, Stuart-Harris (1954) reported finding cough and sputum in 55% of men aged 50-60 in an industrial population, whilst Higgins *et al.* (1956) estimated that 10% of non-miners in the mining community they investigated had bronchitis. Stocks (1947) has drawn attention to the inverse relationship that exists between hours of sunshine and deaths from bronchitis.

It is therefore of some importance to assess critically the value of any treatment of this common disease, particularly in relation to the control of the infective element.

Several workers in this country have already reported their experiences with the tetracycline group of drugs (Helm *et al.*, 1954, 1956; May and Oswald, 1956). In the main these trials have been conducted without adequate controls.

We report here the results of an investigation into certain bacteriological aspects of the infective factor in chronic bronchitis, and of a controlled therapeutic trial, using oxytetracycline alone or in combination with other measures.

Pre-treatment Bacteriology

Single sputum specimens from patients with chronic bronchitis attending the Leeds Chest Clinic for the first time were examined bacteriologically during the period October, 1954, to June, 1956. An early morning specimen was examined within a few hours of collection, and was classified as either purulent or mucoid. Smears of each specimen were stained by Gram and Leishman methods. The presence or absence of Gram-negative cocco-bacilli and other bacteria was noted, together with an estimate of the approximate number of pus cells and of eosinophils per oil-immersion field. Each specimen was cultured on fresh blood and heated blood (chocolate) agar. A simple inoculation technique previously described (Allison *et al.*, 1943; Allibone *et al.*, 1956) was employed. The cultures were examined after 24 and 48 hours' incubation.

Results

Sputum specimens from 320 consecutive patients were investigated, of which 61 were examined in the winter months of 1954-5, 169 during the winter of 1955-6, and 90 in the spring and summer months of the two years 1954-6. Of these sputa, 156 were purulent and 164 mucoid. Microscopical examination for pus cells mostly confirmed these findings. Mucoid specimens contained up to 10 pus cells per oil-immersion field, whilst frankly purulent sputa showed 50 or more neutrophils per field. In the whole series examined eosinophils were rarely found. Table I shows the incidence of the five commonly accepted "potential pathogens" (May, 1954) in purulent as compared with mucoid sputa.

H. influenzae and the pneumococcus were most commonly found. *H. influenzae* was most frequent in purulent sputa (60-70%). In mucoid sputa, however, the incidence was reduced to about half of that in purulent sputa. In contrast the incidence of the pneumococcus was constant in both purulent and mucoid sputa (30-40%).

In 93 of the 102 purulent sputa containing *H. influenzae*, this micro-organism was predominant or present in equal numbers with one or two of the other "potential pathogens." In these 93 sputa (59.7% of the total) *H. influenzae* was present alone in 35, whilst in 48 one other "potential pathogen" was isolated, and in 10 *H. influenzae* was found

with two other "potential pathogens." In no specimens were more than three "potential pathogens" found together.

Of the 158 specimens yielding *H. influenzae* in culture, this organism was recognized microscopically in direct sputum smears in 129 (81.6%). Such Gram-stained films were of little value in forecasting the presence of pneumococci, since they cannot readily be distinguished from other Gram-positive cocci unless capsulation is present.

Therapeutic Trial

The marked predominance of *H. influenzae* and pneumococci in the sputa examined seemed sufficient reason for taking into account only these two micro-organisms when assessing bacteriologically the effect of treatment. In planning the trial the assumption was made that either *H. influenzae* or the pneumococcus or both were pathogenic in chronic bronchitis.

Zinnemann (1950) showed that a number of sulphonamides effectively inhibited *H. influenzae* *in vitro*, and that chloramphenicol was the most effective oral antibiotic, closely followed by oxytetracycline (Zinnemann, 1953).

The purpose of the investigation was to determine the value of an oral antibiotic in chronic bronchitis when given continuously during the six winter months of 1955-6, following a pilot trial which had been carried out during the winter of 1954-5. In view of the reported risk of marrow aplasia following prolonged chloramphenicol therapy, oxytetracycline was selected as the drug of choice in a controlled clinical trial, and we also planned to assess the value of a sulphonamide. In addition, an autogenous *H. influenzae* vaccine was used in an attempt to overcome any allergy to *H. influenzae* that might play a part in the disease. Lastly it was planned to determine whether the effect of the antibiotic could be enhanced by either one or both of these substances.

Methods and Materials

The criteria for diagnosis and entry to the clinical trial were that the patients should be over 20 years of age, should have cough, sputum, shortness of breath for more than a year and some degree of disability arising therefrom, and that there should be no evidence of other causes for these symptoms. Since an autogenous *H. influenzae* vaccine was to be used, it was necessary that that organism should have been recovered from the sputum before acceptance. The nature of the trial was explained to the patients, and their agreement to take part was obtained. As a result 66 consecutive patients who fulfilled these criteria were admitted to the trial between September and November, 1955. There were 57 males and 9 females, aged from 28 to 71, who were all treated as out-patients.

The age and sex distribution of the patients admitted to the trial, and of those who completed the course and were available for analysis, are shown in Table II. More than half the

TABLE I.—Incidence of the Five "Potential Pathogens" Found in the Sputa of 320 Consecutive Chronic Bronchitis Examined from October, 1954, to June, 1956

Organism	Type of Sputum	Oct.-Mar. 1954-5		Oct.-Mar. 1955-6		Apr.-Sept., 1955 Apr.-June, 1956		Whole Period Oct., 1954- June, 1956	
		No.	%	No.	%	No.	%	No.	%
<i>H. influenzae</i>	Purulent	18/25	72	53/87	61	31/44	70.4	102/156	65.4
	Mucoid	15/36	41.6	27/82	32.9	14/46	30.4	56/164	34.1
Pneumococcus	Purulent	10/25	40	30/87	34.5	22/44	50	62/156	39.7
	Mucoid	14/36	38.9	26/82	31.7	25/46	54.3	65/164	39.6
Friedländer's bacillus	Purulent	4/25	16	11/87	12.8	3/44	6.8	18/156	11.5
	Mucoid	4/36	11.1	11/82	13.9	1/46	2.1	16/164	9.75
β -Haemolytic streptococci	Purulent	5/25	20	21/87	24.1	4/44	9	30/156	19.25
	Mucoid	9/36	25	20/82	24.4	2/46	4.2	31/164	18.9
<i>Staph. aureus</i>	Purulent	1/25	4	9/87	10.4	4/44	9	14/156	8.9
	Mucoid	0/36	0	1/82	1.2	1/46	2.1	2/164	1.2

Note.—The criteria used for the recognition of *H. influenzae* and the pneumococcus were:
H. influenzae: Usually poor growth on fresh blood agar, luxuriant growth on chocolate agar; characteristic (indole) odour of cultures and greyish-green colour of colonies on chocolate agar (Allison *et al.*, 1943); microscopical appearance; confirmation by X and V requirements when necessary.
Pneumococcus: Intense yellow discoloration of chocolate agar after 24 hours' incubation; α -haemolysis and typical colonial appearance on fresh blood agar; confirmation by bile-solubility test when necessary. No typing undertaken.

Moderate " "	39	4	31	4
Mild " "	12	4	9	4

patients said their symptoms had been present for longer than 10 years, but proportionately more females reported their continuous persistence from childhood into adult life (see Table III). The mode of onset of bronchitis is also shown in Table III, where it will be seen that about 36% of the patients clearly dated the start of their symptoms from an acute respiratory episode, whilst about 12% claimed that their symptoms originated from a respiratory catarrhal illness in childhood. In the remaining patients the beginning of their symptoms was indefinite and apparently insidious in origin. The degree of disability arising from the bronchitis at the time of admission to the trial is shown in Table III, and was assessed according to the severity of the symptoms, their effects on the patient's livelihood and earning capacity, and on the frequency and duration of acute exacerbations of pulmonary infection.

Organization.—The proprietary preparations "terramycin-SF" capsules and "sulphatriad" tablets were used, and a will subsequently be referred to as oxytetracycline and a sulphonamide respectively. The individual autogenous *H. influenzae* vaccines under test were prepared by two of us. Dummy capsules and tablets and a non-specific *E. coli* vaccine were also used. The two bacteriologists in the team, who were unaware of the clinical findings, allotted the patients to the treatment groups by random selection after balancing for age and sex. They marked the vaccine containers labelled with a code letter, so that neither the patients nor the clinicians knew what treatment was being given. Thus all patients were receiving a brown capsule, a white tablet, and a vaccine, without any difference in appearance between the active substances or their dummy controls. There were therefore eight possible different treatment groups.

Treatment Regimes.—Each patient started treatment with 1.5 g. daily of oxytetracycline or its control, with 1.5 g. of sulphonamide or its control, given in divided doses. This dose was maintained until the sputum became mucoid, when it was reduced to 1 g. daily of each. Further dosage was adjusted on clinical grounds to complete six months' therapy. The vaccine was given at weekly out-patient attendances, starting with a dose of 100 million bacilli and increasing to a maximum of 2,000 million organisms, which

was maintained for the rest of the six months' course of treatment. All the patients were taught breathing exercises and encouraged to practise them regularly.

Periodic Reviews.—Every patient was observed for a period following admission to the trial before therapy was started, in order to establish a baseline. Each patient was issued with a calibrated sputum measure and a chart on which to record each day the 24-hour volume of sputum and its colour, the onset and duration of head colds and when they went to the chest, the time lost from work by going to bed as a result of chest infections, and the number of tablets and capsules taken each day, with details of any upset due to the treatment. The patients were seen every month, when their diaries were scrutinized, their sputum was inspected for purulence, and a fresh sputum specimen was collected for bacteriological examination. In addition a record was made of the results of a series of special investigations consisting of body weight, full blood count, E.S.R., vital capacity, chest expansion, and an x-ray film of the chest taken synchronously by double exposure in full inspiration and full expiration.

Method of Assessment

The final assessment was made according to both the patient's monthly charts and the physicians' monthly records. The same questions were asked at each visit. Marks were accorded under the following main headings:

1. *Sputum.*—(i) Changes of 24-hour volume. (ii) Changes of purulence using the scale: 0 (clear), + (cloudy), ++ (yellow), +++ (green).

2. *Respiratory Disability.*—(i) Changes in degree of dyspnoea, according to a scale adapted from Sinclair (1955). Grade 0: Normal; capable of heavy work. Grade 1: Breathless on walking one mile or more on the flat; moderate work. Grade 2: Breathless on walking 400 yards to one mile on the flat; moderate or light work. Grade 3: Breathless on walking less than 400 yards on the flat; light or sedentary work. Grade 4: Breathless on the slightest exertion; unable to work but can potter about. (ii) Degree of wheezing, which, in the absence of any objective means of measurement, was assessed on clinical grounds and recorded as nil, slight, moderate, or severe.

3. *Physical Disability.*—(i) Change in frequency and duration of head colds. (ii) Change in frequency and severity of acute chest exacerbations. (iii) Variations in time lost from work or time spent in bed according to experience in previous years obtained at entry to the trial.

4. *General Health.*—(i) The patient's own assessment, month by month and at the end of trial, whether any benefit derived had been marked, moderate, slight, or nil, or whether there had been deterioration. (ii) The results of the special investigations carried out monthly. (iii) The clinicians' assessment of progress during and at the end of the trial. All patients at their last attendance were seen by one of us for their final assessment. Progress was recorded as marked, moderate, slight, or no improvement.

5. *Bacteriology.*—Rough estimates of the number of viable organisms present in the sputum were made according to whether growth of *H. influenzae* and/or pneumococci was predominant, moderate, sparse, or nil. The bacteriological results were then assessed by comparing the monthly alteration with the pre-treatment level in the sputum of (a) the presence of *H. influenzae* alone, (b) the presence of both *H. influenzae* and the pneumococcus.

Any change in these factors was then recorded using a simple marking system, one point being awarded for one degree of change, two points for two degrees, etc. These marks were entered as plus or minus according to whether improvement or deterioration had taken place. In this way an objective method of summing up all the different factors was achieved.

Results of Treatment

Of the 66 patients who entered the trial, two died—one from congestive heart failure in the second month and one from coronary thrombosis after two months' treatment. Three patients failed to attend after their first visit, three others defaulted after the first review, two after the second,

and one in the fourth month. One patient did not start treatment until late in the winter, and so did not complete the six-months course in time with the other patients. These patients were all excluded from the final assessment. Another patient's monthly sputum cultures were persistently overgrown with *Proteus vulgaris*, thus preventing full bacteriological analysis, and, although the clinical assessment had been made, he also has been excluded from the final results. The results of the trial, therefore, are based on the remaining 53 patients who completed the full course of treatment. Amongst these 53 it was found that the eight treatment groups were reasonably well balanced for age, sex, duration of symptoms, purulence and volume of sputum, and degree of disability.

In the regime used by us most patients taking active drugs were maintained after the first month's treatment on 0.5 g. or less of oxytetracycline and/or sulphonamide twice daily. Toxic effects from this dosage were not a serious problem, and it was not necessary to withdraw any patients from the trial for this reason.

The special investigations carried out monthly did not seem to show any significant alterations, nor did they appear to be related to the progress or deterioration of the patient; they have accordingly been ignored in the final assessment.

Clinical and bacteriological assessments were carried out on the marking system under the main headings as already

TABLE IV.—Number of Patients Clinically Improved According to Common Factor in Treatment

Common Treatment Factor	Improved	No Real Change	Mean Percentage Improvement
Patients on oxytetracycline ..	21	8	46.4

Autogenous vaccine ..	35.2	-2.8	—	57.5	-2.5	—	33.6	0.9

TABLE VII.—Statistical Significance of Mean Percentage Clinical Improvement of Patients on Various Treatment Regimes

Groups (Derived from Table V)	Treatment Regime	Mean Percentage Improvement	Difference from Control Mean (19.2) (Groups 7 and 8 of Table V)	P	Difference from Sulphonamide Mean (30.9)	P	Difference from Oxytetracycline Mean (41.3)	P
1 and 2	Oxytetracycline and sulphonamide	51.2	32.0 (±5.5)	<0.001	20.3 (±7.9)	0.01	9.9 (±6.6)	—
3 .. 4	Oxytetracycline ..	41.3	22.1 (±6.4)	<0.001	10.4 (±8.5)	—	—	—
5 .. 6	Sulphonamide ..	30.9	11.7 (±7.7)	—	—	—	—	—

described, and the final figures expressed as percentages of the total marks possible. From a scattergraph the median percentage level of improvement of all 53 patients was obtained and found to be 37%. Only those patients with marks in excess of this median level were regarded as clinically improved. Table IV shows the number of patients improved clinically when one common drug factor in treatment is considered. Similarly Table V shows the number of patients clinically improved in each of the eight different treatment regimes. From these tables it appears that the results following oxytetracycline therapy are better than those achieved with a sulphonamide, whilst the autogenous vaccine has little, if any, clinical effect.

Statistical Analysis

The method of marking used by us permitted the results to be analysed statistically. The mean percentage improvement of the patients receiving any of the three therapeutic substances was determined and compared with the mean percentage improvement of their respective control groups. Thus, all patients receiving one substance were compared with those not receiving it, and these comparisons are shown in Table IV. The value of *t* was calculated and the probability determined. This is shown in Table VI, which confirms beyond doubt the clinical value of oxytetracycline in the treatment of chronic bronchitis and suggests that a sulphonamide is not without effect, whilst, if additional proof is required, an autogenous *H. influenzae* vaccine is ineffective. Further, it will be seen that there is no correlation between the bacteriological and clinical assessments. Moreover, with one exception, the difference between the mean percentage bacteriological improvement due to the common treatment factors and their controls is negligible.

All patients receiving autogenous vaccines can therefore be included in the corresponding treatment groups without further regard to this factor. In this way three treatment groups can be derived from Table V by combining groups 1 with 2, 3 with 4, and 5 with 6, while groups 7 and 8 can be regarded as one untreated control group. By so doing a sufficiently large number of patients can be obtained for a further similar analysis by comparing the effects of oxytetracycline alone, of a sulphonamide alone, and of these two drugs combined, with the untreated control group, and with each other. The results of this analysis are shown in Table VII, where the clinical efficacy of oxytetracycline is again confirmed. However, no significant difference between the results following sulphonamide therapy and those of the control group is now evident. The discrepancy between the *P* value for sulphonamide in Table VII and that in Table VI may be due to the inclusion within the sulphonamide series of Table VI of some patients also receiving oxytetracycline.

Table VII shows a trend suggesting that a sulphonamide has some effect in chronic bronchitis, that oxytetracycline is more effective, and that the combination of these two drugs is more effective still than either alone.

Discussion

It is generally accepted that infection plays a part in the pathogenesis of chronic bronchitis (Lancet, 1954) and is associated with relapse or exacerbation (Lancet, 1955). It has also been assumed that purulent sputum is indicative of infection within the bronchial tree, although May (1954) has reported that in some the "purulence" of the sputum is due to eosinophils. The two most commonly implicated organisms in chronic bronchitis are *H. influenzae* and the pneumococcus (Mulder *et al.*, 1952; May, 1953a, 1953b, 1954; Stuart-Harris *et al.*, 1953; Elmes *et al.*, 1953; Knox *et al.*, 1955; Helm *et al.*, 1954, 1956). Both Mulder (1938, 1956) and May (1954) report predominance of *H. influenzae* in about 80-90% of their cases with purulent sputum, whilst in bronchitis with mucoid sputum May (1954) has reported finding 13% with *H. influenzae* and about the same number with pneumococci in first sputum specimens. Helm *et al.* (1954) go further and state: "The fact that the presence or absence of pathogenic bacteria, especially *H. influenzae*, closely paralleled the purulence of the sputum is strong evidence that these are indeed the pathogens in the infections studied."

Although it is confirmed by us that in untreated bronchitic patients the incidence of *H. influenzae* varies considerably with the purulence of the sputum, we observed an incidence of 60-70% in purulent and 30-40% in mucoid specimens. On the other hand, that of the pneumococcus was constant irrespective of the degree of purulence. These results are based on cultural studies, but it is possible to detect *H. influenzae* microscopically in Gram-stained films in about 80% of specimens yielding the organism on culture. This examination should, in our view, be regarded as no more than complementary to cultural methods.

We are in general agreement with most other workers that epidemiologically *H. influenzae* and the pneumococcus are the commonest organisms found in chronic bronchitis. However, during the course of the investigation and at the end of the trial no significant change in the bacterial flora was noted in spite of changes in the clinical picture. It would appear that although the infection with *H. influenzae* or the pneumococcus was not eradicated, clinical improvement with loss of purulence in the sputum was obtained by the use of antibacterial agents. The persistence of *H. influenzae* in the sputum, in spite of more or less marked clinical improvement during treatment with one of the tetracyclines, is also evident in the reports of Elmes *et al.* (1953) and Helm *et al.* (1956).

It therefore remains to consider this discrepancy. It may be that the value of the antibacterial drugs lies in the prevention of superinfection of the bronchial tree from an infected upper respiratory tract, rather than by direct action upon the established bacterial flora of the bronchi. That this may be so can be inferred from the effect of oxytetracycline on the incidence of *H. influenzae* together with the pneumococcus, as shown in Table VI, where the difference in the mean percentage improvement from the mean of the control is far greater than any of the other differences in the bacteriological assessment. It may also be that the dosages employed were too small to effect complete elimination of the "potentially pathogenic" bacteria from the bronchial tree. If, however, much larger doses had been given, the side-effects would probably have interfered seriously with the working capacity of out-patients. Furthermore, a monthly bacteriological examination of the sputum of bronchitic patients is not necessarily representative of its usual day-to-day flora.

The assumption that the maintenance of the symptom complex of chronic bronchitis is due to *H. influenzae* or the pneumococcus has not, therefore, been confirmed or disproved under the conditions of this trial. Of the treat-

ment regimes tested, oxytetracycline stood out as an effective single therapeutic agent, and it appeared that its clinical action was enhanced by the addition of sulphonamide. The latter by itself was not entirely without effect, whereas the autogenous *H. influenzae* vaccine was apparently quite valueless.

It has been remarked how on occasion it is difficult to demonstrate the findings in a clinical trial so that the factual presentation of the overall results reflects the dramatic improvement brought about in some patients (May and Oswald, 1956). We have devised a simple system of assessment, adding or subtracting marks for improvement or deterioration, as compared with the patient's pre-treatment condition, and the figures obtained can be analysed statistically. By this method we have shown that our results following treatment with oxytetracycline are highly significant.

One of the main criticisms levelled at long-term therapy with the tetracycline group of drugs is that of expense. We are in general agreement with May and Oswald (1956) that the cost to the National Health Service of about £45 for six months' treatment—or 23s. a week per patient in our regime reported here—can be an economy if it will reduce the drain on national resources in other directions. Such a drain may derive from the payment of National Insurance benefit or from the use of a hospital bed for two weeks or more each winter. Additionally, loss of productivity to the community and of earning capacity to the patient himself may well be prevented. The second criticism is that drug-resistant organisms may be produced and spread. In the few observations on the development of resistance to oxytetracycline of *H. influenzae* that it was possible to make at the beginning and the end of this trial, either no increase in resistance to oxytetracycline or, at most, only a four-fold increase was found. Similarly, the emergence of oxytetracycline-resistant coagulase-positive staphylococci in the sputum did not constitute a major problem.

Summary

A controlled trial employing a double blind technique with continuous therapy for six months in 53 patients with chronic bronchitis using oxytetracycline, a sulphonamide, and an autogenous *H. influenzae* vaccine is reported.

Continuous administration of oxytetracycline is shown to be an effective measure in the treatment of chronic bronchitis. The improvement arising therefrom is considerable, and the results are enhanced by the addition of a sulphonamide.

The use of a sulphonamide alone is of little clinical value, whilst an autogenous *H. influenzae* vaccine as employed by us is apparently valueless and has no place in the management of chronic bronchitis.

A method of assessment is described for factual demonstration of the degree of clinical improvement found in therapeutic trials where objective methods of measurement are few or difficult to achieve.

In pre-treatment sputum specimens *H. influenzae* is present, with pneumococci, as the predominant "potential pathogen" in chronic bronchitis. The incidence of *H. influenzae* is twice as great in purulent as in mucoid sputa, whilst that of the pneumococcus is unrelated to sputum purulence. No significant change could be detected in the "potentially pathogenic" flora of bronchitic sputa, following clinically effective antibacterial drug treatment.

Some possible reasons for this discrepancy are discussed.

We are indebted to Dr. Edith Robinson and Dr. B. L. Welch, both of the University of Leeds, for advice on the statistical

analysis, and to Dr. D. J. Charley for access to some of his patients. We are grateful to Messrs. Pfizer Ltd. for the generous supplies of terramycin-SF and the appropriate dummy capsules, and to Messrs. May and Baker Ltd. for providing the sulphatriad tablets, together with their controls.

THROMBOSIS OF INTERNAL CAROTID ARTERY TREATED BY ARTERIAL SURGERY

BY

CHARLES ROB, M.C., M.Chir., F.R.C.S.

AND

E. B. WHEELER, M.D.

Surgical Unit, St. Mary's Hospital, London, W.2

Occlusion of the internal carotid artery is now recognized as one of the more common causes of cerebrovascular disease (Adams and Vander Eecken, 1953; Fisher, 1954). The occlusion is almost invariably due to atherosclerosis, and the arterial lesion is similar to atherosclerotic occlusions in other major arteries of the body. Many such occlusions of the aorta and peripheral arteries have been effectively treated by surgical operations designed to restore a normal blood flow. This paper describes the application of these surgical procedures to atherosclerotic occlusions involving the cervical portions of the carotid arteries. Particular attention is paid to the technical feasibility, operative risk, and early post-operative course of carotid surgery. A detailed clinical evaluation of the long-term prognosis after surgery will be the subject of a later article.

Pathogenesis

Occlusion of the internal carotid artery usually begins with the formation of an atheromatous plaque just distal to the bifurcation of the common carotid artery. As the plaque enlarges, the arterial lumen is narrowed and the blood flow is reduced. This narrowing of the lumen may be increased by haemorrhage under the plaque or by the formation of a mural thrombus. Fragments of clot may break away and form cerebral emboli, or the thrombus may extend and completely occlude the vessel. The end-result of these various processes is to decrease or abolish the blood flow through the affected vessel. This deficit in flow causes symptoms of cerebral ischaemia if (1) the cerebral collateral

circulation is inadequate, (2) there is a fall in systemic blood pressure, or (3) the patient becomes anaemic or anoxic. Whether some of these processes also interfere with the cerebral circulation by producing intracerebral vasospasm has been a matter of dispute for many years.

Three points are worth emphasizing. First, the collateral circulation is of paramount importance in determining the clinical effect of any carotid occlusion. Second, a partial occlusion can produce symptoms indistinguishable from a complete occlusion if the collateral circulation is inadequate. Third, the unpredictable nature of these pathological processes leads to great variation in the clinical course of the disease.

Clinical Features

Like atherosclerotic occlusions of other vessels, occlusions of the internal carotid artery usually occur in patients over 40 years of age and are much more common in men than in women. The commonest symptom is unilateral muscle weakness, usually associated with a disturbance of speech if the dominant hemisphere is affected. Other frequent complaints are headache and unilateral sensory disorders, particularly hypaesthesia. Transient blindness of the eye on the side of the occlusion is a characteristic sign when present, and homonymous hemianopsia is occasionally seen. Mental or emotional disorders are not uncommon.

There is considerable variation in the clinical picture, and particularly in the mode of onset. Symptoms may be mild and intermittent in character, or they may be slowly progressive to complete hemiplegia. Occasionally they may be sudden, severe, and catastrophic in onset. Some of the patients may be entirely asymptomatic, depending on the state of the collateral circulation.

There are no pathognomonic physical findings, although a decreased retinal blood pressure on the side of the occlusion is most suggestive. This can be measured directly (Thomas and Petrohelos, 1953) or indirectly by noting the ease of retinal blanching on digital pressure (Denny-Brown, 1951, 1952). Palpation of the carotid pulsation is an unreliable physical sign.

Carotid angiography is an extremely useful diagnostic procedure which yields specific information about the patency of the carotid arterial system. In many cases it is the only way in which the diagnosis can be made with assurance. Although others have emphasized its risk, there has been only one mild exacerbation of symptoms in this series after arteriography. No other investigative procedures have proved of specific value, except by excluding other disease.

For a more detailed exposition of the clinical features of initial carotid occlusions the reader is referred elsewhere (Hunt, 1914; Johnson and Walker, 1951; Behrman, 1954; Shapiro and Peyton, 1954; Millikan and Siekert, 1955).

Risks of Carotid Arterial Surgery

In discussing the treatment of internal carotid thrombosis some authors have emphasized the potential dangers associated with direct surgery on the carotid arteries. The chief fear has always been that clamping the carotid arteries for several minutes might cause ischaemic cerebral necrosis, particularly if the cortex had a poor blood supply prior to the operation. In the case of a complete internal carotid occlusion, clamping the common carotid artery temporarily deprives the cortex of the collateral circulation carried by the external carotid artery, and in the case of a partial occlusion there is the additional loss of whatever flow was passing through the internal carotid artery. In addition, the resulting vascular stasis is a theoretical opportunity for thrombosis to occur. Another potential cause of cerebral ischaemia is hypotension due to anaesthetic agents or to haemorrhage during the surgical procedure itself. A further possible complication is the production of an embolus from the operative site, and a final theoretical danger is the production of intracerebral vasospasm secondary to the operative trauma.

From the experience to date it would seem that many of the theoretical complications of carotid surgery should prove uncommon in practice provided certain routine prophylactic measures are taken. Probably the most important of these prophylactic steps is the use of hypothermia. Lowering the body temperature to 28–30° C. has been shown to decrease the cerebral metabolism (Bering *et al.*, 1956; Stone *et al.*, 1956) and allow longer periods of complete anoxia without loss of function than was formerly believed possible.

An obvious point in the prevention of cerebral damage is to shorten the arterial operating time as much as possible. In practice this means doing the simplest procedure and thoroughly checking the readiness of all instruments prior to clamping the vessels. Our procedure of choice is a thromboendarterectomy (Edwards and Rob, 1956). This was the procedure in 12 out of the 15 patients in this series in whom a good blood flow was re-established. A localized resection and end-to-end anastomosis is the next most desirable procedure (Eastcott *et al.*, 1954).

There are some technical points which are also of value in preventing complications. Heparin should be injected proximal and distal to the clamped-off arterial segment in order to decrease any tendency for thrombi to form in the areas of vascular stasis. The arterial lumen should be left as smooth as possible and should be thoroughly washed out with saline to carry away any clots or atheromatous debris. Only small stitch "bites" should be taken in the arterial wall, and these should not be pulled too tightly, since large, tightly pulled stitches narrow the lumen and produce irregularity of the wall. Since the internal carotid artery may contain a recent non-adherent thrombus, the dissection to free this vessel should be as gentle as possible. It may be advisable, on purely theoretical grounds, to strip bare a portion of the internal carotid artery in order to interrupt vasoconstricting autonomic impulses. It is obvious that more than usual care should be taken during and after the operation to see that no hypotensive episodes occur. Forty-eight hours after operation we place our patients on oral anticoagulants and, if possible, continue these for the remainder of their lives.

Turning from theoretical possibilities to practical experience, there have been two patients with post-operative cerebral complications in this series of 26 carotid explorations. One patient (Case 5) developed a post-operative hemiplegia. This improved rapidly, but he was left with a detectable weakness of the right arm. This was probably the result of cerebral ischaemia from clamping the common carotid artery for 17 minutes at normal body temperature. Another

patient (Case 9) had a post-operative hypotensive episode with an exacerbation of neurological symptoms, with recovery several hours after the blood pressure had been restored. It is possible that both of these complications might have been prevented, in one case by the use of hypothermia and in the other by closer attention to the patient's blood pressure.

It should be mentioned that one of our patients (Case 8) had a non-cerebral complication consisting of a pre-operative cardiac arrest shortly after the start of hypothermia (temperature 35° C.). Whether this was spontaneous or due to the lowered body temperature is a matter of conjecture. Fortunately prompt cardiac massage restored the heart beat and there were no sequelae. The surgical procedure was then carried out uneventfully at normal body temperature.

Operative Results of Carotid Arterial Surgery

To date (May, 1957) we have carried out direct arterial surgery on 27 patients (22 males, 5 females) with internal carotid occlusions. The operative results are given in Table I and the important features of each case are summarized in

TABLE I.—Operative Results in 27 Patients with Internal Carotid Artery Occlusions

Type of Occlusion	No. of Patients	Good Flow Established	Post-operative Course				Death
			Asympt.	Obj. Better	No Change	Temp. Deterioration	
Partial { Hypothermia Normal temp.	9	9	3	2	3*	1	0
Complete	16	2	1	1	12	1	0
Total	27	15	5	3	15	2	2

*One of these patients died at home from a cerebral haemorrhage four weeks post-operatively (see text).

Table II. Of the 27 patients, 5 are asymptomatic, 4 are able to work, 8 are unable to work, 7 are permanent invalids, and 3 are dead.

In brief, the series includes 11 patients with partial occlusions and 16 with complete occlusions. All of the patients with partial occlusions had definite arterial surgery carried out with a good blood flow at the end of the procedure. There has been no later clinical deterioration to indicate subsequent thrombosis in any of these patients.

TABLE II.—Case Summaries of 27 Patients with Occlusions of the Internal Carotid Artery

Case No.	Age and Sex	Type of Occlusion	Side of Occlusion	Mode of Onset	Symptoms					Surgery				Clinical Outcome

after the drug was given, while six hours after administration sickle-cell formation proceeded to completion at the pre-administration rate. The sample of blood taken three hours after the drug was given sickled more slowly than a pre-administration sample.

The absence of any demonstrable inhibiting effect upon sickle-cell formation six hours after administration corresponded to the known rate of excretion of the drug (50% of the dose is excreted in six hours) (manufacturers' data). The diminished activity of the drug three hours after administration is interesting because it occurs between two peaks of activity at one hour and five hours after administration. It confirms, however, the fact observed by the manufacturers that a single dose administered to a dog by mouth results in two peaks of concentration within the erythrocytes. This is described in the section dealing with the pharmacology of acetazolamide.

These results were confirmed by a second experiment, using the same technique but with a reduction in the dose to 2 mg. per kg. of body weight. With this small dose there was noticeable delay in the onset of sickle-cell formation *in vitro* in blood taken one hour, two hours, four hours, and five hours after the drug was administered, and once again three hours after administration the inhibiting effect was less marked.

Effect of Orally Administered Acetazolamide on Sickling Phenomenon in Vivo

The occurrence of sickling in a sealed-slide preparation is an indirect demonstration of the phenomenon *in vivo*. With a view to discovering what proportion of cells were sickled in the venous circulation a further experiment was designed.

Method.—The patient was given by mouth a dose of 2 mg. of acetazolamide per kg. body weight. One hour later 1 ml. of blood was taken by venepuncture from the jugular vein into a syringe containing sterile liquid paraffin to prevent contact of the blood with air. The blood was then immediately injected into 2 ml. of 10% formol-saline solution under a layer of oil, the object being to fix the red cells in their circulating shape. Thin films were made and stained with eosin, and the percentage of sickled cells was counted under an oil-immersion lens. The patient was then given a dose of 7 mg. of acetazolamide per kg. body weight and one hour later 1 ml. of venous blood was obtained anaerobically and injected into 10% formol-saline solution under oil. Films were made and stained with eosin.

TABLE III.—Decrease in Number of Sickled Cells Following an Increased Dose of Acetazolamide

Preparation	No. of Cells Counted	Percentage of Sickled Cells
Films made from blood taken one hour after 2 mg. of acetazolamide per kg. body weight had been given orally	3,000	11.8
Films made from blood taken one hour after 7 mg. of acetazolamide per kg. body weight had been given orally	3,000	7.5

Standard error of difference, 0.75.

The results are shown in Table III. The number of sickled cells present in venous blood after a dose of 7 mg. of acetazolamide per kg. body weight was significantly smaller than after a dose of 2 mg. per kg. body weight.

Pharmacology of Acetazolamide

The structure of the drug is as follows (manufacturers' data)

The drug inhibits the activity of carbonic anhydrase. Its continued administration to man in oral doses of 8 to 16 mg. per kg. body weight per day results in lowering of the carbonic anhydrase activity of the whole blood to one-third of normal value. The drug is remarkably non-toxic and has been given to children for periods up to seven months in oral doses of 25 mg. per kg. body weight per day in the treatment of epilepsy. No toxic effects have been observed on the bone marrow, the liver, kidney, or the central nervous system. The limiting factor to dosage has usually been drowsiness and a feeling of fatigue on the larger doses.

Absorption is complete after oral dosage, since the 24-hour urinary excretion is the same as that following intravenous administration. The drug is excreted unchanged by the kidney, 50% of the oral dose being lost via the urine in six hours. The plasma and red-cell levels in the dog after an oral dose of 20 mg. per kg. body weight are shown in the Chart (Fig. 1).

FIG. 1.—Chart showing the two peaks of red-cell concentration referred to in the text.

Theory of Action of Acetazolamide in Sickle-cell Disease

Carbonic anhydrase catalyses the reaction:

It is therefore required for the evolution of CO_2 from tissue cells. It is also necessary for the combination of CO_2 with H_2O within the red cell to form H_2CO_3 . H_2CO_3 combines in the red cell with oxygenated potassium haemoglobin, with simultaneous release of oxygen. This reaction may be represented as follows (Wright, 1952):

In other words, when haemoglobin becomes reduced the globin molecule gains an H ion in the carboxyl group (marked *). This H ion is derived from the H_2CO_3 which carbonic anhydrase helps to form within the red cell. Therefore, interference with carbonic anhydrase activity retards the reduction of haemoglobin.

Following this line of argument, it becomes apparent that the bicarbonate shift mechanism is also retarded, thereby hindering the plasma buffering mechanism and inducing a mild acidosis.

The CO_2 tension in the plasma is dependent upon the amount of CO_2 in the plasma (in simple solution). The oxygen dissociation curve of haemoglobin is dependent upon the plasma CO_2 tension. If, therefore, the inhibition of carbonic anhydrase lowers the plasma CO_2 tension, it retards also the dissociation of O_2 from haemoglobin.

Since the occurrence of sickling depends upon the presence in the erythrocyte of reduced haemoglobin, a carbonic anhydrase inhibitor would tend to suppress sickle-cell formation.

Fig. 2 illustrates the chemical changes concerned.

FIG. 2.—Chemical changes involved in CO_2 transport and the points of action of carbonic anhydrase.

Therapeutic Trial with Acetazolamide in Sickle-cell Disease

At the time of writing the patient has been under observation for 70 days. In the period of 41 days preceding the administration of acetazolamide there was evidence of active haemolysis on two separate occasions, as shown by deterioration in the haemoglobin levels. The patient has so far been treated with acetazolamide for 29 days and there has been a steady rise in the haemoglobin levels during this period from 7.1 to 9.4 g. per 100 ml. of blood. The child has continued to gain weight and is more alert and active than she was before treatment.

A prolonged period of observation will be necessary, because natural remissions occur in this disease and no conclusions can be drawn from the present remission, which began with the beginning of treatment. A detailed account of the clinical and haematological assessment following treatment will form the subject of a further report.

Observations on the Numbers of Sickled Cells in the Venous Circulation

It has been shown that there was a significantly smaller percentage of sickled cells in venous blood after the administration of 7 mg. of acetazolamide per kg. body weight than there was after the administration of 2 mg. per kg. body weight. It was decided to count the number of sickled cells present in circulating blood while the patient was not having treatment and when she was taking the drug.

TABLE IV.—Variations in Number of Sickled Cells in Venous Blood Before and During Cessation of Treatment and After Restarting Treatment

Sample of Blood	No. of Cells Counted	Percentage of Sickled Cells
Taken 1 hour after last dose of acetazolamide	3,000	8.8
Taken 48 hours after last dose of acetazolamide	3,000	15.6
Taken 1 hour after administration of acetazolamide was restarted	3,000	8.9

Method.—Three 1-ml. samples of blood were obtained from the jugular vein. The first specimen was taken one hour after the last dose of acetazolamide and the second sample 48 hours after the last dose; the third specimen was drawn one hour after administration of the drug had been restarted. The three specimens were obtained by the same technique, as follows: 1 ml. of blood was drawn from the jugular vein into a syringe containing sterile liquid paraffin. The blood was immediately injected into 2 ml. of 10% formol-saline solution under a layer of liquid paraffin. Thin films were made from this blood and stained with eosin. The numbers of sickled cells were counted, using an oil-immersion lens.

The results are shown in Table IV. There was an increase in the number of sickled cells in the venous blood following withdrawal of the drug.

Summary

Evidence has been produced to show that acetazolamide inhibits the occurrence of sickling of red cells *in vitro* and *in vivo*. It is suggested that the drug exerts this effect by inhibiting the action of the enzyme carbonic anhydrase. The enzyme is concerned with the reduction of haemoglobin. The abnormal haemoglobin S in patients with sickle-cell disease undergoes molecular rearrangement during the process of reduction to form long slender rods which alter the shape of the red cell. The pathological manifestations of sickle-cell disease are determined by the alteration in the contour of the erythrocytes which adhere to one another to form intravascular thrombi and which are destroyed in the body, resulting in anaemia.

At the present time there is no effective treatment for sickle-cell disease, and it is suggested that acetazolamide may be employed to control the occurrence of sickling.

The preliminary experiments have shown the ability of acetazolamide to inhibit the sickling phenomenon *in vitro* when mixed with blood from a patient with sickle-cell disease. The effect was noticeable also when the drug was administered to the patient, it then being seen that the occurrence of sickling was inhibited *in vitro* as well as in circulating venous blood.

A therapeutic trial is in progress and the results so far are encouraging.

I would like to thank Professor A. W. Woodruff for his invaluable advice and encouragement, and for permission to publish. I am indebted to Drs. F. D. Schofield, S. Bell, and W. H. Jopling for helpful criticism; to Messrs. A. V. H. Allen and F. J. Barratt, of the pathological laboratory of the Hospital for Tropical Diseases, London, for much technical assistance; and to the nursing staff of Chamberlain Ward. My thanks are due to the manufacturers of acetazolamide (Lederle Laboratories Division, Cyanamid of Great Britain Ltd.) for supplies of the pure drug and permission to reproduce the pharmacological data. I am grateful to the parents of the patient for their co-operation.

FOLINIC ACID IN MEGALOBlastic ANAEMIA OF PREGNANCY

BY

JEAN M. SCOTT, M.D.

From the Research Department, Royal Maternity
and Women's Hospital, Rottenrow, Glasgow

Within the past ten years treatment of the megaloblastic anaemia of pregnancy has been completely revolutionized. Before Vilter *et al.* (1945), in America, and Wilkinson *et al.* (1946), in this country, published their preliminary report on the haemopoietic properties of folic acid, this pregnancy anaemia presented a vexing problem. A large number of the patients did not respond to parenteral liver, even crude preparations (Ungley, 1938; Miller and Studdert, 1942; Fullerton, 1943; Callender, 1944; Davidson *et al.*, 1948; Ginsberg *et al.*, 1950; Scott, 1954), and, on account of the gastrointestinal upsets frequently encountered with this anaemia, few could take oral liver in sufficient quantity to produce a response (Scott, 1954). As a result many patients were labelled "refractory" and the majority had to be kept alive by repeated blood transfusions until delivery.

Folic acid has completely reversed this picture. Since supplies became available an average of 15 to 20 patients at this hospital each year have received this form of therapy, and all have responded well, provided treatment was continued throughout pregnancy and during the first few weeks of the puerperium.

In itself the anaemia is of particular interest not only to those dealing with the pregnant patient but to haematologists in general. It has been shown that the response to parenteral liver and vitamin B₁₂ is very variable and seems to depend on the degree of megaloblastic change in the marrow and the extent of the maturation arrest (Scott, 1954). In contrast to this the specific effect of folic acid gives definition to the field of inquiry and allows for a more accurate determination of the place occupied by folic acid and its derivatives in the hierarchy of enzymes necessary for erythropoiesis.

Recent work (Callender and Lajtha, 1951; Swan *et al.*, 1955) indicates that folic acid ("leucovorin"), derived from folic acid, may be the actual enzyme acting upon the marrow. When supplies of this substance became available it was decided to institute clinical trials in pernicious anaemia of pregnancy; the results were rather startling.

Materials and Methods

In all, 19 patients were given folic acid. Seventeen were diagnosed antenatally, but four went into labour before treatment could be followed for any length of time. In the remaining two cases the anaemia was not spotted until the puerperium, and it is interesting to note that both these patients had pre-eclamptic toxemia.

In six of the cases megaloblasts were found in the peripheral blood and diagnosis was easy, but in the remaining 13 a confirmatory sternal puncture had to be made. Smears and sections were stained by haematoxylin and eosin and May-Grünwald solution and also examined for iron by the prussian-blue reaction. During the reticulocyte response daily reticulocyte counts were made and the blood picture was examined thereafter at weekly intervals. A gastric analysis was carried out in 13 of the cases, the histamine test meal being used. Serum iron readings (Sven Dahl, 1948) were made in another four cases.

Results

All the patients had severe anaemia with haemoglobins ranging between 3.6 and 9.3 g. per 100 ml. and red cell counts between 800,000 and 3,260,000 per c.mm. The blood pictures were macrocytic in five instances, normocytic in 13, and microcytic in one. All but one of the pregnancies were complicated by some other condition. Three of the patients had an infection requiring treatment with antibiotics, and the anaemia developed subsequent to this. Cardiac disease, pre-eclamptic toxemia, and diarrhoea and vomiting accounted for the other complications, and in addition to this there were four cases of twin pregnancy. Before starting treatment a gastric analysis was made on 13 of the cases in order to rule out, so far as was possible, an Addisonian pernicious anaemia, which, in contrast to the megaloblastic anaemia of pregnancy, shows a histamine-fast achlorhydria and responds well to vitamin B₁₂ (Scott, 1954). In the present series six patients had a normal curve and six were hypochlorhydric. Only one patient had a histamine-fast achlorhydria, and when the test meal was repeated after delivery she was found to have a limited amount of free acid.

At the beginning of the trial supplies of folic acid were scarce, and once the initial response to treatment had been observed the patients were dismissed home on a maintenance dose of folic acid. The fourth patient, however, lost her prescription for folic acid, and when she reported to the blood clinic it was found that her blood count had continued to improve and was near normal, though no further treatment had been given. This woman was 33 weeks pregnant when she first received a total of 36 mg. of folic acid intramuscularly. At that time her haemoglobin had been 8.0 g. per 100 ml. and red cell count 2,120,000, yet seven weeks later at delivery her haemoglobin was 10.6 g. per 100 ml. and red cell count 3,280,000 (Fig. 1). In the puerperium she continued to improve and no further treatment was required apart from iron therapy.

FIG. 1.—Case 4. A para-3 aged 20. Effect of treatment on haemoglobin, red blood cells, and reticulocytes.

This remarkable response to such a small amount of folic acid encouraged us to withhold treatment in all subsequent cases, once they had obtained their maximum reticulocyte response. In all, 13 cases were followed. Eight were antenatal patients, their pregnancies ranging from 28 to 39 weeks, and the remaining five were in the puerperium. By varying the amount of folic acid administered daily in each case and watching the reticulocyte response, it was found that the optimum dosage lay somewhere in the region of 6 mg., and in the last 10 cases the following regime was adopted. On the first day of treatment 12 mg. of folic acid was administered intramuscularly. Thereafter daily injections of 6 mg. were given until the reticulocytes reached a peak, usually between 8 and 19%. This commonly occurred around the eighth day, when just over 50 mg. had

been injected. These reticulocyte levels may seem low in comparison with those obtained in Addisonian pernicious anaemia, but it has been shown already (Scott, 1954) that this is the usual finding in pernicious anaemia of pregnancy. Commonly it occurs around the eighth day and falls gradually thereafter, normal levels not being reached until the fourth week.

In the present series no further treatment was given once the reticulocyte peak had been reached, yet all 13 patients continued to improve. At term the antenatal patients had an average haemoglobin of 10.4 g. per 100 ml. and a red cell count of 3,350,000 (see Table), and two

† Second course given; showed no secondary reticulocytosis.

months after delivery the average for the whole series was 12.7 g. per 100 ml. and 4,430,000. The latter figures do not include the results for two antenatal patients who discharged themselves irregularly from hospital after delivery. Seven of the patients reported six months after delivery. All were well and had normal blood counts.

At this stage in the investigation an oral form of folic acid (calcium leucovorin) became available, and the next three patients (Cases 17, 18, and 19) received this form of therapy, the dosage being left unchanged. On the first day two tablets (10 mg.) were given half an hour before breakfast, and on subsequent days this was reduced to 5 mg. All three were antenatal cases, their pregnancies ranging from 29 to 35 weeks. Each received a total of approximately 50 mg., and without exception all three showed responses equal to those obtained with intramuscular therapy. As before, improvement continued though therapy was discontinued. The results are shown in the Table.

Serum Iron Investigations

During the reticulocyte response daily estimations of serum iron were made on four of the patients, and the results are shown in Fig. 2. It can be seen that the earliest

FIG. 2.—Serum iron curves in four cases.

fall in serum iron occurred in the patient with the lowest reading (Case 4). Case 5 went into labour on the second day of therapy, and this was probably responsible for the sudden drop shown by her the next morning (Scott, 1954). The remaining two patients had very much higher readings and their serum iron values fell less steeply. Case 6 had the largest amount of stainable iron in her marrow, and, though she showed a slight initial drop in her serum iron, it remained well above normal levels during the first week of therapy.

Hawkins (1955) stated that the 48-hour serum iron test was a reliable method of assessing the effect of haematinics in the macrocytic anaemias. This is possibly true in the majority of cases, but it would appear that in pregnancy at least the exception can arise. The rate of fall would also appear to be proportional to the initial serum iron reading, and this in turn seems to bear a direct relationship to the amount of stainable iron in the marrow.

Discussion

It is now generally agreed that the megaloblastic anaemia of pregnancy represents only a temporary upset in erythropoiesis and that specific antianaemic therapy can usually be discontinued in the puerperium once the blood count has reached normal levels. Until recently this has been the procedure adopted with all such anaemias in this hospital, but the results with folic acid now show that prolonged therapy is no longer necessary.

From the review of the findings two salient features become evident. Firstly, it was found that folic acid had to be given in sufficiently large amounts initially to produce a satisfactory response. Trial and error showed that the required dosage lay somewhere in the region of 6 mg. daily intramuscularly and that a total of 50 mg. had usually to be given. For example, Case 3 received only 12 mg., and 16 days later she showed a secondary reticulocyte rise of 5% when maintenance therapy with folic acid was begun. On the other hand, no such secondary rise in reticulocytes was observed with folic acid in those patients given adequate amounts of folic acid initially.

The second point is that once a satisfactory reticulocyte response was obtained folic acid could be discontinued. Independent of the degree of anaemia, 13 patients in the present series continued to improve, and repeat sternal punctures, carried out in three instances, showed that erythropoiesis was again normoblastic.

This being so, it seems unlikely that the megaloblastic anaemia of pregnancy can be due to an absolute deficiency of folic acid arising out of the pregnancy. One would expect that, if such were the case, all eight antenatal patients given short-term therapy would have required maintenance treatment until delivery at least. A likelier suggestion is that folic acid acts more as a catalyst at some stage in erythropoiesis, and, owing to its absence or to the "resistance" which Badenoch *et al.* (1955) say may develop in pregnancy, megaloblastic change takes place in the marrow. It is conceivable that the reversal of such a process might require a large amount of catalyst initially, and this would also explain why all 16 cases in the present series needed fairly large doses of folic acid to begin with and why the total amount given seemed to be independent of the degree of anaemia.

It is more difficult, however, to ascertain whether the initial defect on haemopoiesis is caused by a temporary deficiency of folic acid or whether an actual "resistance" does develop in pregnancy. Thompson (1950) and Lajtha (1950) believe that there may be an inhibitor present in Addisonian pernicious anaemia, but Feinmann *et al.* (1952) and Swan *et al.* (1955) were unable to find any evidence to support this thesis. Until proof of its existence in the pregnancy anaemia is forthcoming, the simpler explanation of a temporary deficiency seems the more logical and could be supported by the fact that the anaemia occurs more readily in multiple pregnancy. In the present series four

patients were delivered of twins. Other factors, too, would seem to aggravate or even precipitate the onset of the anaemia: diarrhoea and vomiting, debility from repeated pregnancies, infection, pre-eclamptic toxæmia, and cardiac disease were found in that order in the present series. Only one patient appeared to have had a normal pregnancy, and she had been treated for an iron-deficiency anaemia at the seventh month. With hospitalization and treatment it was possible to deal with these secondary complications and in this way remove any factors which might possibly enhance a deficiency.

Another aggravating factor which may also increase the demand for folic acid once the upset in erythropoiesis has been established is that of more rapid blood destruction. We have been unable to demonstrate the existence of an actual haemolysis in the megaloblastic anaemia of pregnancy, but in all the buffy coats examined there is evidence of erythrophagocytosis, and Pappenheimer bodies, similar to those seen in haemolytic anaemias, are present in some of the nucleated red cells. Ungley and Thompson (1950) reported a more rapid elimination of transfused cells in one of their cases and severe haemolysis in another. With folic acid therapy they found that the haemolysis ceased and the rate of elimination of transfused cells fell to normal. In our cases the erythrophagocytosis disappeared. These findings suggest a possible increase in the rate of red cell destruction, though obviously it is not present to the same degree in all cases. Since treatment appears to reduce this process, one would expect that replacement with new cells would also fall to normal and, in this respect at least, the need for extra folic or folinic acid would be less.

Thus with treatment for both the anaemia and its complications it is possible that the demand for folinic acid may be somewhat reduced, and, with normoblastic erythropoiesis established, the pregnant woman may once more be able to keep herself in balance and maintain satisfactory blood levels. From what has been said previously, however, it is unlikely that the initial effect of folinic acid is purely one of replacement therapy. The evidence rather points to some catalytic action, and it may be that folinic acid has multiple duties, not only associated with the bone marrow, but also with those processes concerned with the production and utilization of the whole folic acid system of enzymes.

Summary

Nineteen patients with megaloblastic anaemia of pregnancy and the puerperium have been treated with folinic acid ("leucovorin") and the results have been reviewed.

Sixteen received treatment over a limited period till the reticulocyte response reached its peak.

Eleven of these were antenatal anaemias, and though their treatment was discontinued all continued to improve. At term their average haemoglobin was 10.4 g. per 100 ml. and red cell count 3,350,000 per c.mm.

In order to produce a satisfactory response with this short-term therapy, it was found that the folinic acid had to be given in sufficiently large amounts initially (approximately 50 mg.) and that the amount necessary appeared to be independent of the degree of anaemia and the route of administration.

From these findings it seems unlikely that the megaloblastic anaemia of pregnancy is due to an absolute deficiency of folinic acid. Instead the latter would appear to act more as a catalyst at some stage in the haemopoietic process, and evidence is brought forward to show how the demand for folinic acid itself may be further reduced once normal erythropoiesis is established.

My thanks are due to Dr. A. D. T. Govan, Director of Research, for his help in the preparation of this paper, and to Lederle Laboratories Division for supplies of leucovorin used in the trial.

RECTAL HYDROCORTISONE

BY

J. D. N. NABARRO, M.D., F.R.C.P.

AUDREY MOXHAM

G. WALKER, M.B., M.R.C.P.

AND

J. D. H. SLATER, M.B., M.R.C.P.

From the Institute of Clinical Research, the Middlesex Hospital, London

Local administration of hydrocortisone in the treatment of ulcerative colitis was mentioned by Truelove and Witts (1955) and by Park (1955). For this purpose the steroid may be given as an ester—acetate or hemisuccinate—or as the free alcohol. The esters may well be inactive until hydrolysed to free steroid, and it is not known whether the large bowel contains suitable enzymes. Enemata of hydrocortisone and its esters could be dispensed as solutions or suspensions, but the free steroid is only sparingly soluble in water. Truelove (1956) used a solution containing 50 mg. of hydrocortisone per 100 ml. of 4.5% alcohol in saline; apparently this concentration of alcohol did not cause any local discomfort, but we preferred to avoid any solution that might aggravate the inflammation of the colonic mucosa. As 1% solutions of hydrocortisone have been used extensively in dermatological practice and the solvent does not seem to irritate acutely inflamed skin, we have used diluted 1% hydrocortisone skin lotion for these studies. A further aspect of the problem about which there is very little information is the extent to which hydrocortisone is absorbed from the bowel. Liddle (1956) has reported 26% absorption of hydrocortisone acetate administered per rectum as suppositories or in an ointment.

We have studied the absorption of various preparations of hydrocortisone administered locally in five patients with ulcerative colitis. We are not in a position to offer any opinion about the value of this form of treatment; this report is concerned mainly with its endocrine implications.

Methods.—The patients were men with mild or moderately severe ulcerative colitis, thought to be suitable for steroid therapy. Daily urine collections were made from 6 a.m. to 6 a.m. Excretion of hydrocortisone and its metabolites was estimated by the total 17-

hydrocorticosteroid method of Appleby *et al.* (1955), using modifications described elsewhere (Moxham and Nabarro, 1956). Urinary 17-ketosteroids, sodium, potassium, and creatinine were also estimated by standard methods.

Results

The first two patients studied were given 20 ml. of 1% hydrocortisone skin lotion* containing 200 mg. of steroid made up to 120 ml. with saline. The fluid was run into the rectum in about 15 minutes, starting at 9 p.m., and the patient was encouraged to retain it as long as possible. The urinary steroid excretions are shown in Fig. 1. Case 1 was treated in this way for 14 days and received 100 mg. daily for a further three days. The hydrocortisone solution was poorly retained, but despite this there was an increase of urinary steroid excretion. Case 2 was an in-patient at the Central Middlesex Hospital, and urine samples were made available through the kindness of Dr. F. Avery Jones. This patient retained the hydrocortisone well and there was a striking increase of urinary total 17-hydrocorticosteroids; on a subsequent occasion 200 mg. of hydrocortisone was given by mouth with only a slightly higher figure for steroid excretion.

Studies in greater detail were made in Cases 3 and 4. Case 3 was referred by Mr. O. V. Lloyd-Davies. The patient started to improve during the control period and continued to do so steadily while steroids were being given. There was no evidence that the rectal steroids influenced the

FIG. 1.—Urinary steroid excretions in Cases 1 and 2.

process. The hydrocortisone acetate and alcohol suspensions and the skin lotion were diluted to 120 ml. and given as in Case 1 above. Five hydrocortisone suppositories, each containing 40 mg. of the alcohol, were given over the 24-hour period. At least two days elapsed between each form of treatment. This patient retained the enemata well, and unexpectedly good absorption of hydrocortisone from the skin lotion was observed (Fig. 2).

We are indebted to Dr. G. D. Hadley for being allowed to study Case 4. This patient's ulcerative colitis was moderately severe; he improved throughout the period of treatment, although the change was greater with hydrocortisone alcohol suspension and solution. The clinical improvement was reflected in the sigmoidoscopic changes (Mr. J. H. Lees

*Roussel Laboratories Ltd.; the solvent of hydrocortisone free alcohol in this lotion is a mixture of glycols.

Ferguson). In this case the steroid suspension or solution was diluted to 100 ml. and given by slow rectal drip lasting approximately two hours. The enemata were retained for 20–160 minutes (acetate suspension), 100–120 minutes (alcohol suspension), and 120–240 minutes (solution). As judged by steroid excretion, absorption was poor, although it improved at the end of study when the patient was given the suppositories (Fig. 2). At this time he was symptom-free.

Case 5 received hydrocortisone alcohol suspension, hydrocortisone hemisuccinate solution, and the hydrocortisone alcohol solution used in the previous cases. With each preparation 200 mg. of hydrocortisone was given in 120 ml. of fluid over a period of 15 minutes. This patient was able to retain the enemata for about 12 hours. The alterations of steroid excretion are shown in Fig. 3. The most striking finding is the increase of 17-ketosteroid excretion.

FIG. 2.—Urinary steroid excretion in Case 5.

Discussion

Oral hydrocortisone is rapidly and almost completely absorbed. Urinary 17-hydroxycorticosteroid excretion in adrenalectomized patients receiving oral cortisone acetate amounts to about 36% of the dose in mg. (Moxham and Nabarro, 1956). Results with patients given hydrocortisone are comparable. From these figures it is possible to assess the approximate absorption of steroid administered per rectum. If, however, treatment is given to patients with intact adrenals there may be no increase in urinary steroid excretion because of suppression of endogenous steroid secretion. The short periods of treatment used in Cases 3, 4, and 5 minimize this difficulty, and the increase of urinary total 17-hydroxycorticosteroid output over the control figure may be taken as approximately one-third of the steroid absorbed. There was no evidence of absorption of hydrocortisone when given as a suspension of the acetate. Up to 30% of the free alcohol was absorbed from a suspension or suppositories. Hydrocortisone absorption from the skin lotion was considerable in Cases 2 and 3 (83% and 66% respectively), but much less in the other three (16%, 30%, and up to 36% in Cases 4, 5, and 1 respectively).

The fact that significant absorption of the steroid can occur raises a number of problems. It is important to ascertain whether the hydrocortisone is absorbed in a physiologically active state or whether it is reduced to inactive metabolites prior to absorption; in the latter case a high urinary steroid figure might still be obtained. Case 3 showed marked sodium retention and potassium diuresis with the free alcohol suspension, solution, and suppositories, and corresponding changes on stopping them. Similar alterations of electrolyte excretion were noted when Case 4 was given solution and suppositories and when Case 5 was given the free alcohol solution. There seems, therefore, to be little doubt that hydrocortisone is physiologically active when absorbed from the rectum. The greatly increased 17-ketosteroid excretion in Case 5 may be the result of bacterial modification of the hydrocortisone in the colon.

The hydrocortisone that is absorbed may produce undesirable side-effects. An important possibility is adrenal cortical suppression with liability to acute adrenal insufficiency following stress, including surgery. Steroid therapy was given intermittently in Cases 3 and 4, but Case 1 had 17 days' treatment with only moderate absorption; despite this there was a significant fall of urinary steroid output when treatment was stopped (Fig. 4). The fact that rectal steroid therapy leads to suppression of the patient's adrenal glands is further confirmation that the hydrocortisone is absorbed in a physiologically active state, and it also means that there are potential dangers in prolonged pre-operative preparation with rectal steroid therapy.

Summary

The absorption of hydrocortisone administered by retention enemata in ulcerative colitis has been studied in five cases.

There was no evidence that hydrocortisone was absorbed from a suspension of the acetate. Absorption occurred when hydrocortisone (free alcohol) was given

as a suspension or in suppositories, and to a slight extent with an aqueous solution of hydrocortisone hemisuccinate. Significant absorption was found when hydrocortisone skin lotion was used; in one patient it was estimated as 80%. One of the patients had a considerable increase of urinary 17-ketosteroid excretion while receiving rectal hydrocortisone.

Rectal steroid therapy may suppress the patient's adrenal glands and, if used pre-operatively, result in acute adrenal insufficiency in the immediate post-operative period.

We are indebted to Dr. A. E. Gremaux, of Roussel Laboratories Ltd., for the preparation of hydrocortisone acetate and alcohol suspensions given to Cases 3 and 4, and for information about the solvent used for the hydrocortisone alcohol solution. We are grateful to Glaxo Laboratories Ltd. for supplying the hydrocortisone hemisuccinate, and to Mr. G. Bryan, chief pharmacist to the Middlesex Hospital, for preparing the suppositories. We wish to thank the Clinical Research Committee for laboratory facilities in the Institute of Clinical Research of the Middlesex Hospital Medical School, and for a personal research grant to one of us (J.D.N.N.). The figures were prepared by Mr. V. K. Asta.

FINGERPRINT SWEAT TEST IN
FIBROCYSTIC DISEASE OF PANCREAS

PRELIMINARY COMMUNICATION

BY

J. C. W. MacFARLANE, M.D., B.Sc.

A. P. NORMAN, M.D., F.R.C.P.

AND

C. E. STROUD, M.B., M.R.C.P.

The Hospital for Sick Children, Great Ormond Street, London

The diagnosis of fibrocystic disease of the pancreas is rapidly becoming more frequent as a result of the more general appreciation of the clinical picture and greater reliability of the laboratory tests confirming it. Recent reports seem to indicate that estimation of the sweat electrolytes is the most reliable of the many tests employed by the laboratory. The performance of this test offers few technical difficulties, but there is concern about its possible dangers, especially when applied to small infants. Many infants do not develop the ability to sweat perceptibly until the age of 6 weeks to 3 months, and, since the test implies wrapping up the infant in a plastic bag and, if necessary, applying external warmth, it can produce a dangerous rise in the body temperature. We have noticed that some small babies, especially where there is severe pulmonary involvement, rapidly become tachypnoeic and pyrexial. Careful supervision is necessary, and, since no untoward effects are produced in the vast majority of cases, this care is too easily relaxed. To our knowledge two infants have died as a result of the test.

A LONG-ACTING INHIBITOR OF
GASTRIC SECRETION

Medical School

This is a preliminary report on (1-methyl-2-pyrrolidyl) methyl benzilate methyl methosulphate (IS 499), a substance having atropine-like properties, which promises to be useful in reducing the gastric secretion of acid in patients with peptic ulcer. Chemical and pharmacological details will be published shortly (Doyle *et al.*, 1957; Acred *et al.*, 1957).

Present Investigation

Twenty-four oral doses of IS 499 varying between 5 and 20 mg. were given to five normal subjects, and the salivary flow was measured from collections with a dental aspirator. Doses of 10 mg. taken by mouth partly inhibited salivary flow after a latent period of two hours, but the maximal effect was not reached until about four hours after taking the drug. The reduction in salivary flow lasted from seven to nine hours. With doses of 15 to 20 mg. the only other effects were tachycardia and slight difficulty in micturition. The unusually long duration of action of IS 499 was an encouraging feature which made it worth while to test the effect of the drug on gastric secretion.

Seven normal subjects were given a total of 98 test meals lasting 30 minutes by a technique which allows the amounts of acid secreted in response to the meal to be calculated. The tests also gave information about the volume of meal remaining in the stomach after 30 minutes (Hunt, 1954). For each subject the response to the meal without any drug was determined several times during the period of the tests. Doses of the drug varying between 1 and 20 mg. were given either at 11 p.m. or at 5 a.m., before the tests were made at 8 a.m., so that two dose-response curves were made for each person. It was found that doses of 1 or 2 mg. given at 5 a.m. or 2.5 mg. at 11 p.m. reduced the secretion of acid in response to the test meal. The Table shows the results of tests in the seven normal subjects and in five patients with peptic ulcer. In 8 out of 12 persons the

The Scientific Film Association, in collaboration with the London University Institute of Education, has recently issued a catalogue of films on psychology and psychiatry. This catalogue is a revised edition of the S.F.A. catalogue of films on psychology (1953), and includes films made available since that date. The size and duration of each film are given, together with a brief description of its content and the type of audience for which it is thought suitable. The catalogue (price 5s. net) is obtainable from the Scientific Film Association, 164, Shaftesbury Avenue, London, W.C.2.

secretion of acid was 40–60% inhibited by the 5-mg. dose given three hours before the test. In 6 out of the 12 persons the secretion of acid was 40–60% inhibited nine hours after a dose of 10 or 8 mg. The output of the alkaline secretions of the gastric mucosa was usually not reduced, but gastric emptying was somewhat slowed. With doses up to 10 mg. there were no troublesome side-effects, the reduction of salivary flow not being noticed by the subjects if it occurred.

Clinical trials of this drug, which in low doses by mouth has a selective action of long duration on the gastric secretion of acid, are now being undertaken with a view to controlling secretion of acid in patients with duodenal ulceration.

We wish to thank our students who took part in the tests; the members of the clinical staff who allowed us to investigate their patients; and Beecham Research Laboratories Ltd. for the supply of IS 449.

Medical Memoranda

Agranulocytosis with Recovery During Promazine Therapy

Promazine, one of the newer ataractic drugs, has recently been introduced for the treatment of certain types of mental illness. Like chlorpromazine it is a phenothiazine derivative, but differs from chlorpromazine in that the chlorine atom is absent from its structure. Agranulocytosis has been recorded during the course of chlorpromazine treatment (Goldman, 1955), and we record below details of a case under our care in which this complication occurred during promazine therapy.

CASE REPORT

The patient, a woman aged 60, was admitted to hospital on March 26, 1957. A severe depressive illness had been present for five months and there were features of considerable anxiety, with restlessness. Physical examination revealed nothing of importance with the exception of moderate hypertension (B.P. 190/110 mm. Hg). There was no anaemia. The W.B.C. count was 6,000 per c.mm. Sedation with amylobarbitone sodium was not effective and was discontinued. On April 2 promazine treatment was begun with 100 mg. thrice daily, and the dose was increased on April 4 to 200 mg. thrice daily. Thereafter the excitement and agitation were observed to diminish. In the ensuing weeks regular white-cell counts fluctuated from 5,000 to 8,000 per c.mm. A representative differential white cell count was: neutrophil polymorphs 62%, neutrophil stab cells 2%, eosinophils 2%, lymphocytes 27%, monocytes 7%.

On April 27 the patient complained of sore throat. There was no fever, and on inspection the throat appeared healthy. On April 29 the temperature rose to 100.6° F. (38.1° C.), the fauces were noted to be inflamed and oedematous, and cervical adenitis appeared. Blood examination revealed a complete neutropenia: W.B.C., 1,900 per c.mm. (lymphocytes 48%, monocytes 52%); Hb, 11 g./100 ml.; platelets, 316,000 per c.mm. Sternal marrow examination yielded only a few islets of fatty tissue with no cellular areas.

Promazine administration was discontinued and 1 mega unit of crystalline penicillin was given twelve-hourly. Daily differential white-cell counts were performed. Corticotrophin gel was given intramuscularly in dosage of 50 mg. twelve-hourly from May 3, and on May 4, for the first time for six days, a differential count done on a buffy film showed

2% of neutrophil stab cells: segmented polymorphs remained absent. On May 5 1 pint (570 ml.) of fresh blood was transfused. Each ensuing day thereafter was associated with a gradual increase in the proportion of neutrophil polymorphs in the peripheral blood, and by May 13 the white-cell count was 11,850 per c.mm. (neutrophil polymorphs 86%; neutrophil stab cells 6%, lymphocytes 5%, monocytes 3%). Clinical recovery from the agranulocytic episode was then complete, and corticotrophin and penicillin were withdrawn.

COMMENT

Agranulocytosis complicating promazine therapy has been reported on one previous occasion (Woodward and Solomon, 1956), and in that case proved fatal. This patient also was a middle-aged woman, and dosage had been instituted at 100 mg. a day, increasing to 1,000 mg. a day over a 42-day period. In contrast to our patient, lymphocytes rather than monocytes had predominated in the peripheral blood during the agranulocytic period, and this is said to indicate a worse prognosis (Whitby and Britton, 1953). It is clear that serious depression of the red bone marrow can occur following both promazine and chlorpromazine administration, and vigilance during their use remains essential.

We wish to thank Professor T. Ferguson Rodger for permission to publish this case.

A Case of Carcinoid Tumour

The general features of carcinoid tumour, with the effects of the substance hydroxytryptamine (5-H.T.) which is secreted by the tumour cells, were described in the *British Medical Journal* (1956). A clinical report of such a case exhibiting many of the classical signs and symptoms of the syndrome is given below. The patient is still alive despite a history dating back for at least eight years.

CASE REPORT

A woman now aged 71 first came under observation in 1949. She was married and had borne four children. The previous medical history was irrelevant until 1948, when she had attacks of abdominal discomfort and flatulence for which her gall-bladder was removed without more than temporary relief.

In 1949 she suffered from definite abdominal pains which were periumbilical, colicky, and intermittent, occurring in attacks at irregular intervals and lasting between 6 and 24 hours. Many such attacks were witnessed during the succeeding four years. They were often associated with a low fever, loose stools, and occasional vomiting, and were succeeded by a few days' anorexia and malaise. During the colicky phases abdominal examination was negative, but during the ensuing days tenderness which slowly disappeared was present in the right iliac fossa. In all other respects clinical examination was negative and her general health and nutrition remained good. Barium meal, barium enema, and stool tests were carried out with negative results. A tentative diagnosis of recurring mild appendicitis was expressed, but in view of the diarrhoea and the absence of maintained pain during the attacks this was not made with great conviction.

The patient was admitted to hospital in March, 1953, as a case of subacute intestinal obstruction. Investigations failed to add light on the diagnosis, and it was decided to perform an exploratory laparotomy on March 17. The

operation report read as follows: "Three feet (91 cm.) above the ileo-caecal junction was a stricture of the ileum, the latter being dilated above this. The affected area of ileum felt hard and there were two small nodules in the wall of the small intestine below the stricture. No glands were seen in the mesentery. Twelve inches (30 cm.) of small intestine was resected, continuity being re-established by end-to-end anastomosis."

The pathological report on the specimen read: "There are three separate primary carcinoid tumours of the terminal region of the ileum. One of these growths is infiltrating through all layers of the gut and has caused much narrowing of its lumen. Metastases were demonstrated in regional lymph nodes."

FIG. 1.—Typical clumps of argentaffin neoplastic cells in carcinoid growth of lower ileum. (H. and E. $\times 110$.)

For some months after operation relief from symptoms was complete, and then there was a return of discomfort, indefinite colic, anorexia, and loose stools.

By April, 1954, an irregular liver edge became palpable and its consistency was noted at the time as one of rubbery firmness. About this date complaint was made of facial flushing in attacks associated with a feeling of bursting pressure in the head. These became more persistent and distressing, and the flushing involved the upper chest in addition to the face. At the time of writing these occurred between 6 and

FIG. 2.—Area of mucosa showing infiltrating clumps of argentaffin neoplastic cells. (H. and E. $\times 112$.)

12 times daily, were provoked by meals or defaecation, lasted about 10 minutes, and if severe were followed by a feeling of chilliness. On the chest the flushing assumed a blotchy distribution, but the face was diffusely involved, with much heightened colour on the malar area, where it could best be described as one of bright reddish blue. The flush was and has remained a striking objective sign as well as an unpleasant symptom. Its increasing frequency over the last two years has resulted in the face appearing permanently bloated and bright red, particularly over the cheeks.

The abdominal findings during this time have shown a very slow increase in size of the liver, which contained easily palpable firm nodules which distorted its surface and edge

and were moderately tender to palpation. An indefinite tender mass was palpable in the right iliac fossa, and another mass could be palpated in the pelvis by rectal examination. The patient was losing weight very gradually, and suffered from moderate abdominal discomfort and a diarrhoea which could be kept in check by simple medicinal measures. She continued to manage her household and was fully ambulant.

At no time has asthma or any element of bronchospasm been shown. A loud systolic murmur has appeared over the praecordium. Its site of maximum intensity was the mitral area, and all second sounds were closed. In particular the pulmonary second sound would not appear to be reduced. There was no hypertension. Neither an electrocardiogram nor an x-ray examination of the chest indicated any degree of right heart strain.

Recent examination of the urine for 5-hydroxyindole acetic acid (5-H.I.A.A.) showed this substance to be present in significant quantity.

COMMENT

A case of carcinoid tumour is described in which the patient is still alive. The following features are of interest. (1) A protracted history amounting to at least eight years. (2) Diagnostic difficulties which were solved only by laparotomy and histological examination of the intestinal tumour. (3) The development of secondary deposits in the liver, which has been felt to increase in size slowly over a period of more than two years and can be inferred from the demonstration of 5-H.I.A.A. in the urine. In addition there appear to be metastases in the pelvis which are most likely originating in the ovaries, a site which has been noted in other cases of this condition. (4) The retention of a remarkably good state of health in sharp contrast to that expected if the present condition was due to carcinoma. (5) The development of flushing and a bursting congestion of the head coinciding in onset with the palpable enlargement of the liver. This fact fits the accepted view that 5-H.T., which is secreted by the gut, is inactivated during its passage through the liver, whereas secondary deposits in the liver secrete the substance and deliver it direct into the venous circulation. An amount stated to be about one-third of the total 5-H.T. secreted in the liver finds its way through the pulmonary circulation and exerts its effect outwardly in the manner described.

The pulmonary manifestations included in the syndrome as originally described by Thorson, Björck, Björkman, and Walderström (1954)—namely, asthma, right heart strain, and pulmonary stenosis—do not appear on clinical, electrocardiographic, or radiological grounds to have become manifest. It may be that the impact of 5-H.T. has not made itself felt on the pulmonary circulation for long enough to produce these changes. On the other hand, the review of 14 proved cases of argentaffinoma of the bowel with metastases by Thorson *et al.*, which included full clinical and electrocardiographic investigations, showed a striking lack of correlation between the cardiac findings in life and those at necropsy. Thus Case 2 of their series was described as exhibiting a systolic murmur over the whole praecordium and a left axis deviation in the electrocardiogram. At necropsy, sclerosis and retraction of the pulmonary cusps and narrowing of the pulmonary ostium were demonstrated, which suggests that a severe degree of stenosis of the pulmonary valve must exist, provided the septum is intact, before clinical evidence can prove its existence. Cardiac catheterization would possibly supply supporting evidence of pulmonary narrowing, but was not regarded as justified in an elderly patient.

For help and advice in the compilation of this note I am indebted to Mr. W. M. Beattie, surgeon, David Lewis Northern Hospital, Liverpool, who performed the operation, and to Dr. Winston Evans, pathologist, for the photomicrographs.

C. H. STEWART-HESS, M.D., M.R.C.P.,
General Practitioner.

Reviews

ESSENTIALS OF SURGERY

The Essentials of Modern Surgery. Edited by R. M. Handfield-Jones, M.C., M.S., F.R.C.S., and Sir Arthur E. Porritt, K.C.M.G., C.B.E., M.A., M.Ch., F.R.C.S. Fifth edition. (Pp. 1,276+xv; illustrated. 75s.) Edinburgh and London: E. and S. Livingstone Ltd. 1957.

A book that has run through four editions and four re-printings clearly must be not only of special merit but meeting a continuing demand. This applies to *Essentials of Modern Surgery*, by Handfield-Jones and Porritt, the fifth edition of which has undergone complete revision, and the many distinguished contributors, who make an impressive list, have, as the preface states, been "ruthless in pruning out-of-date material and meticulous in introducing the newest advances in every branch." We are not therefore surprised to find an entirely new section on radiotherapy and the use of radioactive isotopes, while other aspects of modern work—for example, cardiac and vascular surgery—have been succinctly brought up to date. While making no pretence to have read the 1,250-odd pages of the book from cover to cover, I have picked upon many different subjects at random as a test and find that the information provided is clear, accurate, and well balanced; the pruning which is required in a book entitled "essentials" has been carefully and wisely done.

A book intended primarily for students should have an abundance of good illustrations, for they are no less necessary than the text itself; the 649 illustrations in this volume are well chosen, and the reproduction reaches a high standard owing to the use of semi-art paper throughout, which, although it increases the weight, nevertheless allows of excellent representation of such notoriously difficult subjects as x-ray films. Some of the coloured illustrations are from the skilful brush of Anna Zinkeisen, so there is of course no doubt about their great artistic merit; they do, however, raise the question whether in a book upon such a scientific subject as surgery, and seeing the pitch of perfection in colour values reached in modern colour photograph reproduction, it would not have been better to use photographs. Of course, it must be recognized that the artist can combine in one picture several appearances which might be difficult to display in a photograph of any one specimen, and it may be this aspect which affected the authors in their choice. As would be expected in a book which has passed through several editions there are very few printer's errors; one or two page numbers in the index have escaped revision, and the caption to Fig. 610 has "right" and "left" transposed. This book is an excellent one for the student and goes far to being what is usually described as a "standard textbook"; it can be highly recommended without any hesitation whatsoever.

NORMAN C. LAKE.

PSYCHIATRIC DIAGNOSIS

The Primary Psychiatric Syndromes: Criteria for Clinical Diagnosis. By Dwight L. Moody, L.R.C.P., L.R.C.S., L.R.F.P.S., D.P.M. Foreword by William Blyth, M.D., F.R.F.P.S.G., D.P.M., B.L., LL.B. (Pp. 356+xiv. 37s. 6d.) Bristol: John Wright and Sons Ltd. 1956.

Over the last 50 years there have been changes in both directions in the status of psychiatric diagnosis. While some syndromes, such as that of temporal-lobe epilepsy, have emerged and are becoming increasingly clearly recognizable, there has also been a tendency to abandon diagnosis as a discipline which is no longer rewarding. Instead of diagnosis, with its implications for prognosis and therapy, it has been held more important to understand developmentally in all its complexities the patient's personality. The disadvantage of this approach is its tendency to lead to vagueness and wooliness of thought. Dr. Moody attempts to get back to classical medical methods of classification and to the delineation of established syndromes; he enumerates

in great detail, and in a highly schematized form, the observations in history and examination which will enable a particular diagnosis to be made. The book is a salutary attempt to get away from the "insubstantial and abysmal" dynamic study of individual patients *in vacuo*; and it will certainly, as is claimed, help to protect the young practitioner from becoming bewildered. Its defects are that its form resembles that of a cram book and does not encourage the student to think for himself, and that the concepts which are inevitably used ("introversion," etc.) are themselves so imprecise as to render such a precise formulation at times almost meaningless.

ELIOT SLATER.

ANTONIO SCARPA

Antonio Scarpa in Scientific History and His Role in the Fortunes of the University of Pavia. By Professor Achille Monti. Translation by Frank L. Loria, B.S., M.D., F.A.C.S. Foreword by Michael E. DeBakey, M.D., F.A.C.S. (Pp. 125; illustrated. \$4.50.) New York: The Vigo Press. 1957.

In reading this interesting life of Scarpa one is filled with admiration for the intellectual precocity he displayed, for his classical erudition, his artistic ability, and his anatomical and surgical skills. The excellent work Scarpa did on the internal structure of the ear, on the nerves which supply the heart, and on the anatomical varieties of hernia sufficiently illustrates his powers of observation and minute dissection. His surgical reputation soon became widely known and enabled him to become a rich man. Unfortunately early and great success did not improve his character. When he became possessed of power at the University of Pavia he became jealous of, and behaved meanly towards, any colleague who showed any sign of outstanding ability, and even conducted a vindictive intrigue against Spallanzani. He showed overweening pride and would not even receive into his presence his less prosperous brothers. In general he was cordially disliked. It is sad that such ability should be accompanied by such failings of character.

In an addendum to this book the author justly exalts the part taken by Italian scientists in the furtherance of anatomical knowledge, but most unjustly depreciates the part of William Harvey in demonstrating the circulation of the blood. To say that "the description given by Harvey is the one he had learned in his medical school days at the University of Padua" is a most misleading statement.

ZACHARY COPE.

TROPICAL MEDICINE

Lehrbuch der Tropenkrankheiten. Edited by E. G. Nauck. (Pp. 432+vi; illustrated. D.M. 64.) Stuttgart: Georg Thieme. 1956.

It is 15 years since the last full textbook of tropical medicine was produced by authors associated with the Institute of Tropical Medicine, Hamburg. There is no need to emphasize that during this period the advances made in tropical medicine have been phenomenal; the introduction of sulphonamides and antibiotics for bacillary dysentery, the placing of treatment in cases of malaria on a rational basis, the use of diethyl-carbamazine in the treatment of filariasis, and the introduction of effective prophylaxis against yellow fever all represent advances which have completely changed the medical situation in the tropics and converted regions once termed "the white man's grave" into places in which it is healthy and safe to live. German recovery since the war has been associated with renewed interest in, and trade connexions with, South America and many parts of the tropics, and it is therefore primarily to German doctors handling patients in or coming from the tropics that this book is directed. It is up to date, and, as is to be expected, the diseases of tropical South America are dealt with very fully. Those of some other regions, however, have received sketchy treatment. This applies particularly to some of the West African diseases such as loiasis and onchocerciasis, while kwashiorkor receives less than three-quarters of the

space given to leptospirosis, a disease affecting infinitely fewer persons. There is a tendency also for theoretical considerations to receive prominence at the expense of practical matters. There can, however, be little doubt that this will prove to be a very valuable volume for those whose native tongue is German, but its usefulness in other countries may well be more limited.

A. W. WOODRUFF.

RADIOLOGY OF THE OESOPHAGUS

La Radiologie Clinique de l'Œsophage. By Marcel Brombart. Preface by Ch. Auguste. Introduction by L. Deloyers. (Pp. 466; illustrated. 5,000 fr.) Paris: Masson et Cie. 1956.

This is a new book which is exclusively concerned with the clinical radiology of the oesophagus. The introductory chapters deal in detail with the technique of examination and with the normal radiological anatomy and physiology of the pharynx and oesophagus. These chapters are well illustrated by reproductions of radiographs and supplementary anatomical drawings of a high quality. There is a lengthy anatomical chapter on the functional disorders of long and interesting chapter on the functional disorders of the pharynx and oesophagus, in which this difficult and often controversial subject is fully discussed. Another interesting section deals with extrinsic lesions of the oesophagus, which range from fibrotic and neoplastic lesions of the mediastinum to congenital and acquired lesions of the heart and great vessels. The congenital abnormalities of the aortic arch and other great vessels are discussed from the embryological and developmental aspects, and the characteristic deformities and developmental aspects, and the characteristic deformities of the oesophagus which result from these abnormalities are well illustrated. Congenital lesions of the heart are dealt with briefly in so far as the oesophageal displacement is concerned. There are seldom characteristic except in coarctation. There are other chapters on oesophageal diverticula, hiatal hernia, oesophagitis, and oesophageal ulceration. Considering the importance of cancer of the oesophagus, it is perhaps surprising that the chapter devoted to this subject is shorter than those on the functional disturbances and diverticula. Nevertheless, this is a very useful chapter in that it stresses some of the difficulties which are commonly encountered as well as describing the radiological features of most aspects of this disease. There is a short discussion of the various techniques for demonstrating oesophageal varices. The author is of the opinion that varices are most easily demonstrated with the patient recumbent and either in full inspiration or performing the Valsalva manoeuvre. He concludes, however, that in order to demonstrate the varices most clearly it is necessary to examine the patient in many positions and all phases of respiration.

This interesting book is well produced and all the illustrations are of the highest quality. Each chapter is followed by an extensive and up-to-date bibliography, which alone makes it a very useful reference book. Although primarily of interest to radiologists, it should also prove a useful reference book to anyone interested in oesophageal disease.

J. W. LAWS.

BIOCHEMISTRY OF THE VITAMINS

Les Vitamines, Biochimie-Biologie-Emploi Thérapeutique. By Henri Thiers. (Pp. 626. 4,600 frs.) Paris: Masson et Cie. 1956.

This long treatise, written in French, is a remarkable achievement, to which the reader may react with a mixture of admiration and disappointment. As may be inferred from the subtitle, the author's main interest lies in the biochemistry of the vitamins, including their mode of action. It is difficult to remember any other textbook of a similar size which deals so adequately with this theme or which includes so many structural formulae. The pathology of vitamin deficiencies is also described, but a complete lack of illustrations showing either affected subjects or histological sections is a serious defect. Medical indications for the use of various vitamins are discussed. The author shows evidence of wide reading, and expresses his views in an easy, informal style.

Experts in nutrition will undoubtedly find pleasure, and possibly inspiration, in response to his wide knowledge, enthusiasm, and originality. But the absence of a single reference to the original literature, apart from the mention of a few names and dates in the text, is inexplicable in a book which is obviously written for experts. Expansion into two volumes, with adequate illustrations and references, should be seriously considered for future editions.

T. MOORE.

GYNAECOLOGICAL CYTOLOGY

Grundriss und Atlas der Gynäkologischen Cytodagnostik. By H. Smolka and H.-J. Soost. Foreword by E. Philipp. (Pp. 166+xi; illustrated. D.M. 120.) Stuttgart: Georg Thieme Verlag. 1955.

This volume, which appears under the title of "Outline and Atlas of Gynaecological and Cytological Diagnosis," should be regarded as a small but comprehensive textbook. Much work has been done in this subject during recent years, more particularly with regard to the early diagnosis of cancer of the uterus, but also on the influence of various factors, hormonal and otherwise, on the cell picture of the vaginal smear. All the knowledge thus acquired has been summarized, and is well presented in logical sequence in this relatively small book. The morphology of the normal cell elements, the differences in appearance at the various age periods, and the changes occurring during the menstrual cycle, in pregnancy, in the puerperium, and in abortion are described. There are chapters dealing with the changes found in the vaginal smear due to hormonal influences, whether artificially produced or occurring as the result of endocrine disorder, or to bacterial and protozoal infections, or to various inflammatory conditions in the female genital tract. There is an excellent section on the cytological diagnosis of malignancy; an account is given of the changes produced by radium and x-ray treatment and of the cytological examination of ascitic effusions. There are many beautiful illustrations, some in black-and-white, some coloured, and a number of photomicrographs and diagrams necessary to explain the subject-matter in the text. This should, indeed, be a valuable book to those practising and to those interested in gynaecological cytology.

J. BAMFORTH.

WAR NEUROSES

A Follow-up Study of War Neuroses. By Norman O. Brill, M.D., and Gilbert W. Beebe, Ph.D. (Pp. 393+xviii. No price.) Washington: Veterans Administration. 1956.

After the second world war the Surgeon-General of the United States Army suggested that a research programme be organized so that the extensive experience in the armed Forces and in the Veterans Administration might add to our knowledge of the natural history of disease. As part of this programme of follow-up studies this volume is devoted to the natural history of neurosis. The book is provided with between two and three hundred statistical tables and various figures showing the incidence of neurosis under conditions of call-up, of combat, and of post-war life. Of special importance are the data obtained on the relation between predisposition and military usefulness, and the effect of pensions and other compensation upon prognosis. Much of the information was obtained by the study of patients several years after discharge from service. Many of the men and women were in hospital, others in civilian life. This unique follow-up required and obtained the co-operation of psychiatrists in every part of the United States. The compilers of this volume are to be congratulated for their objectivity and frankness. They do not claim to have produced answers to all the problems studied, as is shown by the last sentence in the book, which reads: "Criteria for evaluating military performance seem badly needed." With the development of atomic weapons much of the material in this volume is already out of date. Nevertheless, as a book of reference it is a valuable compilation and should be on the shelves of every medical library.

SATURDAY AUGUST 3 1957

MATERNAL MORTALITY

In 1928 there were 2,920 women who died as the result of pregnancy or from causes directly associated with it, an incidence of 1 in 226. This appalling mortality stirred the public conscience, and Mr. Neville Chamberlain, then Minister of Health, appointed the Departmental Committee on Maternal Mortality and Morbidity. This committee, in a notable report,¹ analysed the records of maternal deaths and attempted to assess "the primary avoidable factor" in each case. Since that time maternal deaths have been thus analysed and published annually in the Reports of the Chief Medical Officer of the Ministry of Health. In 1951, however, the study and method of assessment of maternal deaths was broadened and more information obtained. A maternal death is now noted by the medical officer of health of the local health authority and he initiates the inquiry. The local consultant obstetrician obtains all the information possible from those who were in attendance on the patient—midwife, family doctor, hospital, or local authority staff. His report is sent to the regional assessor, a senior obstetrician appointed by the regional hospital board, who submits his comments to the Chief Medical Officer of the Ministry. Finally, the Ministry's consultant advisers on obstetrics sum up and assess the case with a view to determining whether avoidable factors were present and whether the death could have been prevented.

A report² has now been issued by the Ministry of Health on the inquiries made in England and Wales from 1952 to 1954, during which confidential reports were received on 1,094 deaths classified as due to pregnancy and childbirth and 316 deaths classified as due to associated causes. This figure represents only 71% of the total registered maternal deaths. It is to be hoped in future that with more complete and exact certification all maternal

deaths will be included. There is no question of the Ministry searching for a scapegoat and exposing a person or institution to public condemnation: it is only by revealing deficiencies in the maternity services that preventable deaths will be eliminated, administration improved, and maternity made safer.

The four largest groups of deaths which together account for two-thirds of the total were due to toxæmia (246 or 22% of the total), haemorrhage (188 or 17%), abortion (153 or 14%), pulmonary embolus (138 or 13%). Sepsis accounted for only 3.8% of deaths, and this remarkable decrease is the most outstanding factor in the reduction of maternal mortality. A quarter of a century ago sepsis was responsible for more than a third of maternal deaths. Among the 316 "associated" deaths, heart disease was much the commonest cause, accounting for 121, more than a third of the total. In the present report two additional groups have been considered—namely, deaths after caesarean section (183) and deaths due to complications of anaesthesia (49).

Although toxæmia of pregnancy is still the disease of theories, yet eclampsia can be prevented by rigid prenatal supervision. It makes depressing reading that 110 mothers died from this disorder, and in the group of deaths from toxæmia avoidable factors were considered to be present in over 50%. The most glaring deficiency was in the quality of prenatal care. A number of these deaths were clearly due to lack of co-operation between doctor, midwife, clinic, or hospital. It is to be hoped that the Cranbrook Committee (appointed in 1956 to inquire into the maternity service) will put this right. Shortage of antenatal beds has been blamed for late admission of patients with severe pre-eclampsia, but this is not reasonable justification for a hospital sending "home to bed" a patient with albuminuria, oedema, and a blood pressure 168/110. Another patient was allowed to return home whose blood pressure was 220/130. Again, when so much time is spent in teaching the importance of an early rise of blood pressure, it is hard to understand how a mother was not referred to hospital when her systolic blood pressure was over 200 mm. Hg.

Is death from obstetric haemorrhage preventable? The assessors were of the opinion that in antepartum cases half of the deaths could have been prevented and in the post-partum group that 90% of the mothers should not have died. Deaths from post-partum haemorrhage with retained placenta presented a higher proportion of avoidable factors than any other group. In many instances the "flying squad" was called too late, or the patient was removed to hospital without resuscitation, or with the placenta un-

delivered. These squads should not be staffed by junior medical officers: the family doctor or midwife needs expert help when calling for it, and an experienced obstetrician and anaesthetist should always be members of the team. It was not always in the home that these deaths took place, but also in the hospital, where attendants did not appreciate the dangers of slow, continuous haemorrhage. Perhaps when ergometrine is given routinely with the delivery of the baby these tragedies, almost wholly preventable, will no longer appear in maternity reports.

There were very few avoidable factors in deaths from pulmonary embolus, but abortion was a different story. Many do not realize that it is more often the married woman with a family who succumbs to the complications of procured abortion: there were 85 such cases. This needless loss of life is likely to continue until recently delivered mothers can more readily obtain skilled advice about family planning. The family doctor may not always possess up-to-date knowledge of contraceptive methods, and not all teaching hospitals arrange instruction in this subject.

Cardiac disease can be a serious complication of pregnancy, and it is regrettable that in one-third of deaths from this cause there was an avoidable factor. It is not appreciated that nearly as many deaths occur during pregnancy as in labour or immediately after. Inadequate prenatal care, including failure to send the patient to hospital, was often an important contributory factor. The truth of the dictum that it is safer to treat the disease rather than the pregnancy is exemplified by the deaths that occurred when abdominal hysterotomy was performed at the time of acute heart failure. Caesarean section is not the safe operation that some would have us believe. The estimated national mortality rate of 4 per 1,000 caesarean sections should be compared with the total maternal mortality rate (excluding abortions) of 0.6 per 1,000 births in 1952-4. In the present inquiry, maternal deaths after this operation amounted to 13% of the total. The immediate causes of death were equally divided between haemorrhage, pulmonary embolus, and shock or collapse. Sepsis accounted for 8% of these deaths. It would appear that this operation is still being performed in maternity units inadequately staffed and equipped to deal with haemorrhage. Some of the indications for the operation were very slender and some of the deaths were directly due to the anaesthetic. It is abundantly clear that maternity units should have the services of an anaesthetist experienced in obstetric work, but there are still departments lacking the help of an anaesthetist—in two of them the obstetric

operator gave the anaesthetic himself and then performed a forceps delivery. The woman who has been lingering in labour for many hours is just as much in need of expert care as the surgical emergency. How many surgeons would allow a nurse or recently qualified doctor to give the anaesthetic in such a case?

In 1955 the risk of an expectant mother dying from her pregnancy or associated causes was 1 in 1,500. It is a remarkable achievement to have made so much progress since 1928. But this report reminds us that there are still some aspects of our maternity services that are "black," for "avoidable factors were considered to be certainly present in 40% of the deaths directly due to pregnancy and childbirth." Plainly there is no room at all for complacency. All would agree with the recommendations that there should be (1) better antenatal care, especially in the early detection and early treatment of toxæmia, (2) more prompt and more effective treatment of haemorrhage, especially through the use of "flying squads" for the emergencies of domiciliary midwifery, and (3) better selection of cases for specialist care at hospital, especially women in the older age groups and higher parities. Time and again the report underlines the lack of cohesion between those responsible for the care of the expectant mother—midwife, doctor, hospital, local authority clinic.

BRITISH MEDICINE ABROAD

Dr. Charles Hill's White Paper on Overseas Information Services is of much interest to medicine and to the B.M.A. At the outbreak of the war of 1939-45 this country became painfully aware of the yawning gaps in its ideological defences. Between the two world wars very little effort had been made to see that foreign countries were supplied with information about the intellectual and cultural products of Britain. Other countries, notably Germany, spared no expense in disseminating their books and especially their professional and technical periodicals in other nations, where there was often a complete ignorance of what was going on in medicine in the Britain of that time. This, for example, made it easy for Germany to conduct propaganda even on medical lines which put Britain in a poor light, and as a result of discussions on how best to combat this there was set up in the offices of this *Journal* in 1940 an overseas abstracting service of British medical periodicals which subsequently formed the basis of the Medical Department of the British Council. And since those early years of the war the Medical Department of the British Council has played a valuable part in increasing

among other nationals knowledge and interest in British medicine. Unfortunately the money at the disposal of the British Council was reduced after the war, and it looked as though once again this country was going to repeat the shortsighted policies that put it at such a disadvantage when the enemy was at the gate in 1939.

Dr. Charles Hill's recommended increase of £2m. in Government expenditure on Overseas Information Services is at least a modest encouragement to those who are helplessly witnessing Britain being forced to the back of the class by the aggressive energies of other countries. Among those parts of the world where an extension of information is needed, according to Dr. Hill's White Paper, are Turkey, Indonesia, South America, India, and Pakistan, and it is principally in those countries that sterling is short and the libraries, universities, and individuals are unable to buy the British books and journals they want. The U.S.A. is giving practical expression to its supremely confident belief in the American way of life by ensuring through subsidies that American textbooks and periodicals are at the disposal of a world hungry for information, especially when conveyed in the English language.

When the Vice-President of the U.S.A., Mr. Richard Nixon, recently visited the new member of the British Commonwealth, Ghana, he presented that country with a collection of 2,000 technical books—a further illustration of the U.S.A.'s intense cultural drive. In 1955 Turkey, because of a currency crisis, had to stop its import of British books and periodicals, and it appears that to-day they are scarcely obtainable in Turkish bookshops while French and German books are fairly easy to get and American publications have stepped into the position previously held by Britain. As recent correspondence in *The Times* has shown, all attempts to jerk the Board of Trade out of its present complacency seem to have failed, and exporters of British books and periodicals are at an unfair disadvantage compared with their American counterparts. On top of this, the recent steep increases in postage overseas, as well as at home, will, with other increasing costs, jeopardize the existence of learned periodicals in this country, probably increase the price of those that survive, and make it still more difficult for the foreign reader to buy British medical periodicals and books—publications which have a unique place in the world's medical literature. It is hoped that something may yet be done to restore and maintain a prestige we are losing, and which we shall lose for years to come once foreign medical textbooks and periodicals replace their British equivalents in other parts of the world, and especially the Commonwealth.

REFORM OF THE N.H.S.

A plan for reforming the Health Service has just been published by the Fellowship for Freedom in Medicine (F.F.M.). As a summary printed in this week's *Supplement* shows, the proposals are closely related to what is happening in other countries, especially Australia, New Zealand, and Norway. Dr. R. Hale-White points out in the foreword to the booklet issued by the F.F.M. that the scheme is "limited in its scope to the methods of financing the general medical, hospital, and pharmaceutical services and to the effects that may be expected to result from the changes proposed." According to the F.F.M. the major faults of the N.H.S. are (1) the virtual abandonment of the insurance principle; (2) the policy of focusing the Service on the hospital rather than on the family doctor; and (3) the widespread delusion among the public that their insurance payments cover the costs of the Service. The F.F.M. believes that the N.H.S. in its present form is having a harmful effect on the practice of medicine, and the purpose of its present report is to advocate a plan of reform based on "real insurance principles." The F.F.M. advocates a "State-subsidized compulsory insurance of doctors' and hospital fees by those in a position to pay for it, and a free Health Service for all others." The effect of the proposals is to give the insured person and his dependants about 90% coverage against the costs of general practitioner and hospital treatment. The pharmaceutical benefit would be limited to what our Australian friends call the "life savers"; patients would, as in all other countries, be expected to pay for the ordinary household remedies. The insured persons would be free to consult any doctor of their choice, and with payment for item of service panel lists would disappear. According to the calculations made by the F.F.M. there would be a net saving to the Exchequer of about £140m. if the N.H.S. were reformed on some such lines as it proposes.

Criticism of the National Health Service has increased rather than diminished over the past nine years, and was brought to a head in the timely and cogent presidential address of Dr. Alexander Hall at the Annual Meeting in Brighton last year.¹ The B.M.A. has reacted to this situation by deciding to set up a committee of inquiry into the N.H.S., a move which has been widely welcomed by its members. The booklet just issued by the Fellowship for Freedom in Medicine is probably the forerunner of many other plans for reform and no doubt will come in for its meed of criticism, but no one can look on the annually mounting costs of the N.H.S. with anything

¹ *British Medical Journal*, 1956, 2, 57.
² *Supplement to the British Medical Journal*, August 2, 1952.

but alarm, especially as there is such meagre provision in its gigantic yearly bill for hospital development. It would, however, be wrong to look on the F.F.M.'s proposals as designed solely or even primarily to put some sense into the financing of the Health Service. The motive behind the scheme is the laudable one of running a service which places at least some direct responsibility on the patient for his health, and by the introduction of token charges to make him at least to some extent aware of the great benefits he receives. This aim is in fact in line with the recommendations made by the World Medical Association in 1952,² which included the following: "Any Social Security Scheme should contain elements that encourage self reliance and a sense of personal responsibility; and . . . any Social Security Scheme should stress the obligation of the individual to make at least part of his contribution directly to the functioning and costs of the Scheme."

HEPATO-LENTICULAR DEGENERATION

In his original description of hepato-lenticular degeneration S. A. Kinnier Wilson¹ suggested that unknown poisons damage the brain and liver. The offending substance has since been shown to be copper. It is deposited in the tissues as the result of a rare inborn error of metabolism, inherited as a recessive trait. Several clinical varieties of the disease are recognized.^{2,3} In about three-quarters of the patients signs of lenticular damage predominate. Tremor and rigidity, similar to those of Parkinson's disease, begin in childhood or adolescence. At first unilateral, they gradually spread throughout the whole body and are accompanied by dysarthria and euphoria and later by mental deterioration and wasting of muscles. Liver disease is clinically unobtrusive in this group, but it can be detected by suitable investigations. In 20% of cases portal cirrhosis accounts for the symptoms, though the characteristic neurological signs are also present. A small proportion of patients develop cirrhosis without at any time showing evidence of lenticular damage ("abdominal Wilson's disease"),⁴ and a few develop tremor and rigidity, usually in middle age, with no abnormality of the liver. The course of the disease may vary from an acute fulminating illness to a chronic illness lasting as long as 40 years; the usual length is four to five years and the outcome is invariably fatal. The characteristic Kayser-Fleischer rings, which are made up of deposits of copper giving a greenish-brown colour to the cornea near the limbus, are present in about 90% of patients, but examination with the slit lamp may be necessary for their detection. Hepato-lenticular degeneration has to be distinguished from Parkinson's disease, disseminated sclerosis (by the absence of pyramidal signs), and other forms of portal cirrhosis.

Much recent research has been directed towards elucidating the biochemical faults in Wilson's disease. Copper is absorbed from the gastro-intestinal tract in

greater than normal amounts, and though excreted in excess in the urine too much is retained in the body.⁵ This is deposited chiefly in the brain, liver, kidneys, skin, and cornea. Normally over 95% of the metal is transported in the serum bound to an alpha-2 globulin in the form of the blue pigment, caeruloplasmin. This is diminished in Wilson's disease,⁶ though the total copper in the serum may be not much below normal (90–120 µg. per 100 ml.) because of an increase in the other copper fractions. Estimation of serum copper is therefore of little value in diagnosis, but copper-oxidase activity apparently reflects accurately the amount of caeruloplasmin, and is said to be a reliable and simple test for hepato-lenticular degeneration.^{7,8} In addition to copper, amino-acids are excreted in excess in the urine,⁹ and, since blood levels are normal,¹⁰ this must indicate a tubular defect in reabsorption. Tests for amino-aciduria and cupriuria have often been done to aid diagnosis, but the methods are somewhat laborious for routine use. A point of more practical interest is that uric acid also appears to be lost in the urine through tubular failure, and this leads to a fall in the level of uric acid in the blood, which is much simpler to estimate.¹¹ Biopsy of the liver reveals a picture indistinguishable from classical portal cirrhosis. Attempts to demonstrate the deposition of copper in the liver during life have not been very successful, though L. L. Uzman¹² has recently described a histochemical method based on the staining of copper by rubanic acid in alcohol which he claims can be applied to liver biopsy specimens. However, abnormalities of copper metabolism may be found in cases of portal cirrhosis, and deposition of copper in the liver has been reported in this condition also.¹³

In spite of much new information the underlying cause of Wilson's disease remains obscure. One view is that the tissues are poisoned by copper as the result of a combination of decreased synthesis of caeruloplasmin and increased intestinal absorption of the metal.⁵ The amino-aciduria therefore is secondary to damage to the renal tubules. Uzman,⁴ on the other hand, believes the primary defect to be an abnormality of protein metabolism resulting in the production of specific dicarboxylic amino-acid peptides which block the reabsorption of amino-acids (and probably uric acid) by competition in the renal tubules. The peptides presumably also act as chelating agents in depositing copper in the tissues. It could be argued, however, that the disturbance in protein metabolism arises as the result of the liver damage, and that the latter itself is connected with the amino-aciduria, a theory that has been put forward to explain the occurrence of cirrhosis in some patients with Fanconi's syndrome. Until recently nothing was known to influence

the steady downhill course of the disease, but there is now some evidence that improvement may follow treatment with dimercaprol (B.A.L.).^{14 15} This drug increases the excretion of copper by the kidneys, and the fact that it gives benefit supports the view that retention of copper in the tissues is responsible for the damage. Treatment with newer chelating agents might likewise be effective, together with copper-free diets if these could be prepared simply and cheaply, but more information is needed about the underlying fault before rational therapy can be planned. Early diagnosis, especially of the "incomplete" forms, is imperative if a drug such as B.A.L. is to be used to greatest effect. For this purpose estimations of uric acid in the blood and copper-oxidase activity, together with histochemical examination of liver biopsy material, may be carried out on the patient and his family.

THE PSYCHIATRIST AS AN ADMINISTRATOR

With the coming of the National Health Service the management committee of King Edward's Hospital Fund for London had to make adjustments to meet the changing financial circumstances. Finding it would no longer be necessary to spend the Fund's income mainly on maintenance grants to what had been till then the voluntary hospitals of London, they wisely decided to devote some part of their resources to the training and further education of the men and women who would hold key positions on the staffs of the new hospital boards and management committees. As a result residential staff colleges were established for hospital administrators, for matrons, and for ward sisters, and in addition a school of hospital catering was founded and is now happily placed at the St. Pancras Hospital, an offshoot of University College Hospital. Most of the courses provided have been of short duration, from one to three months, though the training course for matrons lasts ten months, and the recently introduced national training course for hospital administrators, which the Administrative Staff College shares with the University of Manchester, has a span of three years.

A number of medical men and women have attended some of the short courses in hospital administration, but until this year no course had been arranged solely for members of the medical profession. The report¹ of a committee of the Central Health Services Council on the internal administration of hospitals dealt at length with the much-discussed problem of medical administration in hospitals, and one of its conclusions was that in a mental hospital (say, of more than 250 beds) "the ordinary problems of medical administration make the appointment of a medical administrator acceptable." When, therefore, a strong plea was made to the Fund to provide a trial course of study for physician-superintendents of mental hospitals, the Fund's Administrative Staff College was invited to see what it could do in the matter. A small group of physician-superintendents spent two days in the college discussing the need for such a course, and, once the need was established, the content of the course and who should be invited to

attend it. In the end the group planned a four weeks' course and agreed to submit themselves, together with some others whose names they suggested, to an initial experiment—the first essay of the King's Fund in the field of postgraduate education. The syllabus of this first course, held a few weeks ago, covered a wide range, the main theme, perhaps, being the role of the physician-superintendent as a leader in group therapy and the kind of administrative framework in which the role could best be fulfilled. Visiting speakers were drawn from a wide range of occupations. Every member of the course was able to speak his mind freely, and the result was a most stimulating four weeks, with interest maintained right to the end. On the last day the members reviewed the syllabus and suggested some useful amendments for the next course, which it is hoped may be held in about a year's time. The value of such a course has been amply demonstrated. As things are, the patients in a mental hospital certainly benefit from the work of the medical administrator, and something more than "training on the job" can be of help to him.

WELFARE FOODS

Since the war the number of people taking the vitamin supplements supplied by the State has been much below the number entitled to them. In 1948, for example, the uptake of orange juice was 36% and in 1955 it was 30%. The figures for cod-liver oil were 34% in 1948 and 19% in 1955, while those for vitamin tablets were 37% and 32%. These figures, taken from a report¹ published last week by a committee of the Central and Scottish Health Services Councils, illustrate one feature of the background against which this committee was asked just over a year ago to advise on the present need for welfare food supplements other than milk. Another feature is the relatively higher standard of living now enjoyed by many wage-earners in contrast to the years between the wars. Again, the committee had to consider not only whether there is a need for these food supplements but whether any of them are doing harm by being taken in excessive doses. Finally, it had become evident that, to quote the report, "those whose diets are least likely to be adequate make least use of the service."

In a field of study such as this, where facts are few and opinions vehement, it is not surprising that the committee does not suggest any drastic changes. "Much of the evidence," it says, "has been neither firm nor unequivocal," but it does find that scurvy is almost non-existent after the age of 2 years. It therefore recommends (with two dissentients) that orange juice should be supplied up to the age of 2 but not thereafter. The problem of vitamin D is mainly to decide what part, if any, it plays in the aetiology of hypercalcaemia. A committee of the British Paediatric Association reported last year² that infants should be safeguarded from the possible risks of getting too much of this vitamin. Some figures it published showed that an infant on a commonly recommended diet would receive

¹ Report of the Joint Subcommittee on Welfare Foods, Central and Scottish Health Services Councils Standing Medical Advisory Committees, H.M.S.O., 2s.
² British Medical Journal, 1956, 2, 149.

about 4,000 i.u. a day. This is in striking contrast to the recommendation of a Medical Research Council conference that the intake should be about 400 i.u. a day, a figure the present report adopts. The committee recommends—and by no means too soon—a reduction in the strength and dosage of national cod-liver oil to be made available to children up to the age of 5; while the level of vitamin D in infants' cereals should be reduced. As to nursing mothers, the committee recommends that orange juice and vitamin A and D tablets should continue to be supplied, though there is no firm clinical evidence of hypovitaminosis among them. It may be questioned whether orange juice is the cheapest and most effective way of prescribing ascorbic acid.

Its terms of reference restricted the committee to considering the more specifically medical features of the State provision of welfare foods, but it nevertheless did comment on the distribution of them, saying that the arrangements should be kept constantly under review. The question that must have occurred to its members is whether the people who are taking the welfare foods are receiving much or any benefit from them. In other words, are these foods going mainly to people whose diet is already adequate enough to preclude the need for them? Is the Government guilty of over-prescribing because it sees the shadow of another Government promising more round the corner? The evidence rather points that way, but more facts need to be gathered.

CIRCUMSCRIBED MYXOEDEMA

Though a recent, but not complete, review¹ of the literature on circumscribed or pretibial myxoedema reports only 149 cases, it cannot be very rare, for it occurs in about 3% of patients with toxic diffuse goitre. Many examples probably go unrecognized, because the condition does not usually give rise to discomfort or disability.² P. Watson-Williams³ in 1895 seems to have been the first to describe pretibial myxoedema; his patient was a woman with Graves's disease, and until W. R. Trotter and K. C. Eden⁴ published an important paper on this subject in 1942 little interest was taken in the condition except by dermatologists.

Clinically, certain features are usually present. The patient may complain of vague aching in the legs, but more often the condition is only discovered on routine examination of the lower limbs of patients with hyperthyroidism and exophthalmos. It is doubtful whether pretibial myxoedema ever occurs in the absence of exophthalmos. The lesions first appear on the antero-lateral aspect of the lower half of the legs and later extend, sometimes as far as the knees, to the back of the legs and on to the insteps. The condition is usually bilateral and the skin is raised in irregular firm swellings, the surface being dimpled and faint pink or brown or unaltered in colour. Coarse hairs may be seen over the swellings, and sweating may be a feature. In the course of years spontaneous disappearance of the lesions may occur. Two of the three patients described by R. S. M. D. Inch and C. F. Rolland⁵ had gross

clubbing of fingers, an observation which seems to be unique.

The aetiology is unknown, but the condition seems always to be associated with past or present thyrotoxicosis. In this respect and in its clinical manifestations it differs from the rare lichen myxoedematosus, another condition in which deposits of mucin are found in the skin, usually in papules but sometimes as a diffuse infiltration.⁶ Pretibial myxoedema is most commonly first seen between the ages of 40 and 48, and the male-female ratio is 1:1.8 in contrast to the ratio of 1:4.4 in toxic goitre.⁴ The course of the condition being so similar to that of progressive exophthalmos, it is probable that they have the same aetiology.⁷ In Trotter and Eden's series some patients developed both conditions simultaneously after thyroidectomy, but in half of them pretibial myxoedema appeared before treatment of the thyrotoxicosis.

Hypothyroidism does not usually result in an increase of mucin in the skin, though the term "myxoedema" suggests that it does.⁴ In pretibial myxoedema, however, a considerable amount of material is deposited which stains with thionine blue, a reaction regarded as specific for mucin. Exophthalmos does not seem to result from a similar deposition of mucin in the orbit but from retraction of the lids, swelling of the extra-ocular muscles, and oedema of the orbital tissues, though the problem of its cause is still unsolved.^{8 9} The common factor in the causation of exophthalmos and pretibial myxoedema has been thought to be overproduction of the thyroid-stimulating hormone (T.S.H.) of the anterior part of the pituitary gland in the absence of normal thyroid secretion.^{8 10} I. C. Gilliland and J. I. Strudwick,¹¹ however, found that, while thyrotoxicosis with severe eye signs is associated with a raised level of T.S.H. in the serum, this is comparable with the rise found in spontaneous myxoedema, in which proptosis does not occur. In thyrotoxicosis without severe exophthalmos the level of T.S.H. is not raised. They concluded that T.S.H. alone is not the cause of exophthalmos, but that some other factor which may also be of pituitary origin is involved. This view is supported by the work of A. Querido and L. D. F. Lameyer,¹² who found no relation between T.S.H. level in the serum and exophthalmos, though the level was high in a patient with post-operative myxoedema, slight proptosis, and pretibial deposits.

As might be expected, the treatment of this obscure condition is unsatisfactory. Thyroxine given by mouth or by local injection, administration of cortisone, the injection of hyaluronidase, and simple measures such as massage and radiant heat are all ineffective and cause only temporary and slight improvement. Clearly this disease requires much further investigation.

The president, Dr. HUGH GARLAND (Leeds), took the chair and explained that, owing to the unavoidable absence of the opening speaker, Dr. RAYMOND ADAMS (Boston, Mass.), he would read Dr. Adams's paper on "Recent Developments in Cerebrovascular Diseases." He said that the "stroke case," formerly neglected, was now being subjected to the scrutiny of medical scientists, with promise of substantial gain in knowledge both of vascular diseases and of the function of the human nervous system. A comprehensive classification of cerebral vascular disorders might include nearly 40 diseases under nine main headings, but most of these conditions were in the end attributable to hypertension and atherosclerosis: the ultimate solution of problems in this field might be achieved by whoever learnt the secrets of these two conditions. Subarachnoid and intracerebral haemorrhage from ruptured aneurysm or angioma was a less serious problem since the advent of cerebral arteriography, and its mortality could be greatly lessened by surgical treatment under hypothermia. The hypertensive cerebral

haemorrhage, fatal in about 75% of cases, was more serious and its exact mechanism was still not known. In considering occlusive cerebrovascular disease, Dr. Adams regarded thrombosis (40% of strokes) and embolism (25%) as the most frequent lesions. In cases of embolic stroke, long-term anticoagulant therapy might greatly reduce the incidence of subsequent episodes. In presumed cerebral infarction many factors might play a part, including arterial narrowing, the existence and efficiency of anastomotic channels, and other "ischaemia-modifying factors," including the level of the blood pressure, oxygenation, and vascular spasm. The recent recognition of recurrent cerebral ischaemic attacks resulting from insufficiency of either the carotid or vertebral arterial system was most important, as these episodes might herald an oncoming stroke and the latter might be avoided by anticoagulant therapy. Dr. Adams concluded that many mechanisms played a part in the production of cerebral vascular disease, and the neurologist must understand the nature of those diseases of other organs and systems which could affect the cerebral circulation.

Subarachnoid Haemorrhage

Dr. J. MACDONALD HOLMES (Stafford) described the medical management of cases of subarachnoid haemorrhage. He said that subarachnoid haemorrhage was one of the most common and rapidly lethal of neurological emergencies, and the physician dealing with such cases had several responsibilities, not only those of diagnosis and conservative treatment, but, above all, the selection of cases suitable for surgical treatment. Nowadays it was not enough to make a nominal diagnosis of intracranial haemorrhage, but the source of the bleeding should be located and its cause determined. For this purpose carotid angiography was essential, and this procedure should be used much more widely in general hospitals which had no neurosurgical department. Dr. Holmes had studied a consecutive series of 100 cases seen in the acute phase of the illness between 1936 and 1951; all were managed conservatively, and the initial mortality rate was 43%, but a further 8 patients died of recurrent bleeding subsequently, giving a total mortality of 51%. Since 1952 he had reviewed a further 100 cases, unfortunately not consecutive. Angiography was carried out in 49: 23 cases were treated surgically, with 5 deaths, giving a surgical mortality of 21.5%. The total mortality in the whole series was 35%. Dr. Holmes suggested that the possibility of surgery should be considered in all cases at an early stage of the illness and that the management of the case by the physician should have this end in view.

Radiological Investigation

Dr. JAMES BULL (London) described methods of radiological investigation in cases of cerebral vascular disease. He pointed out that the introduction, little more than a decade ago, of the technique of percutaneous cerebral angiography had provided a fresh stimulus to the more accurate diagnosis and better treatment of cases of this nature. In subarachnoid haemorrhage, for instance, the method was invaluable. In a series of 461 cases of subarachnoid haemorrhage studied up to 1954, carotid arteriography revealed aneurysms in 54%, arteriovenous malformations in 11.5%, and cerebral, cerebellar, or brain-stem haemorrhage in 7.5%; no lesion was demonstrated in 27%. A further series of 574 cases occurring in 1955 and 1956 gave similar findings, except that arteriovenous malformations accounted for only 6.1%. During the past 10 months practically all cases in which no lesion was demonstrated on either carotid tree had been submitted to vertebral angiography. Of these 250 cases, the carotid arteriograms gave positive information in 171 (68.4%). Vertebral arteriography was carried out in 71 of the remaining 79 cases, and lesions were demonstrated in 8 of these (3 aneurysms, 4 angiomas, 1 haematoma); the findings were negative in 60 cases, and in 3 the angiogram failed. Whatever might be the cause of the bleeding in cases with negative angiograms, the prognosis in this group of patients appeared to be good.

Dr. Bull remarked that angiography had also brought into prominence certain other features of strokes, and retrospective clinical analysis had led to a greater accuracy of clinical diagnosis. Angiomas had been shown to be much more common than was formerly realized, while thrombosis of major vessels such as the common or internal carotid, the anterior, middle, and posterior cerebral, and the basilar arteries might be diagnosed with certainty in life. Differentiation between a stroke and a neoplasm or subdural haematoma might sometimes be impossible by clinical means, but angiography would usually establish the correct diagnosis.

Surgical Treatment

Mr. MURRAY FALCONER (London) discussed the surgical treatment of spontaneous intracranial haemorrhage. He pointed out that this condition (excluding chronic subdural haematoma) occurred in two main forms, first intracerebral, and secondly subarachnoid haemorrhage. Both could occur at any age, though they happened most often after the age of 40. Primary intracerebral haemorrhage was much the more common and was usually rapidly fatal, though a few cases survived for some days and then showed the signs of a space-occupying lesion. Primary subarachnoid haemorrhage was less common and was due to a leaking intracranial aneurysm in about 75% of cases or to a bleeding arteriovenous malformation in a further 5 to 10%. Within a few days 30% of cases died, and in the next 1 to 8 weeks a further 30% died of recurrent bleeding; many of the survivors were disabled.

Surgical treatment would seldom avert death in cases deteriorating rapidly in the first few hours or days; its chief value was in preventing death from recurrent haemorrhage or in relieving the effects of a large intracerebral clot. Operation must be preceded by angiography for diagnosis and localization, and was best carried out a week after the ictus. Aneurysms could then be dealt with by carotid ligation or by intracranial operation, and arteriovenous angiomas by excision (preferably) or by clipping the feeding arteries if they were too large to be excised. All large intracerebral clots should be evacuated even if the lesion responsible was not apparent. With increasing experience the mortality rate of surgical treatment in this type of case could be less than 10%, and follow-up studies showed that subsequent recurrent bleeding was rare.

The Management of Strokes

Dr. F. A. ELLIOTT (London) concluded the symposium by reading a paper on the management of strokes. The rising mortality and morbidity from cerebrovascular disease in ageing populations emphasized the need for improved methods of prevention, diagnosis, and treatment. Necropsy findings had revealed a high rate of erroneous diagnosis, and for rational treatment to be applied it would be necessary to distinguish with greater accuracy between haemorrhage, thrombosis, softening without occlusion, embolism, and the much-debated arterial spasm. The treatment of cerebral haemorrhage by means of drugs designed to reduce the blood pressure might be desirable theoretically but was risky in practice, while for thrombosis and embolism the value of anticoagulants had yet to be determined. Stellate ganglion block did not increase cerebral blood flow in hypertensive and arteriosclerotic persons, but the intravenous administration of 50 mg. of tolazoline or of 100-200 mg. of papaverine would occasionally produce striking improvement in cases of thrombosis or embolism. The inhalation of 5% carbon dioxide in oxygen led to profound vasodilatation, but could not be tolerated for more than a few minutes. Dr. Elliott stressed that the careful nursing of these patients was essential and that antibiotics should be given to prevent infection; he advised heroin for headache and paraldehyde for restlessness. All fats of animal origin should be eliminated from the diet, or at least severely restricted, for these increased blood viscosity and coagulability and decreased the action of plasma fibrinolysins. Other methods for increasing fibrinolytic activity

and for producing vasodilatation were being developed. Research workers should aim at devising therapeutic methods which could be used by the family doctor, who saw these cases in the earliest stages.

SECTIONS OF RADIOLOGY AND SURGERY

Wednesday, July 17

Radiological Investigation of the Biliary Tract

With the president of the Section of Radiology, Dr. S. WHATELY DAVIDSON (Newcastle upon Tyne), in the chair. Dr. S. D. SCOTT PARK (Glasgow) opened a discussion by the combined Sections of Radiology and Surgery on the radiological investigation of the biliary tract.

Dr. Scott Park said that there were two contrast media that he used at present: iopanoic acid was given orally and "biligradin" intravenously. The choice of medium depended largely upon the part of the biliary tract which it was most important to see clearly. He and his colleagues had made a comparative study in 1954, giving both media in turn to 100 patients. They found that biligradin showed the main biliary ducts rapidly and completely in 97% of cases. The gall-bladder was usually seen within 90 minutes, although its shadow was faint and often of poor diagnostic quality. Using iopanoic acid they needed fewer films and the gall-bladder shadow was usually of better diagnostic quality. By giving an intense fatty meal the cystic and upper part of the common bile duct had been outlined in 84% of cases. Provided the gall-bladder had filled, there had been no calculi undiagnosed with iopanoic acid, whereas 9 calculi were missed with biligradin. Biligradin, however, was undoubtedly superior when the distal part of the common bile duct had to be seen, and only biligradin could be used after cholecystectomy.

The speaker then turned to the pathological gall-bladder. He felt that in acute cholecystitis the examination was almost bound to fail and might aggravate the inflammation; it was therefore contraindicated. In chronic cholecystitis, and particularly in the mild case when clinical diagnosis was difficult, the radiological signs were often equivocal. With iopanoic acid, neither the time of appearance of the shadow, its density, nor its rate of emptying was conclusive evidence of disease. With biligradin, if no shadow appeared, the gall-bladder was almost certainly diseased but the pathology remained unknown. In cases where iopanoic acid gave little or no shadow and yet biligradin gave a good shadow, cholecystitis was probably present.

Dr. Scott Park finished by pointing out that in the presence of a serum bilirubin over 4 mg. per 100 ml. any form of cholecystography would probably fail.

Radiological Investigation after Cholecystectomy

Dr. J. D. DOW (London) confined his remarks to biligradin examinations after cholecystectomy. He endeavoured to answer three questions:

Firstly, what was the normal appearance of the common bile duct after cholecystectomy, and did it undergo physiological dilatation; secondly, what were the causes of a dilated common duct, visible on a biligradin examination, and was it ever due to biliary dyskinesia; and, thirdly, were there any other appearances visible which could be definitely related to the patient's symptoms?

From his series of cases he concluded that physiological dilatation of the common duct did not occur after cholecystectomy. In addition he found that, in all of six cases in which dilatation of the common duct was present before operation, the duct returned to normal over one or two years after the causative obstruction had been relieved. In endeavouring to answer the second question, Dr. Dow reviewed the histories of 32 patients with dilated common ducts. In 26 of these, operation confirmed the presence of stone in the duct; one patient had a stricture and two had stones demonstrated by biligradin cholangiogram, while in two others there was strong clinical evidence of a stone.

He therefore reached the conclusion that dilatation of the common duct after cholecystectomy was very strong presumptive evidence of obstruction from stones, biliary mud, or stricture.

With regard to other appearances visible on biligradin films which might be associated with symptoms, Dr. Dow had found that kinking of the duct only occurred incidentally to dilatation, and that a cystic duct stump, unless containing a stone, did not seem to cause symptoms. He also found that the time of greatest concentration was difficult to assess and therefore of limited value. Reflux into the pancreatic duct occurred in two patients who were thought to have chronic pancreatitis, but no conclusions could be drawn from so small a number of cases.

Limitations of Cholecystography

Mr. J. DUDFIELD ROSE (Newcastle upon Tyne) said that in the past great reliance had been placed on cholecystography as a method of investigation in biliary-tract disorder. He believed, however, that as carried out at present the method was unable to supply a diagnosis in 60% of patients with biliary symptoms. Classical cholecystography might give adequate information on gall-bladder morphology, but would not give precise information about the motor function of the biliary tract. Boyden's original work on serial cholecystography had recently been revived and elaborated. By taking antero-posterior and lateral films every 10 minutes after a fatty meal, the rate of emptying of the gall-bladder could be calculated and an estimate made of its muscular tonus.

The speaker then referred to a series of 200 consecutive cases out of which a disordered motor function, or biliary dyskinesia, was diagnosed in 126. Diagnosis was made pre-operatively and confirmed by manometric readings during the operation. The gall-bladder might evacuate insufficiently (hypokinesia), and this might be associated with a hypotonic gall-bladder (as in atony). The treatment carried out was right splanchnicectomy with or without cholecystectomy. Hypokinesia when associated with hypertonia suggested an obstructive lesion—either organic or spastic. Vagotomy had been used successfully to abolish spasm of the sphincter of Oddi. On the other hand, too rapid emptying of the gall-bladder (hyperkinesia) could also occur and be associated with hypertonia or hypotonia. In the latter cases right splanchnicectomy had again been carried out.

Mr. Duffield Rose presented cases showing these main types of disorder and stressed that they had all shown a normal classical cholecystogram.

Diagnostic Difficulties

Mr. A. DICKSON WRIGHT (London), president of the Section of Surgery, agreed with the previous speaker in that the present method of radiological investigation of the biliary tract left much to be desired, and emphasized that laparotomy and even opening the gall-bladder might not necessarily provide a diagnosis. He felt, however, that biliary dyskinesia had not yet been established as a cause of the patient's symptoms. He personally had never seen the gall-bladder contract and thought that the general activity of the patient might play a more important part in its emptying than the very sparse musculature of the organ itself.

Mr. Dickson Wright mentioned two other methods of cholangiography—percutaneous and pre-operative air-contrast cholangiography. He added that whenever he explored the common duct he did so via the duodenum, leaving a patulous sphincter. This did not appear to cause any symptoms which might be attributed to biliary dyskinesia. While entering a plea for avoiding unnecessary cholecystography, he pointed out that biliary colic was not a contraindication. Finally, Mr. Dickson Wright said that with the negligible mortality rates now obtaining all patients with gall-bladder pathology should be urged to undergo cholecystectomy in order to avoid such complications as carcinoma.

SECTIONS OF CHILD HEALTH AND GENERAL PRACTICE

Thursday, July 18

Acute Respiratory Infections in Childhood

The president of the Section of Child Health, Professor WILFRID GAISFORD (Manchester), took the chair for the first part of this combined session. The discussion was opened by Professor DONALD COURT (Newcastle upon Tyne), who analysed his experience of 10 years of study of respiratory infection in 800 families in order "to achieve a useful practical classification of acute respiratory disease on which we can base a rational therapy." There were, he had found, two broad but distinct groups: one of colds-bronchitis-pneumonia, much commoner in winter than in summer, more severe in babies than in older people, and more apt to be fatal in social Classes IV and V than in I and II; the other of tonsillitis-pharyngitis and otitis, which had no striking seasonal incidence, but which in some instances persisted in particular families as entrenched streptococcal infection.

Dr. JOHN FRY (Beckenham) pointed out that infections of the respiratory tract accounted for around two-thirds of all work in general practice and must cost more than £10m. a year in treatment, but remained in many respects little understood. Study of the natural history of these infections showed a high prevalence in infancy, rising to a peak at about the fifth year and falling dramatically about the eighth year. Such facts should make doctors give support and explanation while the child was going through the catarrhal age, rather than advising tonsillectomy—an operation undergone each year by a quarter of a million children—or giving antibiotics indiscriminately. Acute respiratory disease was changing. By considering the severity of the illness, the previous history of the patient, and so on, the speaker had been able to restrict his use of antibiotics to 50% of "acute chests," 20% of cases of acute otitis media, and 25% of infections of the throat. This had not resulted in the development of rheumatic fever or nephritis, nor (as he said in reply to several later speakers who advocated greater use of penicillin in otitis) to deafness.

For the second half of the session Dr. S. WAND (Birmingham), a vice-president of the Section of General Practice, took the chair. Dr. J. F. GOODALL (Skipton) had analysed his findings in 384 wheezy children, born in the period 1937-57; nearly half of them had only a single wheezy episode, the others having bronchospasm more frequently. The onset was usually in infancy, but there was another high peak in the sixth year, when (as Dr. Fry had pointed out) infections were most prevalent but when also there were other stresses associated with going to school. Wheezing seemed to be more closely related to the respiratory infections of winter than to allergy—urticaria was commoner, however, in wheezy children than in others and might be important in the 5% of children whose wheezing persisted after childhood.

Professor C. H. STUART-HARRIS (Sheffield), not being a general practitioner or a paediatrician, felt, he declared, like a displaced electron wandering off its orbit. He exploited this opportunity by explaining the point of view of a virologist, complaining of his inability to give clinical help promptly enough and of his subjection to the limitations of techniques. He then proceeded to give a series of character sketches of respiratory viruses: no respecters of anatomy, they might, in Burnett's words, "browse over the respiratory epithelium," cause necrosis or granulation, produce little immunity in the patient, and make their success in attack doubly sure by varying in antigenic construction. After a lightning survey of the laryngo-tracheo-bronchitis of Beale (which is also the C.A. virus of Chanek) and adenoviruses (especially types 3, 4, 7, and 14, which are associated with acute respiratory illness), the speaker (now back on his orbit) concluded with news of Mogabgab's virus, which causes colds in the head.

Dr. A. J. LAIDLAW (Worcester) drew attention to the work already being done in general practice in studying outbreaks of infection. He also pointed out that on the average a child had a respiratory infection six times a year, yet in only one attack in 20 could a bacterial agent be incriminated as the cause. Most of the other attacks were probably due to viruses which are not affected by antibiotics; consequently antibiotics should not be used in such cases: experience with measles had shown that even their employment to prevent the occurrence of secondary infection was harmful.

Dr. GEORGE DAVISON (Newcastle) reminded the audience that there was one condition, rheumatic fever, in which the use of sulphonamides or penicillin prophylaxis against streptococcal infection was important. Dr. A. BARKER (Whitstable) and Dr. MILLER (Newcastle) supported the use of penicillin in acute otitis; Dr. ANDREW SMITH (Newcastle) believed that in penicillin V they now had a reliable oral preparation which helped the doctor to maintain the child's confidence, as it did not hurt him. These were shafts aimed at Dr. FRY, who defended himself with agility and remained unrepentant. He believed that there had been a change in the natural history of these infections so that acute mastoids and running ears had become rare, and he described an investigation of otitis, treated by 17 separate practitioners, which showed no difference in outcome whether antibiotics were used in 98% or 30% of cases. As the discussion evolved it seemed that some of the disputants were describing "a pink drum which lost its lustre, and the child is well and happy" as acute otitis, while others were thinking of relatively neglected cases. Dr. M. W. EDDINGS (Portsmouth), from his experiences in an area of good new housing, was among those who pointed out that it was the quality of their mothers which determined what sort of respiratory infections one had to attend in the children.

SECTION OF ANAESTHETICS

Thursday, July 18

Barbiturates

With a vice-president, Dr. JOAN MILLAR (Newcastle upon Tyne), in the chair, Dr. ERIC NILSSON (Lund, Sweden) opened a discussion on barbiturate toxicity and coma. Treatment with stimulant (convulsive) drugs, he said, did not improve the mortality. In deep coma there were loss of reflexes, shallow respiration, and circulatory failure. Oxygen lack could lead to cerebral injury; the respiratory centre was too depressed to respond to concomitant CO₂ accumulation, respiration being hypoxia driven by carotid-body reflexes. Giving oxygen could therefore cause further respiratory depression, and assistance was often needed.

The course in the past used to be stormy, with hyperpyrexia, respiratory obstruction, and convulsions. Now the course was longer, but quieter. He recognized three clinical stages. In the induction stage early physiological imbalance demanded vigorous treatment of life-threatening complications. In the second stage (stable coma) careful nursing and hourly observation of pulse and blood pressure was necessary, and the haemoglobin was determined every four hours; this stage could be very prolonged. In the stage of recovery reflexes returned but shock could still occur. Death could result from gross overdose with depression of the vital centres, from circulatory failure, from uraemia, or from pulmonary complications. Hyperthermia was seen particularly in cases treated with convulsant drugs.

Treatment at present was based on close and continuous observation with early recognition and treatment of complications. Blood electrolyte and barbiturate levels were determined at least once a day and also creatinine clearance and urine analysis. Care of the respiration included oxygen therapy and tracheo-bronchial toilet. Intubation, if needed, was not continued for more than four days, tracheotomy

SECTION OF OTO-RHINO-LARYNGOLOGY

Thursday, July 18

The Scope of Surgery in the Management of Deafness

With the president, Mr. W. I. DAGGETT (London), in the chair, Mr. I. B. THORBURN (Blackpool) opened a discussion on the scope of surgery in the management of conductive deafness. He reviewed the advances in the last 25 years and said that Lempert's main contribution was his precise technique under magnification. Later advances were the use of the operating microscope and the control of infection with antibiotics. Careful choice of the patient and improved techniques had resulted in useful hearing in 85% of the speaker's second hundred cases, compared with 51% in his first hundred cases. He was a strong believer in the value of the operation. Rosen's operation of mobilization of the stapes was a simple procedure which was reported to give good results in about 35% of cases. He had misgivings about the permanency of the results, but the fenestration operation could always be done subsequently without its outcome being prejudiced. He also considered it unwise to risk labyrinthine trauma with the chance of complete deafness by other operations on the footplate of the stapes.

Referring to the more recent operation of tympanoplasty, he considered this to be the most important development since the Lempert fenestration operation. It was an extension of mastoid surgery towards the restoration of function and offered a solution to the problem of controlling disease and restoring the hearing in a single procedure. He laid down five fundamental principles that must be followed to obtain a successful result. (1) A precise microsurgical technique and control of haemorrhage were essential. (2) The assessment of the changes seen under the microscope in the tympanum as reversible, and therefore likely to subside on removal of the infection, or irreversible. Irreversible changes included cholesteatomata, granulation tissue, and osteitis, and they would not necessarily disappear even when the ear had been dry and healed for years. (3) Antibiotic therapy helped considerably in obtaining a successful result by controlling chronic infection, provided any irreversible lesion had been eliminated. He matched the antibiotic to the sensitivity of the organisms and usually used a combination of penicillin and streptomycin. (4) Full-thickness skin grafts provided a satisfactory medium for the plastic reconstruction of a new tympanic cavity. He used post-auricular skin, as it contained fewer elastic fibres, and laid it on a bed from which the epithelial layer had been removed. For the mastoid part of the cavity he used a "crazy paving" of small pieces of skin to diminish the post-operative formation of granulations. (5) Tympanoplasty attempted to apply basic audiological principles of leverage and phase differential to achieve the optimum transmission of sound waves to the labyrinth. A Eustachian tube free from infection and patent to air currents was essential. Hearing tests were necessary to confirm that an adequate cochlear reserve was present. During the operation it was essential to test the mobility of the stapes by observing movement in the membrane of the round window when the stapes was rocked. Using a diagram prepared by Wullstein, Mr. Thorburn described the five types of procedures employed for functional repair. In type I there was a perforation of the tympanic membrane but the middle ear was normal. Improvement in hearing could be effected by myringoplasty (repair of the perforation). In type II there was disease in the middle ear but the ossicular chain was intact. Such cases required removal of the disease and division of ossicular chain adhesions. Cases in types I and II might show normal hearing, and here surgery aimed at the prevention of future deterioration of hearing. In type III cases the ossicular chain was broken, and the object of repair was to obtain a columella effect on the stapedial head with the grafted drum. Type IV cases had necrosis of the head and crura of the stapes. Improvement in the hearing depended on the formation of a new tympanic cavity in

being then preferred. Appropriate antibiotics were given to control infection. Shock was treated with intravenous dextran, plasma, or blood, noradrenaline being used to combat hypotension. Haemodialysis assisted the elimination of only barbitone. This line of treatment had proved successful in the past seven years and the mortality had fallen from 20% to 2-3%. It could never reach zero, because cases of overwhelming overdose or with long delay in treatment were always likely to prove beyond recall.

Dr. T. J. THOMSON (Glasgow), speaking as a pharmacologist, described an experimental evaluation of the anti-barbiturate effect of bemegride. In 22 patients after minor operations under thiopentone, nitrous oxide, and oxygen anaesthesia, the wakening effects of bemegride 50 mg. were compared with those of normal saline in a double-blind study. This pilot experiment failed to demonstrate an anti-barbiturate effect. But he showed a short film demonstrating that bemegride would rouse patients asleep under the influence of amylobarbitone sodium. One problem was determining the precise moment of awakening. For accurate recording it was necessary to have a sharp end-point between sleep and wakefulness. He found that E.E.G. tracings did not provide earlier or more reliable indication of arousal than careful clinical observation. The failure to dispel barbiturate activity on the E.E.G. did not indicate whether bemegride was a specific barbiturate antagonist or a non-specific analeptic.

Dr. J. W. DUNDEE (Liverpool) discussed abnormal responses to barbiturates. Although the desired action of intravenous barbiturates was on the central nervous system, because of their rapid redistribution they could affect all tissues. A wide variation in onset of anaesthesia had been observed. This could be influenced by the blood flow in the recipient limb. Thus, in a warm environment more rapid onset was likely. Increased duration of anaesthesia might be due to delayed detoxication—for example, during hypothermia—but a commoner cause was synergism with opiates or other depressant drugs such as certain tranquilizers. Limb movements during induction were not necessarily due to a convulsant effect of the barbiturate, but probably represented the second stage of anaesthesia. Depressant effects on the cardiovascular system could prove fatal in poor-risk cases. Myocardial depression was possible, but peripheral vasodilatation was probably more important. Consequent impairment of the venous return was especially serious when the blood volume was reduced.

Severe respiratory depression was rare, varying with the dose given, and being potentiated by opiates. Irritative phenomena such as cough, hiccup, and sneezing could occur before the E.E.G. changes, and so were thought to be mediated via the carotid sinus. True idiosyncrasy was very rare. Skin rashes had been observed but were not associated with other changes in action. In porphyria and dystrophia myotonica adverse effects could result from intravenous barbiturates. Adrenocortical deficiency, which could follow cortisone therapy, was a commoner condition in which intravenous barbiturates could have serious results.

Dr. P. H. SIMMONS (London) reported a trial in 208 cases of alternating thiopentone with buthalitone for out-patient surgery. When producing anaesthesia equivalent to thiopentone the rates of recovery were the same. A tendency to hiccup was noted with buthalitone. He concluded that buthalitone did not represent an advance over thiopentone for out-patient anaesthesia.

With Dr. R. P. HARBORD (Leeds), a vice-president, in the chair, Dr. B. R. M. JOHNSON (London) opened the general discussion. He wondered what was the cause of the failure to demonstrate antagonism of thiopentone by bemegride when the earliest reports had suggested that this agent was a potent barbiturate antagonist. He queried whether there was any absolute contraindication to a sleep dose of thiopentone properly administered.

Dr. M. H. ARMSTRONG DAVISON (Newcastle upon Tyne), Dr. H. GRANT-WHYTE (Durban), and Dr. H. J. V. MORTON (Hillingdon) also spoke.

continuity, with a functioning Eustachian tube over the round window only, the grafted drum being attached to the inner wall of the middle ear between the two windows. With these types mobility of the stapes was essential for success, but where the footplate of the stapes was fixed (type V) fenestration by the Lempert technique was performed in addition. The speaker was encouraged by the hearing results and had been able to salvage some hearing from many deafened ears.

Mr. F. MCGUCKIN (Newcastle upon Tyne) told the meeting of his experience during the previous 17 months in treating 70 cases of chronic otitis media. Cholesteatoma was found in 55, labyrinthine invasion in 15. The ossicular chain was disrupted in 65, with partial loss of the stapes in 23 and total loss in 12. The facial nerve was exposed by disease in 20 cases. However, his sample of cases was not an average one by reason of local conditions and personal interest. He felt that all cases could not have tympano-plastic reconstruction unless insidious disease was eradicated, and that the advances of modern reconstructive surgery must be related to the material presenting. These advances must be regarded simply as advances and not as a final answer until it was known how to prevent insidious otitis media. In many of the cases of advanced disease it was an achievement to produce a dry ear let alone a good functional result. In his view the newer techniques were more of an evolution than a revolution, and they demanded a very high order of judgment.

A colour film with a commentary in French by Pietrantonio, Aguzzi, and Bocca, produced by M. Chilet, was then shown, and it illustrated clearly the techniques of myringoplasty and tympanoplasty. Mr. A. FINLAY BROWN (Blackpool) also showed a colour film of fenestration by the Lempert and Wullstein techniques and of the Rosen operation for mobilization of the stapes. His film had been taken with simple apparatus designed by himself, and was of excellent quality, comparing favourably with professionally produced films.

Friday, July 19

Epistaxis

With Mr. R. G. MACBETH (Oxford), a vice-president of the Section, in the chair, Mr. J. P. STEWART (Edinburgh) opened with a paper on the changing pattern of epistaxis during the last 45 years. Search of his hospital records had shown that in the 45 years since 1912, 4,473 cases of epistaxis had received treatment, one-fifth requiring admission to hospital. 2,014 cases had attended since 1948—i.e., nearly half the cases had been seen in the last nine years. This striking increase since the inception of the Health Service could be due either to a true increase in incidence or to more cases nowadays being sent to hospital for treatment. In favour of a true increase were modern living conditions with their constant anxieties, longevity outrunning the normal resistance of the body tissues to wear and tear, and the steadily mounting number of cases of cardiovascular disease. On the other hand, the increase in hospital attendances might be a consequence of the changing pattern of present-day general practice, with its diminished financial incentive to afford the time to treat patients in their homes. Mr. Stewart thought this last factor was the most likely explanation. The sex ratio in his series was 57% males to 43% females, and 25% of the cases occurred in the 11–20 years age-group whilst 10% occurred in the 61–70 age-group. In 78% of the cases the bleeding occurred from the anterior part of the nasal septum in Little's area.

Turning to treatment, Mr. Stewart said that the homely remedy of cold applications was useful. This was confirmed by Speizman, who had shown that a local cold stimulus to the skin caused vasoconstriction of the nasal vessels. Where the bleeding-point could be identified he advocated the application of fibrin foam soaked in liquid thrombin, and for recurrent cases the electro-cautery or a caustic such as chromic acid or silver nitrate. An inflatable tampon made by tying a thin rubber finger-cot to the end of a rubber catheter was also of value, or the nose could be packed

with oxidized cellulose. In 30 of the cases in his series deep x-ray therapy (2,000 r in one week in five doses) had been employed with successful results.

Epistaxis and General Disease

Dr. H. A. DEWAR (Newcastle upon Tyne) related epistaxis to general medicine. The chief significance of epistaxis was that it might draw attention to important underlying diseases, especially diseases of the blood and hypertension. The former accounted for but one of the three types of disorder—defective clotting mechanism, prolonged bleeding-time, and vascular defect—which gave rise to the haemorrhagic diseases. Recent research now enabled some at least of these maladies to be treated in a way which only a few years ago had been unthinkable.

In the later period of life when the incidence of epistaxis reached a second peak, two processes were at work, arteriosclerosis and hypertension. With arteriosclerosis epistaxis was difficult to arrest, as the blood vessel would not contract normally. It was often stated that epistaxis was a safety valve against cerebral haemorrhage, but out of 250 of his own cases with a systolic pressure over 200 mm. Hg only 23% had had epistaxis at any time; nor did his figures suggest that as the blood pressure rose the incidence of epistaxis increased. There was little evidence that treatment of the hypertension reduced the incidence of epistaxis. Although he had no personal experiences of its use in epistaxis, mecamylamine was a drug which was rapid in action, dependable in effect, and in short-term use almost free from risk, and he thought it would be well worth trying in such cases. He did not think that this would involve any appreciable risk of cerebral thrombosis.

Dr. R. H. MOORE (London) described a simple method of treating epistaxis which he had found successful in almost all cases in general practice. The patient was told to blow out the clots and then douche the nose with cold water, thereafter breathing through the nose to enable a firm clot to form.

Malignant Disease of the Upper Respiratory Tract

With Mr. R. E. JOWETT (Sunderland), a vice-president of the Section, in the chair, Mr. W. A. MILL (London) opened a discussion on the presenting symptoms and signs of malignant disease of the upper respiratory tract. He said it was well known that many of these cases presented themselves for treatment at a relatively advanced stage because the initial symptoms were slight and common to many simple affections of which the patient might well have had previous experience; hence the early symptoms were often disregarded. The patient's medical adviser might also be misled at first by their apparent mildness. It should be a rule, therefore, that if a patient in the cancer age had symptoms of a cold or nasal sinusitis, sore throat, or laryngitis for two or three weeks he should have the benefit of expert examination unless the general practitioner was skilled enough to see all the areas where a new growth might develop.

In malignant disease of the nose or nasal sinuses, the common symptoms were those of nasal obstruction and discharge, at first not unlike those of some infective condition. Later there might be swelling of the face or a blood-stained discharge. The appearance of unilateral polypi in the nose of someone over 50 should always raise suspicions of underlying malignant disease. Similarly, swelling of the face or alveoli, with looseness of the teeth or failure of the sockets to heal, should raise the suspicions of the dental surgeon. In Mr. Mill's experience swelling of the face was the most frequent presenting symptom, although pain and nasal obstruction or discharge had quite often occurred earlier. In the nasopharynx the commonest symptoms were nasal obstruction and catarrh, although deafness was not unusual, and only too often enlargement of the cervical lymph nodes was the sign that led to the discovery of a primary lesion. Pain in the head, ear, face, or jaws was a not uncommon symptom. In the pharynx generally it was well to take note of the slightest discomfort or irritation. Later, of

course, definite pain or soreness on swallowing, or even dysphagia, would appear. Here again the insidious enlargement of cervical nodes may be the first sign of serious trouble.

The outstanding symptom of malignant disease of the larynx was huskiness. It could not be emphasized too strongly that early advice must be sought in all cases of hoarseness which did not readily yield to simple treatment within two or three weeks.

Mr. R. D. OWEN (Cardiff) limited his part in the discussion to malignant disease of the throat and larynx. He mentioned three symptoms, hoarseness, dysphagia, and stridor, any one of which could be the first to appear. Particularly in older people, who often had a multiplicity of vague complaints, the significance of these symptoms might be overlooked. He stressed the importance of a thorough history, as only thus would be uncovered such early symptoms as muffled or alterations in the tone of the voice or a fit of coughing only induced by rapid swallowing. He thought that every general practitioner should know the use and limitations of the laryngeal mirror.

Differential Diagnosis

Mr. J. I. MUNRO BLACK (Newcastle upon Tyne) pleaded for better education of the patient, the general practitioner, and the specialist in what bodily symptoms were normal and what abnormal. Biology should be taught more generally in schools, he thought, and with medical students there should be more emphasis on the interpretation of symptoms. He urged the specialist to keep records of the symptoms and signs rather than the disease. Mr. I. B. THORBURN (Blackpool) considered persistent disorder of function and persistent induration important points in the diagnosis of malignant disease. Diagnosis was often late owing to the nature of the disease. In many instances a good history would obviate the need for endoscopy under general anaesthesia.

Mr. F. MCGUCKIN (Newcastle upon Tyne) said that throat symptoms were often due to psychological causes. It was usually possible to distinguish such cases, although mistakes were occasionally made. He disagreed with Mr. Munro Black, believing that greater knowledge on the part of the patient would lead to more functional disease. Mr. R. G. MACBETH (Oxford) agreed that publicity would increase the number of functional cases seeking medical advice. In his experience premature greying of the hair was a frequent finding in women with pre-cancerous changes in the post-cricoid region. Dr. B. K. S. DYKSTRA (Holland) had gained much help from x-ray tomography in diagnosis. He pleaded for early treatment of the patient with the Patterson Brown-Kelly (Plummer-Vinson) syndrome, as it was a pre-cancerous condition in many cases.

Mr. W. I. DAGGETT (London), president of the Section, mentioned that throat symptoms of psychological origin usually disappeared during meals. In such cases he was not in favour of radiological examination, as it detracted from the reassurances which he gave wherever possible. In reply, Mr. MILL agreed with Mr. Thorburn on the necessity of a good history and the difficulties of early diagnosis. He was always unhappy when he made a diagnosis of functional disease, and instanced a cervical disk lesion as an unexplained cause of throat symptoms. Mr. OWEN, replying, said the diagnosis of a "lump in the throat" was a real problem; occasionally a lesion was found. Of 42 patients with the Patterson Brown-Kelly syndrome 16 had subsequently returned with a post-cricoid carcinoma. Mr. MUNRO BLACK, concluding the discussion, replied that for many years he had followed up his cases of Patterson Brown-Kelly syndrome because of this risk.

SECTION OF CHILD HEALTH

Friday, July 19

Collagen Disorders

The first part of the meeting took the form of a round-table conference on collagen disorders, for which Dr. REGINALD LIGHTWOOD (London), a vice-president of the Section, took

the chair. He proposed that for convenience the discussion should be limited to acute rheumatism, rheumatoid arthritis, dermatomyositis, and scleroderma, systemic lupus, and polyarteritis nodosa. He then asked a series of questions.

"Is the frequency of these diseases changing?" Dr. G. A. ROSE (London) thought that rheumatic fever was declining and that now only 2 or 3% of infants might be expected to have it later on, although 3 to 5% would get rheumatoid arthritis. Systemic lupus might merely be being diagnosed more often, but he had found a real increase in the occurrence of polyarteritis detected at necropsy during a seven-year period.

"Is rheumatic fever or rheumatoid arthritis related to physical features or to blood groups?" Dr. C. O. CARTER (London) said "no" so far as physical features were concerned, but joined the "don't knows" on the question of blood groups, since the deficiency of rheumatic fever patients who belonged to group O or were secretors was not highly significant. He was also asked: "What is the evidence of familial or genetic influence in the aetiology of these two diseases?" Dr. Carter's answer was that systematic studies of rheumatic fever in Florence, New York, and Belfast showed that, whereas the incidence ordinarily was about 2%, it increased to 6–10% in brothers and sisters of patients, and to 12–20% if one parent also had had it, while studies of twins showed a higher concordance of rheumatic fever in monozygotic than in dizygotic pairs.

When asked how ideas of the nature of collagen disease had been illuminated by modern knowledge Dr. ALAN HILL (Stoke Mandeville) swept away several older ideas (such as focal infection) and explained interesting ways in which streptococci might damage tissues in rheumatic fever. Hypersensitivity still held the field because it produced lesions in animals and one could not make confirmatory experiments in man. Dr. ROSE discussed the inconclusive role of drugs in producing polyarteritis.

Before saying how she would treat rheumatic fever Dr. BARBARA ANSELL (Taplow and London) pointed out that, although the combined investigation in the U.S.A. and the United Kingdom showed little advantage to the steroids compared with aspirin, recent studies with larger dosage were slightly more encouraging. In a first attack, seen in the first fortnight, she would give steroids until all signs of activity of the disease had subsided for one month. In early cases streptococci were often still present in the throat, so penicillin was also needed during the first ten days. In prophylaxis she found that 200,000 units daily by mouth would prevent a second attack; it was rather better than sulphonamides for this purpose. Streptococcal infections in brothers and sisters of the patient should be treated promptly with penicillin. Dr. ROSE was guarded in his views on the use of a dangerous drug like cortisone in rheumatoid arthritis, but polyarteritis was a killer, and large doses should be given for long periods; systemic lupus was not as dangerous, but steroids were necessary during the active phase. Dr. HILL was asked to compare the steroids. Cortisone and hydrocortisone he regarded as equivalent, and so were prednisone and prednisolone. The latter were more convenient for prolonged administration because they produced less sodium retention, although possibly they caused peptic ulceration more often. Batches of corticotrophin varied, but some of the best results were obtained with it. For intra-articular injection he preferred prednisolone to hydrocortisone. He condemned mixed tablets of aspirin and prednisolone: it was better to give aspirin alone until it produced its maximum benefit, and then to add a steroid if it was needed.

Iatrogenic Disease in Childhood

Dr. CHARLES PINCKNEY (London), a vice-president of the Section, took the chair for the discussion on iatrogenic disease, which was introduced by Dr. A. WHITE FRANKLIN (London) in an elegant discourse—a cornucopia of old saws and modern aphorisms, case histories, and philosophies. He considered especially the difficulty of deciding when to use a new drug ("we have changed a catapult for a guided missile

... and gone on a glorious therapeutic spree"), for, although each physician need not be the first by whom the new drug was tried, there came a time when "justifiable doubt becomes unjustifiable obstinacy and gives rise to a doctor's dilemma." Abstention from a new treatment might give rise to iatrogenic disease.

Dr. MARY CROSSE (Birmingham) dealt with two conditions. Retrolental fibroplasia was produced by giving a baby with an immature optic fundus oxygen at too high a concentration for too long. "There need be no more blindness due to this cause if everyone keeps on his toes," she said, and proceeded to show the details which need attention if a premature baby is to get oxygen, but not at more than 30% concentration for any long period. In kernicterus the effects of Rh incompatibility or hepatic immaturity may be worsened by synthetic vitamin K or sulphafurazole.

Dr. ALICE STEWART (Oxford) showed that leukaemia had increased two- or threefold between 1931 and 1954 and that it was commoner in more favoured nations and social classes; furthermore, its incidence showed a curious little peak in childhood. Her analysis showed that diagnostic radiotherapy of the mother perhaps doubled the chance of the child's developing malignant disease, but the chance was still only about 1 in 1,000.

Dr. KENNETH CAMERON (London) thought that iatrogenic diseases were not often found in psychiatry: it was more a matter of contributory factors. For instance, the doctor might advise breast-feeding with such fervour that the mother who had to feed the baby on the bottle would feel terrible anxiety about him; therapeutic advice to man and wife at odds with one another to have a baby to bring them together might doom a child to be born subservient to the parents' needs. A doctor's too rigid views on infantile development might cause trouble: "Mother knows best" may have been a fallacy, but at least it was a working hypothesis."

SECTION OF PHYSICAL MEDICINE

Friday, July 19

Treatment of Rheumatism with Steroids

With the president, Dr. HUGH BURT (London), in the chair, Dr. G. R. FEARNLEY (Gloucester) opened a symposium on steroid therapy in the rheumatic diseases. He made no apology for the fact that in this instance he had used the patients' own assessment of their condition as a criterion of improvement as well as their functional capacity. He and his colleagues had found that at the present time prednisone by mouth was a valuable adjunct in the management of severe rheumatoid arthritis, provided always that the complications did not outweigh the advantages. With a dosage in most cases of 5 mg. three times a day nearly 90% of cases treated with prednisone showed marked improvement as judged by change in functional capacity and their own assessment. Dyspepsia was the most common complication, but, even so, was considerably less common (in 22% of cases) than with phenylbutazone (45% of cases). All cases were kept under regular observation. Dr. Fearnley said he was aware that long-term studies might prove his assumptions to be incorrect, but meanwhile the newer steroid preparations appeared to be of great value in selected cases, though the indications were not clear-cut.

Shoulder and Elbow Pain

Dr. JAMES CYRIAX (London) discussed the use of hydrocortisone acetate in the treatment of painful lesions at the shoulder and the elbow. Correct diagnosis was of paramount importance, since the drug had to be accurately placed at the exact site of the lesion. He always carried out a quick preliminary survey of all the moving structures from which such a pain as the patient described could arise. This was followed by a detailed examination of the region

thus singled out, since, depending on which structure was involved, a varying pattern of movements occurred, provided that the examiner tested each separate movement in turn passively, actively, and against resistance. The use of local hydrocortisone had given the best results at the shoulder in non-specific monarthritides ("infective" arthritis for want of a better term), in traumatic arthritis, and in tendinitis. At the elbow the most common lesion encountered which responded to hydrocortisone injection was tennis elbow, provided that the lesion was at or within $\frac{1}{4}$ in. (3.2 mm.) of the tenoperiosteal junction. If lasting relief was not obtained after two injections there was no point in persisting with this form of treatment.

Intra-articular Steroid Therapy

Dr. M. THOMPSON (Newcastle upon Tyne) stated that after six years' use hydrocortisone acetate by intra-articular injection had now become firmly established as a useful adjuvant technique in the treatment of non-suppurative arthritis. The main contraindications to its use remained the presence of septic or tuberculous arthritis and skin sepsis. In view of the stringent aseptic precautions necessary for intra-articular injection it was not a procedure to be recommended in everyday practice. He had recently treated a series of cases of rheumatoid arthritis by intra-articular injection of the newer steroid preparations. Even using paired joints in the same patient it was difficult accurately to compare the effect of the new preparations with that of hydrocortisone. It had been found, however, that there was no significant difference between the effect of prednisolone acetate or the higher ester, trimethyl acetate, when compared with hydrocortisone acetate in the larger or medium-sized joints. In the case of the small joints of the hands the effect of prednisolone acetate was significantly better than that of hydrocortisone acetate and the duration of response was longer. These results suggested that prednisolone was the more effective agent in the treatment of small joints.

When the subject was opened for discussion Dr. D. R. L. NEWTON (London) said that, working with Dr. B. G. B. Christie at St. Thomas's Hospital, he had some early experience in the use of prednisolone trimethyl acetate in the treatment of soft-tissue lesions of the type described by Dr. Cyriax, but that so far there was no indication that it was in any way superior to hydrocortisone. Replying to the president, Dr. THOMPSON said that only slight irritation had been noted when small hand joints had been injected with the new preparations.

Rehabilitation of Injured Miners

Dr. A. N. ZINOVIEFF (Durham) described the staff organization, treatment, and results obtained at the Durham Miners' Rehabilitation Centre. The individual assessment of each case was of great importance in view of the very high standard of physical fitness required in the mines. Only 40% of men were fit at the time of discharge to return to their previous duties. Of the 90% discharged as fit for some type of work, only one in 200 had failed to find work connected with the pits.

During the ensuing discussion many speakers with local knowledge made a plea for closer co-operation between all those responsible for the welfare of the injured miner. Dr. G. A. WILTHEW (Gateshead) suggested that the term "light work" should be discarded for all time and replaced by the more realistic one of "alternative work," the exact nature of this being left to the decision of the doctor on the spot in collaboration with the managerial staff.

Painful Feet

Opening a symposium on the painful foot, Dr. GUY BEAUCHAMP (London) stated that ill-fitting shoes were the greatest single cause of foot deformity and discomfort. He suggested that the medical profession should educate the general public, and particularly parents, to refuse to buy footwear that caused deformity. The British Boot, Shoe,

and Allied Trades Research Association had found that over 50% of girls under 20 had corns, callosities, and bunions. Dr. Beauchamp indicated the importance of good shoe-fitting: shoes that were not comfortable initially would never be "broken in," it being the foot that became deformed to fit the shoe. Some adults might be impressed and children amused by x-ray fitting, but it was of no practical help and was merely a radiation hazard.

Dr. A. T. RICHARDSON (London), discussing the painful heel, said that this was a symptom which should always be taken seriously and properly investigated. Sometimes it was due to local bone disorder such as Paget's disease or infection, or to damage associated with fracture or the use of a Kirschner wire. More often, however, a clinical diagnosis had to be made in the absence of radiological abnormality. The presence of a calcaneal spur was no more than an indication of a chronic plantar fascial strain and occurred in painless heels: its surgical removal was usually followed by disastrous results. Erosive changes in the os calcis occurred in association with both ankylosing spondylitis and rheumatoid arthritis. The commonest cause of pain under the heel as opposed to pain behind the heel was plantar fasciitis, which was generally due to trauma or degeneration or both. Treatment consisted of the provision of an insole which placed the foot in a cavus position, so relaxing the plantar fascia. Pain behind the heel was usually due to a subachilles bursitis, either of traumatic origin or associated with one of the rheumatic disorders. The bursa overlying the tendo Achillis was sometimes involved in gout, but more often as a result of trauma, particularly in nurses. Dr. Richardson mentioned, as did Dr. Beauchamp before him, that physiotherapy had little or no place in the treatment of the painful foot: sometimes local hydrocortisone was useful; more often it was the removal of some mechanical cause that was necessary.

COLOUR TELEVISION

A popular innovation at the annual meeting this year was the programme of "live" closed-circuit colour television shown during the scientific half of the meeting. Sponsored and produced by Smith Kline and French Laboratories Ltd., "colourcasts" of clinical demonstrations and operations at the Royal Victoria Infirmary were relayed for two hours daily to large audiences in the gymnasium of King's College. The cases were demonstrated by members of the staffs of the medical school and the Infirmary. Several subjects were covered at each session, and their diversity gave viewers an excellent opportunity to gauge the medium's potentialities and limitations for medical teaching.

On the first day, Monday, July 15, ophthalmologists showed patients with corneal grafts and plastic lenticular implants, contact lenses, and the technique of intracapsular cataract extraction. This was followed by a demonstration of thyroid disorders. On Tuesday the first half of the programme was devoted to muscular dystrophy, this being followed by two shorter demonstrations on, respectively, the use of intra-articular injections for arthritis and the carpal tunnel syndrome. Wednesday's session comprised demonstrations of the treatment of some common skin disorders, primary tuberculosis of the skin and mucous membranes, a new method of suturing arteries, and a Billroth I partial gastrectomy performed by Professor A. G. R. Lowdon. Thursday's programme was particularly varied. It began with the management of cleft lip and palate; then came demonstrations on the re-education of hemiplegics in walking and on the treatment of fractures of the neck of the humerus; these were followed by Dr. C. N. Armstrong's presentation on the diagnosis of sex; and finally there was a feature on otosclerotic deafness. On the Friday the diagnosis and treatment of torn knee cartilages were demonstrated. The chairmen at the various sessions were Mr. J. S. Arkle, Dr. C. N. Armstrong, Professor F. J.

Nattrash, Professor G. A. Smart, Professor A. G. R. Lowdon, Dr. J. Ferguson Smith (Glasgow), Professor S. D. M. Court, Mr. John Gilmour, Dr. H. G. Miller, Dr. M. Thompson, Mr. J. I. Munro Black, and Mr. J. V. Todd.

B.M.A. FILMS

A diverse programme of films from the B.M.A.'s Film Library were shown during the Meeting, a number of the films being selected because of their relevance to subjects being discussed at the Scientific Sections. The policy of showing the films at set times in the late afternoon on four days proved highly successful, the total attendance amounting to approximately 400.

Most of the films were from surgical departments, and among them was a new film on "Haemorrhoids or Piles" made by Mr. A. Lawrence Abel and Mr. H. G. Ungley (Gordon Hospital). A film made in Capetown by Mr. W. L. Phillips showed the operation of pericardiectomy, and two other aspects of cardiac surgery were seen in a film on an "Experimental Cardiac By-pass" (Mr. C. E. Drew, Westminster Hospital), and one on "The Action of the Human Mitral and Aortic Valves" (Mr. I. K. R. McMillan, St. Thomas's Hospital). Arterial grafting was the subject of a film made by Mr. P. G. C. Martin (Postgraduate Medical School) and lymphangiography of a film by Professor J. B. Kinmonth (St. Thomas's Hospital). Ophthalmology was represented by "A Ptosis Operation" (Mr. H. B. Stallard, Institute of Ophthalmology). The technique of sialography was shown in a film from the Manchester Royal Infirmary, and two films sponsored by the Ministry of Health were concerned respectively with cancer of the larynx and cancer of the lip, tongue, and mouth.

Two films of general medical interest came from the U.S.A. The first was the A.M.A.'s "The Motion Picture in Medical Education," and the second, entitled "The Medical Witness," showed a doctor under cross-examination in a court of law.

FOURTH INTERNATIONAL CONGRESS ON POLIOMYELITIS

[FROM A SPECIAL CORRESPONDENT]

The fourth International Congress on Poliomyelitis was held in Geneva from July 8 to 12 and attracted a large number of representatives from many countries (including 89 from Great Britain). Papers were read by the principal workers in eight main fields with additional brief contributions from other experts.

Immunization with Killed Vaccine

The first main topic was on vaccination against poliomyelitis, and this naturally attracted considerable interest. Dr. JONAS SALK (U.S.A.) opened by considering the biological standardization of the immunizing power of killed vaccine. He pointed out that the essential requirement is adequate sensitization, so that subsequent exposure to the virus leads to a rapid enough increase in antibody to protect the central nervous system. Dr. D. BODIAN (U.S.A.) followed with information about the control of inactivation by formaldehyde. Experience had now shown that satisfactory and reproducible inactivation depended on complete dispersal of viral particles and removal of aggregates. This was greatly influenced by the methods of filtration used in manufacture, as shown by comparisons of batch rejections by different firms. Large-scale tissue-culture tests were the most sensitive way of detecting residual active virus, but this was still supplemented by intraspinal and intramuscular inoculation of cortisone-treated monkeys.

Dr. A. D. LANGMUIR (U.S.A.) then spoke on the results of the mass immunization programme carried out in the U.S.A.,

and produced convincing evidence of the effectiveness of these safety controls used on the 100 million doses of vaccine distributed since "the Cutter incident." Poliomyelitis was still occasionally reported within 30 days of vaccination, but the evidence suggested that such illnesses were due to natural infection and not to live virus in the vaccine, unlike the infections following the original Cutter vaccine.

The immunizing power of the vaccine had been maintained at about 75% (i.e., three out of four vaccinated children protected), but there had also been a reduction in the incidence of paralytic as against non-paralytic illness in vaccinated children. The question which of course still remains unanswered is the length of time protection lasts after the initial course. The short papers which followed included contributions from Professor A. BRADFORD HILL, F.R.S., Professor C. H. STUART-HARRIS, and Dr. J. O'H. TOBIN from Great Britain.

Attenuated Vaccines

Dr. H. KOPROWSKI, Dr. A. B. SABIN, and Dr. J. P. FOX (U.S.A.) followed, as principal exponents of living poliomyelitis vaccines. Dr. KOPROWSKI told of an attenuated type III strain which he has given to volunteers and summarized the earlier results obtained with attenuated types I and II. Dr. SABIN, working with pure clones of attenuated strains, found that even the most stable showed some tendency to revert to neurotropism after passage in the human intestinal tract, but this neurotropism did not increase after further cycles of multiplication, and the virus remained much less pathogenic than naturally occurring strains of virus isolated in interepidemic periods. Professor G. W. A. DICK (Northern Ireland) also spoke of the increase in neurotropism of attenuated type II virus after passage in human volunteers.

A highly significant finding mentioned by several speakers was the failure of formalized vaccine to protect the human intestinal tract (as opposed to the central nervous system) against reinfection. Thus vaccinated children can harbour and excrete naturally prevalent virus. Living attenuated virus on the other hand leaves a local immunity of the intestine which prevents reinfection.

It was generally appreciated that the wide acceptance of the inactivated vaccine would inevitably limit the application of living poliomyelitis vaccines as primary immunizing agents, but there remained the possibility of living vaccine as a booster after inactivated vaccine, especially if the latter allows reinfection of the intestine. Dr. A. M.-M. PAYNE (World Health Organization) concluded with a summary of the differing vaccination requirements in various countries in the light of existing immunity.

Other Enteric Viruses

The next general topic was the enteric viruses that produce diseases simulating poliomyelitis. There were comprehensive reviews of the "Echo" viruses (by Drs. J. L. MELNICK, T. KARZON, and H. A. WENNER, U.S.A.) and the Coxsackie viruses (by Drs. G. DALLDORF and M. L. FURCLOW, U.S.A., and Dr. J. H. S. GEAR, South Africa). Even "Cox-Echo" strains were reported which combine features of both groups, and which have incidentally caused recent widespread epidemics in Britain, as mentioned by Dr. F. O. MACCALLUM (Great Britain).

Virus Studies

For the next four sessions clinicians and laboratory workers each followed their separate and natural bent. The laboratory workers held a session on cultured mammalian cells, and paid considerable attention to nutritional requirements (Dr. H. EAGLE, U.S.A.), pure clones of cells (Dr. T. T. PUCK, U.S.A.), transformation of cells in culture and its relationship to malignancy (Dr. R. C. PARKER, Canada, and Dr. ALICE MOORE, U.S.A.), and mass culture for vaccine production (Dr. W. S. McLIMANS, U.S.A.). There followed two sessions on general properties of viruses. The

first was concerned with virus structure, in which Dr. C. E. SCHWERDT (U.S.A.) described the physical and chemical properties of purified (and crystallized) poliomyelitis virus. This could be compared with the now fully elaborated structure of tobacco mosaic virus described by Dr. G. SCHRAMM (Germany) and Dr. ROBLEY WILLIAMS (U.S.A. and Great Britain), and also with other human viruses examined in thin sections of infected cells by Dr. COUNCILMAN MORGAN (U.S.A.), and with Coxsackie A virus, now purified and crystallized by Dr. C. F. T. MATTERN (U.S.A.). The importance of nucleic acids in viruses was made amply clear by the reports of infection with extracted ribonucleic acid from Mengo virus, and eastern equine encephalomyelitis virus, following the earlier work on infectivity of nucleic acid from tobacco mosaic virus. In the following session Dr. F. L. HORSFALL (U.S.A.) discussed present information on viral multiplication and Dr. M. DELBRÜCK (U.S.A.) spoke on the genetics of bacteriophage. Dr. K. M. SMITH, F.R.S. (Great Britain), gave an interesting account of latent viral infections in plants and the possible relationship to latency and masking of animal viruses, and Dr. T. FRANCIS (U.S.A.) discussed possible approaches to viral inhibition and chemotherapy.

Finally a session was held on laboratory diagnosis of poliomyelitis. The problem was comprehensively reviewed by Dr. E. H. LENNETTE (U.S.A.), who pointed out that virus was recovered from the stools of only 58% of patients with clinically apparent paralytic poliomyelitis. He also discussed the value of serological techniques in diagnosis, as influenced by the current vaccination programme.

Clinical Aspects

Meanwhile, clinicians and physiologists were meeting in another building to consider problems of respiratory distress in patients with poliomyelitis, and the care of patients severely stricken by the disease. Though your correspondent did not attend this section of the Congress the reports clearly showed the importance of basic studies on respiratory physiology as presented by Drs. J. H. COMROE, J. L. WHITTENBERGER, J. MEAD, J. F. BOSMA, and C. W. DAIL (U.S.A.). Dr. J. L. WILSON (U.S.A.) and Dr. H. C. A. LASSEN (Denmark) discussed prognosis and mortality in severe illnesses. Dr. H. L. HODES (U.S.A.) reported that under favourable hospital conditions 85% of patients with severe respiratory impairment survived two years, and that 85% of these eventually became independent of all respiratory apparatus, while Dr. W. RITCHIE RUSSELL (Great Britain) presented comparisons of trends in mortality and prognosis in England and Wales and the U.S.A. since 1955. Dr. B. IBSEN (Denmark) stressed the value of clinical judgment in assessing the need for active treatment of respiratory distress. There then followed several papers on techniques for applying artificial respiration. Subsequent sessions were held on the secondary medical complications of poliomyelitis and on rehabilitation and home care.

Clinicians and virologists were reunited for a final general session with summaries by Dr. C. H. ANDREWES, F.R.S. (Great Britain), and Dr. S. CLEMMESSEN (Denmark) and closing remarks by Mr. BASIL O'CONNOR (U.S.A.), president of the Congress.

General Conclusions

It is perhaps unfortunate that a gathering of this size prevents spontaneous discussion and criticism in the open meetings. This would have been especially appreciated, for example, in the sessions on vaccination. Outside the lecture halls, however, there was a general loosening of tongues encouraged by the generous social entertainment provided by the hosts.

The most striking aspect of the Congress was the variety of topics discussed, varying from plant viruses to alveolar gas exchange, but all contributing to the study of this one disease—poliomyelitis. The organizers of the Congress are to be congratulated on their broadminded approach to the problem.

Correspondence

Dietary Fat and Coronary Disease

SIR,—Your leading article (*Journal*, July 13, p. 89) admirably summarizes present knowledge about the effect of different fat-containing diets and cholesterolaemia and coronary thrombosis. Discussing blood coagulation, you comment that "the picture is far from clear." May I attempt to clarify some small parts of the picture?

Your leader says, "It has still to be proved that the hypercholesterolaemia causes faster blood coagulation." Changes in some blood coagulation tests have been reported only in the immediate post-prandial period. Throughout the digestion of a single meal the cholesterol level in the blood remains unchanged. Under these conditions cholesterol presumably plays no part in any clotting changes observed. No investigations of blood coagulability have been undertaken following prolonged fat feeding of sufficient duration to produce changes in the blood cholesterol. Fullerton *et al.* claimed that there was a shortening of the clotting time of whole blood in a silicone-coated test-tube after a single fatty meal. Merskey *et al.* also gave single fatty meals and did not give "low and high fat diets." This claim has been confirmed^{1,2} and denied.³⁻⁵ Most workers would agree that this apparently simple test is, in practice, extremely sensitive to minute uncontrollable variations in technique and that closely reproducible results are never obtained. The discrepancies mentioned above may, therefore, be attributable to differences in technique. Such a test, with its great inherent variability, is largely unsuitable to reveal any but major changes in the coagulability of the blood. Since the facts are still in doubt, it is profitless at this juncture to discuss their implications.

Merskey *et al.* did not record that "the stypven time of the blood of patients on the high fat diet was lower than that of blood from patients on a low fat diet" (my italics). They used the Russell viper venom accelerated clotting time of platelet-poor plasma—the "stypven" time—and observed the effect of single meals. They found a significant acceleration in the stypven time four hours after a high-fat meal, but no change after a low-fat meal, or when no fat was given. This test, unlike the clotting time of blood, is highly reproducible, and, in fact, there is general agreement with this observation.^{1,2,6-11}

Since thrombocytopenic people are rarely bitten by *Vipera russelli* after eating a large fatty meal, the significance of this empirical test in normal physiology is not immediately apparent. This acceleration of the stypven time may be due to an increase in free fatty acids,¹² but is more likely to be due to an increase in the available active phospholipids in the blood.^{10,13,14} Even if the latter view is correct, it is not known if such an increase is of physiological importance, although, clearly, it might be.¹⁵ It has, however, been shown¹⁶ that after physiological quantities of different fats in many tests there was no demonstrable difference between 20 male patients with proved coronary thrombosis and 20 volunteers of the same age and sex. This suggests either that the immediate post-prandial effects of a fatty meal are not relevant to the causation of coronary thrombosis or that the wrong tests have been performed: blood coagulation studied in the test-tube may have little relevance to the *in vivo* formation of a thrombus. The former view is strengthened by the observation¹⁷ that the incidence of coronary disease throughout the day and night is fairly constant, and had post-prandial lipaemia been a factor the incidence would surely have dropped between 12 p.m. and 6 a.m.—I am, etc.,

Portsmouth.

Infection in *Xenopus laevis* with Human Group A Streptococcus

SIR,—We wish to report an example of a human type streptococcus causing an outbreak of disease in a colony of amphibia kept in the Department of Pharmacology, Welsh National School of Medicine, Cardiff. Two years ago, during the very hot summer weather, an epidemic struck the colony of *Xenopus laevis* in this school. The death rate was high and the pattern of attack was always the same. The toads affected were females being used in routine pregnancy tests. After an injection the toads seemed normal, and then about three days later they were seen to be floating on the surface. Twenty-four hours afterwards the toads were dead. Every animal had a bloated appearance and there were small petechiae on the breast. Fluid withdrawn from the toad had a milky appearance, and on culture a growth of streptococci was obtained. At the time, this observation was not followed further.

This outbreak decimated the stock and certain precautions were taken. The staff were swabbed and were found to be negative. The temperature of the circulating water was dropped to about 17° C. and the artificial heating in the amphibia room was turned off. Every tank was scrubbed with a strong lysol solution. However, the animals continued to die until the general temperature dropped from the higher summer values to more or less normal autumnal figures.

During the next two years there have been sporadic cases and each time the symptomatic picture has been the same. Direct microscopical examination of the fluid in every instance demonstrated the presence of very numerous Gram-positive cocci, in long and short chains, having the morphological appearance of streptococci. Cultures of the lymph sac fluid from nine infected toads were made, and in each case a group A streptococcus was isolated. Typing of the organism showed it in all cases to be 3/13/B3264. The disease was not limited to those toads which had been recently injected with human urine for pregnancy diagnosis, but also occurred in toads which had not been used for some months. The affected animals showed an extreme degree of septicaemia, and a direct-film examination of blood showed large numbers of streptococci. Some animals were treated with 100,000 units of soluble penicillin daily into the dorsal lymph sac with excellent results.

We should like to thank Mr. H. Price and Mr. M. Jones, of the Public Health Laboratory, Cardiff, for valuable technical assistance.—We are, etc.,

R. W. S. HARVEY.
G. M. MITCHELL.

Cardiff.

Dangers of Cigarette-smoking

SIR,—In the *Journal* of July 20 (p. 158) Dr. Robert N. C. McCurdy writes, "Fisher's criticism (*Journal*, July 6, p. 43) . . . would not be so unfair if he had specified what alternative explanations of the facts still await exclusion." I had hoped to be brief. A few days later the B.B.C. gave me the opportunity of putting forward examples of the two classes of alternative theories which any statistical association, observed without the precautions of a definite experiment, always allows—namely, (1) that the supposed effect is really the cause, or in this case that incipient cancer, or

a pre-cancerous condition with chronic inflammation, is a factor in inducing the smoking of cigarettes, or (2) that cigarette-smoking and lung cancer, though not mutually causative, are both influenced by a common cause, in this case the individual genotype.

The latter unexcluded possibility was known to Dr. McCurdy, but he brushes it aside with abundant irony. Is he really persuaded that this is the way to arrive at scientific truth? Dr. McCurdy points out correctly that difference in the genotypic composition of the smoking classes—non-smokers, cigarette smokers, pipe smokers, etc., would not explain the secular change in lung-cancer incidence. I had never thought it would be charged with this task. Is it axiomatic that the differences between smoking classes should have the same cause as the secular change in incidence? Is there the faintest evidence to support this view? Indeed, Dr. McCurdy's belief that cigarette-smoking causes lung cancer would be more secure if he did not encumber it with the *non sequitur* that increase of smoking is the cause of increasing cancer of the lung. For at this point there appears one of those massive and recalcitrant facts which have been emerging through the smoke-screen of propaganda. When the sexes are compared it is found that lung cancer has been increasing more rapidly in men relatively to women. The absolute rate of increase is, of course, obscured by improved methods of diagnosis, and by the increased attention paid to this disease, but the relative proportionate changes in men and women should be free from these disturbances, and the change has gone decidedly against the men. But it is notorious, and conspicuous in the memory of most of us, that over the last 50 years the increase of smoking among women has been great, and that among men (even if positive) certainly small. The theory that increased smoking is "the cause" of the change in apparent incidence of lung cancer is not even tenable in face of this contrast.

For the secular change, therefore, neither the smoking-causation theory nor the theory of differentiated genotype will afford an explanation. For the contrast between cigarette smokers and non-smokers both are available; for the contrast between cigarette smokers and pipe smokers the first theory requires some special pleading, but this has never been lacking. The two circumstances, (1) that heavy smokers show a greater effect than light smokers, and (2) that persons who have voluntarily abandoned smoking react like non-smokers or light smokers, are not independent experimental confirmations of the smoking theory. They are only reiterations of the main association to be explained. Any theory which explains this association may be expected to explain these facts also.

Differentiation of genotype is not in itself an unreasonable possibility. Inbred strains of mice if genotypically different almost invariably show differences in the frequency, age-incidence, and type of the various kinds of cancer. In man cancer of the stomach has been shown to be favoured by the gene for the blood group A. My claim, however, is not that the various alternative possibilities which have not been excluded all command instant assent, or are going to be demonstrated. It is rather that excessive confidence that the solution has already been found is the main obstacle in the way of such more penetrating research as might eliminate some of them. I am sure it is useless to treat the question as though it were a matter of loyalty to a political ideology or of forensic disputation. Statistics has gained a place of modest usefulness in medical research. It can deserve and retain this only by complete impartiality, which is not unattainable by rational minds. We should not be content to be "not so unfair," for without fairness the statistician is in danger of scientific errors through his moral fault. I do not relish the prospect of this science being now discredited by a catastrophic and conspicuous howler. For it will be as clear in retrospect, as it is now in logic, that the data so far do not warrant the conclusions based on them.—I am, etc.,

Cambridge.

RONALD A. FISHER.

Smoking and Lung Cancer

SIR,—Medical research bodies in America, England, Australia, and elsewhere have arrived at the conclusion that the increase in cancer of the lung is linked with the use of tobacco, and that there are proportionately more cases of lung cancer among those who smoke more than 20 cigarettes daily than among those who smoke less than this or do not smoke at all. There are numerous varieties of tobacco, and it is possible that they may not all have the same effect on human beings.

In the past Anatolian tobacco was smoked in large quantities in Europe, and there were not so many cases of cancer of the lung as there are now. Why does tobacco now affect the lungs more than it used to? Is it because of the change from Anatolian tobacco to the almost universal use of Virginian? Before the first world war, Europeans, and particularly Anatolians, smoked Anatolian tobacco; even the Americans used a blend containing a good proportion of this variety. After that war Virginian tobacco rapidly displaced Anatolian. After the second world war Virginian tobacco dominated the market, and where Anatolian was not entirely displaced the proportion of Virginian in the blend increased. Cancer of the lung has rapidly followed this dominance by Virginian tobacco.

Here is an important point for inquiry by research workers. I consider it advisable that they should study carefully and impartially the carcinogenic properties of both Virginian and Anatolian tobacco. The components of both these varieties are different, and therefore their effect may be different.—I am, etc.,

Famagusta, Cyprus.

ANTONIS GEORGEADES.

The Forgotten Thomas Splint

SIR,—Mr. G. P. Arden's letter (*Journal*, July 13, p. 101) will surely be welcomed by surgeons throughout the country, and should be appreciated by all concerned with the transport of casualties. In this county, where accident cases must travel long distances to hospital, an effort is being made to re-establish the use of the Thomas splint. By agreement with the local medical committee, Thomas adjustable splints (each with three rings) and weatherproof stretchers with suspension bars have been placed at strategic points throughout the county for use by doctors, police, and trained Red Cross personnel.—I am, etc.,

Golspie, Sutherland.

B. SOUTAR SIMPSON.

SIR,—It was surprising to learn from Mr. G. P. Arden's letter in your columns (*Journal*, July 13, p. 101) that it is still necessary to reiterate the merits of the Thomas splint. One would have thought, as he has said, that a method of treatment which in 1916 reduced the immediate mortality due to open fractures of the femur from 80% to 20% within a few weeks of its introduction into the front line needed no further advocacy. The long Liston splint in such cases is inadequate and even dangerous. A broken femur is difficult to control by any splint, because the bone is contained within a deep mass of muscle. Liston's splint, lacking the all-important traction element of Thomas's, can hold such a fracture only if it is so firmly bandaged to the limb as to further endanger a circulation often already in jeopardy. Any swelling which occurs after the splint has been applied will obviously still further increase the risk of serious ischaemia. And, apart altogether from these considerations, the splint itself (which extends to the axilla) is uncomfortable in the extreme, and renders it difficult to transport a patient save on an absolutely rigid stretcher.

One feels that one justifiable objection to the Thomas splint in the past has been the difficulty encountered in fitting a splint of the correct size to any given patient, whatever the dimensions of his thigh. R.A.M.C. units carry three different sizes, and one of this range can be found to fit most adult males. Civilian casualty organizations must be prepared to treat women and children as well, and a

consideration of the number of splint sizes necessary may perhaps be involved in any decision to discard the Thomas splint. All will realize, however, that it is quite possible to design a simple modification of Thomas's splint with sides and a ring of adjustable dimensions. My colleague Mr. Roy Maudsley¹ has in fact described such an appliance, which also embodies several other ingenious features. Because an ambulance carrying a splint, or one similar to it, would be able to immobilize adequately almost any femoral fracture. I commend his article to the attention of all concerned with the organization of first-aid services.—I am, etc.,

London, W.C.1.

RICHARD HARRISON.

Insufficiency of Internal Cervical Os

SIR,—I was very interested to read the article by Mr. V. B. Green-Armytage and Professor J. C. McClure Browne (*Journal*, July 20, p. 128) on insufficiency of the internal cervical os in repeated abortion. Particularly valuable was their description of the operative technique. I have successfully treated one such case of cervical incompetence, the details of which were as follows.

The patient had had two full-term normal deliveries in 1949 and 1953 followed by a three-months abortion in 1955. I was called to see this patient on October 3, 1956, with a history that the last period had been on May 12, 1956, and that for about seven days she had been leaking liquor associated with some blood-stained discharge. The uterus was about 20 weeks' size, foetal movements had been felt, and the foetal heart could be heard. On vaginal examination the cervix was seen to be open, the membranes could just be seen, and liquor was leaking through the os. The same day I closed the cervix by inserting two lateral mattress sutures of No. 9 braided nylon, and at a higher level a purse-string suture of similar material. Following this there was no further loss except on October 8 and 9, when there was some slight brownish discharge. I inspected the cervix on October 11 and this was still quite closed and healthy, and the pregnancy was continuing satisfactorily. On November 22 the patient had the misfortune to fall downstairs. This led to some further leakage of the liquor and some intermittent lower abdominal pain. She was readmitted to hospital, the uterine size now being about 28 weeks, and there was a single foetus presenting as a vertex and the foetal heart could be heard. The patient was sedated and the threatened premature labour did not proceed. The and the threatened premature labour could be seen over the left following day a large area of bruising could be seen over the sacro-iliac joint and sacrum. The cervix was inspected and seemed to be healthy, and there was no further leakage of liquor through the cervical os. She was kept in bed for a week and the pregnancy proceeded normally. On January 22, 1957, I removed the three sutures from the cervix in the hope that she would then start in labour, as the blood pressure had been slightly raised despite bed rest for some two weeks or so. When the sutures were removed the cervix immediately opened to the extent of one being able to just see the membranes again. Labour did not ensue, and on February 11 rupture of the membranes was performed and a normal delivery of a live female child occurred two days later.

It seems to me that this simpler method of closing the cervix may be adequate when the insufficiency is not due to amputation of the cervix.—I am, etc.,

Solihull.

H. B. WATSON.

SIR,—I read with interest the paper by Mr. V. B. Green-Armytage and Professor J. C. McClure Browne (*Journal*, July 20, p. 128) describing a modified Shirodkar technique. However, it should be pointed out that the anatomical basis for the operation is not as they describe.

It is accepted that the isthmus uteri and anatomical internal os are incorporated into the ovum chamber in the fourth month of pregnancy. Danforth¹ demonstrated that the cervix uteri is mainly fibrous and the corpus uteri mainly muscular. He described a fibromuscular junction between these two parts located near the lower end of the isthmus uteri—certainly not "between the anatomical internal os and the lower uterine segment." Unfolding of the isthmus uteri occurs down to this junction. The unfolded isthmic

musculature is indistinguishable from corporeal musculature. How then do the present authors define the upper limit of the isthmus delineated clearly in their Figs. 1 and 2? Shaw and Nirula² defined the fibromuscular junction more precisely and described a thick layer of muscle fibres lying beneath corporeal and isthmic mucosa and tapering abruptly into a thin layer lying beneath cervical mucosa. The lower edge of this thick interlacing muscle layer forms a functional sphincter, disruption of which may be associated with habitual abortion and corrected by Shirodkar's operation.

In his excellent paper Hughesdon³ demonstrated that the cervix is a fibromuscular structure with most of the muscle disposed peripherally as internal and external cervical muscles. He described the loosening of cervical collagen in pregnancy and the differential movement of the internal and external cervical muscles in labour. In the course of a study of the lower uterine segment⁴ I have described specimens which suggest that differential movement occurs also in pregnancy, and that the thick muscle ring defined by Shaw is drawn up into the ovum chamber after the twentieth week. Thus, nearer term, the lower part of the isthmic segment is extremely thin. A nylon suture placed around the isthmus uteri in the first half of pregnancy would in the second half be separated from the mucous membrane by an extremely thin layer. The pressure of the suture, and the muscular defect necessitating its insertion, may result in the layer being even thinner than normal. A biopsy performed at the time of removal of the suture would be interesting and add to our knowledge of uterine anatomy.—I am etc.,

London, S.E.1.

Hospital Confinement

SIR,—Your correspondents on this subject seem so far to have quite neglected the *prima donna* in the piece: we, as supporting cast, might do better to consult her in the matter. Where would *she* prefer to have *her* baby? Surely this should be our first question, and we should acquiesce in all cases, subject to considerations as to the available accommodation and facilities, and antenatal progress. If this be not sufficient argument to sway us, we may consider the practical point that, leaving the initial decision to the patient, we cannot be said to have exerted an influence on her for evil.—I am, etc.,

Upton, Hunts.

JOHN K. PATERSON.

Hazards of Tranquillity

SIR,—Your annotation "Hazards of Tranquillity" (*Journal*, July 13, p. 92) raises several controversial issues. You mention the threat of the easy way out which mass tranquillization appears to offer to those millions whose anxiety symptoms are the result of stress. This criticism is not constructive until such ideal times have been reached which make "narcoleptic therapy" unnecessary. However, the purpose of this letter is not to raise ethical issues but to point out that the main facts have been overlooked in this controversy.

Tranquillizers appear to have some good effect in some sufferers. It has now become necessary to investigate why certain tranquillizers are effective in some cases only. In assessing the relative efficacy of a tranquillizer the individual degree of suggestibility, the basic personality, and the clinical syndrome have to be taken into account, and in any clinical trial the matching of the subjects has to be as accurate as possible. If the manufacturers toned down their extravagant claims, if the professional journals insisted on proper experimental designs, and if the investigators paid more attention to clinical entities, the present unsatisfactory degree of vagueness would give way to a more logical and scientific approach to the problem.—I am, etc.,

Rainhill, near Liverpool.

G. C. HELLER.

Congenital Malaria

SIR,—With reference to the case of congenital *Plasmodium ovale* malaria reported by Dr. H. G. Jenkins in your *Journal* of January 12 (p. 88), I should like to report an investigation on a series of 50 births in this hospital over the past three months.

Taking 50 consecutive deliveries, blood slides were taken on the day of delivery for both the mothers and infants. Of the 50 mothers, 32 had a positive blood slide for *P. falciparum*. The mothers with positive blood slides gave birth to 22 babies with positive blood slides; in no case did a mother with a negative blood slide give birth to a child with a positive blood slide. All the mothers were Nigerians living in this area with free antenatal care and treatment available, but only four complained of fever during the antenatal check-ups, and these were treated. Of these four three had negative blood slides at delivery; in the case of the fourth both mother and baby had positive blood slides.

These figures show that with *Plasmodium falciparum* malaria, which is hyperendemic in this area (74% of the population show positive blood slides), the incidence of congenital malaria is very high and suggest that the use of antimalarial and prophylactic drugs during pregnancy would be very worth while.—I am, etc.,

Calabar, Nigeria.

K. J. ATKINS.

Toxic Effects of Meprobamate

SIR,—It is felt that the following report of a case of sensitivity or toxic reaction to meprobamate ("equanil") may be of interest, since certain features of it, while they have been recorded in America, have not, so far as I am aware, been reported in the British literature. However, attention was drawn to the American publications in the *British Medical Journal*,¹ and in the same issue² West and da Fonseca, in a report on a controlled trial of meprobamate, mention five cases of a transient urticarial rash following a single 400-mg. dose. Since that time there have been several reports of a variety of toxic reactions, and now (*Journal*, July 13, p. 92) once again you draw attention to the "hazards of tranquillity."

The patient, a married woman of 22 who was under considerable domestic stress, was given a tablet (400 mg.) of meprobamate (equanil) by a friend to "calm her nerves." She had no family or personal history of allergic disease or drug sensitivity beyond a slight local skin reaction while being treated for conjunctivitis some years previously. Two hours after taking the tablet she began to feel hot and developed a generalized, intensely irritant erythema all over the body, giving the appearance of severe sunburn. The irritation was particularly marked around the pelvic girdle, groins, breasts, palms of the hands, and soles of the feet. This was followed by tender enlargement of groin and axillary glands. Four hours after ingestion of the pill she presented an extremely agitated and tearful state. Her temperature had risen to 100° F. (37.8° C.), but there were no other abnormal physical signs. Shortly afterwards, however, she also developed headache, nausea, and vomiting. Despite the fact that she had never previously taken meprobamate, this picture seemed to contain most of the features of a drug allergy. She was accordingly treated with mepyramine maleate, phenobarbitone, and topical applications of calamine lotion. All her symptoms and signs, except the skin irritation and some residual glandular tenderness, subsided in 24 hours. On the second day, however, she developed a few small vesicles, which later became pustular, over the front of the chest and in the groins. This eruption and all residual symptoms had subsided by the fourth day.

All the features noted in this case have been reported previously by various American observers,^{3,4} but only one aspect has been found mentioned in the British literature.⁵ The features of particular interest were, first, that the reaction was produced by a single 400-mg. tablet with no prior sensitization to the drug, as were the rashes in West and da Fonseca's cases; and, secondly, that a paradoxical cerebral reaction was produced. Friedman and Marmelzat⁴ suggest that a possible explanation of a drug sensitivity

reaction appearing in patients without previous exposure to the drug is that they have been exposed in the past to chemically related compounds such as mephensin. There was no history of such exposure in the present case. No explanation of the paradoxical cerebral effect is put forward, but, as they point out, "paradoxical reactions, where sedation is expected and excitement is produced, have a long tradition in regard to the barbiturates and other sedative compounds." Unfortunately it was not possible to confirm that the observations in this case were without doubt due to the ingestion of meprobamate by repetition of the dose and further observations, as the patient passed out of my care immediately after this episode.—I am, etc.,

Lindholme, near Doncaster.

Sign of Rain

SIR,—As my letter (*Journal*, June 1, p. 1305), questioning the authorship of the poem "Signs of Rain" seems to have aroused some interest (*Journal*, June 29, p. 1530), I thought it worth while pursuing the matter further. Mr. Hawke, for the Royal Meteorological Society, editor of the fourth edition of *Weather Lore*, has kindly furnished me with the evidence that Erasmus Darwin was probably the author. He writes:

"This set of verses was first published anonymously (after a common custom of those times) towards the close of the eighteenth century and was long supposed to be the work of Dr. Edward Jenner. Many years later it was pointed out that the versification was much more in the style of Dr. Erasmus Darwin (1731-1802) than of Jenner, and, further, that Darwin, a minor poet of considerable repute, had studied weather lore and written a good deal about it, whereas Jenner was not known to have taken any interest in the subject."

"Although the origin of the verses has not been conclusively established even now, most modern authorities are agreed that they may be credited with a high degree of confidence to Erasmus Darwin. Among these authorities are the late Sir Napier Shaw, F.R.S., former Director of the Meteorological Office, Air Ministry, and the late Richard Inwards, one-time President of the Royal Meteorological Society and compiler of the standard treatise on weather lore. In Shaw's great *Manual of Meteorology* two of the three references to 'Signs of Rain' ascribe the lines definitely to Darwin, while the third reference mentions that they have also been attributed to Jenner. Inwards² at one time (nearly a century ago) appears to have believed the verses to be Jenner's, but subsequently he fell in with the prevailing opinion that the authorship was much more probably Darwin's."

—I am, etc.,

Dartford, Kent.

Frederick William Pavy (1829-1911)

SIR,—In his article on "Claude Bernard and the Discovery of Glycogen" (*Journal*, June 22, p. 1431), Professor F. G. Young outlined the work of F. W. Pavy on carbohydrate metabolism. Although it is for his writings in this field that Pavy is now chiefly remembered, it may be of interest to recall another aspect of his career which, while much less well known, is nevertheless of no little historical importance. This concerns his work in the sphere of public health.

Following the passing of the Metropolitan Management Act in 1855, every vestry and district board in the London area were required to appoint a medical officer of health. Among the forty-eight men who filled these newly created posts was Dr. Pavy, who, at the age of 26, became the first medical officer of health of the parish of St. Luke, Middlesex. His district comprised the crowded area immediately adjacent to the City on the north side, and now

Obituary

J. D. L. REINHOLD, D.M., M.R.C.P., D.C.H.

Dr. J. D. L. Reinhold, who had recently taken up an appointment as assistant professor of paediatrics in the University of Colorado, died after a motor accident at Denver on July 19. He was 34 years of age.

John Drake Lucas Reinhold, the second son of Colonel Carl Reinhold, M.C., I.M.S. (retired), was born in 1922 in India, where his family had had a long record of service. The Reinholds were of Danish origin, John's great-grandfather having left his native Holstein after the Danish-Prussian war of 1866. He went from Wellington to Trinity College, Oxford, and thence to Guy's Hospital, graduating B.M., B.Ch. in 1945. Illness debarred him from National Service, and after house appointments at Guy's and a year of general practice he joined the rheumatism unit at the Canadian Red Cross Memorial Hospital, Taplow. While there he carried out some interesting research on anaemia in rheumatic fever and published a paper on foetal endocarditis. He took the M.R.C.P. in 1947 and the D.C.H. in 1951. From Taplow he joined the paediatric unit at St. Mary's Hospital, first as senior registrar and then as lecturer. In 1951 he spent one year at the Children's Hospital in Boston, and it was there, under Dr. Nadas, that he developed his interest in paediatric cardiology. From Boston he published papers on red cell fragility and the use of digitalis in infants and children.

On his return to London he continued to work at St. Mary's and built up an exceptionally efficient and pleasantly run heart clinic at the Princess Louise (Kensington) Hospital for Children. His important research at Great Ormond Street on normal and abnormal heart sounds was later published as a D.M. thesis. In 1956 he was appointed assistant to the director of the department of child health at Guy's, his old hospital. He had only been a few days in his new appointment at Denver when he lost his life.

Two former colleagues of Dr. Reinhold write: When John Reinhold left England at the end of June many of his friends must have wondered whether they would ever see him again, but our sense of loss was tempered by the knowledge that he was leaving to take up just the kind of appointment he had always wanted and one which would enable him to achieve the maximum in his chosen field. His tragic death in a car smash, only a week after his arrival in America, has deprived the English-speaking world of a young children's doctor whose achievement in Britain and promise in America were of the highest and whose fine character and charming personality had won him many true friends on both sides of the Atlantic. He was essentially a clinical scientist: much of his research was concerned with the use of instruments to evaluate clinical techniques in an endeavour to enhance their accuracy and usefulness. This was exemplified by his work on phonocardiography.

John Reinhold had had an active boyhood in India, riding, skiing, and fishing, and he felt the need for his family—three girls and baby boy—to live a less restricted life than that offered by a London suburb. For this reason he had already contemplated abandoning cardiological research for the life of a country paediatrician, for which he would have been just as admirably suited. But in the spring of this year he was offered a post which would have enabled him to continue to work in the field of his special interest as well as giving his children the opportunities he had enjoyed. The decision to leave England was difficult for him, but his year in Boston had been happy and productive, and few of his close friends were surprised when he accepted an offer to go to the University of Colorado as associate professor of paediatrics in charge of the congenital heart clinic of the Medical Centre there. But it remained his ambition that his baby son should follow him to Trinity College, Oxford, in due course, and this his friends hope to realize for him.

forms part of the Metropolitan Borough of Finsbury. Shortly after taking up his appointment Pavy invited seven of his colleagues to his house at 3, Finsbury Square, for a discussion of their work, and more particularly to consider the formation of a society. This meeting is a noteworthy event in the annals of public health.¹ Its outcome was an invitation to all the medical officers of health in the Metropolitan area to attend a gathering on May 13, 1856, in the rooms of the Medical Society, Hanover Square. At this meeting, which was attended by thirty of those who had been invited, the Metropolitan Association of Medical Officers of Health was founded, with John Simon as its first president. In the years that followed, this association, which owed its inception to Pavy, gradually widened its scope and membership and became the Society of Medical Officers of Health of the present day.

Pavy continued his work at St. Luke's for nearly thirty years, while, at the same time, conducting his researches into diabetes. This was the period which witnessed substantial improvements in the sanitary conditions of London, and the long series of annual reports which he submitted to his vestry provide an interesting commentary on these changes and serve to illustrate his interest in matters concerning community health. In addition to being medical officer of health Pavy was also the public analyst of his parish. He carried out much of this work himself, and it is interesting to reflect that, while he was engaged on his studies of food and dietetics, he was also testing the milk, foodstuffs, and even the beer sold in his district. In 1884 he resigned his post in order to devote more time to his clinical research and his private practice. He retained his interest in public health to the end of his long life. When in 1906 the Society of Medical Officers of Health celebrated its jubilee, Pavy, then aged 77, attended the commemorative banquet and made a short speech. At his death in 1911 he was the last of the society's original members. Although his principal interest lay in physiological research, his contribution to public health is, I believe, worthy of mention.—I am, etc.,

Preludin and Enuresis

SIR,—May I have the hospitality of your correspondence columns to report a chance observation which may have some therapeutic value?

The patient was a girl aged 11 years. She had become grossly overweight, largely by reason of an easy access to cakes and pastries. I was assured by a paediatrician that there was no endocrine dysfunction, and she was put on a diet. This, however, had no effect at all, as she did not keep to the regime. After some time I decided to give her a trial course of "preludin" (tetrahydro-3-methyl-2-phenyl-1:4 oxazine). She was given the usual dosage of two tablets daily. Her weight gradually began to fall, and it was noted, as well, that her enuresis, which had persisted since early childhood, stopped altogether. When she ceased taking the tablets her enuresis returned.

From the literature it appears that preludin acts directly upon the hypothalamus, the nuclei of which, operating via the autonomic nervous system on the pituitary gland, are said to be responsible for, among other things, the regulation of sleep and the production or suppression of posterior pituitary antidiuretic hormone. Both these factors are of importance when considering enuresis. The role of the hypothalamus in the "exteriorization" of emotions may also be significant. I propose to conduct a small-scale investigation into this matter when suitable cases arise. Until then I would be interested to hear if this phenomenon has been observed elsewhere.—I am, etc.,

Ashton-in-Makerfield.

N. TREVOR BURNETT.

John Reinhold was a very easy person to be with; he was content to be himself and thus allowed his friends to be themselves too. He professed no high ideals, but his way of life implied them. His scientific work was scrupulously accurate, and, though not without ambition, he was not one to jostle in the queue for preferment. Among his many interests outside his work, he was a talented artist, a capable fisherman and golfer, a trencherman of discernment, and an enthusiastic brewer of home-made wines. His strong sense of humour, his acute judgment of people, his sanity and tolerance, his happy family life—for all these qualities he is mourned by his contemporaries. All who knew him either personally or by his work will wish to offer deep sympathy to his young widow, his orphaned children, and his bereaved parents.

M. SYLVIA STOCKS, M.R.C.S.

Dr. Mary Sylvia Stocks, who practised at Chalk Farm, London, died on May 25 at the Royal Free Hospital. She was 63 years of age.

Born at Richmond, Surrey, Sylvia Stocks began her medical training at Bedford College and went on to St. Mary's Hospital, qualifying in 1919. After a term as locumtenent for the obstetric resident at St. Mary's, she became resident medical officer to the Leeds Public Dispensary, and later resident assistant medical officer to the Harton Hospital, South Shields, where she remained for five years until taking over the general practice at Chalk Farm in 1927.

E. S. writes: No wonder that Dr. Sylvia Stock's experience and the influence of her earlier work soon become apparent in the expansion of her practice. She displayed a keen sense of duty at all times, together with a thorough devotion to the well-being of her patients. Deeply interested in the individual, she was prepared to take unlimited trouble to help people in need in the right way and at the right time. During the bombing phase of the last war she shared with only one other medical officer night duties in the deep air-raid shelters of the Camden Town district, accommodation which extended for two and half miles. In addition to this and her private practice she continued lecturing to nurses and even managed first-aid lectures at the local town hall for civil defence purposes. After the war her health became poor and it became necessary for her to give up obstetrics and later to obtain part-time help at her surgery. Until quite recently she continued to lecture at the Occupational Therapy Centre, Merton Rise, Hampstead, where she will be greatly missed. Dr. Stocks was a great character, with sparkling wit and practical wisdom. With other people to care for, she accepted no barriers and was fearless in achieving her objective, but she had real compassion. She faced private difficulties with courage and was quite without self-pity. She is survived by her adopted son.

ROBERT DICK, M.B., F.R.C.S.Ed.

Dr. Robert Dick died suddenly at his home at Liversedge, Yorkshire, on June 27 at the age of 59.

Robert Dick was born at Kilbirnie, Ayrshire, on April 12, 1898. He was educated at Spiers School, Beith, Ayrshire, and, after serving in the Highland Light Infantry during the first world war, entered Glasgow University as a medical student and graduated M.B., Ch.B. in 1924. Two years later he was elected F.R.C.S.Ed. After a short time as an assistant in general practice he was appointed the first house-surgeon to Batley and District General Hospital. On leaving this appointment he became a partner with a fellow Scot, the late Dr. James Nicholson, of Liversedge, where he built up a large practice. During this time he endeared himself to his patients by his thoughtfulness and efficiency. His quick sense of humour and jovial spirit made him the life and soul of any party. His devotion to his patients, which he certainly rendered to the full, did not prevent him from many voluntary services, and he gave an untiring service to the local St. John Ambulance Brigade. He was an honorary

surgeon to Batley and District Hospital, and after the inception of the National Health Service he still served on the medical advisory committee of the management committee. He was a very loyal supporter of the British Medical Association, being chairman of the Dewsbury Division in 1955-6. A director of the local football club, he actively supported many sports in the district. These are just a few of the many activities that he so willingly rendered to the public that loved him so well.—S. M. N.

W. G. LOVE, M.B., Ch.B.

Dr. William Griffith Love died on July 13 at Woodville, near Burton-on-Trent. He was 53 and had practised in Woodville for many years.

Bill Love, as he was known to everybody, was born in Newcastle upon Tyne on July 22, 1903, and educated at Mill Hill School (of which he was later to become a life governor). He studied medicine at Edinburgh University, graduating M.B., Ch.B. in 1925. House appointments which followed included those of resident medical officer at the Royal Victoria Hospital, Edinburgh, and senior house-surgeon at Chester Royal Infirmary. In 1930 he came to Woodville to join the late Dr. S. W. May in general practice. He quickly settled into the medical and social activities of the district, and soon established a high reputation for himself in everything he undertook. A keen Territorial officer, he was called up at the outbreak of the second world war as a company commander in his unit, the 137th Field Ambulance, and was soon promoted to the command of the 172nd Field Ambulance. In 1943 he was posted to West Africa in command of the 6th (West African) General Hospital. His long service in the R.A.M.C. (T.A.) was recognized by the award of the Territorial Decoration (with 1st clasp) in 1950.

On his return to practice he again resumed his busy and varied life. Taking an active part in the work of the Derbyshire local medical committee, he was its treasurer, vice-chairman, and, just before his death, chairman. He was also vice-chairman of the Derbyshire executive council. In the proceedings of these bodies he could always be relied upon to display sound appreciation of a problem and to contribute useful observations. He was, too, a strong supporter of the Conservative Association, and he had been chairman for many years of the local branch. He had held office as chairman of the Burton Division of the B.M.A. and the same office in the South Derbyshire General Medical Practitioners' Group. Soon after the war he was a co-founder and first chairman of the Burton and District branch of the R.A.M.C. Association, and his enthusiasm and example produced one of the most active branches in the United Kingdom.

Bill Love's passing is greatly regretted by professional colleagues and patients alike; to both he was always ready to lend help and assistance. Just over a year ago he underwent a serious operation, and although he was back at work in three months it was obvious that his strength was not equal to the demands he imposed on himself, but he carried gamely on with all his activities until a few weeks ago. It may be truly said that he lived up to the motto of his Corps, *In arduis fidelis*. The sympathy extended locally to his wife and daughter will be echoed further afield.—E. M. R. F.

ALAN GREGG, M.D.

Dr. LEONARD COLEBROOK writes: In your tribute to Alan Gregg (*Journal*, July 27, p. 240) you spoke of the "many British institutions which owe much to him and the Foundation he served" so well. May I put on record that Queen Charlotte's Hospital was one of these, and that the work done there on the sulphonamides was, in part at least, an outcome of the Foundation's generous support—thanks to Gregg's personal advocacy?

In 1930 the hospital, with the valuable help of the Bernhard Baron Trust and others, had built the isolation block and its research laboratories for an intensive study of

puerperal fever. It was an act of faith, for there was no certainty that anything of practical value would come out of the venture. Nor was its financial future assured. The Medical Research Council provided the salaries of several of the laboratory staff from year to year, but over and above these the research programme meant a big bill for Queen Charlotte's to meet, at a time when it was already faced with the task of rebuilding the maternity hospital. In these circumstances I wrote to Alan Gregg. I had never met him, and he had probably never heard of me. But one morning he turned up (unannounced, I think), looked round the laboratory, and for a couple of hours turned me inside out with most intelligent questions about the work we proposed to do. He went back to New York, and, as I heard many years later, met with considerable opposition from some of his colleagues on the Foundation's Board when he backed my application.

In due course came his letter announcing that the Board was giving us £3,000 a year for seven years. There were no strings—and no request for reports. The Board trusted us to do our best. I am sure that Gregg had appreciated that puerperal fever presented a problem which concerned the whole world, not Britain alone. Before the seven years were out "prontosil" had come from Germany, and we were in a unique position at the isolation block for investigating its merits. In after-years Gregg was kind enough to say, on more than one occasion, that the Foundation's contribution to that work was one of the happiest investments it had ever made.

I met Gregg only three times, but always he left on me an indelible impression as one of the finest types of civilized man I had ever had the good fortune to encounter. In his rich personality he seemed a symbol of the wonderful generosity of the American people.

Medico-Legal

DR. J. B. ADAMS FINED ON 14 CHARGES

At Sussex Assizes, Lewes, last week Dr. John Bodkin Adams, of Eastbourne, pleaded guilty to 14 out of 16 charges and was fined a total of £2,400. The 16 charges against Dr. Adams were as follows:

On a day in January, 1952, forged a National Health prescription contrary to section two (2) (C) of the Forgery Act, 1913, and on a day in January, 1952, obtained a quantity of prepared vaccine by a forged instrument, contrary to section 7 (A) of the Forgery Act.

Between January 22 and February 1, 1952, with intent to defraud, obtained a quantity of prepared vaccine by a forged National Health prescription.

In November, 1955, forged a National Health prescription and caused to be delivered to Dorothy Crisford a pair of elastic stockings by a forged instrument.

In April, 1956, forged a National Health prescription. In May, 1956, caused to be delivered to Beryl Galloway an elastic knee support by a forged instrument.

In September, 1956, caused to be delivered to Frances Abrams a bottle of medicine and six 7½-gr. tablets of sodium barbitone by falsely pretending that Frances Abrams was authorized to receive them as a National Health patient, contrary to section 32 (1) of the Larceny Act, 1916.

In October, 1956, forged a National Health prescription, and caused to be delivered to Frances Abrams a bottle of medicine and 24 A.P.C. tablets by a forged instrument.

On February 23, 1950, made a false representation that so far as he was aware he had no pecuniary interest in the death of Amy Constance Clavering l'Anson Ware with a view to procuring the burning of her remains, contrary to section 8 (2) of the Cremation Act, 1902.

On May 30, 1955, made a false representation that so far as he was aware he had no pecuniary interest in the death of James Priestley Downs with the same object in view.

On March 14, 1956, made a false representation that so far as he was aware he had no pecuniary interest in the death of Alfred John Hullett, again with the same object in view.

On November 24, 1956, attempted to conceal certain drugs to which part 3 of the Dangerous Drugs Act, 1951, applied—i.e., two bottles of morphine.

On November 24, 1956, obstructed Detective Constable Brynley Pugh in exercise of his powers under section 14 of the Dangerous Drugs Act, and failed to comply with Regulation 17 of the Dangerous Drugs Regulations, 1953, in relation to the keeping of a register or other records.

Dr. Adams pleaded not guilty to the charge that in January, 1952, he forged a National Health prescription, and to the charge that in October, 1956, he forged a National Health prescription. The pleas of not guilty were accepted.

In pronouncing judgment Mr. Justice Pilcher said that Dr. Adams had not gained anything by the stupid forgeries which he had committed, but if every doctor acted as he had acted it would be quite impossible for the National Health Service to be administered. His offences were really in some ways childish. Adams was fined £150 for these offences.

The Judge said he regarded the offences over the cremation certificates as the most serious. There was a time, he said, when he felt he would not be doing his duty unless he sent Dr. Adams to prison on this indictment, but he was bearing in mind that he was simply dealing with the offences to which Dr. Adams had pleaded guilty there. "I confess that I am impressed to some extent by the fact that it appears to be almost unheard of for doctors, at any rate in your area, ever to answer Question 4 on the cremation form in any fashion other than the way in which you answered it. It is a surprising thing, and it may be, of course, that doctors in this part of the world are never aware with sufficient certainty that they are being left any amount." But, said the Judge, Dr. Adams knew perfectly well that these three people were leaving him money. In view of the fact that he spent some months in prison, he would impose a fine of £500 on each of these three charges. He also imposed a fine of £500 for failing to comply with the regulation in relation to the keeping of a dangerous drugs register, and fines of £250 for the offence of obstruction and attempted concealment of drugs.

The Medical Defence Union instructed Messrs. Hempsons, solicitors, to act for Dr. Adams.

Medical Notes in Parliament

Poliomyelitis Vaccine

Colonel R. GLYN (Dorset, North, Con.) asked the Minister of Health on July 24 what were the prospects of an increase in the present supply of home-produced poliomyelitis vaccine. Mr. J. K. VAUGHAN-MORGAN, the Parliamentary Secretary, stated that Messrs. Glaxo Laboratories had decided to expand their production by 50% on an undertaking by the Government that, for a period of at least a year from the time when the additional vaccine became available and subject to the price being satisfactory, it would make a proportionate increase in the amount purchased. Messrs. Burroughs Wellcome were expected to come into production later this year. If these expectations were realized, they would be able to consider a corresponding extension of the arrangements for vaccination, which were at present restricted to children born between 1947 and 1956 inclusive, but he must repeat and emphasize that nothing in this field was predictable either in this country or elsewhere.

Mr. S. P. VIANI (Willesden, West, Lab.) asked what information had been received of inoculated children developing poliomyelitis during recent outbreaks. Mr. VAUGHAN-MORGAN said on July 26 that during 1957 six cases of poliomyelitis, three of them paralytic, had been reported in England and Wales in children who had had two injections of vaccine. So far, enough vaccine had been issued to local health authorities for the vaccination of over a million children.

Fainting on Parade

Mr. R. W. SORESENSEN (Leyton, Lab.) asked the Secretary of State for War on July 24 what medical inquiry had been made during recent years into the stamina of soldiers and the causes of their collapse on parade; and what guidance was

given them when likely to experience undue strain from heat or other causes. Mr. JOHN HARE replied that the basic cause of fainting was well known and soldiers were trained in preventive measures. They were advised to take enough rest and sleep before parades, and care was taken to see that their clothing fitted properly. They were also trained in a way of standing on parade which reduced the risk of fainting.

Cancer Registration

Mr. W. HANNAN (Glasgow, Maryhill, Lab.) asked what progress had been made in establishing a system for cancer registration in each of the Scottish hospital regions; what were the remaining difficulties; and what proposals the Health Services Council had made to him to overcome them. Mr. NIXON BROWNE replied that a system of cancer registration continued to operate effectively in two of the five regions. The difficulties in other regions related mainly to the methods of collecting data. The Cancer Committee of the Scottish Health Services Council had recommended a detailed organization for cancer services, including ways of securing accurate registration in all regions, and a memorandum based on these recommendations would be issued very shortly.

Preventive Research

Mr. S. AWBERY (Bristol, Central, Lab.) asked the Minister of Health what percentage of the money spent on the health services was expended on preventive research work. Mr. VAUGHAN-MORGAN stated that expenditure by the Medical Research Council was the equivalent of about $\frac{1}{2}\%$ of the Exchequer cost of the Health Service. Much of this expenditure related immediately to prevention, and most medical research had that ultimate aim.

Health Service Reciprocity

Mr. R. RUSSELL (Wembley, South, Con.) asked which countries had been approached with a view to reciprocal arrangements being made for free medical treatment for British residents and visitors. Mr. VAUGHAN-MORGAN stated that since March the agreement with Sweden had been ratified and agreements with Belgium and Israel had been signed. Negotiations with Austria and Yugoslavia were in progress. No countries had refused to negotiate, but reciprocal arrangements had to take account of the basis of existing services, and in other countries the health services were usually based on insurance principles. Some other countries had not so far found it practicable on examination to offer reciprocity.

The MINISTER OF PENSIONS AND NATIONAL INSURANCE announced on July 26 that the previous day an agreement on social security had been signed with Norway. It would cover the benefits provided by the national-insurance, industrial-injuries, family-allowances, and national-assistance schemes, and the Norwegian health service would be made available to British nationals, including tourists.

Anthrax Investigation

Mr. IAIN MACLEOD, Minister of Labour and National Service, announced on July 24 that the committee of inquiry into precautions against anthrax had held its first meeting under the chairmanship of Mr. R. F. Levy, Q.C., and was inviting evidence from interested parties. The four other members were Professor A. K. Cairncross, Mr. T. Eccles, Mr. J. B. Solomon, and Dr. A. J. H. Tomlinson. The committee wants evidence on all matters falling within its terms of reference, which are "to consider the existing legal provisions concerning the importation of goods infected or likely to be infected with anthrax and the precautions to be taken in connexion with such imported goods for the protection of the health of persons and to make recommendations." Persons or organizations wishing to give evidence are asked to communicate with Mrs. V. D. Crane, Secretary of the Committee, at the Ministry of Labour and National Service, 19, St. James's Square, London, S.W.1.

Consultant Appointments

Mr. VAUGHAN-MORGAN informed Mr. KENNETH ROBINSON (St. Pancras, North, Lab.) on July 29 that the number of consultants per 100,000 population in the four metropolitan regions together was 18.7, and in the rest of England and Wales 12.7. Mr. ROBINSON suggested that this showed a serious shortage in the provincial areas. In view of the many hundreds of senior registrars awaiting appointments, would the Parliamentary Secretary consider authorizing a considerable increase in consultant appointments in the provinces? Mr. VAUGHAN-MORGAN said the disparity was not as great as the figures suggested. Expressed as whole-time equivalent they were 12.95 in London and 10.51 in the rest of the country. There was a complicating factor in the higher ratio of teaching to non-teaching beds in the metropolitan area.

Doctors Emigrating

Dr. DONALD JOHNSON (Carlisle, Con.) asked if the Minister of Health was aware of the number of qualified doctors who were emigrating to appointments in the Commonwealth and the U.S.A. owing to not being able to find employment in the National Health Service; and if he would make an inquiry into this. Mr. VAUGHAN-MORGAN replied that it was no new thing for some doctors from this country to take appointments overseas. Figures of the number doing so were not available, but he would willingly consider any further statistics which Dr. Johnson could produce. The report of the committee which had been inquiring into future requirements for doctors and medical students was expected shortly.

Dr. JOHNSON asked the Parliamentary Secretary to take careful note of what was undoubtedly a drift overseas by many competent doctors. Dr. EDITH SUMMERSKILL (Warrington, Lab.): Whatever health scheme was in operation to-day the supply of doctors would still exceed the demand. Mr. BRIAN HARRISON (Maldon, Con.) said that large numbers of doctors were coming here from the Commonwealth, and asked the Parliamentary Secretary to do nothing to stop this exchange, which was of mutual advantage. Mr. VAUGHAN-MORGAN: I entirely agree.

Mental Patients' Letters

Mr. KENNETH ROBINSON asked if the Minister would implement the recommendation of the Royal Commission on the Law relating to Mental Illness and Mental Deficiency that patients' letters should no longer be subjected to censorship. Mr. VAUGHAN-MORGAN stated that superintendents were required by statute to forward unopened all letters addressed by patients to certain specified persons and bodies and might at their discretion forward other letters. The recommendation of the Royal Commission on this subject would be considered with others which involved legislation. Meanwhile he was having a letter sent to superintendents suggesting that in view of the Commission's recommendations, where this was not already being done, they should exercise their statutory discretion to open outgoing letters of patients only where they had cause to think that the contents might be offensive to the recipients.

Post Office Sick Leave.—The average number of days' sick absence per person for non-disabled established staff in the Post Office in the years 1936, 1946, and 1956 was: 1936, 9.0 for men and 10.3 for women; 1946, 12.3 for men and 15.9 for women; 1956, 12.3 for men and 14.8 for women; almost all of this was paid sick leave.

Multiple Packs.—The composite packs available at a single charge under the Health Service are: atomizer, smog mask, vaporizer, hypodermic syringe, urine sugar analysis set, colostomy apparatus, suprapubic belt, douche, Higginson's enema syringe.

Leprosy in Scotland.—Nine cases of leprosy were notified in Scotland in the four years 1953 to 1956 inclusive. All were aged over 15 years and in every case the disease had been contracted abroad. One of these persons was reported to be receiving hospital treatment as an out-patient.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending July 13 (No. 28) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications in England and Wales in the week ending July 20 were as follows, with the figures for the previous week in parentheses: paralytic 105 (68), non-paralytic 84 (65), total 189 (133). Total cases in Scotland were 3 (3), Northern Ireland 14 (10), and Eire 5 (3).

Cases were reported in most counties in England and Wales during the week, with several main sources of infection in the Midlands. In Warwickshire 28 cases were reported (Birmingham C.B. 7, Coventry C.B. 17), in Worcestershire 8 (Worcester C.B. 6), and Lincs, Lindsey 7 (Lincoln C.B. 7). The Kent outbreak continued with 16 cases (Maidstone M.B. 6), and 9 cases were reported in Essex (Colchester M.B. 3, Ilford M.B. 3). In Devon 9 cases were reported (Axminster R.D. 5), in Gloucestershire 10 (Cheltenham R.D. 3), and in London 17 (Islington M.B. 4). In the outbreak at Abertillery (Mon.) 2 more cases were notified.

Of the 14 cases in Northern Ireland, 9 were notified in Belfast C.B.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1948-56 are shown thus -----, the figures for 1957 thus ————. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest variations in the number of notifications of infectious diseases in England and Wales during the week ending July 13 were decreases of 2,093 for measles, from 15,510 to 13,417, 69 for acute pneumonia, from 266 to 197, and an increase of 91 in food poisoning, from 327 to 418.

The number of notifications of measles declined by 100 or more in eight counties; the largest fall was 427 in Yorkshire West Riding, from 2,006 to 1,579. The chief exceptions to the general trend of measles were increases of 138 in Lincolnshire, from 568 to 706; the largest rise in this county was 67 in East Kesteven R.D., from 20 to 87, and 81 in Southampton, from 489 to 570, due to a general rise throughout the county. 413 cases of scarlet fever were notified, being an increase of 13 on the preceding week, and there were no large fluctuations in the local trends. The number of notifications of whooping-cough increased by 30, from 1,631 to 1,661, and the largest variation was a rise of 33 in Lancashire, from 128 to 161. 3 cases of diphtheria were notified, being the same number as in the preceding week.

The notifications of dysentery numbered 465, being 3 more than in the preceding week. The chief feature of the returns of dysentery was a rise of 65 in Yorkshire West Riding. The chief centres of infection were Lancashire 106 (Eccles M.B. 28, Liverpool C.B. 20), Yorkshire West Riding 102 (Leeds C.B. 28, Wakefield C.B. 13, Bradford C.B. 12, Rotherham C.B. 12), Durham 44 (Seaham U.D. 13, Blaydon U.D. 10), and London 23.

The largest increase in the number of notifications of food poisoning was 92 in Yorkshire West Riding, from 18 to 110. The largest outbreaks in this county were 51 in Todmorden M.B. and 30 in Leeds C.B.

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in June was 91, compared with 89 in the previous month and 97 in June, 1956.

The numbers of cases of industrial diseases in the United Kingdom reported during June, 1957, were as follows: lead poisoning 3, phosphorus poisoning 1, mercurial poisoning 1, anthrax 2, epitheliomatous ulceration 15, chrome ulceration 25; total 47. There were no deaths.—*Ministry of Labour Gazette*, July, 1957.

Week Ending July 20

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 544, whooping-cough 1,577, diphtheria 2, measles 12,778, acute pneumonia 156, acute poliomyelitis 189, dysentery 480, paratyphoid fever 5, typhoid fever 5.

Medical News

Royal College of Physicians of London.—On July 25, at a quarterly comitia, officers for the ensuing year were elected. Dr. F. P. LEE LANDER and Dr. E. R. CULLINAN join Dr. A. M. COOKE and Professor A. KEKWICK as censors. Dr. R. R. BOMFORD, physician to the London Hospital, succeeds the late Professor W. G. Barnard as treasurer. Sir HAROLD BOLDERO was re-elected registrar, and Dr. J. R. ELLIS, sub-dean of the London Hospital Medical College, was elected assistant registrar. Sir CHARLES DODDS, F.R.S., was re-elected Harveian librarian. The following awards were announced: *Moxon Medal for 1957*, to Sir JOHN PARKINSON, for his "outstanding contributions to cardiology, and in particular his elucidation of the significance of cardiac pain and its relation to coronary disease"; *Baly Medal for 1957*, to Dr. E. B. VERNEY, F.R.S., Shield professor of pharmacology at Cambridge, for his "outstanding contributions to the nervous and endocrine regulation of water excretion by the kidneys"; *Weber-Parkes Prize for 1957*, to Dr. CARROLL PALMER, noted for his work on the immunization of North American Indians with B.C.G., for his "outstanding contributions to the study of the tuberculin reactions." Sir GEOFFREY KEYNES was appointed Harveian Orator for 1958, and Dr. K. W. DONALD Bradshaw lecturer. The following other lecturers were also appointed: *For 1958*—Lumleian, Dr. J. St. C. Elkington; Goulstonian, Dr. A. Leatham; Oliver-Sharpey, Dr. M. Kremer; Bertram Louis Abrahams, Sir Lindor Brown, F.R.S.; Charles West, Dr. Mildred Creak; F. E. Williams, Professor P. B. Medawar, F.R.S.; Ernestine Henry, Dr. J. N. Morris; and Marc Daniels, Dr. A. L. Cochrane. *For 1959*—Croonian, Sir Macfarlane Burnet, F.R.S.; FitzPatrick, Dr. W. S. C. Copeman; and Watson Smith, Dr. H. R. Vickers.

Memorial to Sir Robert Philip.—On July 26 Mr. WALTER ELLIOT, C.H., F.R.S., unveiled a tablet in Edinburgh to commemorate the centenary of Sir Robert Philip, holder of the first Chair of Tuberculosis. Sir Robert Philip was born on December 29, 1857. The tablet, placed by the National Association for the Prevention of Tuberculosis on the wall of 13, Bank Street, the site of Sir Robert's tuberculosis dispensary, bears these words: "In memory of Sir Robert W. Philip, 1857-1939, physician, statesman of preventive medicine. First professor of tuberculosis in the University of Edinburgh. Near this place, in 1887, Dr. Robert W. Philip founded a tuberculosis dispensary, the first clinic in the world dedicated to fight a disease of which he foretold man's eventual mastery. His vision has brought hope to many lands. In the year 1957, to commemorate the centenary of his birth, this tablet was erected by the National Association for the Prevention of Tuberculosis on behalf of those who inherit his inspiration." In his address Mr. Elliot described Sir Robert Philip as "the very epitome of Edinburgh, its schools, and its scholars. In figure he was the short, combative type we know so well, of which the greatest example, perhaps, was John Knox. His training, his culture, were of the true Scots type—at once intensive and cosmopolitan."

Chair of Bacteriology, Edinburgh.—The court of Edinburgh University has appointed Professor ROBERT CRUICKSHANK to the vacant university chair of bacteriology. The appointment is from January 1, 1958. Professor Cruickshank has held the London University chair of bacteriology

at St. Mary's Hospital Medical School since 1949 and has been principal of the Wright-Fleming Institute of Microbiology since 1955. He will be 58 in September. Graduating in medicine with honours at Aberdeen in 1922, he proceeded M.D. with highest honours in 1925. The next year he obtained the D.P.H. (Ed. and Glas.) and in 1940 the M.R.C.P. (London); in 1946 he was elected F.R.C.P. After various hospital appointments, he was successively McRobert lecturer in malignant diseases at Aberdeen (1927-8), lecturer in bacteriology at Glasgow (1928-36), pathologist in charge of L.C.C. group laboratory (1936-45), and director of the Central Public Health Laboratory, Colindale (1946-8). Professor Cruickshank has contributed to medical journals on epidemiological methods in the control of infectious diseases, and he was joint editor of *Control of Common Fevers*. He is also a member of the Central Health Services Council.

Royal College of Obstetricians and Gynaecologists.—At a council meeting on July 27 Sir CHARLES READ was re-elected president, and Professor A. M. CLAYE and Mr. V. J. F. LACK were re-elected vice-presidents. Also re-elected were the hon. treasurer (Mr. A. C. H. BELL), the hon. secretary (Mr. I. M. JACKSON), the hon. librarian (Mr. A. J. McNAIR), the hon. curator of the museum (Mr. R. A. BREWS), the hon. treasurer of the Australian Regional Council (Mr. J. N. CHESTERMAN), and the hon. treasurer of the Canadian Regional Council (Dr. G. A. SIMPSON). Dr. A. M. RUTHERFORD was elected hon. treasurer of the New Zealand Regional Council, and Dr. F. N. CHARNOCK hon. treasurer of the South African Regional Council. Mr. L. G. HIGGINS, of Woking, was admitted to the fellowship, and Dr. J. A. G. DUNLOP (Australia), *in absentia*, to the membership.

British Empire Society for the Blind.—The seventh annual report of the British Empire Society for the Blind is the last which will appear under this title. At its annual meeting in London on July 17, over which Lord Halifax, the president, presided, the Society decided to change its name to the Commonwealth Society for the Blind. This reflected not only the changed status of some of the countries where the Society was engaged, said Lord HALIFAX, but also the hope that other of the older Commonwealth countries would join in the work of caring for the blind in dependent territories, as Canada was already doing in the Caribbean. The Society's annual report for the year ended March 31 describes progress in work for the blind and the prevention of blindness in 30 Commonwealth countries of Africa, the Caribbean, the Mediterranean, and the Near and Far East; it summarizes the Society's entomological and ophthalmic surveys of onchocerciasis, the cause of "river blindness," and undertaken during the last four years in West Africa; and gives an account of 25 associated organizations and of the activities of 55 schools, training centres, and workshops for the blind. On the basis of the two surveys—the Society's major overseas effort during the period—a three-year plan costing £66,000 has been put forward for the control of the Simulium fly vectors of onchocerciasis in the endemic areas of the Volta river system and Northern Ghana. One of the Society's aims is to teach blind people a craft, and training centres for farmers and village craftsmen have been opened in Tanganyika and Nigeria, and already blind students have shown that they can learn rural skills. In Rhodesia and Nyasaland investigations have confirmed that much blindness is due to the use of harmful "native medicines." A list of 53 of these concoctions has been compiled, and government and local authorities are trying to suppress their use. For the year ended December 31, 1956, the Society's income was £45,285, expenditure £43,409. The Society's offices are at 121, Victoria Street, London, S.W.1.

Commonwealth and International Medical Advisory Bureau.—The post of medical director of these two B.M.A. bureaux falls vacant on January 1, 1958. An advertisement inviting applications for the post will be found at p. 14

of the advertisements in this issue. The salary is £2,000 a year, and the post is suitable for a medical officer retired from the armed Services or from H.M. Overseas Civil Service; other candidates, however, are not excluded.

Pernicious Anaemia Survey.—The College of General Practitioners is mapping the incidence of pernicious anaemia in the United Kingdom. The survey is based on information supplied by doctors about the incidence of pernicious anaemia in their own practices, Professor L. J. WITTS, Nuffield professor of clinical medicine at Oxford, is acting as consultant adviser. All general practitioners in the United Kingdom who have not already done so are requested to forward the following information to the College's recorder for this investigation, Dr. E. SCOTT, Suomi, Westwell, Ashford, Kent: (1) number of patients of all ages in the practice; (2) number of cases of pernicious anaemia at present under treatment in the practice; (3) was the diagnosis made locally or elsewhere? (4) nature of practice—whether urban, semi-urban, or rural. (Partnerships should be treated as a single practice; in a practice where there are many visitors, only data about permanent residents are required.) Nil returns are especially important, to prevent an over-estimate of the incidence of the disease. Comments and inquiries to the recorder of the investigation are welcome. All details about practices will be regarded as strictly confidential.

Ionizing Radiations in Industry.—Last week the Ministry of Labour and National Service issued a "preliminary draft" of the "Factories (Ionising Radiations) Special Regulations" (H.M.S.O., price 9d. net). Their purpose is to protect industrial workers against undue occupational exposure to ionizing radiations. The Regulations, which are made under the Factories Acts, 1937 and 1948, are issued in draft so as to permit their thorough discussion, and if necessary revision, before they are further proceeded with. The last date for the receipt by the Ministry of suggested amendments is October 31.

Chemical Additives in Food.—Leading American food lawyers and British food technologists and public analysts met at the Royal Institution, London, on July 26 to exchange views on the control of chemical additives to foods. It was a joint meeting of the Food Law Institute of the United States with the Food Group of the Society of Chemical Industry and the Association of Public Analysts, and authorities from Canada also participated. In the morning session additives other than antibiotics were discussed; in the afternoon the control of antibiotics in food was the subject.

M.R.C.P.—At the quarterly comitia of the Royal College of Physicians of London on July 25, the following were admitted as members of the College:

H. Barrie, M. A. Barrie, T. H. Beare, J. Benecke, S. Bourne, A. J. Bowdler, O. V. Briscoe, J. T. Bruce, R. T. Bush, R. H. Champion, A. de Souza-Lawrence, M. L. E. Espir, J. Evans, A. S. E. Fowle, J. M. French, M. J. Grayson, S. M. Haque, M. T. Harrison, M. Hartog, J. A. M. Henderson, P. S. Hetzel, K. R. Hill, G. A. Hunter, A. F. Huston, G. H. Jeffries, A. D. Jose, K. N. Kanwar, B. E. Kendall, N. A. Khan, D. K. L. Lecamwasam, P. M. Leeson, M. S. A. Memon, J. F. Mowbray, F. M. Narielvala, T. V. O'Donnell, A. G. E. Pearse, D. G. Penington, S. M. Rab, J. V. O. Reid, B. B. Reiss, A. O. Robson, R. Sathasivam, R. H. Scott, J. T. Smyth, T. B. Stretton, V. F. Weinstein, R. S. Williams, R. E. Williams, and A. G. Zaver.

M.R.C.P.Ed.—At a quarterly meeting of the Royal College of Physicians of Edinburgh on July 23 the following were elected members:

W. Blackwood, A. P. Trimble, D. R. Bhasin, C. R. Gopinathan, A. Annamalai, M. M. P. Ryan, D. S. Rastogie, I. B. Munro, F. J. Ratnesar, L. H. Field, B. Benjamin, A. K. Dutta, M. M. Shyamsunder, G. Shabbir, A. K. M. N. Ali, J. G. Robinson, J. Buchanan, M. E. Burns, M. W. Susser, O. K. Hazari, M. A. T. Waters, V. L. Steinberg, M. S. A. Memon, W. R. Murdoch, C. S. Seah, M. E. Barton, V. V. Odak, A. K. N. Sinha, J. M. J. Supramaniam, D. Todd, K. J. Lim, R. W. Charlton, G. G. Habib, T. M. W. Poon-King, J. Benatar, K. R. Shankar, T. R. Kearney, S. D. Kumar, S. Lal, and B. S. Jain.

M.R.C.O.G.—At the meeting of the council of the Royal College of Obstetricians and Gynaecologists on July 27 the following candidates were elected to the membership:

G. Adams, N. Allan, A. A. Allison, J. P. Alvey, R. D. Atvey, S. A. Aziz, J. D. Baeyertz, V. Benatar, G. K. Bernays, W. P. Black, H. D. Chomse, A. Clark, R. B. Conyngham, L. M. Dhadphale, I. P. Dunnett, P. F. M. Due Toit, A. A. Earn, L. Epsztajn, F. M. Fountain, D. Friedberg, D. M. Gratton, D. E. Gunatilleke, A. D. Hewson, B. K. Higgins, V. Hingorani, A. N. Horwitz, M. H. Hutcheon, E. G. Jonas, I. H. Kidd, D. J. Lancaster, M. E. Larg, M. Lesser, C. N. R. Loveys, T. S. Macdonald, C. N. McFarlane, L. Mehta, H. A. Milne, S. Mitra, K. D. Mullen, B. J. Murphy, B. Needham, P. R. Norris, T. C. O'Connor, C. E. Parr, R. P. C. Perrott, P. M. Russell, A. P. Ryan, R. P. Shearman, D. Singh, G. T. Smedley, J. H. Spurway, D. A. Thatcher, G. H. M. Wallace, J. H. Walters, C. Wei, M. B. Wingate, and E. C. Wood.

Carlsberg-Wellcome Travelling Fellowships.—Dr. S. P. LAPAGE, a trainee bacteriologist in the Public Health Laboratory Service, has been awarded this year's Carlsberg-Wellcome travelling fellowship for a British research worker (see our issue of March 30, p. 775). He will study enterobacteriaceae at the State Serum Institute, Copenhagen. The Danish fellow, Mr. JØRGEN BERGER, will work on ultramicroanalysis at the department of chemistry, Birmingham University.

Dr. D. A. Long, of the National Institute for Medical Research, Mill Hill has been appointed visiting professor in microbiology to the University of Pittsburg for 1957-8.

COMING EVENTS

Semaine Médicale de Paris.—September 28 to October 6, mostly at the Salpêtrière. The week includes postgraduate discussions on paediatrics, therapy, internal medicine, medical biology, pulmonary disorders, and endocrinology and dietetics. Details from the secretary, "L'Expansion Scientifique Française," 15, rue Saint-Benoît, Paris, 6.

International Society of Surgery.—Seventeenth Congress of International Society of Surgery, Mexico City, October 20-27. Members of the society are also invited to the meeting of the American College of Surgeons, Atlantic City, October 14-18. Details from Mr. H. W. S. WRIGHT, F.R.C.S., 9, Weymouth Street, London, W.1.

Hospital Equipment and Medical Services.—First International Exhibition, sponsored by the Institute of Hospital Administrators, May 5-10, 1958, Olympia, London. Space available at 16s. and 19s. 6d. per square foot. Details from Contemporary Exhibitions Ltd., 40, Gerrard Street, London, W.1.

International Congress of Orthopaedic Surgery and Traumatology.—Barcelona, September 16 to 21. Details from Dr. JOSÉ M. VILARDELL, Avda José Antonio 654, Barcelona, Spain.

Fifty-fifth French Congress of Otorhinolaryngology.—October 22-25, Paris. Scientific papers, and discussions on cancer of the ear and on tinnitus. An exhibition will be held in connexion with the congress. Details from the secretary, Cabinet Raimond, 17, rue de Buci, Paris.

NEW ISSUES

British Journal of Preventive and Social Medicine.—The new issue (Vol. 11, No. 2) is now available. The contents include: THE STATURE AND WEIGHT OF MEN FROM ENGLAND AND WALES IN 1941. E. M. B. Clements and Kathleen G. Pickett. RANDOM SELECTION IN THE THERAPEUTIC TRIAL. R. F. Wright. A NOTE ON THE PRACTICAL INTERPRETATION OF 2x2 TABLES. J. H. Edwards. A CRITICAL EXAMINATION OF THE REPUTED PRIMARY INFLUENCE OF ABO PHENOTYPE ON FERTILITY AND SEX RATIO. J. H. Edwards. RECENT TRENDS OF MORTALITY FROM VIOLENCE. W. J. Martin. AN EXAMINATION OF FERTILITY OF WOMEN FOLLOWING PREGNANCY ACCORDING TO HEIGHT AND WEIGHT. Thomas McKeown and R. G. Record.

Issued quarterly; annual subscription, £2 2s.; single copy, 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Industrial Medicine.—The new issue (Vol. 14, No. 3) is now available. The contents include:

ASSESSING THE HEALTH OF THE INDUSTRIAL WORKER. R. S. F. Schilling. THE CONTROL OF INDUSTRIAL BLADDER TUMOURS. T. S. Scott and M. H. C. Williams. A ROUTINE METHOD FOR THE PREPARATION OF THE CELLS OF URINE. Philip Roife. THE TESTING OF LIFE-JACKETS. R. R. Macintosh and E. A. Pask. A STUDY OF THE THERMAL ENVIRONMENT IN NON-FERROUS FOUNDRIES. D. Turner. GAMMA RADIOGRAPHY IN INDUSTRY. J. P. W. Hughes and O. Shaw. THE CORROSION OF METAL BY PALMAR SWEAT. K. J. Collins. EXCRETION OF URINARY COPROPORPHYRIN IN LEAD POISONING. PARTS 1 AND 2. Václav Holeček. TRACHEOTOMY IN MAJOR CHEST INJURIES. S. A. Gueukdjian. MISCELLANEA: A HOUSE-SURGEON'S OBSERVATIONS ON BRONCHITIS IN NORTH STAFFORDSHIRE POTTERY WORKERS IN 1864. A. Meiklejohn. "A STUDY OF ATTITUDES TO FACTORY WORK": A REVIEW. H. G. Maule. THE BRITISH OCCUPATIONAL HYGIENE SOCIETY. BOOK REVIEWS.

Issued quarterly; annual subscription, £2 2s.; single copy, 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Friday, August 9

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. N. C. Oswald: clinical demonstration.

APPOINTMENTS

KING EDWARD VII CONVALESCENT HOME FOR OFFICERS AT OSBORNE, EAST Cowes, Isle of Wight.—The following have been reappointed to the Civil Consulting Staff as from June 4: Sir Francis R. Fraser, M.D., LL.D., F.R.C.P., Sir James Paterson Ross, K.C.V.O., M.S., F.R.C.S., W. D. W. Brooks, C.B.E., D.M., F.R.C.P., D. E. Bedford, M.D., F.R.C.P., D. H. Brinton, D.M., F.R.C.P., Sir Arthur Porritt, K.C.M.G., K.C.V.O., C.B.E., M.Ch., F.R.C.S., H. Osmond-Clarke, C.B.E., F.R.C.S., Sir Ralph Marnham, K.C.V.O., M.Ch., F.R.C.S. MICHELL, E. P. G., M.B., B.Chir., M.R.C.P., D.C.H., Senior Registrar in Child Psychiatry, The Tavistock Clinic, London, W.1. SCALES, JOHN T., M.R.C.S., L.R.C.P., Consultant in Orthopaedic Prosthetics to Royal National Orthopaedic Hospital, London. NORTH-WEST METROPOLITAN REGIONAL HOSPITAL BOARD.—P. J. Carter, M.B., B.S., F.R.C.S., L.D.S., D.L.O., Consultant Ear, Nose, and Throat Surgeon, Edware General Hospital; D. M. Brooks, M.B., B.Ch., F.R.C.S.I., Consultant Orthopaedic Surgeon, Barnet General Hospital; R. H. Marten, B.M., B.Ch., M.R.C.P., Consultant Dermatologist, Royal Northern Hospital; R. I. S. Bayliss, M.D., F.R.C.P., Consultant Physician, Mount Vernon Hospital; S. M. Smith, M.B., B.Ch., D.M.R., Consultant Radiologist, Highlands General Hospital; K. V. Robinson, M.D., D.C.P., Consultant Pathologist, Ashford Hospital; G. I. MacD. Ross, M.B., D.P.H., D.C.H., Consultant Geriatrician, Uxbridge and Staines Groups of Hospitals; Dorothea M. Norman-Jones, M.B., B.Chir., D.P.H., D.P.M., Child Psychiatrist (S.H.M.O.), Bedfordshire Child Guidance Service; S. G. Lamb, M.B., Ch.B., D.P.H., Assistant Physician (Infectious Diseases) (S.H.M.O.), South Middlesex Hospital; D. McIntosh, M.B., Assistant Chest Physician (S.H.M.O.), Hounslow Chest Clinic; C. H. Virar, M.R.C.S., L.R.C.P., L.D.S., Senior Hospital Dental Officer, Hillingdon Hospital.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Brooks.—On July 26, 1957, at the Carshalton War Memorial Hospital, to Barbara (formerly Sutton), wife of Jack W. Brooks, M.R.C.S., L.R.C.P., a brother for Jennifer and Michael—Peter John Sutton. Hendrie.—On July 23, 1957, prematurely, in St. Bartholomew's Hospital, London, E.C., to Sylvia (formerly Oakley-Evans), wife of Dr. John Hendrie, a sister for Paul.

MARRIAGES

Binnewald—Cortese.—On July 24, 1957, at All Saints', Margaret Street, London, W., Bertram Binnewald, M.B., Ch.B., of Capetown, South Africa, to Emilia Cortese, M.D., of Naples, Italy. Hoole—Dobbin.—On July 27, 1957, William Hoole, B.Sc., D.T.A., of the Department of Agriculture, Enugu, Eastern Nigeria, to Muriel Janie Warrington Dobbin, M.B., Ch.B., of 14, Belsize Lane, London, N.W.

DEATHS

de Boissiere.—On July 4, 1957, Raoul Ferdinand de Boissiere, L.R.C.P.S.E., of Remuera, Auckland, New Zealand, aged 77. Claridge.—On July 13, 1957, George Percival Charles Claridge, M.B., of 4, Quebec Road, Norwich, aged 77. Conlon.—On July 17, 1957, at 911, Hyde Road, Gorton, Manchester, Peter Conlon, M.B., Ch.B., B.A.O. Housfield.—On July 12, 1957, Mary Isabella Housfield, M.B., B.S., of 32, Lansdowne Road, Tunbridge Wells, Kent. Johnston.—On July 9, 1957, David Johnston, M.B., Ch.B., of 63, Shrewsbury Road, Birkenhead, aged 65. Millard.—On July 4, 1957, in Dublin, Alfred Sutton Millard, M.B., Ch.B., D.P.H., aged 79. Pratt.—On July 10, 1957, at Salcombe, Francis Young Pratt, M.D., of 9, Bryngwyn Road, Newport, Monmouthshire. Robinson.—On July 15, 1957, at Coedmor, Abersoch, Pwllheli, N. Wales, Harold Robinson, L.M.S.S.A. Wood.—On July 11, 1957, at Kington Rectory, Grantham, Lincs, Mary Catherine Wood (formerly Elliott), M.R.C.S., L.R.C.P., aged 59.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Transvestism

Q.—What is the modern explanation of transvestism? A happily married and socially responsible man, aged 34, admits to this "overwhelming urge." He appears to have no other sexual aberrations or abnormal personality traits. How should such a case be managed, and what prospects of cure does treatment offer?

A.—Transvestism is a complex behaviour pattern combining features of homosexuality, fetishism, and exhibitionism. In its typical form it occurs almost exclusively in males. The transvestite dresses himself and usually masturbates in female clothing, thus acting as a woman in possession of male genitals. In this sexual act female clothing plays the part of a fetish—i.e., of an inanimate object on to which sexual interest normally centred on the genitals of the other sex is displaced. What gives fetishism—and transvestism in particular—its peculiar character is the degree of apparent isolation of a pattern of behaviour which otherwise occurs only in dreams or fantasy, or psychosis, from the rest of the personality, which as a rule seems well adjusted. This discrepancy has been regarded as a manifestation of the psychological mechanism of splitting of the personality which, if it affects behaviour more generally, characterizes schizophrenia. It has been said that transvestites and other fetishists have a special technique of exploiting the mechanism of splitting by which they usually avoid psychosis. It seems that transvestites are nearer to psychosis than other pervers, and some are in fact schizophrenics.

The patient described in the question sounds quite typical. The number of transvestites who have been subjected to psychoanalysis must be very small, because they tend to keep their perversion secret. No statistical data about results of their perversion are therefore available. This man ought to be treated with psychoanalysis or, if this should not be practicable, by psychoanalytically orientated psychotherapy. Such treatment should at least be a help to him in preventing his perversion from damaging him socially and threatening the precarious balance of his personality. These patients usually suffer from guilt and fear and benefit from psychological support even if they cannot be cured.

Tests for Thiamine Deficiency

Q.—Is there any simple clinical test, such as a urine estimation, for clinching a diagnosis of suspected thiamine deficiency?

A.—There is no simple test for clinching a diagnosis of suspected thiamine deficiency. Oldham, Davis, and Roberts¹ have, however, found that the thiamine excreted in a 24-hour specimen of urine varies with the amount consumed in the diet. In those having 295 µg. thiamine per day the output was found to be 22 µg. in 24 hours, and this varied with different diets up to the point at which those having 4,900 µg. in the diet excreted 805 µg. in a 24-hour specimen of urine. Najjar and Holt² have also devised a test in which estimations are carried out of the thiamine present in the urine excreted during the first hour of the day after rising. In those on a poor diet the amount is less than in those who are well nourished. A further test described by Williams *et al.*³ is to administer 1 mg. thiamine subcutaneously and to collect urine for four hours subsequently. In those who are well nourished 50% or more of the thiamine will be recovered during this period, whereas in those suffering from thiamine deficiency the amount in the urine will probably be less than 30-40%. The estimation of thiamine in the urine is, however, not a simple procedure, and most methods require the use of fluorometric apparatus.

The more customary method of assessing thiamine deficiency is to carry out a pyruvic acid tolerance test such as that described by Williams *et al.*⁴ In those who are thiamine-deficient pyruvic acid accumulates in the blood after the administration of a standard amount of glucose to a greater extent than in those who are well nourished. The estimation of pyruvic acid is, however, again not a simple procedure and certainly the technique is unsuitable for use in clinical side rooms.

Missed Kernicterus

Q.—It is clear that exchange transfusion should be performed for erythroblastosis as soon as possible in order to prevent kernicterus. Occasionally a "missed" case is seen for the first time after several days. Recently an infant was seen at the age of six days with neck stiffness, jaundice, and laboratory evidence suggesting ABO incompatibility. Would exchange transfusion at that time be of value in reducing the ultimate degree of neurological damage?

A.—In mature infants with haemolytic disease of the newborn the bilirubin level is usually falling rapidly by the sixth day of life and therefore exchange transfusion is seldom worth while.

Once some definite neurological sign—such as neck stiffness—has appeared, the infant is almost sure to have permanent cerebral damage. In these circumstances it is very difficult to say whether an exchange transfusion is justified. Transfusion may simply prolong survival without arresting the damage to the brain. If, however, the degree of cerebral damage is related to the duration of the brain's exposure to very high bilirubin concentrations, then exchange transfusion would be worth doing even if there was already evidence of cerebral damage. Perhaps the best course is to try to relieve deep jaundice by exchange transfusion except in the presence of really severe neurological signs.

Cyanocobalamin in Pernicious Anaemia

Q.—(1) How often and in what dosage should cyanocobalamin (vitamin B₁₂) be given for treating cases of pernicious anaemia (a) with symptoms, (b) with no symptoms but a haemoglobin level below 100%, and (c) for maintenance therapy? (2) Is there any reason against diminishing the frequency of treatments by increasing the dose? If not, should the dose be increased by the same factor as the interval between treatments is increased, or is the relationship not so simple? (3) Are there any other possible advantages to be gained by increasing the dose of cyanocobalamin above those recommended in answer to the first part of this question?

A.—(1) (a) There is no rule about this; in a very severe case transfusion may be necessary. The sort of dosage that should be used is 100 µg. of cyanocobalamin on each of the first two days intramuscularly, then 100 µg. twice weekly for two weeks, and 100 µg. weekly until the blood count is normal. Alternatively, since undoubtedly the tissues are depleted of something like 2,000 µg. of vitamin B₁₂, it is theoretically correct to give larger doses of the order of 1,000 µg. in each of the first four or five injections, although much of this (about 800 µg. of each dose) is lost in the urine. Clinically, patients appear to do quite well on the first regime, but the second regime might be preferable in patients with neurological complications. Iron therapy should be given in addition in the initial treatment of pernicious anaemia. (b) If there are no symptoms, presumably the case is a less severe one with a relatively high blood count. There is no harm in giving more, but 100 µg. of cyanocobalamin might be given twice weekly until the blood count is normal. (c) For maintenance therapy many clinics give 100 µg. of cyanocobalamin every three weeks, but some give twice this dose and it does not appear to make much difference. If subacute combined degeneration is

present it would be wise to give as maintenance 100 µg. twice weekly for a month and then weekly for a year, and thereafter 200 µg. every three weeks.

(2) There is a limit to the extent to which the frequency of treatments may be diminished by increasing the dose. Probably 500 µg. of cyanocobalamin every month would be satisfactory, but many patients say that they feel better with injections every three weeks. This is possibly, though not certainly, a psychological effect. The relationship between dosage and frequency of injections is rather complex and depends largely upon the proportion of the dose that is immediately excreted in the urine. There is individual variation in this.

(3) The possible advantages that might be gained by increasing the dose have been suggested above. In the initial treatment one desires to fill up the tissue stores, and, where there are neurological complications, as has already been said, the dosage should be greater.

Thyroid and Dieting in Obesity

Q.—(1) *An otherwise healthy obese patient is fed up with dieting. Can his weight be controlled by drugs alone—e.g., with thyroid extract—and, if so, is this a safe procedure?* (2) *To what extent may obesity be the result of "sluggish metabolism"? If the B.M.R. is on the low side, is this a clear indication for thyroid therapy, in addition to any dietetic or other measures?*

A.—(1) There is no substitute for calorie restriction in the management of obesity. Euthyroid subjects are less sensitive to thyroid medication than hypothyroid subjects, but may show evidence of hyperthyroidism, including weight loss, with large doses. Hyperthyroidism is even more uncomfortable than dieting and carries a prohibitive risk of coronary insufficiency. Appetite can be reduced with dexamphetamine sulphate, 5–10 mg. half an hour before meals.

(2) The majority of obese subjects have normal thyroid function. This is not inconsistent with a B.M.R. "on the low side," for in calculating the B.M.R. not only may the muscle mass be relatively low but the estimation of surface area from height and weight is difficult in very fat or thin people. Thyroid is not indicated unless other clinical and laboratory evidence of hypothyroidism is present.

Urinary Odour after Tinned Meat

Q.—*After eating tinned meat there is an unpleasant metallic odour in the urine. What is its cause, and does it indicate anything harmful?*

A.—Several foods contain aromatic materials which pass more or less unchanged into urine and other secretions, giving characteristic odours. This is particularly troublesome with cows, because their milk may develop an unpleasant flavour. Of foods eaten by human beings, asparagus gives a characteristic odour to urine not unlike that of violets.

After eating canned corned beef there is a characteristic aromatic odour in the urine. The odour appears within an hour or so after a meal, and persists, according to the amount of material eaten, for some hours. The exact nature of the substance responsible for the odour is, so far as I am aware, unknown, but it is presumably an aromatic compound formed probably as a result of the procedures used in processing. The odour has no harmful significance.

NOTES AND COMMENTS

Early Symptoms of Parkinsonism.—Dr. A. S. COOK (Uxbridge) writes: Your answer to this question ("Any Questions?" June 29, p. 1541) does not accord with patients seen in general practice. Long before tremor or rigidity there are symptoms of loss of muscular power, loss of concentration, and tendency to sleep at unusual hours. There are also marked emotional changes with hysterical outbursts. All these may be prevalent for some years before any physical signs can be recognized by the neurologist.

OUR EXPERT replies: I cannot accept that there are symptoms of loss of muscular power long before tremor or rigidity; weak-

ness is not a part of the picture of Parkinsonism at any stage, except terminally. Loss of concentration is no part of the picture of this disease except in the form resulting from cerebral arteriosclerosis, and the same applies to "emotional changes with hysterical outbursts." There are about 30,000 Parkinsonian patients in Great Britain at any one moment, so that on average a general practitioner is unlikely to have more than one or two of them in his practice. Your expert, however, has recently had the advantage of reviewing from many angles 200 personal cases, seen since the second world war.

Rupture of Membranes in Concealed Accidental Haemorrhage.—Mr. J. SOPHIAN, F.R.C.S. (London), writes: In your answer in "Any Questions?" under this heading (*Journal*, June 22, p. 1483) you have failed to make it clear that the improvement that ensues in the state of the associated shock by this method is essentially due not to the delivery of the placenta and membranes that you hint at but to (a) the removal of the uterine stretch factor—the foetus, and (b) the cessation of active uterine contractions, both of which by provoking the utero-renal reflex are responsible for renal ischaemia and its accepted sequel cortical necrosis. Of this ample proof has been provided by the Dublin obstetricians who not only rupture the membranes promptly in this condition, but equally promptly, if oliguria threatens, make use of splanchnic block—in spite of its reputed risk of enhancing shock. That renal ischaemia is a factor both in the production of shock and in causing anuria has been further demonstrated recently^{2,3} and there is much evidence now collected to establish its aetiological significance in these two states. A correct assessment of the therapeutic effect of rupture of the membranes would ensure that the damaging effect of the stimulus provoking the utero-renal reflex is correctly appreciated and would lead to a fuller realization of its significance, to which you appear to allude begrudgingly.

- ³ Végheley, P. V., Hársing, L., Laszlo, K., *Lancet*, 1956, 1, 581.

OUR EXPERT replies: Mr. J. Sophian's thesis is, as yet, by no means proved and generally accepted. It was not mentioned in the original answer because of this and because the need for brevity made it necessary to keep to essentials. If the state of shock associated with concealed accidental antepartum haemorrhage were caused entirely by tension in the uterus, then rupture of the membranes should cause an immediate and dramatic improvement in the patient's condition. This is not the case; usually the shock does not disappear completely until the placenta and blood clot are delivered. Moreover, rupture of the membranes does not, unfortunately, always prevent the occurrence of bilateral cortical necrosis. The evidence so far available suggests that this renal complication, resulting as Mr. Sophian emphasizes from ischaemia of the cortex associated with shock, occurs very early in the disease—at the very inception of shock. Unless, therefore, the patient is already in hospital at the onset of haemorrhage, treatment by rupture of the membranes, by splanchnic block, or by any method is probably too late to prevent cortical necrosis, even though it reverses the renal ischaemia.

DETERMINATION OF SUCCESS AFTER MITRAL VALVOTOMY ROLE OF CIRCULATORY OBSTRUCTION OF THE MYOCARDIUM AND OF OTHER FACTORS

BY

PATRICK MOUNSEY, M.D., M.R.C.P.

Sherbrook Research Fellow, Cardiac Department, London Hospital

The object of this paper is to describe the progress during two to six years of patients following mitral valvotomy for mitral stenosis at the London Hospital, and to emphasize the relative importance of circulatory obstruction, the state of the myocardium, and other factors in determining clinical improvement after operative treatment.

Description of the Material and the Investigation

One hundred patients, operated upon by Mr. Vernon Thompson and Mr. Geoffrey Flavell and under the care of the cardiac department, were followed before, during, and after operation by one observer. There were 71 women and 29 men in the series and their ages varied between 17 and 55 years. Fifty-six patients were in sinus rhythm before operation and the remainder in atrial fibrillation. In 68 patients the width of the heart was less than half that of the chest, measured in a postero-anterior radiograph, while in the remaining 32 patients it equalled or exceeded this measurement. Significant pulmonary hypertension was present in 47 patients. Associated valve defects, complicating dominant mitral stenosis, included mitral incompetence which was slight in 30 and considerable in 10 patients, aortic stenosis in 3, and aortic incompetence which was judged to be slight in 17 and moderate in 5. In addition 7 patients had pulmonary incompetence from pulmonary hypertension. No patient with tricuspid stenosis or organic incompetence before operation was included in this series. Severe emphysema and chronic bronchitis were present in four patients.

A detailed history was taken; this not only provided a subjective account of the patient's exercise tolerance but also afforded an opportunity of getting to know the patients, and their reaction to the disease, which was thought to be an important factor in the selection of patients for mitral valvotomy. In addition, in 47 patients pre- and post-operative exercise tests were carried out, the patient being tested on his ability to climb the hospital stairs.

Clinical examination included an electrocardiogram, using the standard leads and CR leads 1, 4, and 7, with the addition of full circumferential V leads in patients with doubtful right ventricular hypertrophy. Teleradiograms were obtained in every patient and each patient was screened, special care being taken to recognize calcification of the mitral valve. Phonocardiograms were recorded before and after operation in 68 patients.

Cardiac catheterization was carried out in 10 patients, and was reserved for those in whom some adverse complicating lesion was present or suspected.

While in hospital awaiting mitral valvotomy, patients, including those in sinus rhythm, were given full doses of digitalis in order to prevent a rapid heart rate, should atrial fibrillation occur during or shortly after operation. A mercurial diuretic was given where indicated. A strict low-salt diet was in general avoided before operation, in the belief that it predisposed to serious electrolyte disturbances during the immediate post-operative period.

At operation a careful appraisal was made of the valve aperture, the state of the valve, and the degree of mitral incompetence, if any. Valvotomy was performed by fracturing the valve commissures with the finger, but in 12 patients the use of a knife was found necessary. Two types of knife were used, that described by Vernon Thompson (1954) and that devised by Brock. After the valve had been split, the resultant relief of stenosis was immediately assessed and the presence of any mitral incompetence looked for.

After operation the patient was followed in the cardiac department, at first at three-monthly intervals and later at intervals of six months to a year. The data thus obtained were analysed on the Powers Samas sorting machine, for in this way it was hoped that the many variables in the clinical picture could be more readily integrated.

General Progress after Mitral Valvotomy

Before discussing individual factors which may have been responsible for success or failure, a description is given of the progress of the group of patients as a whole following mitral valvotomy. In addition there is a short account of the patients who died following operation.

General Note on Grading of Effort Tolerance.—Five grades of effort tolerance were recognized: very good, when the patient was able to lead an almost normal life, indulging in active sports; good, when he could live a normal working life, avoiding strenuous exertion; moderate, when activities were restricted to light household duties in the case of a woman or to light work in the case of a man; poor, when the lightest duties, such as cooking and dusting, could be performed only with difficulty; very poor, when the patient was either completely or partially confined to bed or was in chronic congestive failure.

The overall general improvement during the first two years after mitral valvotomy is shown in Table I, where the patient's exercise tolerance before and after operation is compared. Whereas before operation most patients could only do light work, such as cooking and dusting in the case of the housewife or relatively light work in the case of a man, after operation they were

TABLE I.—Relationship Between Pre- and Post-operative Grades of Effort Tolerance in 92 Patients in First and Second Years After Operation; Also in 55 Patients in Third to Fifth Years

Post-operative Grade	Pre-operative Grade				
	Very Good	Good	Moderate	Poor	Very Poor
3rd to 5th Years (55 Cases)

Very good	—	2	3	9	1
Death within 3 months	—	—	—	6	2

able to resume full duties, provided they avoided heavy manual exertion. Relief of other symptoms closely paralleled the improvement in effort tolerance. Thus paroxysmal nocturnal dyspnoea which was present in 52 patients, haemoptysis which occurred in 50, and cardiac pain which was present on effort in 32 patients were completely abolished in every patient, whose effort tolerance was also satisfactorily improved.

Those who were least incapacitated before operation obtained a higher proportion of very good and good results. Nevertheless, the relative improvement of some of the more severely handicapped was very impressive and the operation seemed equally worth while if it enabled bedridden patients to return to an ambulant fuller life, even though their effort tolerance remained relatively poor. Severe disablement before operation, however, did not necessarily mean that a good or even a very good result could not be looked for, and one patient, who was in congestive failure before operation with tight mitral stenosis, obtained a very good result, being able once again to follow his previous hobby of long country walks.

Fifty-five patients have been followed for three to five years since operation. In general the initial improvement seen in the first two years was maintained in the third to fifth years (Table I). Fourteen patients, however, deteriorated. No correlation was seen between this late deterioration and the degree of incapacity before operation, for those who had been most severely incapacitated before operation showed no greater tendency to regress than other groups.

Patients Who Have Died Since Operation

Four patients died within three days of operation. Cerebral embolism resulting from extensive intra-atrial clot was the cause of death in two of them: in one, recurrent emboli followed after the first 24 hours, whereas in the other the embolus occurred at the time of operation. Technical accidents contributed to a fatal outcome in the other two patients. In one the valve was approached through the left common pulmonary vein because of clot in the atrial appendage; the vein tore during the valvotomy and the patient died of ventricular fibrillation on the opera-

ting table; at necropsy she was also found to have a cerebral embolus. In the other the valvotomy became impacted in the valve orifice and severe haemorrhage resulted.

Four patients died within the first three months. Technical anaesthetic difficulties were probably responsible for the death of one, who had a second operation for post-operative haemothorax. Associated aortic stenosis of severe degree caused progressive left ventricular failure in another patient, who was treated by mitral valvotomy alone. In the remaining two patients extreme rigidity of a heavily calcified valve and associated incompetence counteracted the functional improvement resulting from mitral valvotomy.

Seven more patients died within the first five years of operation—three with calcific mitral stenosis and incompetence, three with severe emphysema and bronchitis complicating mitral stenosis, and one from cerebral embolism. They are described below in greater detail in considering the influence of such lesions on progress after valvotomy.

Role of Obstruction, the Myocardium, and Other Factors

Mitral stenosis is by definition an obstructive lesion. The relative importance, however, of obstructive and myocardial factors in the development of symptoms in mitral stenosis has long been a matter of controversy. Sir Henry Souttar (1925) and Cutler and Beck (1929), in their pioneer work in the surgical treatment of mitral stenosis, believed that the obstruction at the mitral valve was of dominant importance; others, including Sir Thomas Lewis (1946), held that cardiac enlargement and the cardiac reserve were the most important factors. Although since the era of mitral valvotomy the importance of obstruction at the mitral valve is no longer questioned (Baker *et al.*, 1950), there remained to be decided the relative importance of the state of the myocardium (Harvey *et al.*, 1955) and of general factors, including age and rhythm, and of pulmonary hypertension, which is an additional obstructive factor. It is now proposed to describe each of these, to consider their influence on clinical improvement after mitral valvotomy, and to try to assess their relative importance.

The obstructive effects which are considered are the degree of mitral stenosis, the increased functional stenosis produced by rigidity of a heavily calcified mitral valve, the presence of associated aortic stenosis, and the presence of complicating pulmonary hypertension.

Degree of Mitral Stenosis

In the assessment of the degree of stenosis the most reliable clinical guide was found to be the amount of breathlessness on effort, although auscultatory and radiological signs provided valuable confirmatory evidence. Effort

FIG. 1.—Correlation of the pre-operative effort tolerance with the length of the mitral valve diameter as estimated by the surgeon at operation (96 patients).

tolerance was assessed on a careful history, and a simple exercise test helped to distinguish functional from organic dyspnoea in nervous patients. The relationship between the long diameter of the mitral valve estimated at valvotomy and the effort tolerance is shown in Fig. 1.

In patients with pure mitral stenosis a definite correlation was found between the grade of exercise tolerance and the size of the mitral valve orifice. It will be seen that most of the patients with a poor or very poor exercise tolerance were found to have a mitral valve whose long diameter was between 0.75 and 1 cm. In seven patients, on the other hand, in whom rigid calcific stenosis with complicating incompetence was present, a more severe degree of breathlessness was met in relation to the length of the diameter of the mitral valve, for the measurement gave no index of the amount of functional stenosis from immobility of the valve cusps nor of the amount of incompetence. In the remaining 12 patients, complicating lesions were present which contributed to their breathlessness, and these included aortic stenosis, aortic incompetence of moderate degree, emphysema, and bronchitis and functional dyspnoea. No direct relationship, therefore, existed in this group between the degree of breathlessness and the size of the mitral valve.

In this selected series the heart sounds and murmurs were found to give qualitative rather than quantitative information about the state of the mitral valve, and detailed estimation of their characteristics and timing in the phonocardiogram did not afford accurate information about the size of the mitral valve orifice.

Radiological evidence of hilar clouding and of interlobular lines (Kerley, 1933; Short, 1955) provided confirmatory evidence of significant stenosis, but in this series were not found to correlate directly with the valve size at operation.

Neither the volume of the pulse nor the level of the blood pressure was found to be a reliable indication of the degree of mitral stenosis, although in general the pulse was small and the systemic pressure low or normal in the presence of tight stenosis.

In assessing the degree of splitting and surgical enlargement of the mitral valve, the subjective nature of the impressions of the operator makes it difficult to compare directly the findings of one operator with those of another. In this connexion, therefore, only the findings in the 60 patients operated upon by one surgeon (V.C.T.) are discussed. The size of the mitral valve orifice pre-operatively was not found to influence the ultimate size obtained by valvotomy. The amount of valvular distortion, however, including shortening of the chordae tendineae, fusion of the musculi papillares to the valve cusps, and of calcification of the valve, must predetermine to a large extent the success obtainable by valvotomy. Surgical technique, on the other hand, and in particular the degree of splitting aimed at, varied during this series, and, whereas enlargement of the valve to a length of 2 cm. was considered adequate initially, later every effort was made to attain a length of at least 2.5 to 3 cm. For this reason a knife was used more frequently in the later patients in this series.

During the first two years after valvotomy patients appeared to do equally well, irrespective of the amount of enlargement of the orifice obtained at valvotomy. The initial improvement, however, was not maintained in those patients whose valve had been less fully split, in the third, fourth, and fifth years after operation (Table II) (Baker *et al.*, 1955). It is probable that there is a critical size of the mitral valve orifice, when the length is about 1 cm., and below this a marked increase in the left atrial pressure and results and symptoms develop. Even a small increase in size of the valve above this critical measurement will relieve symptoms by reducing left atrial pressure. The deterioration seen in the group with an incomplete valvotomy probably indicated some re-stenosis, whether from refusion of the commissures or from increasing rigidity of the valve due to fibrosis or calcification. It is possible that the same process may have taken place in some of those in whom

TABLE II.—Correlation of Length of Mitral Valve Diameter Achieved After Valvotomy With the Post-operative Grade of Effort Tolerance in Short- and Long-term Follow-up Periods. 33 Patients Operated Upon by One Surgeon (V.C.T.) and Followed for at Least Three Years After Operation

a more complete valvotomy was obtained and who have remained symptomatically well, the valve orifice being still above the critical measurement. Apart from one patient with a heavily calcified mitral valve, with some complicating incompetence, no patient whose mitral valve had been enlarged to a length of 2.5 cm. or more deteriorated during the first three to five years after operation.

Two patients treated by a second valvotomy had deteriorated after initial conspicuous success following the first valvotomy. One had the second operation four years after the first, and a good split of the anterolateral commissure was obtained. Once again the patient was greatly benefited, and, although in pulmonary oedema before operation, was able to return to a normal quiet life. The second patient had a second valvotomy two years after the first operation and was again improved. The repeated improvement following two valvotomies in these patients suggested that obstruction at the mitral valve contributed materially to their symptoms, although each in addition had severe pulmonary hypertension, which was an additional cause of breathlessness.

Calcification and Rigidity of Mitral Valve

Calcification of the mitral valve, when extensive, could always be recognized on screening or on a penetrating radiograph, but lesser degrees could only be diagnosed on palpation of the valve at operation. Auscultation added further confirmatory evidence of the extent of the calcification, a soft or absent opening snap and soft or normal first heart sound being related to extensive calcification of the valve, as estimated at operation (Fig. 2).

Extensive calcification was commoner in men in this series, 12 of the 29 men showing it, but only 8 of the 71 women. Calcification, on the other hand, was not related to the length of valve diameter, the age of the patient, a history of rheumatic fever, or the duration of symptoms.

Mitral incompetence of considerable degree was a more frequent complication of dominant stenosis where extensive

FIG. 2.—Correlation of the loudness of the first heart sound and of the opening snap with calcification of the mitral valve as estimated at operation (100 patients).

calcification was present (Fig. 3) (Wood, 1954; Belcher, 1956). There were seven patients with calcific, stenotic, and incompetent valves. In the three patients in this group who have come to necropsy it was seen that incompetence resulted from irregularity of the margins of the heavily calcified cusps, which could not therefore close during ventricular systole (Fig. 4). It was not due to shortening and retraction of the cusps, as in isolated mitral incompetence, and in only one of the three patients was the incompetence of sufficient degree to give rise to left ventricular hypertrophy. All these patients had an apical pansystolic murmur, which proved to be the only reliable sign of mitral incompetence complicating dominant stenosis in this series (Mounsey and Bridgen, 1954).

MITRAL INCOMPETENCE

A minor degree of calcification was not found to be an adverse factor after mitral valvotomy. In fact, splitting of the valve was sometimes easier when it was brittle from calcification than when it was tough from fibrosis.

In patients with extensive calcification, rigidity of the valve cusps prevented the full separation in diastole which freeing of the commissure at valvotomy would otherwise have allowed, stenosis being due as much to the rigidity of

the cusps as to their fusion (Sellors *et al.*, 1953). The long-term results of operation in this group have been poor, although some patients obtained considerable temporary improvement for one or two years (Table III). Those with

complicating mitral incompetence had the worst results, and five of the seven patients with this combined lesion have now died in congestive heart failure, two within the first three months, one within two years, and two within four years of operation. In one of these patients a second valvotomy effected a second period of temporary improvement, which was again followed by deterioration a year and a half later. At necropsy the valve orifice was seen to be 3 cm. in length and crescentic in shape, but the cusps were so rigid, especially the anterior, that no effective opening or closure of the valve could take place and extreme functional stenosis as well as moderate incompetence was present. Of the 13 patients with a heavily calcified mitral valve but no incompetence, four have maintained their original degree of improvement, a further seven patients have deteriorated, and two died within three years of the operation, death being due mainly to emphysema and bronchitis, which complicated mitral and aortic valve disease.

Aortic Stenosis

Severe aortic stenosis complicating mitral stenosis is generally accepted as a contraindication to mitral valvotomy, unless a simultaneous aortic valvotomy is considered (Turner and Frazer, 1956). Relief of the obstruction at the mitral valve causes increased filling of the hypertrophied left ventricle; the ventricle is unable to increase its output through the stenosed aortic valve, and consequently fails.

Three patients in this series had aortic stenosis in addition to tight mitral stenosis. In two it was of only moderate degree and only slight left ventricular hypertrophy was found at necropsy, both patients dying from other lesions—cerebral embolus in one and emphysema and bronchitis in the other.

Clinically the lesion presented as aortic incompetence rather than stenosis, since the basal systolic murmur was soft, owing to the low stroke-output from associated tight mitral stenosis.

FIG. 4.—Calcific mitral stenosis with considerable incompetence. A=Semilunar deficiency in margin of posterior valve cusp, through which incompetence arose. B=Grossly thickened and calcified valve cusps, seen in cross-section. C=Left atrium. D=Left ventricle.

One patient had severe aortic stenosis in addition to mitral stenosis, with evidence of left ventricular preponderance in the electrocardiogram. After successful mitral valvotomy she went into progressive left ventricular failure and died six weeks after operation. Necropsy confirmed the presence of severe aortic stenosis in addition to mitral stenosis.

Pulmonary Hypertension

The presence of pulmonary hypertension was assessed in this series on clinical, electrocardiographic, and radiological evidence. Cardiac catheterization was also carried out in 10 patients. Forty-one patients had severe pulmonary hypertension, judged by a parasternal tap and heave, a loud pulmonary component of the second sound, right ventricular preponderance in the electrocardiogram, with a dominant R wave and T wave inversion in right chest leads, radiographic evidence of great enlargement of the pulmonary artery, and in 16 patients a sound in early systole (Leatham and Vogelpoel, 1954). A further six patients were thought to have pulmonary hypertension, because of their clinical signs and the great enlargement of the pulmonary artery, although the electrocardiogram showed only early right ventricular preponderance. In the remaining 53 patients the resting pulmonary arterial pressure was judged to be normal or only moderately raised.

Pulmonary hypertension was met with in this series only in the presence of severe mitral valve disease, either tight mitral stenosis or calcific stenosis with incompetence. Normal resting pulmonary arterial pressures, however, were also met with in the presence of stenosis of equal severity.

In comparing the post-operative course of patients with and without pulmonary hypertension, allowance was made for other variables, including the amount of splitting of the valve at operation, the presence of calcific mitral stenosis with incompetence, aortic valve disease, and severe emphysema and bronchitis, where this appeared to be an independent disease. When due allowance was made for these, which accounted for most instances of deterioration and death in the pulmonary hypertensive group, there appeared to be little difference in clinical improvement between those with and without pulmonary hypertension during the first two to five years after operation (Table IV). The signs of pulmonary hypertension persisted after operation in all patients,

although in 13 the electrocardiogram suggested that this was of diminishing severity, which was confirmed by modification in the clinical signs. No patient developed right heart failure with oedema from pulmonary hypertension after successful valvotomy, although six had been in gross congestive failure before operation.

Role of the Myocardium

In attempting to determine the role of the ventricular myocardium in clinical improvement after mitral valvotomy two main factors will be considered: first, the possibility of active rheumatic carditis; and, secondly, enlargement and failure of the right ventricle in response to circulatory obstruction.

It is unlikely that active rheumatic carditis played any part in determining the post-operative course of the patients in this series. In only two patients was there clinical evidence of rheumatic fever immediately before the operation, and both have done outstandingly well since valvotomy, which was undertaken as soon as rheumatic activity had subsided. No patient has had a recurrence of rheumatic fever since operation. It should be emphasized, however, that only three patients between the ages of 17 and 20 and six between the ages of 21 and 25 were included in the series, and that, if younger patients were submitted to valvotomy, the possibility of active rheumatic carditis might play a part in determining their post-operative progress.

Left atrial biopsies were taken from 69 patients at valvotomy, but, in these, no correlation was seen between histological evidence of round-cell infiltration or Aschoff's nodules and the post-operative course of the patients. Forty-two patients were shown to have round-cell infiltration in the atrial wall, involving especially the subendocardium, and in five Aschoff's nodules were also present. None of these patients, however, had clinical signs of rheumatic activity and the erythrocyte sedimentation rate was normal in every case. The exact significance of these histological findings therefore remains in doubt.

Generalized cardiac enlargement affords an indication of the reaction of the right ventricle to circulatory obstruction. The generalized enlargement in mitral stenosis in the postero-anterior view is due primarily to right ventricular and right atrial enlargement. No patient with great enlargement of the heart or with a giant left atrium was included in the series. The best overall results from valvotomy were obtained in patients with smaller hearts. Good results, however, were also seen in patients with larger hearts, although only one patient with considerable enlargement achieved the best grade of post-operative result, and she was under 21 at the time of operation (Table V).

It is convenient to consider the associated effects of atrial fibrillation and the patient's age when discussing cardiac enlargement in relation to post-operative progress. Atrial

fibrillation before operation was almost confined to patients over the age of 30. It was more often associated with larger hearts, half the patients who were fibrillating having considerable cardiac enlargement, compared with less than a fifth of the patients in sinus rhythm. In Tables VI and VII and in Fig. 5 the interrelationship between age, heart size, and pre-operative cardiac rhythm and its effect on post-operative progress is shown. It will be seen that the group of patients with small hearts under the age of 35 and in sinus rhythm formed the great majority of those obtaining a very good result from valvotomy, both

in the short- and long-term follow-up periods (Evans, 1956). Good results, however, were none the less obtained in older patients with larger hearts and in atrial fibrillation. The better results in the younger age group reflect in part the greater exercise tolerance which would be expected in normal subjects of this age, whereas the poorer results in the older age group suggest that the length of time during which rheumatic disease had been present affects the final outcome. As might be expected, very good results, in which the patient was able to indulge in sports, were rare among patients who were in atrial fibrillation, for their heart rate is often unstable on exercise, even with adequate digitalization.

Post-operative atrial fibrillation, coming on within the first fortnight of operation, occurred in 25 patients. In 14 no attempt was made to restore sinus rhythm with quinidine, and fibrillation persisted. Of the remaining 11, quinidine was used successfully to restore sinus rhythm in nine and two reverted spontaneously. The rhythm of this group of 11 patients has on the whole proved unstable (Goodwin *et al.*, 1955) and only six have remained in sinus rhythm in the longer-term follow-up period. In only one patient fibrillating before operation was an attempt made to restore sinus rhythm after operation, and this was unsuccessful.

Recurrent attacks of right heart failure with oedema occurred in 22 of the patients before operation. In 14 of these severe pulmonary hypertension appeared to be the

precipitating cause, but in the remaining eight patients electrocardiographic and clinical signs did not suggest that this was the dominant lesion. As a group, patients with a history of recurrent attacks of right heart failure did less well after mitral valvotomy than the remaining patients, who had never been in failure or had had one episode of failure only, but considerable benefit was none the less obtained in many individual patients (Table VIII). Only two

remained in right heart failure after operation, in each of whom some complicating lesion was present—calcific mitral stenosis in one, and severe tricuspid incompetence developing after operation in the other.

Other Factors Determining Success After Mitral Valvotomy

A functional overlay to organic symptoms was seen in six patients before operation. In general this consisted in exaggerating their disability or drawing attention to real incapacity in such a way as to attract attention to themselves and thus remain the centre of interest and attention in the home. Two of these patients were found to have only moderate mitral stenosis at operation, from which the physical disability cannot have been great. It is significant that in five patients the functional symptoms became temporarily worse after the operation, and in two hallucinations and delusions developed in the immediate post-operative period. In only one did functional symptoms improve after operation.

A history of recurrent bronchitis was given by 71 patients. In 67 of these bronchitis was thought to be a secondary manifestation of mitral stenosis, the high pulmonary venous pressure dilating pulmo-bronchial venous anastomoses, and these in turn giving rise to congestion in the bronchial mucosa and predisposing to bronchial infection. In four patients, however, all of whom were men over the age of 30, severe emphysema was present in addition to chronic bronchitis, and in these the chest disease was thought to be an independent primary lesion. Bronchitis was usually worse in the winter, but many of the patients described themselves as "chesty" all the year round. Bronchospasm was a prominent symptom in many, and 14 noticed purulent sputum during bad attacks of bronchitis. Bronchitis was commoner in patients with pulmonary hypertension, being present in 40 out of 47 patients.

After successful mitral valvotomy, 29 patients with secondary bronchitis noticed a marked improvement in the frequency and severity of attacks of bronchitis, and in 12 these ceased altogether. In the long-term follow-up period, however, bronchitis returned in six of the patients and developed for the first time in 17; these patients have lost much time off work, especially during the winter, and their breathing has remained embarrassed by bronchospasm most of the year round. In the four male patients with severe emphysema the symptoms of bronchitis were completely unrelieved by valvotomy: three have now died, and in each the respiratory disease was the major cause of death.

Cerebral embolism occurred in three of the four patients dying at or immediately after the operation. In two calcification in the wall of the left atrium had been seen in the radiograph and in all three thrombosis within the left atrium was extensive. Although temporary carotid occlusion with tapes and digital pressure may lessen the danger of this catastrophe, it cannot completely remove it, and where

thrombosis in the left atrium is found to be extensive an open method of operation with interruption of the circulation will probably prove more successful.

A history of recent systemic embolism, on the other hand, is sometimes an indication for mitral valvotomy, provided extensive atrial clot is not present, since valvotomy diminishes stasis in the left atrium and thus helps to prevent clot formation. Of 10 such patients in this series, in only five of whom intra-atrial clot was found at operation, only one had a recurrence of systemic embolism after valvotomy.

In three patients without atrial clot at operation, systemic embolism occurred for the first time in the immediate post-operative period, possibly from detachment of a small thrombus at the site of incision or of a piece of calcium from the mitral valve in one of them. The arteries affected were the posterior inferior cerebellar, a branch of the retinal, and the popliteal in the third; all three patients have made good functional recovery in the area involved.

Valvular incompetence seldom played an important part in influencing post-operative progress in this selected series of patients with dominant mitral stenosis. Although some mitral incompetence was judged to be present at operation in 40 patients, it was only of slight degree in 30 of these, and appeared to detract from the success of the operation in only the seven patients whose mitral valve was heavily calcified. Mitral incompetence created during splitting of the valve and commissures was felt by the surgeon in four patients and confirmed by the development of an apical pansystolic murmur; the incompetence was slight in all and has not affected post-operative progress. Aortic incompetence, which was slight in 17 and moderate in five patients, was never accompanied by left ventricular preponderance in the electrocardiogram. In only one patient, who also had pulmonary hypertension (Table IV), did aortic incompetence appear to modify the success of mitral valvotomy, the signs of incompetence becoming more marked after operation.

Tricuspid incompetence developed for the first time after operation in six patients. All except one have remained well in spite of this complication, reporting a marked improvement in their breathing since valvotomy; in the remaining patient the tricuspid incompetence has been of sufficient degree to cause gross oedema and symptoms of a low cardiac output. Four of the patients did not show this complication until their first attendance in the out-patient department after valvotomy, but the other two developed signs of tricuspid incompetence during the second week after operation. None had pulmonary hypertension, and hence right heart failure secondary to this was not the explanation of the incompetence. All had fibrillation after operation, although three had been in sinus rhythm pre-operatively. There was no evidence of active rheumatic carditis in this group of patients at the time of operation. One developed a pericardial and pleural effusion with pain, pyrexia, and a raised erythrocyte sedimentation rate in the immediate post-operative period—a syndrome which was met with in 21 other patients in this series and which was thought to be a simple post-operative pericardial effusion (Papp and Zion, 1956).

In each case valvotomy was successful and no special difficulty was encountered in splitting the commissures of the valve.

A possible explanation of the syndrome of post-operative tricuspid incompetence without right heart failure is old rheumatic scarring of the tricuspid valve, which becomes incompetent when the right ventricle is called on to increase its output after removal of the obstruction at the mitral valve. The prognosis appears generally to be good, and patients have not been unduly troubled by the slight ankle oedema which has been present in some of them.

Summary and Conclusions

The progress of 100 patients during two to six years after mitral valvotomy has been examined and an attempt made to assess the relative importance of circu-

latory obstruction, the state of the myocardium, and other factors in determining clinical improvement.

Success after mitral valvotomy, maintained in the long-term follow-up period, was related to the degree of surgical success in removing obstruction to blood flow through the mitral valve. A short-term remission of symptoms was often obtained in patients in whom only a small amount of enlargement of the valve had been effected, but in the third and fourth years many of these patients began to deteriorate.

Calcification of the mitral valve, when extensive, presents an added obstructive factor in mitral stenosis, the stenosis being due as much to rigidity of the cusps as to fusion of their commissures. In the long-term follow-up period most of these patients have had disappointing results, and this was especially so in patients in whom extensive calcification of the stenosed valve was associated with moderate incompetence.

Associated aortic stenosis of severe degree was present in one patient treated by mitral valvotomy alone. Relief of circulatory obstruction at the mitral valve precipitated left ventricular failure and death. Special care should therefore be given to the recognition of this lesion, the physical signs of which may be partly masked by the associated mitral stenosis.

Pulmonary hypertension presents another form of obstruction to the circulation in mitral stenosis. During the two to six years over which patients have so far been observed since operation, the clinical improvement of those with and without pulmonary hypertension has differed little when allowance has been made for other causes of deterioration. Although a proportion have shown electrocardiographic evidence of regression of hypertension, in none has the electrocardiogram returned to normal.

With regard to the myocardium, acute rheumatic carditis has not been seen in any of the patients after operation, and it is therefore unlikely that active rheumatism played any part in influencing the response of the myocardium to circulatory obstruction.

The degree of cardiac enlargement is one index of the state of the myocardium. The best results after valvotomy were seen in patients with smaller hearts, especially where they were young and in sinus rhythm. Satisfactory progress, on the other hand, was often seen in older patients in atrial fibrillation and with larger hearts.

Recurrent right heart failure suggests considerable myocardial damage, and such patients did less well after valvotomy when considered as a group, although some individual patients were improved.

Certain specific factors affected the outcome of surgical treatment directly. A functional reaction to the pre-operative symptoms usually tended to hinder and delay improvement. Bronchitis, although often alleviated by successful valvotomy, has tended to recur in some patients in the long-term follow-up period. Where severe emphysema was present in addition to bronchitis, patients have followed a uniformly downhill course.

Mitral valvotomy in the presence of massive intra-atrial thrombosis was followed by fatal cerebral embolism in three patients, in two of whom calcification in the wall of the left atrium was seen in the radiograph: such patients probably require open operation. A recent history of systemic emboli was considered an indication for valvotomy, since removal of obstruction to the circulation diminishes the likelihood of clot formation, and in only one of 10 such patients did embolism recur after valvotomy.

Associated mitral incompetence did not appear to influence post-operative progress in this series, except in the presence of a heavily calcified mitral valve. With one exception aortic incompetence was not of sufficient degree to modify the success of the operation. Tricuspid incompetence developed for the first time after operation in six patients; except in one case, it did not seriously detract from clinical improvement.

In conclusion, relief of circulatory obstruction at the mitral valve has been shown to be a dominant factor in determining clinical improvement after mitral valvotomy, but enlargement and failure of the right heart consequent on this obstruction, and other factors, including particularly intercurrent emphysema and bronchitis, affect adversely the degree of success achieved by surgical treatment of mitral stenosis.

I thank Dr. William Evans, Dr. Wallace Brigden, Mr. Vernon Thompson, and Mr. Geoffrey Flavell for their help, encouragement, and advice in the preparation of this paper; Professor Dorothy Russell and her staff for the morbid anatomical findings; Mr. John Knight for his patient assistance with mechanical sorting on the Powers Samas machine; the registrars of the cardiac department for their help; and Mr. William Dicks, Mr. Arthur Gallup, Miss Gwen Clarke, and Miss Patricia Archer for technical assistance.

TEETH OF 5-YEAR-OLD LONDON SCHOOLCHILDREN (1955) WITH A COMPARISON OF RESULTS OBTAINED FROM 1929 TO 1955

BY

MAY MELLANBY, M.A., Sc.D.
HELEN COUMOULOS, Ph.D., D.D.S.

AND

MARION KELLEY

With the Assistance of GWENNETH NEAL
(From the Medical Research Council, Hampstead, London)

A survey of the dental condition of 5-year-old children attending London County Council day schools in 1955 was made in continuation of a series begun in 1929 at the request of the Board of Education, and from 1943 until 1951 carried out at two-yearly intervals. As it proved impossible to undertake one in 1953, the latest survey was made only after an interval of four years. References to papers on the earlier work are given at the end of this report.

The schools were scattered throughout the Metropolitan area, and those visited in 1929 were, so far as possible, used for the succeeding surveys. The same probe-and-mirror methods of examination and the same

criteria for structure and caries were employed in all cases. These were developed by one of the authors (Mellanby, 1934), who took a prominent part in all the inspections.

A tooth was said to be hypoplasia-free (Hy₀) when its surface was smooth and shiny. Any roughness was graded according to type and degree, differentiation being made between gross hypoplasia (G-Hy) and M-hypoplasia (M-Hy) (King, 1940). The gross type, which is found in relatively few teeth, is the only one recognized by some dental surgeons; M-hypoplasia, on the other hand, is found in the majority of teeth. A tooth was regarded as caries-free when no disease could be diagnosed by the method of examination employed, and a child was considered to be free from caries only if all its teeth (with the exception of the few naturally shed incisors) conformed to this standard. Any history or evidence of extractions or fillings automatically barred it from this category. When the earliest inspections were made in 1929, very few of the children were free from dental disease, and it was decided by the Board of Education (1931), which was responsible for publishing the results, to bracket with such children any who had up to three teeth which were carious to a very slight degree. Even with this addition, however, only 4.7% could be brought into the so-called caries-free category, now referred to as "caries-free and almost caries-free," a classification which has been perpetuated for the other years in order to make comparison with the 1929 findings possible.

In presenting the results of the various investigations, the surface structure of the teeth is expressed both as the percentage incidence of the different grades of hypoplasia and as the average hypoplasia figure (A.H.F.). The latter, which relates only to M-hypoplasia and gives a rough computation of the extent of this type of defect, is obtained by allotting a number to every tooth in each grade (1 for M-Hy₁, 2 for M-Hy₂, and 3 for M-Hy₃) and dividing the sum of the numbers—that is, the total M-hypoplasia figure for any group—by the number of teeth in the group, excluding those showing gross hypoplasia. Caries is expressed as a percentage incidence and as the average caries figure (A.C.F.), which is estimated in a similar way to the A.H.F. The numbers 1, 2, and 3 are allotted to the carious teeth according to their grading, and the total caries figure is divided by the number of teeth in the group. For both A.H.F. and A.C.F. the maximum possible value is 3; therefore the greater the number of teeth with the more severe grades of M-hypoplasia and caries, the nearer the figures approach to this number.

1955 Survey

In this survey the teeth of 1,205 children were inspected. The tables of results are self-explanatory and need little comment.

Surface Structure

The 21,627 teeth which it was possible to examine for surface texture, amounting to about 90% of the full complement, were graded according to type and degree of roughness. The remainder, which could not be graded, consisted of shed incisors, extracted teeth (mainly molars), and teeth which were too carious or too extensively filled for an estimation of their structure to be made.

In Table I are shown the incidence and extent of M-hypoplasia and the incidence of G-hypoplasia in each type of tooth and in all types taken together. The "pattern" approximates to that found in the previous surveys of the series and in others made in residential homes (institutions)

and private schools. The best structure occurs in the lower incisors (only 15.6% of the centrals and 22.0% of the laterals showing any degree of M-hypoplasia) and the worst in the molars, particularly the upper second (89.7% with M-hypoplasia). The upper incisors, especially the centrals, are much more hypoplastic than the lower. It must again be emphasized that there is altogether a much greater incidence of M-hypoplasia than of gross—59.1% compared with 3.1%.

Caries

Incidence and Extent.—Details of caries incidence and extent in 1955 are given in Table II, and again the "pattern" for each type of tooth and for all types together resembles that found in previous years. Teeth extracted because of caries are included in the severe caries group (C₃), although there is no evidence that they were all necessarily in this category; the total percentage of carious teeth is therefore equivalent to the D.M.F. figure per 100 teeth. Least caries, as well as least M-hypoplasia, occurs in the lower incisors (5.2–5.3%), and most, as is also the case with M-hypoplasia,

in the molars. There is considerably less disease in the upper first molars (41.7% carious) than in the others; the most affected are the lower second molars (70.2% carious), in spite of the fact that these teeth are the last to erupt. According to the above-mentioned standards, 15.5% of the children examined were caries-free and 21.2% "caries-free and almost caries-free" (see Fig. 1).

Superficial Staining of Teeth.—In 1955, as in our previous surveys, children who had black or dark-brown superficial stains on some, at least, of their teeth had, in general, a lower incidence of caries (20.2%) than children with no stains (29.1%), and much less than those with green stains (39.2%) (see Table VII).

Treatment and Natural Arrest of Caries.—There had been an appreciable amount of treatment prior to the inspection of the children, 16.7% having been filled and 11.1% extracted (see Table VIII). On the other hand, 15.0% of the carious teeth observed showed natural arrest. As recorded in these surveys, arrest is not necessarily the final, typical condition mentioned in textbooks, for the surfaces of the cavities,

An urgent appeal to governments, scientists, and industry to intensify research into the global problem of insect resistance has been made by the Technical Conference on Insect Resistance called together by the World Health Organization in Geneva recently. According to a statement issued by W.H.O., in 1946 only two kinds of insects of public health importance, the house-fly and certain kinds of mosquitoes, were resistant to D.D.T. To-day they number 38, among them several species of malaria-transmitting mosquitoes, plague-carrying fleas, and typhus-bearing lice. Countries all over the world have spent huge sums of money to control the great insect-borne pestilences. Faced with the possibility of failure, they have no practical solution for the control of resistant insects except emergency switching from one insecticide to another. But scientists are running out of effective insecticides which are at the same time economic and non-toxic to man, although chemical firms are testing as many as 50,000 compounds a year for their insecticidal properties. The world may soon face an emergency because of the dynamic nature of the resistance problem as opposed to the more static nature of many other scientific and technical problems.

X-ray Examinations.—Barium-meal and follow-through examination carried out elsewhere shortly after the first attack of pain showed the signs of an entero-enteric intussusception of the upper jejunum. Three subsequent barium follow-through examinations were carried out: the first two

produced local effects, particularly in the hypoplastic teeth. Systemic influences due to nutritional and metabolic variations may have affected the composition of the saliva and also have altered the resistance of the teeth to caries. It is now well known that, even after development, living teeth are to a limited extent susceptible to changes in the composition of the body fluids. This was shown by Hevesy *et al.* (1937) in their isotope experiments, and more recently emphasized and greatly extended by Sognaes *et al.* (1955) and by other research workers.

Comments

Is there any reasonable explanation of the rapid improvement in the dental condition of the L.C.C. schoolchildren between 1943 and 1947, as compared with that occurring between 1929 and 1943, and of the increased amount of caries in the later years?

Since there is so much controversy about fluoride, oral hygiene, and sugar, and their possible effects on the problem of caries, a word must be said about them in relation to the children under review.

It is unlikely that fluoride in the water supply played any part, either in the reduction of caries from 1929 up to 1947 or in its subsequent increase, as it has been ascertained that the fluoride content of the drinking-water in the areas from which the children were drawn was low (0.15 to 0.20 p.p.m.) and was constant within those limits for the period covered by the surveys. Nor is the marked improvement in the caries position until 1947 likely to have been due to changes in oral hygiene. There is no evidence of an increased use of the toothbrush, at least during the war and immediate post-war years.

From 1940 supplies of sugar, and from 1942 sweets and chocolates, were controlled in Britain by rationing. There were slight variations in allocations from time to time, but the average supply was very low and more or less constant until after 1947, and indeed continued at a low level until 1951 or after. It seems doubtful, therefore, whether on this basis sugar could have had much bearing either on the progressively lower caries incidence from 1943 to 1947 or on the higher incidence from then until 1951. Although caries continued to increase after 1951, the difference between the incidence in that year and 1955 (during which period sugar and sweets were decontrolled) was not as great as that occurring in the previous four years. It is difficult to see how the presumably greater sugar consumption at this time may have affected the situation; it certainly does not appear that it could have played a major part.

It is our belief that the improvement in dental condition from 1929 to 1947 and the later increase in caries were partly, if not largely, due to nutritional changes that had taken place, especially those affecting the foetus and the young child. The reasons for this view have been fully stated in reports on the earlier surveys, and a brief reference to them will suffice here.

It was a well-known fact prior to the second world war that one of the main defects of the British diet was its poor calcifying quality. When war broke out, necessitating the

rationing of foods in short supply, one of the first steps taken by the Government, on the advice of nutritional scientists, was to direct foods with high calcifying properties to those classes needing them most—namely, expectant and nursing mothers and infants. These measures included priority supplies of milk and eggs, and allocations of cod-liver oil, and later (for expectant mothers only) vitamin D and A tablets as an alternative to the oil. It must be emphasized here that vitamin A, as well as D, is necessary for the normal development of bones and teeth and for increasing the resistance of the dental tissues to disease. In addition, the Government decreed that vitamins D and A should be added to all margarine and calcium carbonate to all flour. The addition of the calcium was necessary because the raising of the extraction rate of the flour from the pre-war level of 70–73% to the wartime level of 85%, or even higher, greatly increased the phytate content, and phytate is known to decrease the availability of calcium in the food. The added calcium served to neutralize the phytate effect, and any excess would help to promote or to maintain the calcification of bones and teeth and to assist other physiological functions which required optimal calcium supplies.

In a report on the 1943 survey it was stated: "It is possible that the elimination of dental caries may not be attainable until its immediate cause is known, but even without this knowledge it is probable that a continuation and extension of the present nutritional policy and its more whole-hearted adoption by the public would bring about further improvement in the architecture of teeth and in their subsequent resistance to decay." This forecast was fulfilled when the findings in the 1945 and 1947 surveys were assessed, for, as has been shown, the structure of the teeth continued to improve and the percentages of caries-free children and caries-free teeth continued to increase above the 1943 level.

After 1947 the picture is not so clear. Though the availability of supplies of foods containing calcium and vitamins D and A may have remained at the wartime level, it is not known to what extent they were used by the mothers and young children. There is some circumstantial evidence, however, that the consumption fell as a wider range of food came on the market with the gradual relaxing of controls from 1948 onwards and the final ending of rationing in 1954. If this were so, then it could, in our view, have been a contributory factor to the increased caries susceptibility of the teeth examined in the later surveys, though there must have been many other factors at work, systemic and local.

Our thanks are extended to many who have helped directly or indirectly with the investigations. We are especially grateful to Dr. W. J. Martin for his kind interest throughout and for his statistical assessment of many of the figures. We would also like specifically to acknowledge our indebtedness to the London County Council and Dr. J. A. Scott for permission to carry out the 1955 survey, to the head teachers and their assistants for the trouble they took to make our visits to the schools such a pleasure, to Dr. E. Windle Taylor, of the Metropolitan Water Board, for information about the fluoride content of water supplies, and to the Medical Research Council for financing the work.

From the Diabetic Clinic, the Middlesex Hospital, London

In 1955 Franke and Fuchs, in Germany, discovered that a sulphonamide, *carbutamide* (1-butyl-3-sulphanilylurea; BZ 55), reduces the blood sugar in normal subjects and in many patients with "mild" diabetes. This type of diabetes usually appears in middle-aged or elderly patients who are or have been overweight, who are relatively resistant to insulin, and who even when untreated rarely become ketotic. The drug is of no value in the treatment of "severe" or "juvenile" diabetes, for which insulin is essential. It frequently causes rashes and neutropenia, and deaths from agranulocytosis, and sulphonamide sensitization with myelocytosis and granulomatosis, have been reported from America (Kirtley, 1957). Carbutamide has now been superseded by a similar compound, *tolbutamide* (1-butyl-3-*p*-tolylsulphonylurea ("rastinon," "orinase," "artosisin," D 860), which is equally effective and apparently much less toxic.

We present here the results of a trial of tolbutamide in 72 patients observed for up to one year. The response of some of them to carbutamide has already been reported (Walker *et al.*, 1956).

Method

The trial was conducted on an out-patient basis. Patients were selected who were not grossly obese and had "mild" diabetes (as defined above) that could not be satisfactorily controlled by calorie and carbohydrate restriction alone. All controlled by calorie and carbohydrate restriction alone. All our patients who were taking carbutamide and a few who were having insulin were transferred to tolbutamide. Those who had been taking insulin were initially given the same dose of tolbutamide. Those who had been taking insulin were given reduced doses for a few days; the injections were then stopped and tolbutamide was started the next day. Patients who had had neither carbutamide nor insulin were observed on a strict low-carbohydrate diet for at least a month, and if their mid-morning blood sugar remained above 200 mg. per 100 ml. they were given tolbutamide. The starting dose for these patients and for those transferred from insulin was 0.5 g. two or three times daily, taken with the main meals. The dose was subsequently adjusted to a maximum of 4 g. daily, according to the blood-sugar response.

Patients transferred from insulin were seen daily during the withdrawal period and for the first week of tolbutamide treatment. Special attention was paid to ketonuria, which was regarded as an indication for stopping the drug and the resuming insulin treatment. Subsequently these and other patients were seen weekly for the first month and then at least once monthly. At each visit a record was made of symptoms, weight, urine, and blood sugar, and blood cell and platelet counts were made monthly, and liver-function tests (serum proteins and electrophoresis, serum bilirubin and alkaline phosphatase, thymol turbidity, serum bilirubin and alkaline phosphatase tests) were performed when treatment began and subsequently every two or three months.

The Patients

Of the 72 patients, 41 had previously been treated by diet alone, 19 were transferred from carbutamide (dose 0.5 to 2 g., mean 1.1 g. daily), and 12 were transferred from insulin (dose 12 to 60 units, mean 26 units daily); 12 other patients, including four in the carbutamide group, had taken insulin at some time.

The age at diagnosis varied between 22 and 78, mean 53 years, and the duration of the diabetes between 1 and 30, mean 6.6 years. Thirty-five of the patients were within 10% of their "expected" weight when treatment was started, 20 were more than 10% overweight, and 17 were more than 10% underweight. Seven patients are known to have been mildly ketotic at some time and five had diabetic retinopathy.

The necessity of following a strict diet was stressed, and the diets prescribed varied from 1,000 calories with 80 g. carbohydrate, to 2,200 calories with 220 g. carbohydrate, depending on the weight and activity of the patient.

Results

Duration of Treatment.—The trial started in July, 1956. Details of the period of observation of patients who are still taking or have stopped taking the drug are as follows:

Treatment in Weeks:	< 14	14–26	27–39	40–52
Still on drug { Transfers ..	0	1	4	7
New cases ..	15	12	10	4
Stopped drug { Transfers ..	4	0	2	1
New cases ..	10	2	0	0

Dosage.—The number of patients receiving different dose levels as a maximum dose and for maintenance in those still on tolbutamide is as follows:

Dose in Grammes Daily	0.5	1	1.5	2	3	4
Maximum	—	19	35	10	7	1
Maintenance	1	15	29	7	1	—

Withdrawals.—Nineteen patients stopped treatment for the following reasons: Resistance (requiring insulin), 2; failure to respond, 6; rash, 2; abdominal symptoms, 4; not required, 1; irregular attendance, 2; returned to insulin at own request, 2.

Blood-sugar Response.—The overall effect of tolbutamide on the blood-sugar levels of the 72 patients is shown in Fig. 1.

FIG. 1.—Overall effect of tolbutamide on the blood-sugar levels of the 72 patients treated. *The latest level is shown only for the patients still receiving tolbutamide.

Of the 53 patients who had not been treated with carbutamide, 7 showed no response, 33 showed an "immediate" response, the blood sugar falling during the first week of treatment, and 13 showed a "delayed" response, the blood sugar falling to a minimum over 12 to 16 weeks, irrespective of changes in weight. Twenty patients (61%) who showed the "immediate" response and 9 (69%) who showed the "delayed" response appear to be satisfactorily controlled by tolbutamide. Examples of the two types of response are shown in Figs. 2 and 3. All patients who had responded to carbutamide did so to tolbutamide, but one (Fig. 4) became resistant to it.

FIG. 2.—"Immediate" type of response to tolbutamide. A. Woman aged 56. Diabetes 4 years. No insulin. Expected weight 131 lb. (59.4 kg.). B. Woman aged 73. Diabetes 26 years. Transfer from P.Z.I. 16 units. Expected weight 127 lb. (57.6 kg.). C. Woman aged 62. Diabetes 4 years. Previous insulin. Expected weight 130 lb. (59 kg.).

FIG. 3.—"Delayed" type of response. A. Man aged 81. Diabetes 30 years. No insulin. Expected weight 145 lb. (65.8 kg.). B. Woman aged 67. Diabetes 1 year. No insulin. Expected weight 119 lb. (54 kg.). C. Woman aged 76. Diabetes 2 years. No insulin. Expected weight 130 lb. (59 kg.).

Relief of Symptoms.—Twenty-six patients complained of diabetic symptoms (thirst 13, polyuria 20, and pruritus vulvae 6). Of these, 23 responded to tolbutamide, and their symptoms were relieved as the blood sugar fell.

Side-effects encountered were: Rash, 2 cases—tolbutamide stopped in each; abdominal pain, 4 cases—tolbutamide stopped in 2; vomiting, 1 case—tolbutamide stopped; activation of duodenal ulcer with melaena, 1 case—tolbutamide stopped. Details of the last case are as follows.

A married man, aged 66, was found to be diabetic in 1951 and was treated with a 1,250-calorie 125-g. carbohydrate diet and

intermittently with small doses of insulin (6-12 units daily). He was admitted to hospital in March, 1957, with an infected foot; at that time he was known to have diabetic retinopathy, cataracts, peripheral neuropathy, and arterial disease. His diabetes was well controlled with a 1,250-calorie 125-g. carbohydrate diet and soluble insulin 6-8 units twice daily. He was transferred to tolbutamide, 0.5 g. thrice daily, but 11 days later he complained of abdominal pain and had a melaena for which blood transfusion was required. The pain was closely related to taking the tablets; it disappeared when the dose was reduced to 0.25 g. twice daily, and returned when it was put up to 0.5 g. twice daily. Tolbutamide was then stopped and the pain ceased altogether. A barium-meal examination showed a small hiatus hernia and a chronic duodenal ulcer. The patient denied previous dyspepsia or melaena.

There was no effect on the white-cell and platelet counts or on the liver-function tests.

Resistance.—Two patients who showed a good initial response failed to maintain a satisfactory blood-sugar level despite increasing doses of tolbutamide, strict adherence to a suitable diet, and failure to gain weight. They were both transferred to insulin treatment. It seems that four other patients are also becoming resistant to the drug.

A married man aged 64 was found to be diabetic in 1955. His symptoms were mild and were relieved by a 1,750-calorie 125-g. carbohydrate diet, but random mid-morning blood sugars remained above 200 mg. per 100 ml. and he was started on carbutamide, 0.5 g. twice daily, in May, 1956. He responded satisfactorily and was transferred to tolbutamide, 0.5 g. thrice daily, in August. After an initial response the blood sugar began to rise and continued to do so despite increasing doses of tolbutamide (Fig. 4). He was admitted to hospital two weeks after

FIG. 4.—Development of resistance to tolbutamide. Case report in text.

stopping the drug and given carbutamide, 1 g. twice daily for 10 days, without any effect on his blood-sugar level. He became mildly ketotic and was eventually stabilized on a 2,250-calorie 225-g. carbohydrate diet with I.Z.S. 44 units daily. His weight was virtually constant throughout.

Failures.—Seven patients showed unequivocal failure to respond to tolbutamide. These include two who had been transferred from insulin treatment and four of the seven who were known to have been mildly ketotic at some time.

Effect on Weight.—Most responsive patients showed an increase in weight, and this was sometimes associated with decreased effectiveness of the drug. The overall effect on weight is shown below:

No. of Patients	Before Treatment	During Treatment		
	Weight as % of "Expected" (Kemsley, 1951-2)	Gained	Unchanged	Lost
20	More than 10% overweight	8 (0)	7 (1)	5 (0)
35	Within 10% of "expected" weight	20 (0)	10 (3)	5 (2)
17	More than 10% underweight	10 (0)	2 (1)	5 (0)

The figures in parentheses give the number of patients in each group who failed to show any response to the drug.

Present Assessment.—In 22 of the 53 patients still taking tolbutamide control is unsatisfactory as judged by a mid-morning blood sugar which is persistently more than 200 mg. per 100 ml. The reasons appear to be: failure to follow diet, 11 cases; response decreasing as weight increases but still not overweight, 6 cases; probable failure to respond, 1 case; probable resistance, 4 cases.

Discussion

The hypoglycaemic sulphonylureas (including carbutamide and tolbutamide) cannot act without physiologically active endogenous insulin (Fajans *et al.*, 1956), and are effective in the treatment of "mild" diabetes only. Patients with "mild" diabetes have demonstrable insulin activity in their plasma (Bornstein and Lawrence, 1951) and pancreas (Wrenshall and Best, 1956), while those with "severe" or "juvenile" diabetes do not.

Ketosis is a feature of "severe" but not of "mild" diabetes. Seven of our patients, although in all other respects "mild" diabetics, are known to have been mildly ketotic at some time, and four of these failed to respond to tolbutamide. Of the 12 patients who were taking insulin until transferred to tolbutamide, two did not respond. We suggest that lack of response is due to inadequate endogenous insulin activity.

The "immediate" and "delayed" types of responses seen in patients not previously treated with carbutamide do not appear to have been reported hitherto. We cannot explain them. So far as can be told from observation of a small number of patients for a relatively short time, there does not appear to be any difference in the ultimate behaviour of the two groups.

The effectiveness of the sulphonylureas (and insulin) decreases as weight increases, but we have confined the term "resistance" to describe an escape from control in patients who continue to follow a suitable diet, who do not gain weight, and who are given increasing doses of tolbutamide. We suppose that it is due to decreasing endogenous insulin production, but do not think that the phenomenon necessarily supports the hypothesis that the sulphonylureas stimulate insulin secretion, as a similar rise of blood sugar is sometimes seen in patients treated by diet alone. Both patients who developed resistance became mildly ketotic, suggesting reduced endogenous insulin activity.

Side-effects are less common and less serious with tolbutamide than with carbutamide. In particular we found no effect on the white-cell and platelet counts and only two patients developed a rash. Both had had a rash with carbutamide and the drug was stopped in each. Tolbutamide has a greater tendency to cause abdominal symptoms than carbutamide. Four patients complained of upper abdominal pain unaffected by meals and antacids, and the drug was stopped in two of them. Treatment was also stopped because of vomiting in one case and because of activation of duodenal ulcer in another.

It is not yet possible to judge whether controlling the blood sugar with tolbutamide will modify the incidence or severity of diabetic "degenerative" complications (retinopathy, cataracts, arterial disease, neuropathy, and nephropathy).

Conclusion and Summary

A study of 72 patients treated with tolbutamide for up to one year suggests that about 50% of patients with "mild" diabetes that cannot be controlled by diet alone will benefit from it.

We feel that, as it is a relatively new drug and its mode of action and possible long-term ill effects are not yet known, tolbutamide should be used cautiously and that patients treated with it should be selected and supervised carefully. It should be given only to adults who are not excessively overweight, whose diabetes cannot

be controlled by diet alone, and who do not become ketotic even when untreated. The response may be evident immediately or only after several weeks.

Patients who respond usually gain weight and must follow a diet restricted in calories and carbohydrates. Increasing weight is often associated with decreasing effectiveness of the drug, but two patients who did not gain weight became truly resistant.

We wish to thank Messrs. Horlicks Limited, who provided most of the tolbutamide ("rastinon"), and the British Insulin Manufacturers, who provided the remainder. We are grateful to the staffs of the Courtauld Institute of Biochemistry and the Bland-Sutton Institute of Pathology for the biochemical and haematological investigations, to Mr. V. K. Asta, who prepared the figures; and to the Clinical Research Committee of the Middlesex Hospital for a personal research grant to J. D. N. N.

Member of the Scientific Staff, Medical Research Council

There is no doubt that the oral antidiabetic drugs, the sulphonylureas, reduce the hyperglycaemia of certain diabetic patients, and it is now certain that tolbutamide (D 860, "rastinon," "orinase," "artosisin") causes far fewer toxic effects than its forerunner carbutamide (BZ 55, "invenol," "nadisan"). These statements are substantiated by many papers which have appeared in several medical journals (see references). In consequence this drug is likely to be more widely used. The following remarks are intended to assist doctors in deciding which patients are suitable for oral therapy. The scheme we give for administration of tolbutamide is based on our experience during the past 18 months.

Selection of Cases

Those patients in whom glycosuria is discovered in middle life are most likely to prove suitable. The chances of successful treatment with tolbutamide appear to be greatest if the patient is over 40 years of age, is obese or thick-set, has not previously received insulin therapy or is adequately controlled by less than 40 units of insulin a day, and has no previous history of diabetic coma or ketosis. We now know that some patients not fulfilling all these criteria may respond, but the following rules are recommended in general practice. Tolbutamide should not be used in children, in patients receiving over 40 units of insulin a day, or in patients who are prone to acetonaemia.

It will be appreciated that tolbutamide is likely to be successful in those patients who in the past have been controlled by diet, either alone or with small doses of insulin. By control we mean that the patient's blood sugar two to two and a half hours after lunch is less than 180 mg. per 100 ml., and that the urine tests performed four times a day before meals show no more than an average of one green ($\frac{1}{2}\%$) result each day. Some of these patients will hear of and request the oral form of therapy, but we do not recommend the doctor to change over to tolbutamide if diet and insulin are satisfactory. However, there are some cases in which such a regime of diet and insulin is impracticable, inconvenient, or ineffective, even with the ancillary services available to a hospital clinic.

Thus some patients cannot follow a diet because they are unwilling to curb their appetite. Other patients are not mentally or physically capable of carrying out the necessary manipulations for measuring and injecting the insulin, so that continuous and close supervision by the district nurse or some responsible relative is required to maintain control. Still other diabetics are so haphazard in measuring insulin and arranging their diet that the danger of hypoglycaemic reactions is always present. Though they are not numerous, these patients are a source of concern, especially if they drive a car or live alone. Oral therapy offers an attractive method for smooth control of their hyperglycaemia.

We have not found tolbutamide of value in the management of so-called "brittle" diabetics—that is, young patients whose hyperglycaemia is inadequately controlled by large doses of insulin (over 80 units a day) but who on such doses run the risk of frequent hypoglycaemic attacks. However, in older patients who cannot be controlled successfully, or who have hypoglycaemic symptoms, tolbutamide may be tried even if the patient does not satisfy all the criteria given above.

Trial and Maintenance of Tolbutamide Treatment

We know of no single test to distinguish which patients will ultimately be satisfactorily controlled by tolbutamide. Under these circumstances a therapeutic trial is necessary for each patient. It is advisable to defer the trial if the patient is temporarily out of control through infection or at the time of an operation. There are no reports of patients being treated with tolbutamide during pregnancy, and we have no experience of this clinical problem.

Arrangements for a preliminary period of observations of one to two weeks should be made. The patient's diet and insulin should be fixed, and instructions given for the urine to be tested for glycosuria four times a day; if sugar is present the urine is also tested for acetone. If definite acetoneuria is found at any time during this preliminary period the patient must report immediately to his doctor for prompt treatment with insulin. Ketosis indicates that treatment with tolbutamide alone is likely to be unsuccessful.

After the preliminary observation period of one to two weeks the patient's diabetic status and the need to start tolbutamide are assessed as follows:

Patients on Diet but No Insulin.—A proportion of these cases lose their glycosuria during the control period. The explanation seems to be that the procedures encourage the careless patient to pay attention to his diet so that no tolbutamide is needed. If the patient shows glycosuria despite the dietary regime, trial of tolbutamide is not difficult to manage. The patient should be seen each evening for assessment, at least during the first week of tolbutamide therapy. Tolbutamide is begun in doses of 2 to 3 g. a day. On the first day two 0.5-g. tablets are taken with breakfast, two tablets with the midday meal, and one to two tablets with the evening meal. Thereafter the dose is one to two tablets three times a day. It is reduced as the hyperglycaemia lessens. Glycosuria usually disappears within the first week, whereupon the dose should be fixed at the minimum which gives adequate control. If glycosuria is not less by the end of the fourth day the dose of tolbutamide may be increased to 1.5 g. three times a day and the trial continued for as long as three weeks.

Patients Controlled on Insulin.—It is advisable to extend the observation period in these patients so that the effect of reducing the dose of insulin can be tested. For those controlled by up to 20 units of insulin a day the dose may be reduced by 4 units a day until mild glycosuria occurs, provided the situation is reviewed each week. In some of these cases it has been found possible to discontinue insulin. For those receiving 20–40 units of insulin a day the dose must be reduced with more caution. These patients are less likely to benefit from tolbutamide therapy, so it is less justifiable to risk loss of control of the diabetic state. The patient should therefore be seen at least twice a week and the dose of insulin reduced by not more than 4 units a day at each visit. If the patient finds more than 1% of sugar in his urine (a yellow or orange Benedict or "clinitest") he should test his urine for acetone, report to his doctor, and return to his previous insulin dosage. Patients receiving over 40 units of insulin a day should be admitted to hospital for the change over to tolbutamide. When the insulin has been reduced so that mild glycosuria occurs regularly, treatment with tolbutamide may be started. The dose given is the same as in those patients not receiving insulin, and the degree of glycosuria from day to day serves as a guide to the effect of treatment. In patients who respond it is usually possible to reduce the insulin by about one-fourth on the second and subsequent days, till by the end of the fifth day insulin is no longer required. If there is no reduction of glycosuria after three to four days the dose of tolbutamide may be increased to 1.5 g. thrice daily.

Patients Uncontrolled on Insulin Therapy.—If the patient is known not to be controlled by insulin therapy, tolbutamide may be started after he has undergone sufficient preliminary observation to ensure that any subsequent effect of tolbutamide, or lack of effect, will be clearly recognizable.

Response to Tolbutamide

The rapidity of response to tolbutamide varies in different patients, so that a therapeutic trial should last for three weeks and be cut short only if there is evidence that the diabetes is getting out of control. This is shown in Fig. 1.

FIG. 1.—Mean results from 10 diabetics whose hyperglycaemia has been controlled subsequently by tolbutamide for up to one year. Two of these had recently shown mild acetoneuria. The rise of mean blood sugar on days 4, 5, and 6 cannot be attributed to reducing the insulin dosage, since it also occurs in patients not on insulin.

which refers to a group of patients who were ultimately controlled for periods of up to a year. It will be seen that in some patients the hyperglycaemia and glycosuria were not finally brought under control until the end of the first week and in others not until during the second or third week. A reduction of glycosuria and hyperglycaemia on the second or third day of treatment does not necessarily indicate that control will be maintained, as is illustrated in Fig. 2.

During the period of substitution of insulin by tolbutamide we have followed the above routine and have been worried

neither by loss of control of the patients' diabetic state nor by the occurrence of hypoglycaemic attacks. Tolbutamide is less likely than insulin to produce a hypoglycaemic attack because its full effect takes place about four hours after administration, by which time the next meal is due.

Maintenance.—If satisfactory control is achieved the patient may be maintained indefinitely on up to 3 g. of tolbutamide daily. Such control should not be allowed to encourage any relaxation of the dietary restrictions.

FIG. 2.—Mean results from 12 diabetics who showed a temporary response to tolbutamide but could not be maintained on it. Five of these patients had recently shown heavy acetoneuria.

Side-effects.—In very few instances so far has tolbutamide had to be discontinued because of side-effects. Skin rashes appear to be the most common complication. They clear within a few days of discontinuing the drug, but antihistamine therapy may be indicated if the patient complains of much irritation. Early reports from the Continent suggested that a gain in weight was to be expected by patients maintained on the drug, but the average weight of our patients on tolbutamide has not increased during nine months or more. Blood dyscrasias, which were the major drawback to treatment with the sulphonamide carbutamide, are rarely seen with tolbutamide, which is not a sulphonamide. Renal damage has not been encountered, but it should be noted that tolbutamide is excreted in the urine as an oxidation compound which, under certain circumstances, gives a coarse flaky precipitate with sulphosalicylic acid and thus might be confused with albumin.

Long-term Treatment

Since clinical trials of tolbutamide were begun by the Hoechst Laboratories in Germany in August, 1955, some 150,000 patients have been treated with the drug in this country, in Germany, and in the U.S.A. for periods of up to two years. Though no one can be certain of the long-term effects of the drug, few other drugs can have had more extensive trials to ensure their safety.

We should guard against the mistake of believing that control of hyperglycaemia and glycosuria indicates cure of diabetes. The main therapeutic problem in the type of diabetes in which tolbutamide is successful is to prevent the progress of such complications as arterial disease, retinitis, neuritis, and renal disease. Insulin probably has some effect in preventing or reducing these complications, though it certainly has not eradicated them. It will be some years before we can assess the value of tolbutamide in the prevention of complications. So far it seems unlikely that it will be more effective than insulin. It will not prevent ketosis or the exacerbation of the diabetic state associated with infection or trauma. In one of our patients the rapid progress

of retinitis and neuritis was not halted during a period of three months, during which time tolbutamide produced satisfactory control of the hyperglycaemia and glycosuria. It is necessary, therefore, to end on a note of uncertainty. Though tolbutamide may effectively control the hyperglycaemia of diabetes mellitus, we have yet to learn its effects on the progress of the underlying diabetic state and the development of diabetic complications.

Summary

Tolbutamide has proved an effective and apparently safe compound for controlling blood-sugar levels in some diabetics, especially the older stable type of patient, but there are no means of deciding which patients will respond satisfactorily short of an actual trial.

Criteria for selecting patients are given together with the details of a scheme which we have found useful in testing the patients' response to tolbutamide.

Previous experience (Bertram *et al.*, 1955; Duncan *et al.*, 1956; Wolff *et al.*, 1956) has demonstrated that the sulphonylurea carbutamide (BZ 55) when given by mouth is capable of controlling the diabetic state in some patients. However, carbutamide was shown to have occasional toxic effects (Duncan *et al.*, 1956; Phemister, 1957), and in view of this fact another sulphonylurea, tolbutamide, is now being tried. Tolbutamide differs from carbutamide in that a methyl group replaces the *p*-amino group. Unlike carbutamide, it is therefore not a sulphonamide.

The present study has been undertaken with the following aims: (1) to assess the value of oral tolbutamide therapy in controlling diabetes, particularly in newly diagnosed cases; and in those patients successfully controlled by the drug, to see whether relapse occurred when this therapy was discontinued. (2) To determine whether tolbutamide behaved as insulin does in lowering plasma amino-acid nitrogen and inorganic phosphorus. (3) To correlate blood tolbutamide levels with the control of sugar in the blood and urine, with particular reference to the administration of tolbutamide as a single dose and in divided doses.

Method

Of 42 diabetic patients selected for trial with tolbutamide, 28 were newly diagnosed and had had no treatment prior to attendance at the diabetic clinic. Not all new diabetics were included; some refused to come into hospital, some had diabetes severe enough to need insulin immediately, while in many the diabetes was so mild that dietary restriction alone was sufficient. Of the diabetics previously diagnosed, two were on insulin but requested tablets, while the other 12 were relapsing or badly controlled on their current dietary regime without insulin.

All patients were admitted to the wards and during the first week were treated by dietary restriction alone. Diets were prepared in the diet kitchen under the supervision of the dietitian, and varied from 1,500 to 2,200 calories daily, containing from 150 to 220 g. of carbohydrate, depending on the patient's height, weight, age, and activity. Patients who showed steady diminution of urinary and blood sugars during this period were not treated with tolbutamide and were excluded from this trial. The remaining 42 diabetics, having shown persistent glycosuria and hyperglycaemia while on the diet, were started on tolbutamide on the eighth day. They were kept in hospital for at least another week and were then seen each week as out-patients. On discharge from hospital the importance of adherence to diet was stressed. Patients were maintained for a total of six weeks on tolbutamide and thereafter for a further six weeks on dummy tablets unless relapse occurred, in which case tolbutamide was reintroduced. After this period out-patient attendances were at fortnightly intervals, and no further tablets were prescribed if control was satisfactory.

The diagnosis of diabetes was confirmed in each new case by a standard glucose-tolerance curve. At each out-patient visit blood was collected from all patients for a haemoglobin estimation, white-cell count, platelet count, and blood-film examination.

The dosage was 3 g. on the first day and 2 g. daily thereafter. In the first 28 patients (referred to as group 1) the whole of the dose was given in the morning at 8 o'clock, whereas in the next 14 (group 2) the dose was divided into two equal portions and given at 8 a.m. and 12 noon.

Blood sugars were estimated by the method of Hagedorn and Jensen (1923). Venous blood was collected at 8 a.m., 12 noon, 2 p.m., and 6 p.m. on each alternate day while in the ward and once at each out-patient attendance.

TABLE I.—Blood- and Urine-sugar Levels for One Week Before and One Week After Beginning of Tolbutamide Treatment

			Blood Sugar (mg./100 ml.)				Urine Sugar (g./24 Hours)

			Range	Range	Range	Range	Range
			6 to -95	30 to -57	143 to -89	163 to -33	0.2 to -45.6

Urine sugar was determined by Benedict's quantitative method (King, 1951). Daily 24-hour specimens were analysed in ward patients and at each visit in out-patients.

Plasma tolbutamide was estimated by the method of Forist *et al.* (1955, personal communication), and two to four samples for plasma blanks were taken from each of 19 patients before treatment was started. Eleven of these were on a single dose of tolbutamide and eight on a divided dose. Blood was collected at 8 a.m., 12 noon, 2 p.m., and 6 p.m.

Plasma amino-acid nitrogen was measured by Folin's method as modified by Danielson (1933) and Frame *et al.* (1943). Blood was taken from 13 group 1 in-patients at 8 a.m., 12 noon, and 6 p.m.

Plasma inorganic phosphorus was determined by the method of Fiske and Subbarow (1925) in 11 group 1 in-patients at 8 a.m., 12 noon, and 2 p.m.

Results

Of 42 patients treated with tolbutamide, 30 responded well, with a return to normoglycaemia, and a complete or almost complete disappearance of glycosuria. Twelve patients responded poorly or not at all. Of the newly diagnosed diabetics, 18 responded well while 10 failed to respond. The age, sex, and centile weights of these patients are set out in Fig. 1, and it can be seen that the majority of patients who responded were middle-aged or elderly, with centile weights lying in the 5-95 range, only three being considerably overweight. Examination of the urine by

FIG. 1.—Age, sex, and centile weights of 42 diabetics treated with tolbutamide. New diabetics: male ♂, female ♀. Previously diagnosed diabetics: male ♂, female ♀. *Centile weights according to Kemsley (1951-2).

Rothera's test during the control period revealed that all the patients who failed to respond had acetone in the urine.

Only one of the successfully treated patients had persistent acetonuria, although some others showed acetone on occasion. The mean blood-sugar and urine-sugar levels were lower in patients who later responded than in those who failed, but there was a wide and overlapping range. The mean reduction of blood and urine sugars in the successful group is contrasted with that in the failures in Table I.

Thirty patients who had been successfully controlled by tolbutamide while in the ward were maintained on this treatment as out-patients for a total of six weeks. Dummy tablets were substituted for a further period before discontinuation of all tablets. Fig 2 shows that seven patients

FIG. 2.—Follow-up of 30 cases after discontinuance of tolbutamide. New diabetics: male ♂, female ♀. Previously diagnosed diabetics: male ♂, female ♀.

relapsed when tolbutamide was stopped, six within the first two months. All but one of the seven had had previous treatment for diabetes. Two had been treated with insulin immediately before the trial and four had had insulin in the past. The one new patient had responded slowly to tolbutamide but had become normoglycaemic and sugar-free. She began to relapse three months after discontinuation of tolbutamide. Twenty-three patients remain well controlled on dietary regime alone after six weeks on tolbutamide, and Fig. 2 shows how long they have so far been observed after the discontinuation of tolbutamide without evidence of the relapse. These 23 patients include all but one of the 18 newly diagnosed diabetics. Three of this group were above the 5 to 95 centile weight range while all the others lay within it.

Of the seven patients who relapsed when tolbutamide was discontinued, six responded well to its reintroduction and are now again satisfactorily controlled on 2 g. daily. One patient developed sepsis of a toe, and this was assumed to be responsible for the relapse in her diabetic state. Although the sepsis was controlled with penicillin, she failed to respond to a second course of tolbutamide. Despite coaxing, she refused insulin. Carbutamide was therefore substituted for tolbutamide in the same dosage (2 g. daily) and led to a return to normoglycaemia.

Biochemical Findings

Plasma Tolbutamide

Twenty-eight patients (group 1) were treated with a single dose of tolbutamide given at 8 a.m.—3 g. on the first day and 2 g. thereafter. The next 14 patients (group 2) were given the same amount of tolbutamide, but this was split into two equal doses, one given at 8 a.m. and the other at 12 noon. In the patients responding to tolbutamide in the ward, the mean reduction in mean blood-sugar levels was throughout the day and in the 24-hour urine sugar was the same whether the patients had been treated with a single or divided dose (Table I). The mean levels of plasma tolbutamide for the first day of treatment and the mean levels from the third to the seventh day inclusive are shown in Tables II and III.

In group 1 patients, peak levels were reached in from four to six hours after the administration of tolbutamide

TABLE II.—Tolbutamide Given as a Single Daily Dose at 8 a.m. (11 Patients). Plasma Tolbutamide Levels (mg./100 ml.)

	1st Day of Treatment			3rd-7th Day of Treatment		
	12 Noon	2 p.m.	6 p.m.	8 a.m.	12 Noon	2 p.m.
Mean	12.8	13.5	7.8	0	11.1	9.2
Range	4.5-22.0	7.8-18.5	One estimation only	0	1.8-30.7	0-7.2

TABLE III.—Tolbutamide Given in Two Doses at 8 a.m. and 12 Noon (8 Patients). Plasma Tolbutamide Levels (mg./100 ml.)

	1st Day of Treatment		3rd-7th Day of Treatment		
	12 Noon	2 p.m.	8 a.m.	12 Noon	2 p.m.
Mean	4.3	7.2	2.1	11.3	12.0
Range	2.0-8.4	1.6-13.7	0-8.8	1.4-26.6	3.8-17.0

and some was still present after 10 hours (mean level 5.6 mg./100 ml., range 0 to 16.6 mg./100 ml.). No tolbutamide was detected after 24 hours. In group 2 patients higher tolbutamide levels were found at 6 p.m. (mean levels 8.9 mg./100 ml., range 5.7 to 12.5 mg./100 ml.), and some tolbutamide was occasionally found the next day. The mean levels at 2 p.m. (12.0 mg./100 ml., range 3.8 to 17.0 mg./100 ml.) were somewhat higher than in group 1 patients (9.2 mg./100 ml., range 0.7 to 22 mg./100 ml.) at the same time. There were three failures among the group 1 patients and one failure in group 2 on whom plasma tolbutamide was determined. Plasma tolbutamide levels similar to those of the successes were found in these four failures.

Plasma Amino-acid Nitrogen

Out of a total of 207 amino-acid nitrogen estimations, only six were above the upper limit of normal (taken as 7.8 mg./100 ml.); the raised values being 7.9, 8.0, 8.1, 8.1, 8.3, and 8.7 mg. One value of 8.1 mg./100 ml. was found during the period of treatment with tolbutamide. The other raised values were seen in four patients during the control period, but the levels had returned to normal before the beginning of treatment. Tolbutamide produced some reduction in blood sugar in all the 13 patients concerned, and in nine patients ("successes") the blood sugars were substantially reduced. However, it will be seen from Tables IV and V that no effect of tolbutamide on the plasma amino-acid nitrogen can be demonstrated.

TABLE IV.—Plasma Amino-acid Nitrogen Levels (mg./100 ml.) on First Day of Tolbutamide Treatment. 3 g. Tolbutamide Given at 8 a.m.

Plasma Inorganic Phosphorus

Although tolbutamide produced some reduction in blood sugar in all the patients studied and in eight patients ("successes") the blood sugars were substantially reduced, it will be seen from Tables VI and VII that no effect on the plasma inorganic phosphorus has been demonstrated.

TABLE VI.—Plasma Inorganic Phosphorus Levels (mg./100 ml.) on First Day of Tolbutamide Treatment. 3 g. Tolbutamide Given at 8 a.m.

Other Findings

No toxic effects were recorded in any patients during this trial. There were no skin rashes and no changes in the blood picture, in the white-cell count, or in the platelet count.

Weight recordings failed to reveal any particular trend. The majority showed no weight change while on tolbutamide. When the tolbutamide was discontinued there was a mean reduction of 3 lb. (1.36 kg.) in weight in patients observed over the next two months.

Discussion

Forty-two diabetic patients presenting with mild symptoms of the disease were admitted to the ward and treated with tolbutamide when dietary restriction alone had failed to reduce hyperglycaemia and glycosuria. As with carbutamide, it soon became apparent that tolbutamide could not control the diabetes in all the diabetics to whom it was administered. Young diabetics were not included in this trial, nor were patients presenting with severe acidosis and provocative symptoms of the disease. Even so, of 42 patients treated with tolbutamide 12 failed to respond. Although none of these could be described as severe diabetics they all showed acetone in the urine and tended to have higher blood and urinary sugars than those who responded. However, there was no reliable method of predicting which patient would respond, since one of those who did respond showed acetone in the urine while some who responded showed higher blood sugars than others who failed.

Patients whose diabetes was controlled successfully by tolbutamide in the ward were maintained on this treatment for a total of six weeks and the drug was then discontinued. It is a striking fact that of 18 diabetics newly diagnosed only one has so far relapsed after discontinuation of tolbutamide. While it is true that more may relapse in time, it seems unjustifiable on this evidence to treat new diabetics who respond to tolbutamide for indefinite periods with these tablets. The mode of action of the sulphonylureas is unknown, as are their long-term effects, and these

are good reasons for not prescribing these drugs unnecessarily. It seems preferable to treat responsive diabetics with a six-weeks course of tolbutamide, especially as the drug can be given again to patients who relapse. There seems to be nothing to lose by adopting this plan, for, excepting one patient whose relapse was due to sepsis, all the other patients who relapsed when tolbutamide was discontinued responded equally well when it was reintroduced.

The purpose of treating diabetics for a limited period with tolbutamide is to reduce hyperglycaemia and hence to enable the patients by simple dietary restrictions to remain controlled by their endogenous insulin. Dohan and Lukens (1947) have shown experimentally in cats that the insulin-secreting cells of the pancreas can become exhausted in an attempt to control a sustained hyperglycaemia, and that reducing the blood sugar may break a vicious circle and allow the beta cells to recover. It has been commonly observed that many diabetics started on insulin because of persistent hyperglycaemia show a steadily diminishing need for it, and the insulin can be safely discontinued after a time without relapse. It is precisely in this type of diabetic that tolbutamide may offer a simple and apparently safe alternative to insulin.

As to the question of dosage, although patients on the divided daily dose showed a higher blood level of tolbutamide at 2 p.m., 6 p.m., and 8 a.m. the following day than patients on the single dose, the mean reduction in blood and urinary sugar was the same in both groups where the drug was successful. This suggests that the level of blood tolbutamide is not the determining factor in the fall in blood and urine sugar. The fact that similar levels of tolbutamide were found in both successes and failures would lead to the same conclusion.

If tolbutamide acts by stimulating the release of insulin from the pancreas (Loubatières, 1955), or by inhibiting the breakdown of insulin by insulinase (Mirsky *et al.*, 1956a, 1956b), the general physiological effects of tolbutamide should be those of insulin. Insulin increases glucose uptake and the fall in plasma inorganic phosphorus which takes place is associated entirely with the peripheral utilization of glucose (Nichols, 1955). The fact that in the present series the plasma inorganic phosphorus did not fall during tolbutamide therapy is in accordance with the findings of Renold *et al.* (1956) and Purnell *et al.* (1956) and indicates so, it can be assumed that tolbutamide does not itself act by stimulating the secretion or preventing the destruction of insulin.

Lotspiech (1949) found that insulin promoted the synthesis of proteins from amino-acids. The resultant lowering of the plasma amino-acid nitrogen level could be seen in normal individuals (Luck *et al.*, 1928) as well as in diabetic patients. The lack of effect of tolbutamide on the amino-acid nitrogen levels in the present trial indicates again that tolbutamide does not act in the same way as insulin.

Summary

Tolbutamide was used in the treatment of 42 patients on standard diets whose diabetes was neither so mild as to be controlled by diet alone nor so severe as to need insulin immediately.

All 12 patients who failed to respond showed acetonuria with a tendency to higher blood- and urine-sugar levels than those treated successfully.

Thirty patients responded to tolbutamide and were maintained on this therapy for six weeks. In 23 of these relapse has not occurred so far on discontinuation of treatment.

Seven patients relapsed following discontinuation of tolbutamide. The drug was successfully reintroduced in six of these.

When tolbutamide treatment was given in the form of 1 g. twice daily the concentration of the drug in the

blood differed from that found when treatment was by a single dose of 2 g. However, the effect on the blood and urine sugars was the same in both cases.

Analyses of plasma amino-acid nitrogen and inorganic phosphorus indicate that tolbutamide has a mode of action different from that of insulin.

No toxic effects due to tolbutamide were observed.

We express our thanks to the Medical Research Committee of the North-west Metropolitan Regional Hospital Board for a grant to pursue these studies, and also to the Wellcome Foundation for supplies of tolbutamide and placebos. We are grateful to Dr. J. McSorley for blood estimations, to Mrs. Collins for diet supervision, and to Miss J. Savage for laboratory assistance.

HALOTHANE: ITS USE IN CLOSED CIRCUIT

BY

H. REX MARRETT, F.F.A.R.C.S., M.R.C.S.
 Consultant Anaesthetist, Coventry and Warwickshire Hospital

This paper describes experience of the use of halothane ("fluothane") in a closed circuit. Others (Johnstone, 1956; Bryce-Smith and O'Brien, 1956) have reported on its open and semi-open administration. Halothane was given from a standard Marrett apparatus to over 1,550 cases during a period of nine months.

Preliminary Trial

Halothane was placed in the large ether jar of a standard Marrett machine. The flow of gas was usually 400-500 ml. of oxygen per minute. The level of liquid in the jar was not kept constant, but this made no noticeable difference to the control setting until the level fell below 2 fl. oz. (57 ml.).

The ether control on the Marrett apparatus is divided into four divisions. During the travel of the control knob from "off" to "1/4 on" (the first two divisions on the scale) only the patient's breath passes into the jar. The gases from the flowmeters are delivered direct to the inlet unidirectional valve. This range of the control is equivalent to the full range of closed-circuit vaporizers on most other machines.

To ascertain the relative strength of halothane, a personal trial was undertaken. With half a litre of oxygen a minute

and the control set at three-fourths of the first division (see Diagram), no irritant effect was noticed; nor the buzzing in the head so characteristic of nitrous oxide and other inhalation anaesthetics. Loss of consciousness, accompanied by marked jaw relaxation and loss of corneal reflex, took three minutes, and recovery was complete in five minutes, with no subsequent headache or nausea. With the control set at the second division (full on for the closed circuit) the vapour produced coughing, but was soon tolerated, and loss of consciousness took one minute, with 10 minutes for recovery and again no headache or nausea. It was therefore clear that the concentration was safe and that halothane was likely to be most useful for inductions, particularly if an intravenous anaesthetic was contraindicated as in the very old or emergencies; it would probably also be useful for resistant dental cases, provided only a few breaths were given to allow the third stage to be established. It remained, however, to find out if there was any accumulation in the body after a long administration in closed circuit, or if there was any "build up" of concentration in the breathing circuit.

Induction and Maintenance

Although premedication causes respiratory depression, for the patient's comfort the premedication usual at this hospital was continued—that is, "omnopen," 1/4 gr. (22 mg.), and scopolamine, 1/150 gr. (0.43 mg.), for the healthy adult up to 56; morphine, 1/4 gr. (10 mg.), and atropine, 1/100 gr. (0.65 mg.), were used for the elderly, and atropine, 1/100 gr. (0.65 mg.), for the bad risk and those over 70.

As halothane itself is known to depress respiration, for induction a dose of thiopentone varying from 0.15 to 0.25 g. was used in healthy adults instead of the usual 0.5 g. The mask was then placed on the face with the halothane control at three-fourths of the first division and an oxygen flow of half a litre a minute. Sometimes the respiratory depression from the thiopentone persisted when the halothane was added, though normal respirations would return immediately after a painful stimulus or pulling on the chin. At this stage a tough individual might become restless, but if the control was put to the second division (full on) he would quieten after three or four breaths, although he might cough. With a strong vapour patients might cough, but laryngeal spasm was never encountered, nor was it possible to produce one purposely—a most useful attribute.

For a major abdominal operation the control was then slowly advanced until the abdomen relaxed. At this stage depth of respiration was normal for the closed circuit, and blind or direct intubation could be performed early owing to the complete relaxation of the jaw and larynx. After this all cases were conducted on the principle of physiological breathing, full relaxation for all abdominal operations always being obtainable. At the start of the series p-tubocurarine was used in doses of 5-10 mg. for abdominal operations, but with further experience this proved unnecessary; also, apnoea often occurred and the systolic pressure might fall as low as 45 mm. Hg, although this would rise quickly after an injection of atropine, 1/100 gr. (0.65 mg.).

The maintenance of anaesthesia was usually with the control set at three-fourths of the first division 2% halothane, and at the first division 2.4% for abdominals. A setting beyond the first division was always too much. The margin between light and deep anaesthesia was narrow, so if the patient became too "light" a few breaths of a slightly stronger concentration would soon settle him; but unless this concentration was very soon reduced apnoea developed. If from overdose respiration became too shallow recovery occurred quickly on cutting down or turning off the halothane. On closure of the peritoneum the halothane and soda lime were switched off, and nitrous oxide, oxygen, and air substituted for the remainder of the operation.

The patients all recovered quietly, with a remarkable lack of post-operative vomiting and nausea, and were quite obviously little affected by their operation when seen the following day. There was never the slightest suggestion of

accumulation of the drug: all patients recovered their jaw tone and swallowing reflexes within a few minutes of leaving the theatre, however long their anaesthesia. Nor was there any "build up" of concentration during administration, as the drug had to be given for the most part continually, otherwise the patient quickly showed signs of becoming "light." Consumption varied between 4 ml. and 6 ml. per hour. Considering the high price of halothane, this is very economical compared with open and semi-open administrations.

Discussion

The fact that halothane produces a fall in blood pressure gives rise to no anxiety unless there is serious loss of blood

Sketch of the apparatus.

or D-tubocurarine has been given. For this reason halothane should not be used in operations where blood loss is inevitable, such as caesarean sections and some orthopaedic operations, unless a transfusion is started at the outset. Further, if an unexpected loss of blood occurs during an operation under halothane anaesthesia, the blood must be replaced before the patient is returned to the ward. In operations where a raw surface is left—for example, tonsillectomy, cholecystectomy, etc.—such areas were often found to start oozing again when the halothane was turned off. I suggest therefore that in these cases the halothane should be turned off for several minutes so that any oozing can be dealt with, and then turned on again if necessary to produce relaxation for closure of the peritoneum; otherwise there is a risk of reactionary haemorrhage. This vasodilatation bears no relation to the level of the blood pressure and also occurs during induction, when again the halothane concentration in the blood is low. On the other hand, during surgical anaesthesia, when the halothane concentration is higher vasoconstriction occurs, giving a relatively bloodless field. Again this is unrelated to the blood pressure.

In the series described 1 in 400,000 adrenaline in normal saline was used for infiltration in mastectomies, thyroidectomies, and abdomino-perineal operations, etc., in quantities ranging from 200 to 400 ml. without effect on the pulse. No adverse action on the heart due to halothane was noted, although some of the cases were known to have conditions such as recent rheumatic fever, mitral stenosis, and auricular fibrillation.

Halothane is most useful for the induction of bad-risk emergency cases, because it is non-irritant and the passage through the second stage until the jaw and larynx are sufficiently relaxed for intubation is rapid and tranquil.

With increasing experience the use of D-tubocurarine with halothane was abandoned, as adequate abdominal relaxation could be obtained when using the closed circuit and easily maintained on a low concentration 2-2.4% of anaesthetic without recourse to controlled respiration. This property of

halothane has proved most useful in the conduct of such difficult minor operations, from the anaesthetist's point of view, as gynaecological examinations. The legs of such patients can be relaxed for the lithotomy position within a minute or two and the abdominal wall relaxed for ease of examination. Versions are also easy to perform. Likewise cystoscopies in males are quickly performed without a mobile patient or unnecessarily deep anaesthesia. Being non-explosive and non-inflammable, halothane simplifies the anaesthetic technique if diathermy is needed.

Halothane has been most useful for bronchoscopies and oesophagoscopies. For the former a "sleep" dose of thiopentone (0.1-0.2 g.) is given, followed by halothane and oxygen for about three minutes. A bronchial sucker tube is then inserted 3 in. (7.6 cm.) into the trachea and anaesthesia is maintained by insufflation with halothane and oxygen. This results in quiet respiration and no coughing, and obviates the need for local analgesics. My experience of halothane for chairside anaesthesia in dentistry is limited, but it has proved most useful in hastening the resistant patient into the third stage when using nitrous oxide and oxygen. Only a few breaths should be given, so that the reflexes return quickly.

Lastly, halothane's chemical reactions must be briefly mentioned. It is perfectly stable and does not react with soda lime. Although halothane has been used continuously for the past nine months in a Marrett apparatus, there has been no chemical damage to the mechanism of the machine, nor has there been any noticeable effect on the corrugated tubes or reservoir bag. Halothane is known to attack metals, particularly aluminium and tin, in the presence of moisture, but my experience suggests that if the apparatus is made of chrome, nickelled brass, and copper these reactions are of no consequence.

Summary

The administration of halothane ("fluothane") in closed circuit with a Marrett apparatus for both induction and maintenance of anaesthesia is reported, and the techniques are described. Halothane was used to anaesthetize over 1,550 unselected cases during a period of nine months. There were no deaths during anaesthesia or in the post-operative period.

Anaesthesia was characterized by a smooth induction, excellent relaxation, without the need for relaxants, and the rarity of post-operative nausea and vomiting and shock. Halothane also proved particularly useful for minor procedures where maximum relaxation is required, such as gynaecological examinations and versions, and for various endoscopic examinations. Being non-inflammable, halothane is safe to use with diathermy. No corrosive action on the Marrett apparatus used in the trial was observed.

So far as disadvantages are concerned, profound respiratory depression was invariably due to overdosage; this can quite easily be avoided, as only a moderate dose is required to obtain excellent abdominal relaxation. The fall in blood pressure caused by halothane constitutes no hazard unless aggravated by blood loss or the use of D-tubocurarine. The latter was found to be unnecessary, as relaxation was excellent without it. When halothane is turned off previously dry raw surfaces tend to ooze. This must be guarded against because of the possibility of unseen reactionary haemorrhage, and a method of doing so is suggested.

The indications and contraindications for the use of halothane are discussed, and it is concluded that the drug can be successfully and safely used in a standard closed-circuit apparatus.

I wish to thank Dr. L. B. Wevill and Mr. A. G. Fishburn, of Imperial Chemical (Pharmaceuticals) Limited, for the supplies of "fluothane" and chemical reports on its properties. Also Airmed Ltd., of Harlow, Essex, for the drawing.

SARCOSPORIDIOSIS IN MAN WITH PERIARTERITIS NODOSA*

BY

R. J. MCGILL, M.B., M.R.C.P.Ed.

Physician, Royal South Hants Hospital, Southampton, and
Lymington and Milford Hospitals, Hants

AND

R. A. GOODBODY, M.D.

Pathologist, Royal South Hants Hospital, Southampton

Sarcosporidiosis is a very common protozoal parasitic infestation of muscle fibres in animals in this and many other countries; it has rarely been observed in man. Since its discovery first in mice by Meischer, in 1843, it has been extensively studied in animals.

The life-cycle remains unknown, but the spores are probably ingested in food and eventually gain entry to the striated musculature. There they form large cysts within individual muscle fibres and may attain 5 mm. in length. Each cyst when fully developed shows characteristic division by septa into chambers containing myriads of sickle-shaped spores, which appear to degenerate towards the centre. Infestation has often appeared to be harmless in animals, but when heavy it has produced serious pathological effects and death. Transmission to other animals is probably due to rupture of cysts into the alimentary canal and faecal contamination of food thereby (Scott, 1943). We suggest that the disease is conveyed from animals to man by means of contamination of uncooked food by animal faeces.

We have reviewed the human cases reported, and we accept the eight cited by Feng (1932), who added a case of his own, two reported by Vuillemin (1902), and one each by Lorenz (1904), Hewitt (1933), Gilmore *et al.* (1942), Kean and Grocott (1945), Pugh (1950), and Mackinnon and Abbott (1955).

An eighteenth case is here reported because of the apparent rarity of the condition in man and also because the parasitic infestation was associated with various pathological lesions, including periarteritis nodosa, which have not been described before. In addition, no pre-mortem case has come to full necropsy examination. A complement-fixation test devised by Awad and Lainson (1954) has been used in the present case for the first time in establishing the diagnosis during life.

Case Report

A European official aged 60, retired from India before 1939, was well until April, 1953. Suddenly he collapsed.

*Based on papers read before the Wessex Physicians Club and the Association of Clinical Pathologists.

almost losing consciousness, with, however, no specific weakness, and next morning he had recovered fully. Eight months later he suddenly lost the use of his right arm, and examination revealed diminished power there with increased tendon reflexes but no sensory changes. Complete recovery gradually took place during the next two weeks. One month later a similar sudden weakness of the left arm occurred and again recovery was rapid. Complete physical examination then proved normal, and the B.P. was 140/80. During the next five months exertional dyspnoea began and rapidly increased. Chest radiographs revealed scattered ill-defined but discrete opacities in both lung fields, suggestive of disseminated vascular lesions; biopsy of a pectoral muscle was therefore performed. Subsequently a right homonymous hemianopia developed with right hemiparesis, headache, and mental deterioration. The signs of congestive cardiac failure progressed, and he died on June 21, 1954.

Laboratory Investigations.—No abnormality was found in the blood count and differential count on any occasion. The urine was repeatedly normal. The C.S.F. was normal. E.S.R. was 30 mm. in one hour, rising later to 80 mm. in one hour; serum albumin, 3.4 g. per 100 ml.; serum globulin, 3.0 g. per 100 ml.; liver-function tests normal; W.R. negative; serum complement-fixation test for sarcosporidiosis, positive 1:32; complement-fixation test for toxoplasmosis negative.

Three series of electrocardiograms taken in the last week of his life showed combined heart strain.

Muscle Biopsy.—No evidence of periarteritis nodosa was found, but a number of cystic structures were seen within individual muscle fibres (see Fig.). Each cyst had a delicate

Left-side pectoral muscle with sarcocyst. Note very thin capsule and internal septa. A thin rim of sarcoplasm still surrounds the parasite. (H. and E. $\times 145$.)

hyaline wall and contained a large number of minute basophilic sickle-shaped spores. In longitudinal section the cysts were seen to be at least 1 mm. in length and to be divided by septa into separate chambers. The spores seemed to be produced at the periphery and to degenerate towards the centre of the cyst. No inflammatory reaction was found. These appearances are typical of sarcosporidium (*Sarcocystis*).

Necropsy Findings

Necropsy confirmed that death was due to congestive right heart failure. The heart was moderately enlarged owing to left and right ventricular dilatation. Attached to the base of the tricuspid valve and spreading on to the ventricular and auricular walls was an enormous mass of friable grape-like vegetations; smaller vegetations arose in the pulmonary conus and from the papillary muscles. No vegetation was found within the left heart, but the interventricular septum showed fibrous scarring. The lungs were bulky, and all lobes contained small, firm, often yellowish stellate scars, associated with which were multiple thrombi in the branches

of the pulmonary arteries. The left kidney contained a recent infarct at one pole; small infarcts were present in the spleen. The liver showed severe chronic venous congestion.

A number of lesions were present in the brain. The left occipital pole was infarcted, apparently owing to thrombosis of the left posterior cerebral artery, and there were several small superficial cortical infarcts—two in the left parieto-occipital cortex and one in the right frontal cortex.

Microscopical examination showed the vegetation in the right heart to be granulomatous in nature. Its delicate fronds had a structureless acellular core apparently composed of laminated fibrin clothed with a thick layer of loosely packed endothelial cells, quite frequently in mitosis. Very few leucocytes were present and no bacterial colonies. The heart muscle beneath was scarred, and several coronary arterioles showed necrotizing arteritis. No sarcosporidial cysts were recognized with certainty in the myocardium. The pulmonary lesions were also largely vascular and typical of periarteritis nodosa. Often monocytic infiltration surrounded the thrombosed arteries, whilst older lesions showed organization and fibrosis. In the kidney the wall of the thrombosed polar artery showed gross destruction and disorganization with replacement fibrosis and intimal proliferation. An occasional hepatic arteriole was occluded by a plug of monocytic cells. A subacute arteritis affected the superficial cerebral vessels related to the cortical infarcts. Surrounding such arteries there was an intense monocytic infiltration, with occasional polymorphs and plasma cells. The arterial wall was in places necrotic, but no giant cells were seen. The cortical lesions were typical of ischaemic infarction.

Discussion

The occurrence of periarteritis nodosa in the present case seems likely to be related to the parasitic infestation. Experimental pathology has incriminated bacterial hypersensitivity in the aetiology of periarteritis nodosa (Pagel, 1951), and the disease has already been described in association with another protozoal disease—namely, trichiniasis (Reimann *et al.*, 1943). The presence of antibodies to sarcosporidia was demonstrated in the present case by the new complement-fixation reaction. Absence of an inflammatory reaction around the intact cysts would perhaps suggest that in this phase the organism may not be antigenic. However, an alternative explanation is the presence of the thick hyaline capsule, which may be impervious to the passage of antigenic protein. Spores from ruptured cysts were utilized to provide antigen in the complement-fixation test, and the presence of an antibody to them was demonstrated. Thus it is possible that cysts when they do rupture produce an allergic reaction, manifest as periarteritis nodosa. It is further possible that an as yet unobserved stage in the life-cycle of sarcosporidia may have been responsible for these pathological changes.

All the cases of human sarcosporidiosis previously reported have been diagnosed by the accidental discovery of the parasite in voluntary or cardiac muscle. With two possible exceptions the condition has been asymptomatic. Lorenz (1904) notes the occurrence of associated dermatomyositis, while Pugh (1950) found sarcosporidia in a case manifesting transient recurrent subcutaneous nodules resembling urticaria with an eosinophilia. A few cases of reaction to the parasite have been reported in the veterinary literature, and include myositis, heart-block, congestive heart failure, and an eosinophilic reaction (Saloman, 1935; Clark and Jackson, 1942; Wang, 1950).

The pathogenesis of the granulomatous vegetation in the right heart is obscure. Largely composed of proliferating endothelial cells, it seems more likely to represent a local reaction to the presence of a parasite than a tissue response of an allergic nature. The vegetation contained basophilic granules, but these could not be recognized definitely as parasites. Similar endothelial proliferation was seen in the lungs, liver, and cerebral arteries, and is not typical of periarteritis nodosa.

An attempt by us to transmit the infection to mice was unsuccessful. Animals were fed with suspensions of muscle tissue and the cardiac vegetation, and a second group received intraperitoneal inoculation. After twelve weeks the mice were killed, and preparations of cardiac and voluntary muscle were examined. No evidence of infection was obtained. Many previous attempts to demonstrate the pathways of transmission of the sarcosporidium have also been made without success. Experimental infections have been difficult to establish, and the feeding of large numbers of cysts to various animal species has usually failed to transmit the disease.

In view of the very heavy infestation of domestic animals used for food in this country, the incidence of human infestation must be much higher than the small number of cases reported in the literature would lead one to expect. With others we consider that the apparent infrequency of this condition is simply due to the fact that it has not been sought for in muscle fibres.

A survey of sera from a cross-section of the population using the complement-fixation test of Awad and Lainson would provide interesting data on the frequency of human sarcosporidiosis.

Summary

Sarcosporidiosis in animals and man is briefly described.

The literature in human cases is reviewed, and the eighteenth case is recorded. This is the first human case to have the diagnosis confirmed in life by the new complement-fixation test and to come to full necropsy.

Periarteritis nodosa was also present, and its association with sarcosporidiosis is discussed.

An unusual granulomatous condition was found in the right heart.

We are indebted to Dr. C. H. Devereux for referring this case to us, and to Dr. F. I. Awad, Major E. J. Balmer, Dr. L. B. Blair, Colonel C. F. J. Cropper, Dr. E. S. Duthie, Lieutenant-Colonel A. M. Pugh, and Mr. K. G. Morgan for their assistance.

ADDENDUM.—The results of the complement-fixation tests are significant in view of the recent investigations by Dr. I. A. B. Cathie (*Lancet*, 1957, 1, 816) on the occurrence of antibodies to sarcocysts and toxoplasma.

The Scientific Film Association has recently issued a catalogue of films on cerebral palsy. The listed films are grouped according to their bearing on the disease, the sections being physiology, aetiology, clinical (general), clinical (case records), clinical (differential diagnosis), treatment, and general. An index of film titles is included. In common with the other S.F.A. catalogues of films a description of each film is given, together with size, running time, and the name of the distributor. Intending borrowers may book films through the S.F.A., but the association itself does not distribute the films. The publication of this catalogue has been made possible by a grant from the National Spastics Society. The catalogue is obtainable from the Scientific Film Association, 164, Shaftesbury Avenue, London, W.C.2 (price 2s. 6d. net).

CAVERNOUS TRANSFORMATION OF THE PORTAL VEIN FOLLOWING UMBILICAL SEPSIS

BY

K. SOMERS, M.B., M.R.C.P.

Hospital for Sick Children, Great Ormond Street, London

The interpretation of splenomegaly in childhood is often difficult. When infective conditions, blood dyscrasias, reticuloses, lipoidoses, and cirrhosis of the liver have been excluded, there remain some cases of splenomegaly in which no obvious disorder can be demonstrated. A number have formerly been diagnosed as Banti's disease, the existence of which as an entity is doubtful. The syndrome is no longer regarded as a primary condition (Sherlock, 1955). A variety of conditions resulting in portal hypertension—for example, cirrhosis of the liver and obstruction of the portal vein—may produce it. The use of the descriptive term "chronic congestive splenomegaly" is therefore preferable.

Whipple (1945) classified portal hypertension into two major categories—those in which obstruction to portal blood flow is intrahepatic and those in which obstruction is extrahepatic. Cirrhosis of the liver is by far the commonest cause of intrahepatic portal obstruction.

Extrahepatic portal obstruction is commonly due to thrombosis of the portal vein. Less commonly, cavernous transformation of the portal vein may cause extrahepatic portal obstruction. The condition has often been reviewed, notably by Klemperer (1928) and more recently by Gibson and Richards (1955) and Parker and Seal (1955), and with reference to the surgery of portal hypertension by Learmonth (1951), Walker (1954), Hunt and Whittard (1954), and Schuckmell, Grove, and Remenchik (1955).

Pick (1909) first postulated that the lesion was an angioma, and Walker (1954) stated that it was congenital in origin, a true venous angioma. Gibson and Richards (1955) reject the previously used term "cavernomatous" in preference for cavernous transformation. They mention, which was used by earlier German writers, that the condition is seldom if ever a hamartoma and never a true neoplasm. Together with Parker and Seal (1955), on the basis of post-mortem findings, they regard thrombosis of the portal vein and its tributaries as of major importance in the pathogenesis of cavernous transformation, recanalization, and the development of collateral circulation resulting in the cavernous picture. Although historical evidence was lacking in their cases, they concluded that thrombosis was probably a complication of past intra-abdominal infection—for example, umbilical sepsis in the neonatal period and appendicitis in the adult. A theory suggested by Wallgren (1927). The possibility of extension of the normal obliterative process in the umbilical vein into the portal vein after birth was not entirely excluded.

Van Crefeld and Levy (1930) suggested that cavernous transformation in their patient, a 4-year-old boy, resulted from the transmission of umbilical infection along the umbilical vein to involve the portal veins. Cavernous transformation of the portal vein in the case reported here, proved at percutaneous splenic venography, is of interest because of the positive history of umbilical sepsis

and of the presentation as splenomegaly without any of the complicating features of portal hypertension, particularly bleeding from oesophageal varices.

Case Report

A girl of 7½ years was first seen after an exacerbation of upper abdominal pain which she had had for the previous two years. The spleen was palpable three-fingerbreadths below the costal margin and she was referred to Great Ormond Street.

The history on admission was that she had been born of a normal pregnancy and there had been no neonatal jaundice. Apart from mild bouts of abdominal pain she had been an active healthy child. Her growth and development had been normal.

She had never been abroad, and there was no past history suggestive of hepatitis, nor was there a family history of blood disorder. Splenomegaly was the only abnormal physical finding. Routine haematological investigations and liver-function tests were within normal limits. X-ray examination of the bones revealed no infiltrative lesion. The Wassermann reaction was negative. Cirrhosis of the liver was thought to be a possible diagnosis.

She was readmitted for review eighteen months later, when aged 9 years. Since her previous admission she had bruised easily and had had occasional mild abdominal pain. Apart from a cold associated with enlarged cervical lymph nodes for the past fortnight, she had remained well. There had been no episodes of haematemesis or melaena. On direct questioning the mother stated that the child when 17 days old had been admitted to a local hospital with an inflamed anterior abdomen. On inquiry, the hospital reported: "She was suffering from cellulitis . . . arising from sepsis of the umbilicus." She had been treated with penicillin and apparently recovered uneventfully.

On examination she looked well, apart from a few recent bruises on the legs. There was no jaundice, anaemia, or purpura. She had no vascular spiders. The posterior cervical lymph nodes were enlarged and tender on the right side. The throat looked healthy. A firm, non-tender spleen was palpable four-fingerbreadths below the left costal margin. The liver was not palpable, and there was no ascites.

Haematological investigations showed: haemoglobin, 11.6 g. per 100 ml. (79%); film, normal; reticulocytes, 1.2%; white cells, 3,800 per c.mm. (neutrophils 80%, eosinophils 3%, lymphocytes 16%, monocytes 1%); platelet count, 222,000 per c.mm.; E.S.R., 17 mm. per hour. Coagulation time (Lee and White), 3 minutes at 37° C.; bleeding-time, 7 minutes (Duke's method); prothrombin time (1 stage), 11 seconds; red-cell fragility, normal. Bone-marrow examination was normal. Biochemical tests revealed: bilirubin, less than 0.5 mg. per 100 ml.; thymol turbidity, 2 units; zinc sulphate turbidity, 6 units; alkaline phosphatase, 5 (K.A.) units; plasma proteins, albumin 3.91 g., globulin 3.11 g. per 100 ml.; electrophoresis, normal; blood urea, 25 mg. per 100 ml.; urine, no excess urobilin. Barium swallow with Valsalva manoeuvre revealed no oesophageal varices, and stools were negative for occult blood. Repeat x-ray examination of the bones revealed nothing abnormal.

The cervical lymph nodes subsided in a few days, confirming their infective origin. Further blood counts continued to show mild anaemia (haemoglobin, 79 to 84%), leucopenia (W.B.C., 2,300 to 3,800 per c.mm.), and thrombocytopenia (platelets, 159,000 to 184,000 per c.mm.). The cause of the splenomegaly remained uncertain. A provisional diagnosis of portal hypertension probably due to extrahepatic portal venous obstruction was made. Cirrhosis of the liver seemed an unlikely cause because of her normal development and absence of clinical stigmata of the disease. She was referred to Dr. Sheila Sherlock at Hammersmith Hospital, where a percutaneous transsplenic portal venogram

was done under general anaesthesia. At the same time a liver biopsy was obtained, the consistency of which felt normal and microscopically showed no abnormalities.

At portal venography, as described by Atkinson, Barnett, Sherlock, and Steiner (1955), splenic pressure was 10 mm. Hg (normal 3–17 mm. Hg). Dr. R. E. Steiner's report on the venogram stated that the film clearly demonstrated extensive cavernous transformation of the portal vein. Some of the contrast medium had in fact reached the liver and a lot of blood was shunted through extensive gastric varices and mediastinal veins into the azygos vein (see Fig.).

Percutaneous transplenic venogram showing extensive cavernous transformation of the portal vein.

To conclude, this patient had extrahepatic portal obstruction, doubtless resulting from thrombosis of the portal vein following neonatal umbilical sepsis.

Discussion

Cavernous transformation of the portal vein is most probably a sequel to portal vein thrombosis, which begins as a complication of one or other intra-abdominal infection. Umbilical sepsis in infancy could certainly cause portal thrombosis without recognizable signs at the time. In later life it might be difficult, if not impossible, to prove that this has occurred.

A history of umbilical sepsis was wanting on first admission. Even after portal venography a congenital anomaly was thought a possible explanation for the cavernous transformation. The documented history of neonatal umbilical sepsis was not learnt until later. Despite adequate treatment it had been followed by portal venous obstruction. The importance of umbilical sepsis as a cause of intrahepatic portal obstruction is particularly significant in the paediatric age group.

The clinical diagnosis of extrahepatic portal venous obstruction was confirmed by portal venography. Until recently extrahepatic portal obstruction could be diagnosed only at laparotomy. In the last five years percutaneous transplenic portal venography has become a recognized procedure in the clinical investigation of suspected cases of portal hypertension (Atkinson *et al.*, 1955). It is possible to make accurate diagnosis and locate an obstruction or other anomaly of the portal vein. A greater proportion of oesophageal varices are revealed in this way than either by barium swallow or by oesophagoscopy alone or in combination. With careful technique it is free of serious risk in selected cases.

With development of surgical operations for the relief of portal hypertension, portal venography is advisable to diagnose the site and nature of obstruction. The venogram obtained determines the most appropriate procedure. Thrombotic occlusion of the portal vein or its tributaries virtually precludes porto-splenic anastomotic operations, as the part of splenic or portal vein remaining patent is usually inadequate for an anastomotic operation.

Haematemesis from bleeding oesophageal varices is a common complication of portal hypertension from extrahepatic portal obstruction. Because the patient has had none, portal hypertension is unlikely to be marked. The impression is confirmed by a normal intrasplenic pressure at venography, and it looks as if the colossal collateral azygos circulation has relieved any portal hypertension that might have been present previously.

Although varices were outlined at venography in the above case, it is possible that the child might never suffer from haematemesis.

Chronic neurological complications are particularly common in association with portal venous thrombosis (Sherlock, Summerskill, White, and Phear, 1954). Fortunately, again, the above patient did not show any of the neurological symptoms and signs of porto-systemic encephalopathy.

The blood picture of mild anaemia, leucopenia and thrombocytopenia, and prolonged bleeding-time suggests hypersplenism. She will certainly have to be closely watched with regard to her blood picture.

Abdominal pain of one sort or another is a common symptom in cases of cavernous transformation, and may even suggest intestinal obstruction. Gibson and Richards (1955) offer as explanation minor attacks of thrombosis in peripheral radicles of the portal vein. In three of their cases sudden massive thrombosis of the superior mesenteric vein resulted in fatal intestinal infarction. The attacks of upper abdominal pain in the above case, though mild and transient, need careful observation, but it would be difficult to prove whether or not these are due to minor episodes of thrombosis.

Summary

A case of cavernous transformation of the portal vein following neonatal umbilical sepsis, proved on percutaneous transplenic portal venography, is described in a 9-year-old girl who first presented with abdominal pain and splenomegaly.

The diagnosis and complications of extrahepatic portal obstruction are discussed with reference to recent views on the aetiology and clinical picture of cavernous transformation of the portal vein. A greater recognition of neonatal umbilical sepsis as a cause of portal hypertension in childhood is indicated.

Thanks are due to Dr. A. P. Norman and Dr. Sheila Sherlock for their encouragement; to Dr. R. E. Steiner for permission to use the findings at portal venography, and to Mr. Derek Martin for the x-ray photograph.

EFFECT OF A GLUTEN-FREE DIET IN IDIOPATHIC STEATORRHOEA

BY

ALEXANDER BROWN, M.D., F.R.C.P.Ed.

F.R.F.P.S.

University Department of Medicine,
Royal Infirmary, Glasgow

It is now well established that some children with defective fat absorption are affected unfavourably by the inclusion of wheat gluten in the diet. It seems, indeed, that there is in such cases an inherent abnormality in the gastro-intestinal tract which may not be sufficient in itself to disturb the assimilation of fat, and that the steatorrhoea may be gluten-induced.

The incidence of the "gluten-induced" type of steatorrhoea among young coeliacs is high. Ross *et al.* (1955) report that 28 out of 30 with the coeliac syndrome responded to a gluten-free diet. Since the condition is a chronic relapsing disorder which even in its less overt forms is capable of having a very adverse influence on growth and development (Gerrard *et al.*, 1955; Lindsay *et al.*, 1956), assessment of the value, and limitations, of the treatment is of obvious practical importance. It may also help to throw some light on the alimentary defect which exists in these patients.

The purpose of the present report is to describe the remarkable benefit achieved by a gluten-free diet in two adolescents with established steatorrhoea and in one woman of 40 in whom the diagnosis had been made eight years previously, but in whom the disease may have been present for a much longer time.

Case 1

A girl aged 13 had been a known coeliac for eight years when she was admitted to the medical unit with obvious malnutrition, a megaloblastic anaemia, gastric achlorhydria (histamine-responsive), and defective fat absorption (77% absorption over a 10-day period). The radiological appearances of the small intestine were typical of steatorrhoea and there was defective absorption of glucose given by mouth. Serum vitamin B₁₂ levels were normal (370 µg./ml.), but a folic acid excretion test indicated marked deficiency: plasma folic acid=0.24 µg./litre (1 mg. of folic acid given by mouth); plasma folic acid=0.88 µg./litre one hour later; five-hour urine folic acid=6.7 µg.

A gluten-free diet was begun on June 29, 1953; no other treatment was given. Under these conditions there was a reversion of erythropoiesis from the megaloblastic to the normoblastic type, but the blood picture remained unaltered (R.B.C., 3,870,000 per c.mm.; Hb, 65%) one month later. Folic acid (20 mg. a day) was given from July 30 to August 10 (in addition to the diet). No haematological improvement resulted. A further folic acid excretion test showed that the deficiency had been made good. In view of the presence of a dimorphic blood picture suggesting a defect in haemoglobinization, oral iron therapy was given from August 10 to September 1. It was without benefit, and iron-absorption tests indicated that this was due to defective absorption. Intravenous iron (900 mg.) was given from September 5. It was followed by a rise in blood values (to 4,900,000 per c.mm. and 80%) in 10 days.

The gluten-free diet was continued for 15 months, until September, 1954. The patient remained in excellent health and showed a weight increase of 26 lb. (11.8 kg.). In January, gluten-free diet was discontinued in September. In January, 1955, the general condition was normal; there were no symptoms, and there was no anaemia.

Case 2

After about 15 months (January–February, 1956) on normal diet she developed pallor and languor, and was reinvestigated in the metabolic department of Professor A. C. Frazer in Birmingham, where she had taken up residence in the meantime. Relapse was shown to have occurred and she had again to be put on the gluten-free diet.

A girl aged 15 had a history of intermittent diarrhoea, undue pallor, failure to thrive, and variable abdominal distension for about 10 years when she was admitted to the medical unit. At this time she was obviously underdeveloped—no secondary sex characteristics, height 4ft. 8 in. (142 cm.), weight 4 st. 10 lb. (30 kg.)—with obvious steatorrhoea confirmed by test (83% absorption of fat over a four-day period) and defective oral glucose absorption. The radiological appearances of the small bowel were suggestive of steatorrhoea and there was evidence of coeliac rickets. The blood picture was normal.

A gluten-free diet was begun on October 2, 1952; no other treatment was given. In six weeks lassitude had disappeared and weight increased by 25 lb. (11.3 kg.). The stools were normal in appearance. The patient was discharged from hospital to continue on the diet.

In April, 1953, her general health was excellent. Fat absorption was normal (96% and 97% in two separate test periods each of four days), but oral glucose absorption was still impaired. There was no anaemia. Radiological investigation of small-bowel function now revealed nothing abnormal.

In December, 1954, improvement was maintained. Her height had increased by 9 in. (23 cm.), weight by 5 st. (31.8 kg.). Normal puberty changes were present. There was no anaemia. The gluten-free diet was discontinued.

In October, 1955, her general health was excellent, her weight was still increasing, and she was asymptomatic. There was now no evidence of defective bone metabolism radiologically.

In April, 1956, though asymptomatic, she was found to have a hypochromic anaemia (Hb, 65%). She was readmitted for assessment and found to have relapsed (fat absorption 80%). She was given oral iron therapy and put again on the gluten-free diet.

Case 3

A married woman was found to have idiopathic steatorrhoea in 1947, when she was 32. At that time she had a megaloblastic anaemia associated with free hydrochloric acid in the gastric juice, pelvic deformity of typical osteomalacic type and some general skeletal decalcification, defective fat absorption (82% and 84% absorption on two separate four-day test periods), and an oral glucose-tolerance test of the "flat" variety. The anaemia responded at first to an oral liver preparation and later to folic acid.

She failed to attend for supervision following her discharge from hospital, and in 1952 was admitted to a hospital nearer her home, when she was found to be pregnant and severely anaemic. She was maintained fairly well thereafter on folic acid and iron therapy until 1954, when she began to suffer from malaise and lack of energy; and the occasional diffuse pains in the back and limbs from which she had suffered during the previous seven years became incapacitating. She was admitted to the medical unit for further investigation on February 6, 1955.

The salient features on examination were slight finger-clubbing and slight kyphotic deformity of the spine. Walking was almost impossible on account of pain in the legs, hips, and lumbar region.

Blood examination revealed a mild hypochromic anaemia (R.B.C., 4,000,000 per c.mm.; Hb, 68%), and bone-marrow examination showed that erythropoiesis was normoblastic. On radiological examination general skeletal decalcification was present and there was typical osteomalacic deformity of

the pelvis. The serum calcium was 4.6-4.8 mEq/l.; inorganic phosphorus, 3.2 mg./100 ml.; alkaline phosphatase, 3.3 Bodansky units.

A gluten-free diet was given from February 22. A course of parenteral iron therapy was also given for the anaemia, the response being satisfactory. She was discharged to attend as an out-patient on March 1. From this date onwards she felt much improved and the skeletal discomfort, which had previously been incapacitating, showed a very steady improvement. Her weight, which had been 5 st. 2 lb. (32.7 kg.) in February, 1955, rose by 10½ lb. (4.8 kg.) in the next three months, and when last seen on October 5, 1955, she had put on a total of 16 lb. (7.3 kg.); she felt very well and had been quite free of pain for over five months. Bowel function appeared normal and the stools were well formed and normal in colour. She was still adhering to her diet. X-ray examination of the skeleton on October 5 revealed that there was no evidence of decalcification in the pelvis or long bones. The serum calcium level was the highest so far recorded in her case—namely, 5.7 mEq/l.

Discussion

Case 1 is remarkable in that a proved folic acid deficiency which had been manifested clinically as megaloblastic erythropoiesis was rectified by withdrawal of gluten from the diet. The dimorphic anaemia was due not only to this avitaminosis but also to iron deficiency, which was almost certainly due to defective absorption. It is clear also that the dietary regime was ineffective in increasing iron absorption to a useful degree even in the presence of increased iron intake.

The second patient was not anaemic; the major manifestation of disordered metabolism was arrested development. The response to dietary treatment was an increase in height by 9 in. (23 cm.), and in weight by 5 st. (31.8 kg.) in 19 months. Glucose tolerance was unchanged by the treatment, but fat absorption returned to normal and the flocculation pattern previously present on intestinal radiological examination disappeared.

In Case 3 the major manifestation of alimentary defect was found in the skeleton, and the evidence indicated that this was of a progressive nature and on the point of immobilizing the patient completely. On several occasions in the previous eight years she had received supplements of calcium (as lactate and chloride) and vitamin D without benefit. After the starting of the gluten-free diet there was progressive symptomatic benefit. Not only did her general health improve, as evidenced by her feeling of well-being and her increase in weight, but her bone pain disappeared entirely; she was able to resume normal activities; and finally, 10 months later, radiological examination indicated that there was then no evidence of defective calcification in the skeleton.

The response to withdrawal of gluten from diet has been employed as a basis for the classification of cases of defective fat absorption (Frazer, 1955). The "gluten-induced" type can now be separated from the others. The main benefit is the very practical one of treatment, but the basic significance of the gluten effect is not understood. Furthermore, the limitations of the aetiological entity which includes gluten-induced steatorrhoea are uncertain. Presumably there is an inherent defect which does not directly affect fat absorption. It may nevertheless be associated with defective glucose absorption (Cases 1 and 2, above; Ross *et al.*, 1955) and also perhaps with iron absorption. The evidence on the latter is, however, incomplete. Badenoch and Callender (1954) have demonstrated that in the untreated case absorption of iron from the intestine is reduced; and in Case 2 there was evidence of defective absorption even when the patient had been on a gluten-free diet for three months. Ross *et al.* (1955) found that the diet alone was insufficient to correct hypochromic anaemia in coeliacs, but thought that this might be due to deficient body stores.

It is difficult to assess instances of folic acid deficiency in idiopathic steatorrhoea, but it is probably high (Girdwood, 1956); in Case 1 the deficiency was decidedly improved by excluding gluten from the diet. Whether it is induced or merely aggravated by the gluten is uncertain.

Of more immediate and practical importance is the demonstration once again of the great value of the exclusion of gluten from the diet in cases of idiopathic steatorrhoea. It should be tried in all cases irrespective of age and of the nature or duration of symptoms.

Finally, it is in accordance with the observations of others (Frazer, 1955) that relapse ultimately occurred on resumption of a normal diet, even after two years' restriction of gluten. Whether the restriction will require to be permanently imposed has not yet been demonstrated, but it seems very probable that it will be so.

Summary

The beneficial effects of the exclusion of gluten from the diet in three patients with idiopathic steatorrhoea are reported. Two of the patients were adolescents in whom the defect had existed since early childhood. The third was an adult in whom the disorder had probably existed for many years. The major disturbances in these patients were folic acid deficiency and iron deficiency (one); severe retardation of general development and puberty changes, and coeliac rickets (one); and skeletal decalcification (one—adult).

The exclusion of gluten from the diet was sufficient to correct the defect in fat absorption and also the other disturbances, with the exception of the iron deficiency, which was shown to be due to non-"gluten-induced" iron-absorption defect. The two adolescents showed "flat" oral glucose-tolerance curves which were not influenced by the exclusion of gluten.

The dietary regime in Cases 1 and 2 was imposed for 15 and 24 months respectively. In both cases features attributable to relapse appeared 15 months after a normal diet was resumed, and at this stage defective absorption of fat was shown again to be present.

The significance of these findings is briefly discussed.

I am grateful to Professor A. C. Frazer for information regarding the relapse of Case 1; to Dr. G. H. Spray for the assay of folic acid; and to Dr. G. I. M. Ross for the assay of vitamin B₁₂. Part of the expenses of this investigation was borne by the Rankin Research Fund of the University of Glasgow.

The World Health Organization has issued a report entitled "Role of Hospitals in Programmes of Community Health Protection." This is the first report of the Expert Committee on Organization of Medical Care, and appears as No. 122 in the Technical Report Series. The report considers the role of a general hospital, and its relationship to the community it serves; the functions of a hospital both towards cure and prevention of disease; and the use of a hospital as a teaching and research unit. The geographical position of hospitals, together with their administration and organization are also discussed. The report is available, price 1s. 9d. net, from Her Majesty's Stationery Office, P.O. Box 569, London, S.E.1.

Medical Memorandum

Case of Stove-in Chest Injury

The patient with a stove-in chest injury is likely to be admitted to the traumatic unit rather than the chest unit both because of his other injuries, which are usually the more obvious, and because traumatic units are the more numerous. As a result the surgeon may not have had much experience of this type of injury, and may not appreciate the urgency of treatment for the chest condition.

In these cases the injured part of the chest falls in during inspiration and is blown out during expiration, a process of paradoxical respiration which prevents filling of the under-lying lung and may result in air travelling uselessly from one lung to the other as well as impairing proper filling of the heart by depriving the great veins of the normal help to the filling and emptying provided by effective changes in intrathoracic pressure. Secretions accumulate in the lungs, and, as the patient cannot cough, he is liable to drown himself.

Coleman and Coleman (1950) described this condition and its physiology and pathology, and reviewed the literature. They stated that usually there are double or comminuted fractures of a number of ribs, and advocated operative exposure and fixation of the rib fractures by wiring them, thus restoring normal chest movements. In December, 1956, Bickford and Grant wrote on the subject to the same effect. Previous methods of dealing with the problem have ranged from external compression of the injured part, through the use of a mechanical respirator (Hagen, 1945), to traction from the fractures to an external frame (Proctor and London, 1955).

This literature does not appear to be widely known, and I was certainly ignorant on the subject when the following case was seen.

CASE REPORT

A man of 58 was admitted to hospital on November 24, 1956, after a head-on collision with another car. He was suffering from concussion, a fracture of the right patella, and a double fracture of the sternum through the manubrium and a double fracture of the body some 2 in. (5 cm.) sternal junction and through the body some 2 in. (5 cm.) lower down, with fractures of the left second, third, and fourth ribs. His condition was not regarded as dangerous, and he recovered from his concussion during the night. The next day he began to develop paradoxical respiration as the fracture through the manubrium-sternal junction appeared to increase in mobility, but his condition still appeared good. He was given oxygen by nasal catheter with benefit, but later he began to deteriorate further, and his chest was sucked out. Relief was temporary. His left upper chest and the fractured part of the sternum now fell in alarmingly on inspiration and blew out on expiration, and his chest was clearly filling up with fluid secretions. It seemed clear that normal chest movements had to be restored somehow if he was to survive.

A mechanical respirator appeared the logical answer to the problem, and he was placed in this. The logic proved faulty, however, as the patient and the respirator seemed to breathe at cross-purposes, and he became increasingly distressed and exhausted. Presumably a respirator works best when extensive paralysis prevents the patient offering resistance to its action.

He begged to be removed from the respirator and to be allowed to die in peace, and his priest was sent for. The anaesthetist offered to give a general anaesthetic and to aspirate him with a bronchoscope as a preliminary to some operation. Failing this it was obvious that the man would die. What the operation was to be was at this stage not clear to anybody; but it was to be something that would restore normal chest movement.

It was clear that the fractures of the sternum must be fixed or at least the middle one of the fractured ribs, or possibly both. The simplest way to fix the sternal frac-

tures would obviously be to apply a plate along the sternum, and the rib fractures might be fixed by intramedullary introduction of a segment of Kirschner wire.

Theoretical objections to plating the sternum were many. The surface was not flat enough; the bone was not offering much cortex to hold screws; it was unlikely that any of our screws would be short enough to avoid protrusion behind the sternum; it was difficult to see how the sternum could be held up while being drilled; and, finally, even if the operation were a success initially, would the plate hold long enough to do any good?

It was decided to attempt plating of the sternum as the first choice. A six-hole 4½-in. (11.4-cm.) plate was applied from the manubrium downwards along the body through a midline incision. It was found that by inflating the lungs the anaesthetist was able to hold up the sternum against the drilling adequately; that, as the sternum offered very little resistance to the passage of a drill, great caution was required; that the hold for individual screws was not very firm, but that by using six screws the plate itself was well held; and that ½-in. (13-mm.) or in places ¾-in. (16-mm.) screws were not too long. No serious attempt was made to bend the plate to conform to the ridges on the sternum, and probably these ridges, by holding the plate slightly away from the bone, made the available screws long enough and not too long. A 7/64-in. (3-mm.) drill was used to give the screws the maximum possible hold on the bone.

The immediate effect of the operation was very satisfying. The chest moved normally at once, with only very slight persistent concavity over the rib fractures, and it was not necessary to interfere with these. Ultimately two of the screws in the sternum did appear to work slightly loose, but this did not allow the plate to loosen, and the patient recovered remarkably, after an initially stormy convalescence.

Two weeks after this operation he underwent an operation under local analgesia for the patellar fracture, which was wired and screwed together.

COMMENT

The procedure outlined is very simple to carry out with the help of a good anaesthetist. It is life-saving in itself, and allows the patient to be nursed without any inhibitions in regard to taking up the position he finds most comfortable, free from any traction apparatus. It should, however, be carried out sooner than it was in this case—before it appears necessary, and before treating any other injuries.

X-ray pictures in this case were relatively uninformative, and the diagnosis is essentially and easily a clinical one.

I should like to express my appreciation of the magnificent skill and courage of Dr. Neil Budge, who gave the anaesthetic and bronchoscoped the patient when all the signs pointed to a "death on the table." I thank Dr. G. R. Vesey and Dr. Z. N. Dhabalia, the house-surgeons, for their stimulating help at all phases, and Sister Thomas and her nurses for their usual high standard of care.

L. HENRY, M.D., M.Ch.Orth., F.R.C.S.,
Consultant Orthopaedic Surgeon, North Gloucestershire.

The team entered by the Rochdale and District Hospital Management Committee won the national competition between mobile first-aid units of the National Hospital Service Reserve for the Minister of Health's challenge cup. The finals were held at Cardiff on July 20. Entrants came from all the hospital regions of England and Wales. In the absence of Mr. DENNIS VOSPER owing to his illness, the Minister's challenge cup was presented by Mr. J. K. VAUGHAN-MORGAN, Parliamentary Secretary to the Ministry of Health.

Reviews

INDIAN MEDICAL SERVICES

Official History of the Indian Armed Forces in the Second World War, 1939-45. Medical Services. Edited by B. L. Raina. Director Bisheshwar Prasad, D.Litt. Administration. (Pp. 679+xxvi; illustrated. Rs. 30.) *Medicine, Surgery, and Pathology.* (Pp. 906+xlvi; illustrated. Rs. 40.) New Delhi: Combined Inter-Services Historical Section India and Pakistan. 1955.

The history of war is always of immediate interest though often soon forgotten, only to be revived at a much later date. It is comforting to know that Caesar's cohorts were able to retire to winter quarters, and no doubt it will be valuable 2,000 years hence to learn of the medical care of the armed forces in India between 1939 and 1945. These two volumes, however, will have a very limited temporary appeal. Volume I (of 672 pages) was completed in 1953; this is entirely devoted to administration and not likely to be of interest except to the professional military doctor. The second volume (of 906 pages and completed in 1955) is a survey of medicine, surgery, and pathology. The size of the chapters varies enormously and without any apparent relationship to the importance of the contents. For example, venereology is dismissed in 12 pages with two short appendices, but this was a very important aspect of military service in India, and it is disclosed in the first volume that venereal disease was the commonest single reason for rejecting Indian recruits on medical grounds in 1945. Of the first 70 specimens examined by the neuropathologist in 1944 22 were from fatal cases of arsenical encephalopathy arising in the treatment of syphilis. Tuberculosis is dismissed in nine pages but sprue is allotted 105.

It is clearly not within the powers of a single reviewer to assess the accuracy of the whole of these large volumes, and this reviewer is only familiar with one aspect of the subject. Here, unfortunately, serious errors are found. It would seem that the opening page of the chapter devoted to military neurology was written by one person and then drastically edited by another, unfamiliar with the terminology. In paragraph 3 of the first page neurology, neurosurgery, and neuropathology are hopelessly confused and the whole paragraph is senseless. It is also curious that the names of the officers who developed the Neurological Centre, India Command, and who did almost the whole of the work at that centre, are not named, although their successors, who arrived when the war was over, are given honourable mention. On the following page it states that "The chief neurological disorders occurring in base areas were meningococcal meningitis, acute poliomyelitis, epilepsy, peripheral neuritis, late effects of head injury and neurological complications of malaria and heat stroke." This may have been true of depots for Indian troops, but neurologists will not be surprised to learn that in the Neurological Centre the commonest diagnosis was neurosis, followed by sciatica, head injury, and epilepsy. In an appendix to this chapter there is a review of work done on peripheral nerve injuries, but the editors have overlooked this contribution and peripheral nerve injuries make a re-entry of 16 pages much later.

These volumes suffer through multiple contributors being subjected to uneven editing by an editorial board that could not have been in possession of all the facts.

HUGH GARLAND.

FAITH HEALING

Eleven Lourdes Miracles. By D. J. West, M.B., Ch.B., D.P.M. (Pp. 134+x. 15s.) London: Gerald Duckworth and Co. Ltd. 1957.

Some Thoughts on Faith Healing. Edited by Vincent Edmunds, M.D., M.R.C.P., and C. Gordon Scorer, M.B.E., M.A., M.D., F.R.C.S. (Pp. 60. 2s. 6d.) London: For the Christian Medical Fellowship by the Tyndale Press. 1957.

In February next year it will be exactly 100 years since a peasant girl gathering wood in the neighbourhood of Lourdes

is said to have had a vision of the Virgin Mary standing in an opening in the rock. This opening has become the famous healing grotto which is now a place of pilgrimage from all parts of the world. More than three million pilgrims and over twenty thousand sick visited Lourdes in 1949, and since then it is said that the numbers have increased still further. Lourdes has become a considerable centre for tourist and souvenir industries.

It is well known that alleged "cures" at Lourdes are relatively infrequent and that claims for anything in the nature of a miracle are scrutinized with great care by Catholic officials appointed to these duties. The manner in which these officials function is fully described by Dr. D. J. West in his book *Eleven Lourdes Miracles*, in which he gives a critical examination of the medical documents relating to eleven "miraculous" cures reported from Lourdes between 1937 and 1950. These eleven cases are each discussed in detail and substantiated by quotations from relevant documents. An appendix gives a list of all the cures accepted by the Lourdes medical bureau in the period 1925-50, 98 in all, but only about 10% of these have been proclaimed to be "miraculous." In other words, the official "miracles" represent only a small minority of the cases accepted by the Lourdes bureau as genuine instances of remarkable cures.

A close examination of the eleven alleged miracles provides very little indication of anything in the nature of inexplicable recovery, and, as for the so-called remarkable cures (not claimed to be miraculous), these for the most part refer to conditions which often are said to get better of their own accord. The only remarkable feature was the speed and manner in which the recovery occurred. The incompleteness of the medical information on most of the cases makes any kind of appraisal exceedingly difficult, but, as Dr. West says, "As far as it goes, and taking the dossiers at their face value, the evidence for anything 'miraculous' in the popular sense is extremely meagre."

Dr. West undertook this investigation at the instance of the Parapsychology Foundation of New York. He visited Lourdes in 1955 and was given access to the original dossiers of the medical bureau, so he speaks with first-hand knowledge of what he has himself investigated. It is to be hoped that copies of this objective and disinterested study will be made easily available to all members of the medical bureau at Lourdes and that they will pay attention to the suggestions Dr. West makes as to ways in which they might improve the documentation of the evidence they collect.

The modest title *Some Thoughts on Faith Healing* scarcely does justice to the pamphlet of sixty pages recently published by the Christian Medical Fellowship. It would be better described by the title "Common-sense Thoughts on Faith Healing," because this is a most reasonable and sensible exposition of a subject about which a lot of nonsense has been written. The study circle responsible for this booklet seems to have been meeting at about the same time as the B.M.A. Committee or soon after, because reference is made more than once to the recently published Report to the Archbishops' Commission. The conclusions of the Christian Medical Fellowship Group are much the same as those of the B.M.A. Report, but if points were to be given for readability, constructiveness, and sense of conviction there is little doubt that this booklet by Dr. Edmunds and Mr. Scorer would win on points.

CUTHBERT DUKES.

FLUID BALANCE

Essentials of Fluid Balance. By D. A. K. Black, M.D., F.R.C.P. (Pp. 127+xiv; illustrated. 18s. 6d.) Oxford: Blackwell Scientific Publications. 1957.

Dr. Black has made important original contributions to our knowledge of water and electrolyte balance in health and disease. There is no one better qualified to write a guide to the subject. His declared purposes have been to keep the book as short as possible, consistent with clarity, and to make the presentation helpful to the general medical reader, including the undergraduate student. Anyone who has tried

to achieve these aims in regard to this particular topic knows the difficulty of the task. He has succeeded, and this concise book may be recommended to anyone who wishes to obtain up-to-date knowledge of fluid-balance problems and to understand how to treat patients presenting them.

The book is split up into six chapters dealing with the general properties of body fluid and then, respectively, the balance of water, sodium, and potassium, and acid-base equilibrium; finally, considerations governing treatment are discussed. The references are reasonably comprehensive and well selected. The final index is full and useful.

It is curious to reflect that general medical appreciation is only of the very great practical importance of dehydration is only a feature of the last twenty or twenty-five years—apart from a few individuals like J. B. Murphy. Yet enormous numbers of doctors were gardeners and realized that plants died without water. It was perhaps the biggest and most persistent of all medical blind spots. To-day there is general awareness of the essential importance of water and electrolytes, but often the awareness is not linked with much knowledge. Dr. Black's book fulfils the needs of those seeking a basic grounding regarding fluid balance.

H. L. MARRIOTT.

PARTICLES IN CELLS

Mitochondria and Other Cytoplasmic Inclusions. Symposia of the Society for Experimental Biology. Number X. of the Society for Experimental Biology. Published for the Company of Biologists on behalf of the Society for Experimental Biology. Cambridge: At the University Press. 1957.

The tenth symposium of the Society for Experimental Biology must, indeed, have been a fascinating experience. Occupied with the latest discoveries and opinions about small particles found in animal and plant cells, its official record is an indispensable addition to a literature that increases at a terrifying pace. We must therefore be grateful to the group of workers who have put aside their experiments, for the time being, to bring some sort of order out of technical chaos.

The Golgi controversy, as it is aptly named, is discussed in lively fashion by Baker, Lacy and Challice, and Dalton and Marie Felix in three highly critical communications. Many aspects of cytoplasmic particles and fractions, especially the vexed question of enzymic and biochemical heterogeneity, are ably dealt with by Green, de Duve, and Novikoff. Extremes meet in the papers by Crawford on the snail amoebocyte, by Chayen and Sylvia Fitton Jackson on particles in plant roots, and by Randall on a protozoan on *Spirostomum ambiguum*. Slater gives a masterly survey of muscle mitochondria, and Barer and Joseph place us greatly in their debt by explaining, with admirable clarity, the principles of phase-contrast and interference microscopy as applied to the investigation of cell structure.

Barely 200 pages suffice to place the reader in the centre of an exciting frontier of biology and medicine. Excellent photographs and careful editing round off a venture that should win many appreciative readers.

G. R. CAMERON.

ABOUT "NERVES"

Nerves Explained: A Straightforward Guide to Nervous Illnesses. By Richard Asher, M.D., F.R.C.P. (Pp. 157. 10s. 6d.) London: Faber and Faber Ltd. 1957.

"If people want to read about nerves they will manage it somehow," says Dr. Asher, and his reason for writing a popular book is that he would prefer them to read sense rather than some of the books on the subject which at present fill the shop windows and which are as likely as not either to frighten or to give the impression that one of the theoretical approaches has the sole key to the problems of mind. His method is to take each field of psychological medicine in turn, and, after dealing with some of the current fallacies which may mislead or alarm even the

intelligent layman, to give a brief account of the subject as it is likely to be encountered by a relative or a close acquaintance of the patient. He has an easy style, uses plain English without talking down to his reader, and has succeeded in giving an account which will carry conviction while keeping strictly to scientific fact. Dr. Asher is a physician who has seen the impact of psychiatry on his patients and mistrusts its separation from the solid ground of medicine. If every physician cannot be his own psychiatrist he would prefer his psychiatrist to be a physician. He has not hesitated to give his views on current trends, but only the exponents of exclusive schools of thought are likely to quarrel with him seriously. In dealing with everyday domestic, nursery, and marital problems, and especially in his choice of what to leave out, he has shown a sureness worthy of Walter Alvarez. Medical men may be a little suspicious of yet more ammunition for quotation by their patients, but they may be glad of a book to recommend to the relatives of the nervous, the mentally afflicted, and those unfortunate sufferers from chronic and painful illness who have been told that their condition is "psychosomatic" and ask what they should do about it. As an example of how to put psychological medicine to the layman this book has much to commend it. It could be used with advantage as a preview for the preclinical student as well.

ALEXANDER KENNEDY.

PRACTICAL GASTROENTEROLOGY

Praktische Gastroenterologie. By E. Hafter, with contributions by H. W. Hotz and F. Deucher. (Pp. 380+vi; illustrated. D.M.48.) Stuttgart: Georg Thieme. 1956.

During the last few years progress in gastroenterology became so important that it is impossible for the physician non-specialized in this domain even to survey it. For the practitioner, the medical specialist, the x-ray specialist, and the surgeon the problems have to be faced from an entirely different angle, and the co-operation of all concerned might be unsatisfactory because of local and personal reasons and reasons of time. It seems to be justifiable now to omit the historical and theoretical aspects from a short book and to concentrate on the guiding principles of practical diagnosis and treatment. The authors rightly emphasize the need for taking a thorough history as a help in the differential diagnosis from carcinoma of the gastrointestinal tract, cholelithiasis, and especially cholecystolithiasis, diseases of the pancreas, regional ileitis, and gastrointestinal allergy. This is an excellently produced book. The literature refers mainly to sources in the French and German languages.

E. FORRAI.

CONTINENTAL CARDIOLOGY

L'Année Cardiologique Internationale. Book 5. Under the direction of C. Lian. (Pp. 374; illustrated. 2,200 fr.) Paris: Expansion Scientifique Française. 1956.

In this book, the fifth in the series, Professor Camille Lian contributes the first article on the treatment of hypertension. He has given up methonium compounds, and relies on rauwolfia, up to six tablets a day. There are 23 other articles. Among papers dealing with congenital lesions are those on Ebstein's deformity and pulmonary stenosis and on aortic-pulmonary communication. Subjects of papers on vascular diseases include the syndrome of arterial spasm, coronary and cerebral syndromes, and obstructive arteritis of the arms. The late results of mitral valvotomy are considered, and the therapeutic effects of heparin and salicylates discussed. In all, the volume provides an interesting cross-section of Continental thought and progress, and this includes Turkey, Italy, Greece, and Spain. There are some very poor skiagrams. The photomicrographs are rather indistinct; the cardiograms and ballistograms often faint. It would be nicer if the interleaved advertisements all came at the end.

TREMOR

Tremor is a constant feature of muscle contraction, though its amplitude may be so small as to be almost unnoticeable. As L. Binet¹ pointed out in 1920, "all normal subjects show tremor which disappears only when the part of the limb under investigation is in a state of complete rest, totally relaxed, on a resisting plane." In healthy people the rhythm has a rather constant frequency of about 10 cycles per second. This was first shown by E. A. Schäfer and colleagues² and has been repeatedly confirmed by other investigators. Recordings of action potentials from motor units in the muscle, on the other hand, show that the rate of stimulation of the muscle may vary widely. E. D. (now Lord) Adrian and D. W. Bronk³ recorded human motor units firing at from 5 to 50 cycles a second, and, though rates as low as 5-10 a second are undoubtedly found in weak voluntary contraction, the frequency is not constant but alters with the strength of contraction.

It has been recently suggested by J. Marshall and E. G. Walsh⁴ that the more or less fixed frequency of tremor is simply a function of the inability of the muscle to respond with mechanically discrete contractions to frequencies of stimulation above 15 per second. There is no doubt that, as they point out, the muscle does act effectively as a "low pass filter," allowing only slower frequencies to appear on the myogram; but it seems questionable whether this in itself is the explanation of the tremor frequency. A. M. Halliday and J. W. T. Redfearn⁵ have recently carried out frequency analysis on the finger tremor of 46 healthy subjects, recorded photoelectrically. By this means even relatively small changes in the

frequency of peak tremor, which might escape detection by visual inspection of tremor records, could be automatically recorded. Loading the finger with 50 or 100 g., and thus increasing the tension exerted by the muscle, failed to produce any significant change in tremor frequency, though the mean firing rate of the motor units would have been expected to rise under such circumstances.⁶ The mechanical properties of the limb also appeared to be insignificant, so that tremor is not produced by mechanical resonance. It seems difficult to escape the conclusion that the tremor is a secondary rhythm, superimposed upon and modulating the individual rates of firing of the motor units.

The fact that tremor and the alpha rhythm both have a frequency of about 10 cycles per second suggested that the tremor might originate in the motor area of the contralateral cortex and reach the spinal motor neurones by way of the pyramidal tract.⁷ H. H. Jasper and H. L. Andrews⁸ reported a close similarity between tremor recorded photoelectrically from the finger and the alpha rhythm recorded over the pre-motor area of the brain on the opposite side, but these results were in conflict with those of L. E. Travis and C. N. Cofer.⁹ These workers recorded finger or toe tremor simultaneously with the electroencephalograph from several areas on both sides of the head, but found that the two rates were invariably different. T. Lindqvist¹⁰ has further shown that, when the normal alpha rhythm is replaced by slower waves after hyperventilation or, pathologically, in epileptics, there is no corresponding slowing of the tremor rhythm. It has been left to G. G. Sutton¹¹ to provide the *coup de grâce* to the alpha rhythm theory by showing that under certain conditions the tremor rhythm can be made to disappear on closing the eyes, which is precisely the circumstance under which the alpha rhythm appears or becomes accentuated.

Those disappointed by the cortex as a possible pacemaker for the tremor rhythm might well turn to the now more fashionable brain-stem reticular system as a likely candidate, for the effect on tremor of emotional stress and anxiety shows it to be exceedingly sensitive to the influence of the higher centres. But there is evidence that the rhythm can be produced at spinal level. Victor Horsley and E. A. Schäfer¹² were able to demonstrate it in the myogram after electrical stimulation of the cut end of the spinal cord at thoracic level in the cat, rabbit, dog, and monkey, provided that the stimulus itself had a rate faster than the tremor rhythm. If the motor nerve was cut, however, and its peripheral end was stimulated in the same way, the muscle followed the rate of stimulation faithfully up to that of a fused tetanus, which

they found to be at 30 cycles per second or more. These results seem to establish that tremor could not simply be due to mechanical smoothing, as Marshall and Walsh suggest. Horsley and Schäfer also noted that the tremor rhythm was present in spontaneous or reflex movements, and a similar finding in man has recently been reported for the flexor withdrawal reflex elicited in two patients with clinically complete spinal transection due to transverse myelitis.⁴

If it is accepted that the tremor pacemaker is situated at the spinal level, the question still remains whether the rhythm is centrally or peripherally determined. R. Jung¹³ thinks that it lies in the system of spinal interneurons which play upon the motor neurone pool; but the phenomenon of clonus shows that the stretch reflex arc is itself capable of going into self-maintained oscillation, and it has been suggested that tremor too may be produced in this way.^{5, 11} There is no reason to suppose that clonus occurs only at high amplitudes; every degree of transition between complete asynchronism and complete synchronism can be obtained in the firing of a motor unit in a laboratory preparation simply by altering the posture and modifying the proprioceptor inflow. On the other hand, centrally determined rhythms undoubtedly exist at spinal level, as is seen, for instance, in the scratch reflex of the spinal cat.¹⁴ Here the muscles contract intermittently at 5 beats a second. This rhythm does not depend on the proprioceptors, since it persists after section of the dorsal roots; clonus is naturally abolished by this procedure. Destruction of afferent nerves can therefore provide important evidence about the site of the tremor pacemaker. Halliday and Redfearn¹⁵ have recently reported the results of an investigation of tremor in tabetic patients. They found that in those patients with more severely damaged afferent nerves the 10 cycles per second rhythm may disappear, and this would seem to be strong circumstantial evidence in support of the view that tremor is an oscillation in the stretch reflex arc. But there are certain difficulties which at present remain unexplained, such as the slower rates of tremor reported in children.⁴

Are all tremors produced in the same way? It seems that the type of tremor met with in hyperthyroidism¹⁶ and in anxiety states¹⁷ is of the same frequency as that encountered in healthy subjects. The greater amplitude of tremor in these conditions can probably be regarded as an accentuation of the normal. The slower and coarser tremor of extrapyramidal disease appears to be a distinct phenomenon. Indeed, both "normal" and extrapyramidal tremor may be seen together in the same patient—for instance, on the unaffected side in unilateral cases of

paralysis agitans,⁴ or when sleep has abolished the much greater Parkinsonian tremor.¹⁸ Moreover, the electromyograph shows a different pattern of innervation.¹⁷ Further work may throw more light on the significance of these differences.

TOLBUTAMIDE IN DIABETES

The new oral hypoglycaemic agents have now been used for nearly two years in several diabetic clinics in Great Britain. The first compound to be studied—carbutamide—was found to cause agranulocytosis and thrombocytopenia in a few patients.¹ Fatal toxic reactions have now been reported from the United States. W. R. Kirtley,² in an analysis of 7,193 patients treated with carbutamide, refers to eight deaths "occurring under circumstances which might indicate that the drug had contributed"; necropsy reports suggested that generalized sulphonamide sensitivity was the commonest cause. The other new hypoglycaemic substance—tolbutamide—is not a true sulphonamide, and seems at present to be less toxic than carbutamide. It is now available on prescription.

Tolbutamide is not a form of insulin. It will lower the blood sugar in normal subjects and in some diabetics, but only if some insulin is being secreted by the pancreas. This is of practical importance, because it means that the "insulin-deficient" diabetic will rarely benefit from tolbutamide therapy. The way in which these drugs lower the blood sugar has been the subject of careful study. Insulin does so by increasing peripheral utilization of glucose and by reducing output of hepatic glucose. Tolbutamide has little or no effect on peripheral utilization but acts mainly by reducing hepatic output,³⁻⁵ possibly by interference with enzyme systems of the liver. On the other hand, there is evidence that pancreatic secretion of insulin is increased by the action of tolbutamide⁶; possibly the amount secreted is only sufficient to affect hepatic production of glucose without increasing peripheral utilization. There are obvious dangers in the long-continued use of a drug with these actions. Interference with liver enzymes may ultimately

¹ *British Medical Journal*, 1956, 2, 465.² Kirtley, W. R., *Diabetes*, 1957, 6, 72.³ Hennes, A. R., et al., *Metabolism*, 1957, 3, 63.⁴ Kibler, R. F., and Gordon, G. G., *J. Lab. clin. Med.*, 1956, 48, 824.⁵ Berson, S. A., and Yalow, R. S., *Diabetes*, 1957, 6, 274.⁶ Colwell, A. R., et al., *Metabolism*, 1956, 5, 749.⁷ Bander, von A., et al., *Disch. med. Endocr.*, 1957, 15, 48.¹⁷ Dulake, M., at the 11th Banting Memorial Meeting, Oxford, July, 1957.

produce severe hepatic damage, and continued stimulation of the pancreas an aggravation of the diabetes. Furthermore, though it lowers the blood sugar in selected diabetics, there is no evidence that the other metabolic disturbances are corrected. Dr. W. J. H. Butterfield and colleagues in a paper at p. 325 of the *Journal* this week sound a warning note on some of these hazards. The late complications, like retinitis and kidney damage, may not be due to hyperglycaemia and may still develop although the blood sugar has been kept within the normal range by tolbutamide.

The type of diabetic suitable for trial of tolbutamide therapy has been well defined in published reports,⁷ and Professor D. M. Dunlop discusses this at p. 351 this week. The insulin-deficient diabetic rarely benefits, though there may be a transient response in the early stages before production of pancreatic insulin ceases altogether.⁸ Insulin-deficient diabetics include nearly all of those diagnosed before the age of 40 years, all who have had ketosis to a significant degree, and most of those who were underweight at the time of diagnosis. Patients likely to respond are in the older age group, usually have mild diabetes, and tend to be overweight. Single-dose tests have been suggested to help in the selection of suitable patients, but H. Dolger⁹ has found them unreliable and recommends therapeutic trial. Obesity should be regarded as a contraindication to tolbutamide therapy, because in most cases the diabetes can be controlled by diet, and if tolbutamide is given there is usually further gain in weight. A final point in selection of suitable cases is the patient's attitude to his disease. Regular supervision and adherence to diet are essential while this new treatment is being tried, and tolbutamide should be prescribed only for patients who will co-operate fully with their doctors.

Studies in Great Britain and in the United States have been concerned for the most part with long-term maintenance of diabetic patients on tolbutamide. In a small group of cases investigated at the Whittington Hospital in London and reported in the *Journal* this week (p. 327) the value of a short course of tolbutamide to facilitate the initial control of mild diabetes has been assessed. This method of using the drug will need further study before its place in the treatment of diabetes can be decided.

Patients not receiving insulin may be considered for a trial of tolbutamide if they are of average weight or underweight, and if despite adherence to a low carbohydrate diet they have hyperglycaemia but no ketonuria. Initial dosage should be 0.5 g. three times daily after meals. Divided dosage is essential because of rapid absorption and excretion, and it is better to

give the drug after meals, because on an empty stomach it is apt to cause dyspepsia. If the response is inadequate dosage may be increased, but at the present time 3 g. daily should probably be regarded as a maximum dose. Patients receiving small doses of insulin, less than 30 units daily, if they fall into this group of stable, middle-aged diabetics, may also be considered for trial of tolbutamide. The insulin may be reduced gradually and tolbutamide and insulin given for a few days before stopping insulin completely and relying on tolbutamide alone. Hypoglycaemic attacks may occur during the period of combined therapy, and as an alternative insulin may be stopped over a few days and the tolbutamide started subsequently. In any case the patient must be seen daily and the urine tested for sugar and ketones, because an apparently suitable patient may really have the insulin-deficient type of diabetes and develop severe ketosis when the insulin is reduced or stopped. In many cases it will be safer for the patient to be in hospital for a few days if transfer from insulin to tolbutamide is contemplated.

While on maintenance therapy the patient must remain under strict supervision. Side-effects so far reported include allergic skin reactions in about 1%, leucopenia, and thrombocytopenia.^{10, 11} Gastro-intestinal symptoms have been noted,¹² and also facial flushing after alcohol.¹³ One or two deaths have occurred in old people, apparently from hypoglycaemia.¹⁴ Tolbutamide administered in pancreatectomized dogs has produced alarming evidence of impairment of liver function,¹⁵ but this has not so far been described in diabetic patients. During maintenance therapy there may be evidence that the patient is becoming resistant to the hypoglycaemic action of the drug.¹⁶ Dr. G. Walker and colleagues in a report from the Middlesex Hospital (p. 323) point out that in many cases the resistance will be due to dietary failure or associated with increase of body weight. They do, however, produce evidence that in some cases there may be true resistance, possibly due to exhaustion of pancreatic insulin.

With the general release of tolbutamide, general practitioners may be considering whether any of their diabetic patients would benefit from it, and patients themselves are likely to raise the question of "tablet treatment." The results of trials at King's College Hospital¹⁷ and the Middlesex Hospital in London, and the Royal Infirmary, Edinburgh,¹¹ were given recently at a meeting organized by the British Diabetic Association. Of 369 patients selected as being likely to respond to tolbutamide, 291 showed some response, but after an average of about four months' treatment control was satisfactory in only 191 (52%). These

figures are disappointing, and when deciding whether a trial of tolbutamide is justified the clinician has to bear in mind that there are some untoward toxic effects, the mode of action of the drug is still uncertain, and nothing is known of the results of long-term administration.

THE LIVER

In many respects knowledge of the normal and abnormal behaviour of the liver still lags behind that of other organs. Among the reasons for this are the extreme complexity of the functions of the liver, and in contrast the relatively limited response of this organ to a variety of injuries. Much of the earlier experimental work on animals is not directly applicable to man, and attention is being devoted more and more to studies of the human liver, based on modern biochemical and morphological techniques. This approach is exemplified in the latest issue of the *British Medical Bulletin*,¹ which contains fifteen papers on "some physiological and clinical aspects" of the liver. In his introduction Sir Harold Himsworth says that this is "a publication teeming with fresh information," and its appearance illustrates the current interest in liver disease. In spite of much progress, however, there are still enough unanswered questions to satisfy the most enthusiastic research worker. For example, C. H. Gray gives a lucid account of the recent discovery that bilirubin is conjugated on its passage through the liver (thus explaining the forty-year-old mystery of the van den Bergh reaction), but points out that almost nothing is known of the way in which bilirubin is formed from haemoglobin or of the pathways for the excretion of bilirubin by the kidneys. Similarly C. B. Cameron ends an excellent review of steroid metabolism with the admission that, in spite of much work, there appears to be little obvious relationship between the steroid hormones and those features of liver disease—salt and water retention, circulatory changes, and alterations in sexual function—which are thought to depend on these hormones. Papers by J. C. Waterlow and G. Bras on nutritional liver damage in man and by N. H. Martin and A. Neuberger on protein metabolism show that there is still uncertainty about the part played by malnutrition in causing liver disease. However, advances have been made in this field, particularly in classifying varieties of tropical liver injury; and the belief that a fatty liver can progress to fibrosis is now no longer tenable.

E. R. Cullinan in a paper on the course and prognosis of infective hepatitis emphasizes the benign nature of the disease, and refers to a follow-up study of Army cases which is still in progress and should throw light on the ultimate prognosis. Both he and J. F. Stokes and M. L. Rosenheim stress the importance of alcohol, exercise intolerance, and various anxiety symptoms which may interrupt convalescence from this disease. The latter two authors discuss the treatment of the various clinical syndromes associated with diffuse liver disease, and Sheila Sherlock's review of liver failure demonstrates

clearly how rational therapy can be based only on detailed knowledge of the mechanisms involved. Two papers on the rare diseases haemochromatosis (J. C. Houston) and hepatolenticular degeneration (J. M. Walshe) are justified by recent advances in elucidation of their aetiology and in the development of effective treatment. D. Sutton contributes a useful article on new methods of radiology, such as splenic venography and "biligrafin" cholangiography, which are important aids in the operative treatment of liver disease.

On the whole the clinician can be well satisfied with the progress that has been made in the last few years in our understanding of liver disease. But it is surprising how many fundamental problems remain to be solved. The present symposium points the way.

LUNG CHANGES DURING METHONIUM THERAPY

The development of distressing tachypnoea during treatment with methonium compounds was first described by I. Doniach and colleagues¹ in three of a series of 54 severely hypertensive patients. The first patient became increasingly dyspnoeic after seven months' treatment with high doses of hexamethonium. The radiological changes in the lungs were sufficiently like tuberculous infiltration to justify a course of antituberculous therapy, and hexamethonium was temporarily stopped. The symptoms improved and did not recur when the drug was restarted. In the other two cases, also on large doses, dramatic relief of dyspnoea occurred with rest in bed, and radiological clearing on stopping hexamethonium. Unfortunately, however, the blood pressure rose and both patients died as the result of their hypertension. At necropsy the lungs showed a diffuse inter- and intra-alveolar fibrosis, with preservation of the alveolar elastic pattern, typical of the process known as "carnification." The chief cause of carnification is failure of absorption of a fibrinous alveolar exudate, such as may occur in prolonged cardiac or renal failure. However, in spite of the fact that the radiological changes resembled those seen in pulmonary oedema, neither cardiac failure nor uraemia appeared to be responsible for the dyspnoea. In fact the authors were cautious in attributing the syndrome to hexamethonium, and suggested that it was not necessarily an indication for abandoning treatment.

H. M. Perry and colleagues² have recently reported a further eight cases in patients who were not uraemic but whose hypertension was poorly controlled in spite of large doses of blocking agents. The clinical and pathological findings are similar to those reported by Doniach *et al.*, and, though "fibrinous pneumonitis," as they call it, was identical anatomically with that occurring in untreated patients dying of renal failure, it was significantly more common in the methonium-treated group. Moreover, it was rare in non-uraemic patients, except in those receiving methonium compounds, and the authors suggest that these substances may have a similar action

¹ Doniach, I., Morrison, B., and Steiner, R. E., *Brit. Heart J.*, 1954, 18, 101.

on the lungs to the products of nitrogen retention. A series of patients with cardiac failure due to mitral stenosis was also studied, but fibrinous pneumonitis was uncommon. This finding, with the fact that circulation times were normal in the methonium group, tends to rule out increased capillary permeability and cardiac failure as causative factors. The mechanism therefore remains a mystery. The fact that apparently only two papers have appeared describing this syndrome suggests that it is an infrequent accompaniment of methonium therapy. It is not mentioned, for example, by F. H. Smirk³ in a review of 250 patients. It would be instructive to know the true incidence of lung changes attributable to methonium compounds, and whether their appearance is an indication for discontinuing treatment.

PNEUMOCONIOSIS IN COAL WORKERS

Pneumoconiosis continues to present many problems. An extensive study, based on the prevalence rate of this disease in coal workers in the British Isles, has recently been made by the members of the Medical Research Council's Pneumoconiosis Research Unit at Cardiff.¹ The importance of the prevalence rate, as distinct from the mortality rate, is twofold: it serves as a measurement of the actual load on the community, and it is also a preliminary step to measuring the attack rate and the progression rate. In this investigation it is estimated solely on the basis of radiological appearances, classified into the categories of simple pneumoconiosis (1, 2, and 3) and progressive massive fibrosis (P.M.F., A, B, C, and D). The technique of repeated radiography has been greatly improved, both by technical developments of apparatus and by increased skill of the observer, so that with a subdivision of miners and ex-miners into six groups it has been found possible to achieve a 90% level of repeatability. The classification used by these authors to estimate disability from pneumoconiosis shows that with all groups of simple pneumoconiosis this is slight, but that P.M.F. is a seriously disabling condition; it probably reduces the expectation of life, though less than previous work has suggested. Application of this technique to the diagnosis of concurrent tuberculous infection presents some difficulty because of the slight distinction between the shadows due to early P.M.F. and those of tuberculosis. It has been found possible to distinguish between "clinically significant" (that is, indicating the necessity for continued observation) and "inactive healed" tuberculosis in miners within category 1, but not in categories 2 and 3; these two have therefore been included in category A (P.M.F.). Unlike the American and German investigators, these authors have not found it possible to make a reliable clinical distinction between P.M.F. and tuberculosis; the only reliable subdivision is based on the presence of bacilli in the sputum.

In choosing the population for investigation it was decided to radiograph only the underground workers in areas, in England, where the prevalence was low; in Wales both the surface and underground population were usually examined, or community surveys were

made. The prevalence rate of radiological abnormality in the underground population of twelve British collieries was found to range from 60% to 20%, while the surface population of eight of these (in Wales) showed prevalence rates ranging from 40% to 20%. In four of these Welsh collieries the prevalence was similar to that of French collieries and higher than that of Ireland. Belgian miners have a higher percentage of simple pneumoconiosis but a low rate of P.M.F., attributable possibly to the fact that Belgian miners go to the coal face at a later age than the Welsh.

Estimation of the social and medical damage done by coal dust was made by analysing the factors of "dust dosage"—age of the miner, his years underground, and his years at the coal face. Consideration of this last factor shows that the attack rate of pneumoconiosis in men working at the coal face has been very high in the past. On the whole, however, there appears to have been a true fall in the prevalence rate of both simple pneumoconiosis and also of P.M.F. in the younger miners and ex-miners of the Rhondda during the past five or six years. There is a definite relationship between the radiological category and the level of unemployment, when due allowance is made for age; and the more advanced cases of P.M.F., unlike those of simple pneumoconiosis, are associated with loss of weight. All the evidence, in fact, goes to show that simple pneumoconiosis, while not itself a condition entailing severe pulmonary disability, carries nevertheless, except for cases in the first category, a liability towards the development of P.M.F. This is a much more chronic, progressive, and disabling disease, with an increasing tendency to association with tuberculosis. It is thus evident that preventive measures must be focused on an attempt to reduce dust concentrations to a level where simple pneumoconiosis, the forerunner of P.M.F., will affect the minimum number of miners. Routine radiography, with removal from the mine of men who fall into a category higher than that of simple pneumoconiosis, would further reduce the number of cases of P.M.F. and of tuberculosis in the collieries.

MEASURE TO MAID

The beautiful proportions which artists throughout the ages have been able to portray in the female figure must often have amazed doctors, or beachcombers for that matter. For when an unselected sample is examined, the human body is notable more for its extreme departures from the average in every direction than for its resemblance to the figures on the Parthenon frieze. But if we are inclined to see the women of ancient Greece through the eyes of Phidias, or of twentieth-century France through the eyes of Matisse, posterity will have the advantage of knowing what our contemporary British women were like by turning to *Women's Measurements and Sizes* (a study sponsored by the Joint Clothing Council Ltd.).¹

In 1950 the clothing industry decided there was a need to measure a large sample of British women in order to gather data from which to manufacture better-fitting clothes. With the help of the Ministry of Health,

this laudable project soon got under way. Investigators were trained, employers approached, volunteers measured, electronic machines fed with data, and finally a book produced which, though written to help the clothing trade, contains something of interest to medical men engaged in anthropometry. In all, about 200,000 measurements were made on 5,000 women, whose ages ranged between 18 and 70. The results are recorded with thoughtful objectivity. Owing to the ways in which the subjects were obtained, the sample is not strictly representative of the British population; rather too many of the women came from southern England, for instance, and too many of the married women were working in some paid occupation. But an analysis of some of the subgroups shows roughly what allowance, if any, ought to be made for the various sources of bias when attempting to generalize from the sample.

On the whole the measurements seem to have been admirably made, and, when all 200,000 of them are thrown into the electronic cauldron and boiled down, an average woman emerges. She bears a striking resemblance to Renoir's women, and incidentally none at all to those rakish fashion models advertising clothes alike in the glossy magazines and the stores catalogues. Split up into age groups, the average woman weighs about 9 stone at 18–29 years, 9½ stone at 30–44 years, and 10 stone at 45–64. But while her weight goes up her height goes down, and in these three age groups she measures 63.4, 63.0, and 62.1 inches. Strongly correlated with weight are bust girth, waist girth, and hip girth, and on the average they all increase with age. Height varies by as much as 2 inches with economic status, being (on the average) 62.6 inches for women earning under £3 a week and 64.7 inches for those earning £10 or more, with a continuous gradient in between. A curious feature is that at all ages married women who have borne children are slightly shorter than married women without children. The expected tendency for them to be heavier is there, but is not so consistent. As to girth, it must be a matter of common observation that the top-heavy film star profile of large bust and small hips is, statistically, a trifle freakish. The data here show that among British women the hip girth is larger than the bust girth in 66% and the same size in 25%, while the bust exceeds hips in only 9%. Nor are things very different in the U.S.A. A comparison with an American survey carried out on similar lines, and summarized in this publication, shows that the average American woman, when compared with the average British woman, is slightly heavier, slightly longer in the body and shorter in the leg, and much smaller in the bust. However, differences in technique may account for part of the differences in measurements.

Men have not been slow to notice that women's clothes combine two elements in their design—utility and adornment. The former was represented by a mass-bearskin and the latter by woad in earlier times. Mass-production has nowadays made clothes at once more closely tailored but less individually cut. The consequences of this in the shoe industry are not always

beneficial, as correspondents have recently been pointing out in our columns. But good fit need not be at odds with new fashion, and the sponsors of this study have performed a useful service in doing their best to see that it shall not be.

SEEING IN THE DARK

In time of war the ability of Service men to see well under conditions of low illumination is of great value on land, at sea, and in the air. At the beginning of the second world war the selection of personnel with good night vision became a problem of great urgency and importance. One of the research groups set up by the Medical Research Council to study this problem has now published its results.¹ The luminance (brightness) levels required to resolve black Landolt rings (broken circles) of different sizes were measured by testing 22 young adults. The luminance levels were found to correlate closely with absolute threshold measurements made by exposing a disk of light to the subject for 0.2 sec. Furthermore, the ability of an observer to perceive under dim lighting a complex visual scene, such as an unusual Hogarth print, also correlated well with the absolute sensitivity of the eye. Stated simply, an individual with high visual sensitivity to a simple flash test "sees" more in a complex scene than an individual with a low sensitivity. This was a point which was not widely appreciated in military circles in 1940, when this research began.

The careful measurements detailed in this report are also of theoretical interest, for they confirm that under ideal conditions the dark-adapted retina will respond to a few quanta of absorbed light energy. A quantum is the smallest discrete "parcel" of energy that can be transferred from one system to another.² The application of quantum physics to the physiological mechanism of vision is opening up new areas of thought.³ R. L. Gregory, V. Cane, and H. B. Barlow,^{4, 5, 6} at Cambridge, have applied those mathematical concepts originally developed by engineers for dealing with the problems of communication to a variety of visual thresholds in the hope of producing a basic theory which will account for the many properties of the retina. This application of physics and mathematics to sensory physiology may well show further interesting developments in the future. Optical factors also play a part in the detection of objects in the visual field both at low and at high levels of illumination.⁷ The accommodation mechanism of the eye does not remain stationary under conditions of low contrast, and there may be a tendency for the observer to become myopic.⁸ Some recent work suggests that this myopia may be a problem in fast flight at high altitudes.⁹

FUNGOUS DISEASES AND THEIR
TREATMENT

[FROM A SPECIAL CORRESPONDENT]

On July 22, 23, and 24 a symposium on "Fungous Diseases and Their Treatment" was held at the Institute of Diseases of the Chest, Brompton Hospital, London, in association with the Institutes of Child Health, Dermatology, and Obstetrics and Gynaecology. The occasion was a notable one, because for the first time at such a meeting it was possible to include reports of successes in the treatment of the systemic mycoses. The audience of 120, of whom 15 were from abroad, was invited, and represented a wide variety of interested specialties.

Pathology and Immunology

The first session was on pathology, with Professor R. CRUICKSHANK in the chair. Dr. R. W. RIDDELL (London) opened by discussing under three main headings the fungi pathogenic to man, the filamentous, yeast, and dimorphic organisms. This morphological division represented an ascending scale of parasitism. The fungi that cause skin lesions could be grouped according to their ability to invade keratin and to parasitize subcutaneous tissues, and a similar division in pulmonary infections was illustrated by contrasting locally invasive fungi, such as *Aspergillus fumigatus*, with organisms which disseminate, such as *Cryptococcus neoformans* and *Histoplasma capsulatum*. Professor W. St. C. SYMMERS (London) dealt with the wide range of tissue reactions which occurs in the deep-seated mycoses, illustrated by patients seen in Britain in the last ten years. Yeasts might be simulated by a number of artifacts, mucus-secreting carcinoma cells and Flemming's stainable bodies of nuclear debris. The use of special stains, in particular the periodic-acid-Schiff and silver impregnation methods, was of value in histological diagnosis. Further, the parasitic form of one fungus might closely resemble that of another, so that certain diagnosis was possible only by culture and by animal inoculation. Dr. F. MARIAT (Paris) described infections due to the aerobic Actinomycetes, particularly mycetomata of the exposed parts. His *in vitro* studies suggested that sulphones might be effective against these infections.

The question of immunity in yeast infections was discussed by Dr. H. I. WINNER (London), who cautioned against transferring direct to mycology concepts of immunity gained from bacteriology. The size of the yeast cell led to foreign-body reactions, and its more complex antigenic structure could be assumed to influence the host's response. In animals innate and probably also acquired immunity to yeasts could be demonstrated, and experimental studies suggested that both a mechanical and a toxic "specific metabolic factor" contributed to the death of animals experimentally infected with *Candida albicans*.

Miss CHARLOTTE CAMPBELL (Washington) described the serological diagnosis of histoplasmosis and emphasized the importance of employing two antigens (one yeast-phase suspension, the other histoplasmin) in complement-fixation tests. The collodion agglutination test should also be included. By so doing, circulating antibodies could be demonstrated soon after exposure and before histoplasmin skin-test conversion occurs. A positive result would indicate the cases where mycological culture would be profitable, at a stage when this was most likely to be successful. In surveys serological tests were of assistance in detecting local areas of disease in zones of low endemicity. In long-standing or quiescent cases histoplasmin skin tests were helpful, for in such patients circulating antibodies were often no longer demonstrable.

Dermatology

In the dermatological session, over which Dr. G. B. DOWLING presided, the pathogenesis, epidemiology, and treatment of skin infections were discussed by, respectively, Professor R. VANBREUSEGHEM (Antwerp) and Dr. J. G.

HOLMES (Coventry), Miss MARY ENGLISH (Bristol), and Dr. BRIAN RUSSELL (London) and Dr. A. J. E. BARLOW (Huddersfield). Dr. A. TICKNER (London) described the chemistry of pigments isolated from the dermatophytes. *Trichophyton rubrum* infections, according to Dr. C. D. CALNAN (London), were increasing in frequency and now presented a serious problem because of their resistance to treatment. In the discussion opened by Dr. C. H. WHITTLE (Cambridge) the only person to report success in treating these infections was Professor H. GOTZ (Munich).

Medicine

Dr. J. G. SCADDING, dean of the host Institute, presided at the first session on the second day. Dr. M. L. FURCOLOW (Kansas City) described the protean clinical manifestations of histoplasmosis which had partly accounted for the delayed recognition of the disease. Dr. PHYLLIS EDWARDS (Washington) presented the results of large-scale surveys to define the distribution and prevalence of histoplasmosis in various parts of the world. The recording of the size of the skin reactions as percentage frequency-distribution curves provided a useful basis for distinguishing specific from non-specific histoplasmin sensitivity, for in some areas the adoption of the traditional 5 mm. criterion for a positive reaction could be misleading. Dr. Edwards suggested that infections other than histoplasmosis or coccidioidomycosis might account for the histoplasmin sensitivity found in some places.

Dr. K. F. W. HINSON (London) described the pathology and diagnosis of aspergillosis, a fungal infection seen not infrequently in Europe. The two main types of infection were the saprophytic (mycetoma) and the allergic. He was followed by Dr. G. SEGRETAIN (Paris), who discussed the mycological findings in 15 cases of aspergillosis. In some cases there had been invasion of the tissues. Dr. C. J. FULLER (Exeter), describing a group of patients with "farmer's lung," defined a syndrome which has probably a greater incidence than is generally realized. Within a few hours of working in heavy concentrations of hay or threshing dust susceptible subjects develop shortness of breath, tightness in the chest, fever, and malaise. Though no radiological changes were evident at first, fine mottling, particularly in the middle and lower lung zones, became apparent if initial exposure had been heavy or if exposure was repeated daily. Fibrosis of lung might be an ultimate result. Dr. J. W. PIERCE (London) summarized the radiology of the pulmonary mycoses, and showed that, although no one finding could be regarded as characteristic, there was during the course of each disease some feature which might suggest a fungal aetiology. Dr. K. CITRON (London) described his preliminary findings with direct bronchial sensitivity tests using fungal antigens, some of which gave positive results even when skin tests were negative. Opening the discussion, Dr. J. L. LIVINGSTONE (London) said that the allergic group of aspergillosis cases with fleeting radiological shadows and eosinophilia were usually cases of asthma with a superadded mycotic infection.

Therapeutics

Professor L. P. GARROD (London) set the stage for the session on therapeutics by emphasizing the barrenness of this field in the past. Dr. T. ANDERSON (Glasgow) said the incidence of *Candida albicans* in sputum had doubled since the use of the broad-spectrum antibiotics; in the faeces the increase was very much greater, probably because of the considerable residue of antibiotic left in the bowel. The frequency of its isolation led to the ready incrimination of this organism as a pathogen, though it was equally difficult to absolve it from blame. Diarrhoea and glossitis occurring during antibiotic therapy were, he said, unlikely to be direct results of the presence of yeasts. Dr. N. S. PLUMMER (London) reported rather depressing results in the treatment of aspergillosis save where local resection was possible. Treatment of pre-existing disease—for example, bronchiectasis—should not be ignored in favour of antimycotic therapy, and he warned against the operative difficulties

often encountered in these cases and the risk of post-operative fungous infection.

Mr. O. S. TUBBS (London) said they could now expect to cure cases of actinomycosis by giving large doses of penicillin over long periods. He also discussed the indications for surgery. Dr. E. DROUHET (Paris) reviewed a large range of fungicides many of which are, unfortunately, too toxic for clinical use. He dealt with antibiotics under three groups—those which are antibacterial, those which have both antibacterial and antifungal activities, and the purely antifungal agents. This last group included cycloheximide and the polyenes (nystatin and "amphotericin B"). With the latter group a new horizon has opened, as was confirmed by Dr. M. L. FURCOLOW (Kansas), who described encouraging preliminary results from the use of amphotericin B in the treatment of cryptococcosis (torulosis) and histoplasmosis. Laboratory and clinical studies suggested that this agent might prove a "broad-spectrum" antifungal antibiotic.

Dr. G. T. STEWART (Croydon) concluded this session by considering the mode of action of various substances active against pathogenic fungi and illustrating their effect on fungus morphology. Most of these drugs were fungistatic, though fungicidal activity was occasionally achieved at therapeutic levels with polyene, diamidine, and oxyquino-line substances. The active compounds had in common the property of unsaturation, and he suggested that the polyenes act by a highly specific interference with a critical phase of dextrose metabolism.

Gynaecology

With Professor W. C. W. NIXON (London) as chairman, Professor I. DONALD (Glasgow) opened the session on gynaecology on the last day by reviewing the clinical features of vulvo-vaginal moniliasis. Monilial infections accounted for a significant number of cases of vaginal discharge even in the absence of both glycosuria and pregnancy, and the high incidence of carriers of *C. albicans* made it essential to adopt scrupulous techniques in vaginal examination if transference of infection was to be avoided; examination if transference of infection was to be avoided; perfunctory rinsing of gloves in antiseptics between patients was inexcusable. In a gynaecological out-patient department the only practical way of preventing cross-infection was to use a fresh sterile pair of gloves for each examination. Subpreputial infections in the male might also be a source of female infection. Nystatin would often relieve symptoms of vulvo-vaginal moniliasis after one day of treatment. Eight-four per cent. of pregnant patients had been cured symptomatically and culturally of *C. albicans* infection. Similar good results had been obtained in 13% relapsing. Where glycosuria was controlled, and also in non-pregnant patients without glycosuria, and also in diabetics provided the glycosuria was controlled. Where it appeared that an infected cervix accounted for recurrences of infection, he recommended diathermy conization of the endocervix. Although so far there was no evidence of the development of fungal resistance to nystatin, excessive use of this drug should be avoided. Dr. R. F. JENNISON (Manchester), supporting these observations, quoted his own results from a trial comparing the results of treatment of vulvo-vaginal moniliasis with nystatin or 1% gentian violet; failures in the nystatin group were all in pregnant subjects.

Dr. SYLVIA DAWKINS (London) gave the results from her survey of the incidence of yeasts in vaginal secretions in pregnancy. *Candida albicans* occurred no more frequently in later pregnancy (12–15%) than at 16 weeks, but its incidence was significantly reduced in the post-partum period. In all her patients with severe pruritus *C. albicans* was isolated on culture, an isolation rate four times that in patients without this symptom; but other yeasts were less frequent in patients with pruritus. There was the same positive correlation between the incidence of *C. albicans* (but not other yeasts) and severe or moderate vaginitis, vulvitis, and curdy discharge as had been observed in a previous series of non-pregnant subjects. There was no significant incidence of *C. albicans* in babies' mouths up to 10 days of age. In the discussion it was stated that women might acquire vulval

infection from paronychia infection of their hands and that a high percentage of the mothers with babies suffering from thrush had been found to have moniliasis.

Paediatrics

For the final session on paediatrics Professor A. A. MONCRIEFF (London) took the chair. Dr. J. B. BOUND (Blackpool) described monilial infection as a definite and characteristic type of napkin rash to be differentiated from excoriated buttocks, seborrhoeic and ammonia dermatitis. While emphasizing the importance of any monilial infection in the mother, he pointed out that less than one-third of these babies with monilial napkin rash had oral lesions. Dr. M. BODIAN (London) described necropsy findings in infants and children with secondary moniliasis. In the neonatal period secondary moniliasis was found only in babies who had associated congenital deformities. Later in childhood, although it might occur in any debilitating state, the condition was particularly associated with leukaemia, nephrosis, or the prolonged administration of antibiotics as in the treatment of children with bronchiectasis and fibrocystic disease. Dr. I. A. B. CATHIE (London) said that in children moniliasis was almost invariably secondary to debility from some infective or nutritional cause.

Dr. J. MARTIN BEARE (Belfast) reviewed the treatment of ringworm in children, and emphasized the importance of diagnosing by culture the particular fungus responsible. He advised x-ray epilation in all cases of *Microsporum audouinii* infection of the scalp, although this was disputed by some in the audience; he believed that other types of tinea capitis could be treated by topical application.

The particular value of small symposia of this kind, with restricted audiences, was evident from the lively, informed, and critical discussion sessions. The proceedings of the symposium, which was supported by a grant from Messrs. E. R. Squibb and Sons, will be published in full in due course.

JOINT MEETING OF AMERICAN AND
BRITISH CLINICAL PATHOLOGISTS
IN LONDON

On July 9 and 10 the Association of Clinical Pathologists and the American Society of Clinical Pathologists met in joint session in London. On the first day the American pathologists, assisted by some of their British colleagues, demonstrated a "workshop" on clinical haemoglobinometry. The workshop is a form of practical tutorial which the American Society has found useful, and this was the first extension of the idea to Europe. The workshop was held at the Royal Army Medical College, Millbank. On the second day papers were read and discussed at the Royal Society of Medicine.

Workshop on Clinical Haemoglobinometry

The director, Dr. F. WILLIAM SUNDERMAN, introduced the workshop himself, ably assisted by Dr. VERNON E. MARTENS, of America, and Dr. ARTHUR JORDAN, of Sheffield, while the surgeon-general of the United States Navy, Rear-Admiral HOGAN, assisted in its preparation, as he had done previously in America. Dr. M. LUBRAN (London) acted as assistant director, and a number of prominent clinical pathologists from both sides of the Atlantic took part as demonstrators. The 62 participants, ranging from registrars to consultants, were taken through all the stages of haemoglobinometry, from the calibration of pipettes to spectroscopy, being treated to an admirable survey of present-day practice. The British pathologists also gained valuable experience of this new method, thanks to the excellent arrangements made by Dr. Sunderman and his colleagues.

Papers at the R.S.M.

Dr. E. M. DARMADY and Miss FAY STRANACK (Portsmouth) opened the proceedings with a summary of their work, which attempts to correlate function with anatomy in

familial metabolic diseases associated with abnormalities of the renal tubules. Histological and microdissection techniques were described, and photomicrographs of the tubules in the Fanconi syndrome, familial nephrosis, vitamin-D-resistant rickets, and pitressin-resistant diabetes insipidus were shown. The pictures illustrated the "swan neck" lesions of the tubules in Fanconi disease, the narrow neck of the junction of the glomerulus and the tubule in familial nephrosis, the undifferentiated tubule in familial pyelonephritis, the increased translucency in the vitamin-D-resistant group, and the calcium-like plaques on the proximal tubules in cases of hyperchloraemic acidosis.

Dr. JOAN TAYLOR (Salmonella Reference Laboratory, P.H.L.S.) demonstrated the technique of testing the pathogenicity of *Bact. coli* by means of ligated rabbit gut. This method, which depends on a reaction of dilatation and inflammation in the isolated gut, assists in differentiating pathogenic from apparently non-pathogenic strains of the same serotype.

Dr. G. WETHERLEY-MEIN and his colleagues from St. Thomas's Hospital, London, discussing the mechanism of anaemia in leukaemia, showed that there was an occult haemolysis as demonstrated by radioactive isotope techniques with labelled iron and chromium. The pattern of uptake and disposal showed no specific pattern except in chronic myeloid leukaemia, where there was a high plateau of uptake in the liver. Curves were demonstrated showing combinations of aplasia, hypoplasia plus degrees of haemolysis, and normal patterns, the clinical picture depending on the degree of compensation or decompensation. A film from the Westminster Hospital on the cytological variation in monocytic leukaemia ended the morning session.

In the afternoon Dr. MAGNUS HAINES (Chelsea Hospital for Women) gave a short résumé of the clinical manifestations of endometrial tuberculosis. Any type of menstrual abnormality could occur—from menorrhagia to amenorrhoea—and vaginal discharge was common. The condition had been found after abortion and ectopic pregnancy, in puerperal patients, and associated with post-menopausal bleeding. A history of previous tuberculous infection was given in 50–80% of cases. Pathologically the main investigation was endometrial biopsy with culture and guinea-pig inoculation. Tiny non-caseating granulomas were found histologically at the edge of an endometrial gland, but to avoid missing them it was essential to examine more than one section. The best time for curettage was within a week of the expected onset of a period. Dr. Haines preferred guinea-pig inoculation to culture for confirmation of tuberculous infection and obtained a high percentage of positive results.

Dr. H. A. SISSONS (Institute of Orthopaedics, London) demonstrated the value of radiographic methods in bone pathology, thin slices of osteogenic sarcoma, for example, showing areas of "tumour bone" not revealed by x-ray examination before operation. Rarefaction of bone following immobilization was also much more dramatically demonstrated by this method. The slices of bone were embedded in polymerized "perspex," and the very thin sections showed up great differences in density in the bone, the greyer Haversian systems indicating newer bone. Dr. M. J. H. SMITH ended the session with a discussion on the biochemistry of salicylate poisoning.

Preparations and Appliances

ROLLER CRUTCHES FOR RHEUMATOID ARTHRITIS

Dr. W. S. TEGNER, physician-in-charge, department of physical medicine, London Hospital, writes: A rheumatoid arthritic may have great difficulty in using conventional crutches, owing to arthritis of the elbows and hands in addition to the affliction of the hips and knees. In the course of treat-

ing such arthritics Miss S. G. Orme, principal of the London Hospital School of Physiotherapy, and her staff have designed a form of roller crutches which have proved to be a great help to such patients.

Trough supports are used for the forearms, and the crutches are mounted on eccentric roller bearings. The following advantages are gained: (1) stability is obtained, and the patient does not have to worry about learning the alternative crutch-and-leg gait. Support is continuous, and the patient never has to feel relatively unsafe when lifting crutches. The roller crutches have a heavy base, and there is no danger of a crutch ferrule slipping. (2) No help is needed in getting the crutches into position; therefore the patient feels more independent. The patient can move continuously, not with the stilted crutch gait, and can turn without losing support owing to the eccentric arrangement of the rollers.

These crutches are now manufactured by Remploi Ltd., of Queensway, Croydon, from whom they can be obtained.

WALKING-AID FOR PARAPLEGICS

Dr. R. S. ALLISON, senior physician, department of neurology, Royal Victoria Hospital, Belfast, writes: I should like to draw attention to a new type of walking-aid which has proved to be a great help to many patients suffering from spastic or ataxic paraplegia. Designed originally by Mrs. James Kirkpatrick, of Ballynagashel House, Ballymoney, N. Ireland, the original model, of which an illustration is given, was constructed to her specification locally. Since then it has been patented, and an improved light-weight model is now available.

The apparatus has the advantage of being relatively small, light, and compact. It can be folded and carried easily in the back of a car or by hand. The base is mounted on four wheels and is secure enough to prevent accidental overturning. When in use as a walking-aid, the patient's weight is distributed over the upper as well as the lower limbs, the hands grasping the handles and the trunk being tilted slightly forwards in the act of walking. Speed is regulated by a brake, and the wheels can be locked in position when desired so as to afford firm support in standing. The apparatus can also be converted into a temporary seat by means of an adjustable canvas sling so that such activities as washing or household duties can be performed with safety.

This walking-aid is of particular value in relatively stationary or chronic cases of paraplegia where the disability is not great enough to preclude standing or walking with the assistance of another person. The presence of gross muscular weakness or ataxia in the upper limbs is, of course, a contraindication to its use. Apart from these restrictions, the apparatus has been found both safe and simple to manipulate, and it should be of great service to many paraplegics in enabling them to move about the house more freely without danger of falling and to take short walks out of doors when opportunity offers.

The apparatus is manufactured by Messrs. Carter, 65, Wigmore Street, London, W.1, under the name of the "Warkirk" and weighs 21 lb. (9.5 kg.). The price is approximately £30.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Oral Hypoglycaemic Compound

SIR,—From the advertisement published in the *Journal* of August 3 (advertisement p. 13)—a most cautious and restrained announcement—it would appear that the hypoglycaemic compound for oral use, tolbutamide ("rastinon"), is now available for general prescription. During the past year this preparation has been intensively investigated in the department of therapeutics, University of Edinburgh, and from the experience gained it would seem that only diabetics conforming to a certain type are usually suitable for this form of treatment: (1) they should have developed the disorder over the age of 40; (2) they should have shown no previous tendency to develop ketosis easily; (3) their daily insulin requirements should not exceed 40 units; (4) their fasting blood glucose when receiving no insulin should not exceed 300 mg. per 100 ml. Only about two-thirds of patients satisfying these criteria prove ultimately suitable for this form of treatment. Of those who do not react favourably a small proportion even of seemingly mild diabetics will quickly develop ketosis after the withdrawal of insulin, so that the substitution of tolbutamide for insulin should always be made under careful hospital supervision. The hyperglycaemia of nearly all obese diabetics can also be controlled by tolbutamide, which, however, will merely perpetuate the obesity; the correct treatment for such persons is dietary restriction, which by itself will correct the obesity and restore the hyperglycaemia to normal levels.

The total daily dose of tolbutamide ranges from 1 to 4.5 g. divided into at least two doses. No one dose should exceed 1.5 g. Although it would appear that tolbutamide, in contrast to carbutamide, is relatively free from immediate toxic effects, we know nothing of the possible consequences of its long-term administration. Its exact pharmacological action is still unknown, but it is certainly quite different from that of insulin, which has stood the test of time. Although the experience so far gained with it justifies its more extended use, its indiscriminate prescription without careful prior assessment is to be deprecated.—I am, etc.,

D. M. DUNLOP.

Edinburgh, 3.

Listerial Meningitis

SIR,—Drs. P. N. Edmunds, D. N. Nicholson, and D. M. Douglas (*Journal*, July 27, p. 188) state that "no published case of human listeriosis has occurred in Britain since 1941." Commenting on this in your annotation (p. 209), you draw attention to the possibility of mistaking *Listeria monocytogenes* for a contaminant diphtheroid bacillus. We have a little doubt that our "case of meningitis apparently due to a

Corynebacterium" reported in 1954¹ was in fact a case of listeriosis, and the organism only narrowly escaped the fate of being disregarded as a contaminant. It closely resembled the "diphtheroid bacillus" reported in 1935 by Gibson² and now known to be a type 2 *Listeria* strain. Since becoming aware of its true nature, we have made numerous unsuccessful attempts to demonstrate motility, but it has been possible to induce the production of rough colonial variants on a number of occasions. We have not so far made or obtained *Listeria* antisera with which to confirm the new identification of our organism. As is pointed out in your annotation, one of the cases reported by Dr. Edmunds and his colleagues and two of those in Dedrick's series³ were infants in the second week of life. Our patient developed meningitis when 11 days old. We were able to examine swabs from the mother's vagina and nose within the next few days, and also others from various attendants and members of the family, but we found no source of infection.—We are, etc.,

Compulsory Powers over Mental Patients

SIR,—Your readers will doubtless take cognizance of the wise words of Dr. C. R. Birnie in this connexion (*Journal*, July 27, p. 234). It is desirable in every way that, in the initial stages of acute mental disturbance, it should be possible to move a patient to a suitable hospital without the necessity of legal formalities—in just the same way as is done with an unconscious or concussed person. It is equally undesirable that such a detention, on medical authority alone, should last any longer than it takes to establish a diagnosis (in which not only medical but social factors must be taken into account) of the patient's complaint. For this a period of two to four weeks seems reasonable and adequate. At the end of that time an assessment can be made which can be presented in coherent fashion to a suitable form of juridical authority, who can then take the responsibility for putting into effect such recommendations as it considers necessary for the continuation of compulsion. The profession will thus be relieved of the odium of this responsibility, while at the same time, provided the "recommending" authority is properly constituted, the individual liberty of the patient will be protected at the proper stage. An appeal from such a decision can still lie at a suitable stage of the proceedings to the mental health tribunals recommended by the Royal Commission.—I am, etc.,

House of Commons.

DONALD McI. JOHNSON.

Physique and Mental Illness

SIR,—Dr. S. E. Finlay (*Journal*, July 20, p. 160) draws attention to certain differences which he claims exist between the physiques of a comparatively small sample of 71 students with mental illness at Leeds University and those seen at Oxford. So far no test of statistical significance has been published confirming the alleged differences, but even if confirmation should be forthcoming there is still the manner of selection to be considered. Many general practitioners in Oxford have extensive experience of student problems and in general need to refer only a comparatively small proportion of the cases they see for second opinion. The Oxford sample contained 40% of mental hospital admissions, many with severe schizophrenic breakdown, which in young adults tends to concentrate in the Lf sector (Linear with fat). Thus the sample represents illness that is much more severe than would ordinarily be manageable in a student health service. At a recent meeting of the Royal Medico-Psychological Association it was demonstrated that young muscular men not only break down with schizophrenia less often, but also

to educate them to wear fashion shoes only for social occasions and not all day and every day. But, they ask, what are they to wear for everyday?

Here we come to a new set of obstacles: (1) the fact that only the sketchiest formula on shoe design for foot health is provided by the medical experts; (2) that most health features and fitting qualities plus anatomical proportions have been for some years confined to styles for older women; (3) that this has made the words comfort and health in relation to feet suspect among younger women; (4) that, although good shape and ranges of widths and fittings exist in attractive styles, they are not always intelligently handled or available in many shops; (5) that, while agreeing with the medical profession that many fashion shoe shapes are not good for feet, we must admit that sound advice based on recognition of the problems of shoe manufacture is the exception rather than the rule.

It is too late to tackle many aspects of this footwear problem in some age groups. The Foot Health Education Bureau is working through public health departments to bring foot care on to the same level as care of the teeth, eyes, diet, hygiene, immunization, etc. Through talks to mothers, in clinics and welfare centres, mothers' clubs, women's organizations, and parents' meetings, the foundation of good sense is, we hope, being laid for future generations. To-day's worst foot health problem is represented by the teen-agers. The girls, who have more money to spend than they ever had, missed any foot health education courses organized during the last four years. The teen-age boys are often the victims of an economy plus durability policy in buying shoes to the detriment of their feet. Incidentally fathers, not mothers, are the worst offenders, compromising often with heavy and ill-fitting shoes for their sons, which are certainly poor economy in foot fitness.

Mr. R. T. Payne suggests (*Journal*, May 18, p. 1180) that a young doctor might turn to chiropody, and that the Ministry of Health might talk to the Board of Trade on the subject of footwear hazards. Unfortunately it is not as simple as that. Fashion shoes as a social factor cannot be dealt with through legislation or prescription. Do we need more foot specialists and chiropodists? Do not we need rather closer collaboration between the foot-care professions and the footwear industry, plus a more realistic approach to public education on foot health needs?—I am, etc.,

London, W.C.1.

Phenylbutazone

SIR,—I have read with disquiet the contribution of Dr. G. R. Venning on aplastic anaemia due to phenylbutazone (*Journal*, July 20, p. 146). The disquiet is not aroused by the case history. I have read in your columns from time to time of deaths following the use of penicillin, morphine, and aspirin, without rushing off to alter the contents of my little black bag. What I find shattering is the implication in his comment on this particular tragic case. To use one single case to damn a drug out of hand is surely as illogical as to forbid the use of antibiotics because one patient has died following a penicillin injection. I hold no brief for phenylbutazone. In the limited bounds of my own practice I have made a point of following the advice of many leading consultants and research workers that this is a drug which should be used with caution. I have used it with care and the precaution of frequent blood counts with considerable relief to my patients, where aspirin has been ineffective and other methods have produced no real benefit. The disadvantage of this drug is the need for such caution, and that, as a result, its field of service is limited. I do not think that those who recommend it make any greater claims.

If Dr. Venning is really sufficiently naive as to believe that aspirin "used in the manner recommended by the Medical Research Council and Nuffield Foundation report

(1954)," to use his own words, is the "V" sign in the battle against rheumatism, my only answer is that this is the best propaganda to date for the suggestion that all prospective consultants should be forced to spend a considerable period of time in general practice. While one must pay a certain amount of respect to medical findings based upon statistics, a unique record surely has been established here, where the deductions have been drawn from a consecutive series of one case. Dr. Venning will surely sleep peacefully in the knowledge that, although that record might be equalled, it can never be beaten.—I am, etc.,

Manchester, 19.

SIMON FREEMAN.

SIR,—No one will dispute the value of publishing fatalities following the use of pharmaceutical preparations—as it is only by so doing that similar avoidable disasters can be prevented. Dr. G. R. Venning's article on aplastic anaemia due to phenylbutazone (*Journal*, July 20, p. 146), while rendering a service in drawing attention to this problem, unfortunately gives a completely erroneous impression of the place of phenylbutazone in the treatment of rheumatic diseases. As the purpose of this letter is to be brief and constructive, it will neither attempt to refute his misinformed comments nor criticize his selection of this particular patient for phenylbutazone therapy. For the guidance of others, however, the following suggestions are offered.

(1) In certain stages of rheumatoid arthritis, ankylosing spondylitis, and gout, phenylbutazone frequently gives very excellent results which can be obtained by no other available pharmaceutical equivalent. (2) Dosage: a total of 200 mg. daily should not be exceeded; full blood counts should be carried out before treatment and at regular intervals during treatment. In all the published cases in which I have read of fatal toxic effects following the use of phenylbutazone (including Dr. Venning's case) the dosage recorded has been much higher than this amount. (3) Patients should be warned of possible toxic manifestations and should be instructed to report any such effects immediately.

By following this regime and by careful selection of patients, phenylbutazone has been most successfully used in many hundreds of cases attending my hospital clinics over the past six or seven years, with only a very few minor and easily controlled toxic effects. Moreover, in the very near future, certain less toxic metabolites derived from phenylbutazone, but with equal pharmacological effects, may become available. In conclusion, the medicinal treatment of rheumatoid arthritis at present rests mainly on the triad of salicylates, phenylbutazone, and the corticosteroid hormones. It would therefore be a retrograde deprival if any one member of this triad ceased to be available.—I am, etc.,

Coventry.

JOHN SHULMAN.

Polyneuritis and Illness in Cats

SIR,—I was most interested in the letter from Dr. P. J. Bannison (*Journal*, July 27, p. 237) about polyneuritis and cats. I feel that with his experience and that of Dr. T. G. Reah (*Journal*, July 13, p. 100) the association is more than coincidental. Before the publication of Dr. Bannison's letter I had been following up the possibility of an association with the commonest cat influenza disease, which has mainly respiratory symptoms. My veterinary colleagues told me that this was due to a large virus related to the lymphogranuloma inguinale group. On this suggestion we exposed the patients concerned to a Frei test, which was uniformly negative, but, on the suggestion of Dr. Bannison, we were probably following up the wrong infection in the cat and it would be more helpful to follow up the feline enteritis disease, which causes a high mortality in cats and is very often epidemic. As a result of Dr. Bannison's letter, we intend to follow this up on these lines. His letter has been most helpful, and I am most grateful to him for publishing it.—I am, etc.,

Bristol, 8.

A. M. G. CAMPBELL.

Polytetrafluoroethylene Films in Baking

SIR,—From time to time we have drawn attention to the need for evaluating the extent of residues resulting from the projected use of new processing aids in the food industry.¹ Thus, some years ago,² we discussed the potential take-up of silicon by bread from silicone resin pan glazes when used as a replacement for tin-greasing, and showed that no health hazard appeared to be involved in their use. These glazes have now been introduced in domestic cooking utensils to have now been introduced in domestic cooking utensils to reduce, for example, the quantity of fat used in frying, and because of their non-sticking properties. Similarly, the plastic polytetrafluoroethylene (P.T.F.E., "flon") may be applied to metal surfaces, either in the form of a dispersion which is sprayed on and then cured or used in the form of prefabricated sheets or cylinders. Because of its non-sticking properties, it is potentially useful as a coating for bread and cake tins. We have examined the uptake of fluorine by bread and cake baked in pans treated with P.T.F.E. As such a use might find its way into domestic practice, as in the case of silicones, we felt our experience may prove generally informative.

Bread was baked in P.T.F.E.-coated tins for two differing baking times (1) at 400° F. on five successive days and (2) at 550° F. on another five days. Control loaves were baked in the conventionally greased tins. Fluorine was determined on the air-dried samples by the Society of Public Analysts' method,³ and in the control loaves the natural fluorine content of the crust was found to be 0.70 p.p.m. and of the crumb 0.75 p.p.m., the difference not being significant. Four loaves were prepared in each bake under the conditions mentioned using P.T.F.E.-coated tins. The products were bulked after air-drying, and on analysing aliquots it was found that the fluorine content at the first bake in the coated tin at 400° F. was 1.80 p.p.m., falling to 1.50 p.p.m. at the fifth bake, rising to 2.55 p.p.m. when the baking temperature was increased to 550° F. and falling to 0.90 p.p.m. at the fifth bake at this higher temperature. Although after a number of bakings the fluorine content of the crust was reduced to an amount closely approaching the natural fluorine content of bread it was thought advisable to ascertain whether an initial heat treatment or "curing" would reduce the take-up during the initial bakings. Accordingly, comparisons were made of the fluorine content of the air-dried crust from loaves baked in tins (A) without curing, (B) by sintering for 15 minutes, and (C) by sintering for 60 minutes at 626–662° F. The following fluorine contents in p.p.m. were obtained after allowing for the natural fluorine content of the bread.

Tin	A	B	C
1st baking	5.6	3.1	2.2
2nd baking	3.8	3.2	1.5
3rd baking	2.0	1.5	1.1
5th baking	0.7	0.7	0.4

Clearly, an initial heating of the tins before use has considerably reduced the fluorine uptake. A longer sintering time of 3–4 hours at 680° F. was then examined with the following results on bread subsequently baked in the tins so treated. After allowing for the natural fluorine content present in bread, the uptake of fluorine was calculated and is again expressed in p.p.m. in the air-dried samples, and as before the crust portion is approximately one-fifth of the loaf.

Number of bakings	Excess fluorine in whole loaf	Excess fluorine in crust
1	0.19	0.94
3	0.12	0.60
5	0.0	0.0

Thus it will be seen that curing under these conditions has resulted in a very small fluorine uptake. The overall increase in fluorine content is reduced to as little as 0–0.19 p.p.m. beyond the natural content of fluorine in bread baked in non-P.T.F.E.-treated tins, which in this latter series of experiments was 0.90 p.p.m.

Madeira, sponge, and high ratio cakes were then baked in contact with P.T.F.E. coatings sintered under the last-mentioned conditions. The natural fluorine content on the air-dried sample of the Madeira cakes was 1.25 p.p.m., and the fluorine content at the 1st bake on the treated tin 1.23 p.p.m., and at the 11th bake 1.23 p.p.m. Corresponding data for sponge cakes were 0.92 p.p.m., 0.92 p.p.m., and 0.92 p.p.m. at the 10th bake, and in the case of high ratio cake 0.78 p.p.m., 0.81 p.p.m., and

0.84 p.p.m. at the 10th bake. This clearly demonstrates that the uptake is negligible when adequate "curing" has been given.

It is interesting to note that the fluorine contents of the bread or cakes in the experiments in which suitably "cured" P.T.F.E. coatings were used were considerably less than the proposed limit for the fluorine content for self-raising flour of 3 p.p.m. Thus it emerges that the fluorine uptake from P.T.F.E.-coated tins or baking sheets is considerably reduced by "curing" at 680° F. for 3–4 hours. Indeed, in these circumstances there is little or no increase in the total fluorine content of the products baked thereon. We have advised the baking industry of the desirability of the "curing" process, and should P.T.F.E.-treated utensils be offered to the public we feel it would be advantageous if this practice was also followed, and, if possible, prior to their sale.—We are, etc.,

Speed Warning Device

SIR,—It was a nice compliment of Mr. D. T. Dickinson (*Journal*, July 20, p. 162), but I do remember the comparatively docile "T" model Ford. Indeed, I witnessed one of its favourite tricks. Years ago in the outback of Australia, where this car was very popular because of its easy clearance over tree stumps, I watched a sheep farmer being gently run over after starting his car on the handle, get up uninjured, chase his runaway, remount, and calmly continue the inspection of his boundary fences. It proved to be the only amusing and harmless car accident of my experience. Perhaps Mr. Dickinson remembers the day when it was the law for a mechanically propelled vehicle to be preceded by a man on foot carrying a red flag. We have come a long way since then.

The prevention of road accidents requires much more than a man carrying a red flag before the vehicle, or red lights on, and hymns from its dashboard. Now any young Tom, Dick, or Harry with an ordinary licence is permitted to drive a car capable of speeds far exceeding 100 m.p.h. The result of this "freedom of the road" is on the record. The first motor-vehicle road traffic fatality in this country occurred on August 17, 1896, at the Crystal Palace, South London, when Mrs. Bridget Driscoll was run down and subsequently died of her injuries. Since then 232,000 have died and 10,000,000 have been injured from road traffic accidents. What will the record be for the next 60 years? Although the motor-vehicle fatality rate per unit of travel has been halved during the last twenty years, the great increase in the use of cars, trucks, and buses on our roads has yearly increased the numbers of casualties. Last year's total was the highest on record, with nearly 5,400 fatalities and over 262,000 injuries (damage to property and goods in transport is not recorded, but must be considerable). If this is to be our average then the next 60 years will, unless we do something about it, result in 324,000 killed and 15,720,000 injured. Figures alone do not tell the whole story. Most road accident victims are in the younger male age groups. This is significant in terms of the personal and productive resources of the country. Accidents now rank first as the cause of death in all males between the ages of 1 and 35 years, and are outranked in older age group males only by cancer and the so-called degenerative diseases. The man-days lost from work each year, as a result of injuries, are enormous.

At the recent Annual Meeting of the British Medical Association in Newcastle, the panel discussion on road accidents (*Journal*, July 27, p. 231) was in unanimous agreement that additions to the present hospital casualty treatment

services represent the first stage in the avoidance of delays, essential to improved methods of treatment if in the future we are to lessen the number of deaths and improve our standard of functional recovery. The panel had not the time to consider accident prevention. Yet within the 24 new major accident departments they recommended there is a very strong case for the establishment of research teams to study the wide field of prevention. These, working alongside clinicians and helped by police and ambulance reports and on the evidence of the accident victims themselves, should produce worth-while factual evidence on which to base improved methods of prevention.

Road accidents have all the characteristics of a mass disease of epidemic proportions, capable of study by established epidemiological methods. The "noxious agent" is clearly the motor vehicle, the "host" its driver, who is conditioned not only by his behaviour but equally by his environment—i.e., the design and state of the roads he drives on and the vehicle under his control. There is no easy solution to this serious and growing epidemic. Prevention and treatment demand, and must one day receive, the full measure of medical attention they deserve. Propaganda for better speed-warning devices, campaigns to make the public more accident-conscious, are only makeshifts. Fundamentally the problem is the concern of preventive and curative medicine. The men and the knowledge are available. It is a matter for the Ministry of Health first to accept the responsibility and next to mount the attack by attracting the right type of staff, at all levels, to get on with the job. The cost would be insignificant compared to the overall costs of accidents to the nation.—I am, etc.,

Birmingham, 15.

WILLIAM GISSANE.

Churches' Council of Healing

SIR,—Dr. Jane H. Thompson's letter (*Journal*, July 27, p. 238) is welcome, but we are a conservative profession demanding intellectual satisfaction before taking any new step. In this context we ask to be convinced on two particulars: (1) that there is such a thing as spirituality; (2) that the Newtonian laws of gravitation and motion (on which we are trained) must now give place to the laws of relativity. The latter change the meaning of the term gravitation, so that it now applies to the field of radiation extending from a mass centre to a peripheral plane with the probability of a two-way transfer of energy. The universe is the gravitational field of its own mass and both are finite. The nature of the action which restores the co-ordinates of curvature to the peripheral plane is unknown, but it would not outrage reason if Dr. Thompson equated the spiritual plane with the Einstein two-dimensional boundary. So much is valid theory. Since Einstein's special theory has been confirmed by the nuclear physicists, there is every reason for philosophers and biologists to assume that the general theory is also valid. Dr. Thompson and her friends can therefore assert with Einstein himself that the appearance of the co-ordinates of curvature (that is, the emergence of 3-D space out of the 2-D plane) is an act of intelligent creation. They can assert that the unbounded 2-D plane is the spiritual plane which the pure of heart are said sometimes to reach.

If applied to the understanding of the nature of knowledge, the general theory teaches that the sensory order occupies the finite space-time continuum and is separated by a calculable boundary from the infinite plane. The materialized part of space is comprehended through the five senses. The not-yet-materialized remainder is comprehensible only by mathematical and intellectual constructions. That is, man may aspire to comprehend the entire unified field, but there remains the infinite plane which cannot be comprehended by reason, because all its co-ordinates are zero. It is accessible only by intuition or revelation, which term we prefer.

In the system of thought for which the Churches' Council of Healing stands, the property of spiritual discernment is given to man and the gift proves his unique relationship to

the first cause. An intellectual exercise to formulate a basis for pneumato-psychosomatic medicine may intrigue many who now find themselves extruded from the practice of medicine at 65 and may even produce a twentieth-century theory for the future of medicine.—I am, etc.,

Caernarvon.

GRIFFITH EVANS.

Heartburn of Pregnancy

SIR,—Since entering general practice I have been impressed by the frequency of heartburn of pregnancy and the discomfort that it produces for the patient. I have tried in turn, with little benefit, the various treatments described in the standard textbooks on obstetrics. During the past year, however, I have had considerable success by using pyridostigmine ("mestinon").

Sixty-one patients have been treated, and of these only two have not responded. Dosage has been one tablet daily for 5 to 10 days. No side-effects have been encountered. A country general practice does not allow a controlled study to be made, but on clinical impression the results appear excellent and may interest other practitioners who find that the treatment of this common complaint is a problem.—I am, etc.,

Swords, Eire.

FRANK McLOUGHLIN.

Foreign Body in Stensen's Duct

SIR,—I think the following case may be unusual enough to warrant its inclusion in the correspondence section of the *Journal*. A short time ago, while visiting an outlying farm cottage, I was asked to look in and see the baby next door, as it had been having difficulty in eating solids for the past two days. The child was about 13 months old and looked well. On examining the inside of its mouth I noticed a small bead of pus on the mucous membrane of the cheek with what appeared to be the tip of a thorn protruding from it. After some difficulty I managed to get a grip of it with a pair of dissecting forceps, and, to my astonishment, pulled out something which looked like a black worm about 2 in. (5 cm.) in length coated with pus. On floating it out in a cup of water I was amazed to find that it was a feather which must have penetrated the duct orifice, quill end first. In view of the age of the child and the minute size of the opening, I think this must be considered a unique type of accident. I shall be very surprised if I ever come across another such case. I should be very interested to learn if a similar case is on record.—I am, etc.,

St. Albans.

D. HARDY KINMONT.

POINTS FROM LETTERS

Fainting on Parade

Dr. A. H. SKINNER (Southland, New Zealand) writes: Newspapers in Great Britain regale us with pictures of soldiers on parade who have fainted and fallen, emphasizing the effect of the heat wave. There is no need to name any one regiment, but presumably every such casualty has a medical officer. Would he speak up? Say there are 5,000 men on parade and there are 10 fallen fainted and carried off. Suppose on inquiry it was found that none of these ten were non-smokers, would that be significant in any way? Or is the number too small? It seems a pity not to extract some information from a hot-day parade.

St. Luke's Tide Services

Dr. J. B. GURNEY SMITH (Royal Earlswood Institution, Redhill, Surrey) writes: Reading the recent letter of the Bishop of Lichfield (*Journal*, July 13, p. 105), which refers to a panel of doctors who would assist in the pulpit at St. Luke's Tide, prompts me to make a few observations. . . . I would like to draw the attention of communicant Anglican doctors to the existence of the Union of St. Luke, founded in 1948 especially to unite such doctors in a living spiritual fellowship and to work in close harmony with the clergy. The union is thus nearly 10 years old and numbers some 70 doctors and 12 clergy as members. A growth in membership is most desirable, and, as a foundation member office-bearer, I would be glad to hear of any intending members, to whom a warm welcome is extended and to whom full details of membership will be sent.

AUG. 10, 1957

Obituary

N. W. BOLTON, M.B., B.Sc., F.R.C.S.

The death of Mr. N. W. Bolton on July 8, at the age of 53, came as a great shock to his many friends in Stockport.

Norman William Bolton studied medicine at the Manchester Medical School and graduated M.B., Ch.B., with honours, in 1925, taking the degree of B.Sc. two years later. He was awarded the medical clinical prize and gained distinctions in pharmacology and pathology, but in spite of these successes on the medical side it was soon evident that surgery was his main interest, and he took the F.R.C.S. in 1930. After several resident surgical appointments at Manchester Royal Infirmary and the Christie Hospital he became resident surgical officer at Stockport Infirmary, and later at Ancoats Hospital, Manchester. The board of management of the Stockport Infirmary was trying gradually to introduce a full specialist staff, and Mr. Bolton's appointment as honorary surgeon in 1933 was a further step in that direction which brought tremendous benefit to the hospital and to the hundreds of patients who came under his care. He remained on the staff until his death, and although he held staff appointments for shorter periods at several other hospitals it was always to Stockport Infirmary and Stepping Hill Hospital that he was most closely attached. In recent years he also worked at Macclesfield Infirmary.

Since 1948 he had been a member of the hospital management committee of the Stockport and Buxton group of hospitals. He was a regular attendee at their meetings, and the members of these committees greatly valued his opinion and advice; they knew that with him the welfare of the patient was always foremost in his mind. He was a first-class surgeon, quick and neat in operating, and he worked exceedingly hard. The local practitioners liked him because they could always rely upon his help with an urgent case at any hour of the day or night. In fact, it was his devotion to duty which made him continue at work when he was obviously ailing, and which probably weakened his resistance and contributed to his untimely death. Throughout his life, and his work came first and he hated to be off-duty even for a single day. One incident several years ago was typical of his conscientiousness. A gastric illness causing him considerable pain compelled him reluctantly to call in a physician colleague late at night: next morning the physician called to see him and found, to his discomfiture, that the patient had left home at 8.15 a.m. to begin his usual surgical list at 8.30 a.m.

Mr. Bolton was interested in children's surgery and served for many years on the staff of the Manchester Children's Hospital. Always very fond of children, he had no difficulty in gaining their confidence, and he was never happier than when entertaining a party of youngsters at his house. His long association with the area in which he lived and his excellent work will make his absence keenly felt by patients, hospital staffs, and friends alike.

Mr. Bolton is survived by his widow, two daughters, and one son.—R. S.

R. F. DE BOISSIERE, L.R.C.P.&S.Ed.

Dr. R. F. de Boissiere, of Remuera, Auckland, New Zealand, died on July 4 from injuries received when he was knocked down by a car near his home. He was 77 years of age.

Born in Trinidad, Raoul Ferdinand de Boissiere left that country at the age of 17 to study medicine at Edinburgh, taking the Scottish triple qualification in 1901. He then held the appointment of clinical assistant in the medical out-patients' department at Edinburgh Royal Infirmary, and for a time was resident physician and clinical assistant in the medical out-patient department of the Victoria Hospital for

Consumption at Edinburgh. In the latter post he worked under the late Sir Robert Philip, whom he helped with the organization of the British Congress on Tuberculosis held in London in 1901. Shortly afterwards Dr. de Boissiere went to Fiji, where he remained until just after the end of the first world war, working at different times in various provinces in the islands. During the war he was acting senior medical officer at the Colonial Hospital, Suva. After the cessation of hostilities he moved to New Zealand, practising for some years at Hastings, in the North Island, where he specialized in the treatment of tuberculosis. Some twenty years ago he retired from practice and went to live at Remuera. An outstanding personality, he was widely respected in New Zealand. The Maoris especially appreciated the friendly care he gave to his patients. He is survived by his widow and two daughters.

JOHN BROWN, M.B., D.P.H.

Dr. John Brown, one of Aberdeen's oldest and most respected family doctors, died on May 3 while on holiday at the home of his elder daughter at Chatham. He was 80 years of age.

John Brown was born on November 17, 1876, in a humble home in Footdee, Aberdeen, and was the second youngest in a family of nine. He was about 2 years old when his father died, and from the age of 14, when he left school, he had to earn a living to augment the family income. From an early age he had cherished an ambition to become a medical missionary, but for a number of years he went to work in Aberdeen's shipyards, and learned Latin and Greek idioms on his way to and from work. After many years of hard work and financial hardship, which included two years voyaging as a ship's carpenter, he eventually passed the necessary initial examinations and gained entrance to Aberdeen University, where he graduated M.B., Ch.B. in 1908. Four years later he took the D.P.H., and later saw service with the R.A.M.C. Because of having been gravely ill with double pneumonia he was rejected for overseas service, and for the same reason at another time he was not accepted for missionary work.

Dr. Brown began to practise in Aberdeen before the first world war and returned there in 1918, building up a good practice founded on the concept of Christian service and able doctoring. His outstanding quality was his unflinching readiness to help all who came to him regardless of reward. He was more than a doctor, as a patient was once heard to say: he was a minister, too. He was appointed public vaccinator in 1927, and in that capacity was lecturer in vaccination at Aberdeen University up to 1948. He will be remembered to his students by the nickname "Men Brown," given to him because of the way in which he started his lectures. He retired from medical practice in 1954 at the age of 78, and, while reluctant to leave the care of his patients to others, looked forward to a well-earned retirement with his family and their children, whom he adored. But this happiness was not to be his for long. His wife predeceased him this year by some weeks, and in her he lost his lifelong partner. His own illness was mercifully brief without much suffering. His light-heartedness not even pain or sorrow could quench, for at an early age he responded to the call of God in Jesus Christ. He was a Christian humanitarian, and the east-end folk and the poorer people were his first care.

Dr. Brown is survived by a son, who is a consultant ophthalmologist in Bristol, and by two daughters, who have both married into the profession.—A. F. N.

DAVID JOHNSTON, M.B., Ch.B.

Dr. David Johnston, who was for many years in practice in Birkenhead, died suddenly on July 9 aged 65.

David Johnston, who was born on August 23, 1891, was educated in Scotland, studying medicine at Glasgow University and graduating M.B., Ch.B. in 1914. During the first world war he served with distinction in the R.A.M.C.,

gaining a high reputation as a most understanding and skilful medical officer in Egypt, India, and Salonika. His memories of this campaign remained vivid, and he often gave entertaining accounts of it. Early in 1914 he had gone to Liverpool, holding various resident appointments in the hospitals there, and after the war he joined the late Dr. W. R. Floyd in practice at Birkenhead. From the early 1920's his interests centred around this town. He was for some years honorary physician to the Birkenhead and Wirral Children's Hospital, where he is still remembered with gratitude. During the last war he was active in many ways. Not only did he carry on his own practice with great diligence, but he gave notable assistance to his colleagues who were in the Services—his fidelity in this matter was entire. He served as a major in the Home Guard and also worked in the civil defence service, being in charge of a large first-aid post. He lectured instructively and entertainingly to the Red Cross and civil defence workers, and many are the heartening stories still told of him in those days of stress. He joined the National Health Service at its inception in 1948, but soon found this new form of medicine uncongenial and resigned within the year.

For many years a member of the British Medical Association, whose conferences he regularly attended and much enjoyed, he was most active and extremely helpful in the many medical committees and societies of Birkenhead. He served for many years on the council of the Birkenhead Medical Society, and in 1946 was elected president of the society. In 1950 he had the unusual distinction, possibly a unique one as a general practitioner in Birkenhead, of being elected the president of the Liverpool Medical Institution. This was an honour which his colleagues in Birkenhead felt he fully deserved and one in which he honoured them as he honoured himself. He was a ready and witty speaker, and his knowledge of medicine was very great. He was helpful not only to the many patients who will greatly regret his passing, but also to those doctors who were his competitors and colleagues throughout the years, and among whom he made none but friends. The wives of those doctors with whom he was professionally most closely associated remember particularly his reassurance when asked to do an emergency call, and his promise of help always given with a joke and the hint of a smile dispelling "flap" like a charm. Since his retirement from active practice two years ago he has been greatly missed. His widow and two daughters survive him.—J. K. R.

O. PASTEAU, M.D.

With the recent death in Paris of Dr. Octave Pasteau at the age of 86 there passes away the last surviving founder member of the International Society of Urology. Pasteau was the Society's first treasurer and later became successively secretary-general and vice-president. Octave Pasteau was born in 1870 and received his medical education in Paris, where he graduated in medicine in 1898 with a thesis on the lymphatics in diseases of the bladder and prostate. Subsequent books and papers from his pen were concerned almost entirely with urological subjects.

A. C. M. writes: A man of great personal charm, Octave Pasteau was *persona grata* with all his foreign colleagues at the congresses of the International Society of Urology. His knowledge of the literature was remarkable. I remember, on the occasion of the London meeting in 1933, the visit of the delegates to Oxford. Pasteau's enthusiasm on entering the Bodleian Library for the first time was infectious. "At last," he said, "I have come to Mecca."

J. D. L. REINHOLD, D.M., M.R.C.P., D.C.H.

The obituary of Dr. J. D. L. Reinhold was printed in the *Journal* of August 3 (p. 301).

We are indebted to Dr. M. C. JOSEPH for the following appreciation: John Reinhold's publications were numerous and his interests in medicine wide; he described a clinical

sign in atrial septal defect and took part in the scheme for home care of sick children at St. Mary's Hospital. He was shy but had a keen sense of humour. Although fully occupied with his young family, he was always ready to help colleagues and friends. John Reinhold found time to do many things well; he was an expert in judo, played squash for Guy's, and painted occasionally. He appreciated good food and wine and enjoyed brewing beer at home. His early death robs the profession of an outstanding doctor who had already contributed so much to medical knowledge.

Dr. A. BATTY SHAW writes: From Oxford John Reinhold and I together entered Guy's, his father's hospital. From an early stage in his clinical studies he revealed an aptitude and interest in paediatrics, and was appointed house-physician to Professor (then Dr.) R. W. B. Ellis. He was also editor of *Guy's Hospital Gazette* and represented the hospital at squash racquets. After completing his house appointments illness temporarily interrupted his career, when he learnt to paint; then, after holding various resident posts, he was appointed to the juvenile rheumatism unit at Taplow. This was the critical post in his career, for while at Taplow he combined his interest in children with a valuable tutelage in cardiology, together with a fostering of his investigative mind. From there followed junior staff appointments at St. Mary's, Great Ormond Street, and Guy's, with a year at the Children's and Infants' Hospital, Boston. During this busy period of appointments several valuable papers appeared from his pen, but he led a life full of other interests. His happiest days were spent with Jeune, his wife, and their young family in the home where friends were always made welcome. Sparse of build, and with a distinctive walk, John Reinhold might at first appear a little aloof, but a smile of great charm would soon disarm this and his kindness would be found to be very great. A sad sense of loss was felt by his many friends when they heard of his appointment to Denver, but they were not to know that this loss was to be so tragically complete.

Medico-Legal

IMPRISONMENT OF MENTAL DEFECTIVES

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Section 17 (2) of the Criminal Justice Act, 1948, provides that no court is to impose imprisonment on a person under 21 unless the court is of opinion that no other method of dealing with him is appropriate. In deciding whether any other method is appropriate, the court is to obtain and consider information about the circumstances and take into account any information there is before it relevant to his character and physical and mental condition. Section 8 of the Mental Deficiency Act, 1913, empowers a court on conviction of a person of a criminal offence punishable by imprisonment to have him dealt with as a mental defective, if satisfied on medical evidence either given at the trial or in other proceedings or called for the very purpose that he is a defective within the meaning of the Act. The definition of "defective" is found in s. 1 of the Act, which uses the familiar classification of "idiot," "imbecile," "feeble-minded person," and "moral imbecile."

The implications of these provisions were considered by the Court of Criminal Appeal¹ on the appeal of Roy Speake from his sentence of life imprisonment imposed at Hereford Assizes, which was heard on July 29. Speake, who in November, 1956, had been convicted of arson and put on probation because he was not then considered to be certifiable as a feeble-minded person, had lured a small boy to a lonely spot and indecently assaulted him. When the boy said he would tell his father, Speake battered him to death.

¹ *The Times*, July 30, 1957.

The defence at the trial was diminished responsibility, and on evidence which, according to the trial judge's report to the Court of Criminal Appeal, was just over the borderline the jury brought in a verdict not of murder but of manslaughter. It was argued for the appellant that as the medical evidence at the trial was unanimously to the effect that he was a mental defective the judge ought to have ordered him to have been dealt with as such under s. 8 of the Act of 1913, and that s. 17 (2) of the Act of 1948 bore this out. The Court of Criminal Appeal, however, decided that it was clear that s. 17 left it open to the court to imprison Speake if it thought right, provided his character and mental and physical condition were taken into consideration. There was no suggestion that that had not been done. Moreover, s. 8 of the Act of 1913 was in terms permissive, and was intended to enlarge the power of the court in dealing with offences punishable with imprisonment by making it possible, when the offender was a mental defective, to deal with him as such rather than send him to prison. It was a matter for the discretion of the court.

Speake's appeal was accordingly dismissed.

REGISTRATION OF SEX

A case was reported from Scotland last week in which the Registrar-General was refused permission to correct the entry of a person's sex in the register.

A 50-year-old Perthshire man, father of two children, was said to have been living as a woman for several years. His chromosomes were of the male type, and physical changes were referred to but not reported in detail. The secretary of the Registrar-General's office therefore petitioned, on behalf of this person, to alter the registered particulars of sex and Christian names from male to female.

In his judgment Sheriff A. M. Prain¹ said that the Registration of Births, Deaths, and Marriages (Scotland) Act, 1954, could not be invoked to correct the entry of birth. The Act was directed towards the correction of an entry which was erroneous at the date when the information was given. It did not give sanction for recording changes which subsequently occurred. The register was essentially a record of fact and not a narrative of events. There was no doubt that the particulars relating to this person's birth were a correct statement of fact as at their date. They could not be "corrected" because of some subsequent change of circumstances. In any event, the Sheriff added, the changes so far noted in this person's condition did not justify a correction of the register, even if that course was competent.

This judgment illustrates the law of England as of Scotland. The facts recorded in the register are the facts land. The facts recorded in the register can be made only ascertained at that time. A correction can be made only when the facts are ascertained incorrectly. It cannot be made to take account of later changes.

Medical Notes in Parliament

BAN ON IMPORTS OF SALK VACCINE

Late on July 31 Mr. J. CRONIN (Loughborough, Lab.) brought up the question of poliomyelitis vaccination, in order to make up the question of vaccination was progressing too slowly, four points—that vaccination was progressing too slowly, that the Ministry of Health should use imported Salk vaccine, that the public relations aspect was being unhappily handled, and that the virtual embargo on the importation of Salk vaccine should be removed.

He said that in January last year the Minister of Health promised that enough vaccine would be available for 300,000 persons by June, 1956, but as it turned out only 200,000 children were vaccinated by the end of the year. Of the children eligible for registration to be vaccinated only about 30% had been registered. It had been announced that Glaxo Laboratories Ltd. were to increase the production of

¹ *Scotsman*, July 31, 1957.

vaccine by 50%; but why only now, and why only 50%? Burroughs, Wellcome and Co. were to start production next year. Why next year? It was the Government's duty to place contracts on such terms as would cause a rapid fulfilment of the demand.

In his continued refusal to use Salk vaccine, available from the United States, Canada, and Australia, was not the Minister being overcautious? Since the Cutter incident in the U.S.A. in 1955 the regulations there had been tightened up considerably, and over 100 million injections had been given without any serious ill effects. He quoted in support Professor Trueta's letter in the *Journal* of June 15 (p. 1417).

The House should be assured that the ban on Salk imports was not purely for research reasons. It had been suggested that the Medical Research Council was anxious to have the results of the English-produced vaccine assessed without the complication of an imported vaccine interfering with the figures. It had been suggested that the British vaccine was more suitable; but was there any evidence at all to suggest that the American vaccine would not give as much protection, or nearly as much? The fact that two-thirds of the parents and children for whom vaccination was available had not taken advantage of the offer suggested that there was not much in the way of favourable publicity. One last point: one could obtain the Salk vaccine provided it was sent as an unsolicited gift. Why deprive the general public of a known means of protection? Why this interference with the doctor's right to prescribe any drug he thought fit? Unsolicited gifts must be confined to people who had travelled or had connexions with the U.S.A. It was a privilege to a very limited class. Smuggling was developing on a large and increasing scale, the privileged traffic was gradually approaching black-market proportions, and there were real dangers of improper handling and unscrupulous production.

Government Reply

Mr. J. K. VAUGHAN-MORGAN, Parliamentary Secretary, Ministry of Health, supported the Minister's decision, taken on advice given by specialists through the Medical Research Council. Smuggling was a matter for the Customs. He would have been happier if Mr. Cronin had produced more evidence before making such a statement. On the unsolicited free gifts, Mr. Vaughan-Morgan pointed out that as no import licence had been issued consignments arriving were detained by the Customs. There was no wish to exert a rigid control over small gifts of vaccine sent for family use, and the Customs had therefore been authorized to release such packages where it was clear that a doctor had taken responsibility for injection. The numbers of such parcels had been 33 in May, 48 in June, and 53 in July. In addition, there might be some parcels brought by travellers. Unless there was a radical change he saw no justification for interfering with a personal decision by individual parents whose doctors were prepared to take responsibility for injection.

On the wider question of importation of the Salk vaccine he quoted the Minister's statement on May 15, that it had been decided on expert advice that the vaccine to be used in this country should have a different composition from the American vaccine, which included the virulent Mahoney strain. That advice had not changed. If in the light of experience other advice was given the Ministry would be ready to reconsider their policy. If any virus survived the manufacturing process and remained undetected, the Mahoney strain was a paralyzing virus, and the Brunenders strain in the British vaccine was not. There had been so many disappointments in production that he could not commit himself too far in the production programme. About the incidence of poliomyelitis, he said the worst year this country had ever had, 1950, was less than the lowest year in the United States. Even in this heavy year for us (1957) and this light year for the United States, the incidence was still very comparable. As time went on, and more protection became available, he prayed that this would be yet another of the diseases that had been driven away.

Monthly Cheques

Mr. G. LAGDEN (Hornchurch, Con.) asked on July 30 whether the Minister of Health would arrange for general medical practitioners to be paid monthly instead of quarterly, as at present, without having to make a special case on grounds of difficulty or hardship. Mr. J. K. VAUGHAN-MORGAN, the Parliamentary Secretary, replied "Yes." In agreement with the General Medical Services Committee of the B.M.A. he proposed that as from the quarter beginning in October executive councils should be enabled to do this after consultation with the local medical committee. The necessary amending regulations would be laid before the House as soon as possible. [Similar arrangements are to be made in Scotland.]

Consultants' Retirements

Mr. VAUGHAN-MORGAN informed Mr. K. ROBINSON (St. Pancras North, Lab.) that in the past five years (ending in June) the number of consultants leaving the hospital and specialist service in England and Wales had been: 1953, 168; 1954, 162; 1955, 158; 1956, 146; and 1957, 144. Separate figures showing resignations, retirements, and deaths were not available, nor figures for the whole-time equivalents.

Group Practice Loans

The SECRETARY OF STATE FOR SCOTLAND told Miss M. HERBISON (North Lanark, Lab.) that 24 applications for doctors for loans to help to set up group practice were considered in 1956, and 10 were approved. Miss HERBISON asked why the 14 were turned down. Mr. MACLAY said the number of loans approved was governed by the amount of money the profession had agreed to set aside from the general remuneration pool. The amount for Scotland was £12,000 a year, and the 10 loans took £11,700. Miss HERBISON commented that the amount of money that was agreed upon might have been much greater if the Minister of Health and the Secretary of State had tried to honour decisions previously reached.

Infectious Travellers

Mr. R. W. SORESENSEN (Leyton, Lab.) wanted to know what arrangements existed between the Ministry of Health and the Ministry of Transport and Civil Aviation in respect of the medical examination and detection of smallpox and other infectious or contagious diseases among passengers to this country from Africa, India, and elsewhere. Mr. VAUGHAN-MORGAN, replying on July 29, said he assumed this related to air traffic. It was a joint responsibility to arrange for health control at State-owned airports. This gave wide powers for dealing with any case or suspected case of communicable disease arriving in this country, including medical examination and surveillance of passengers where necessary. The scheme was operated by local authorities through airport medical officers.

Medicinal Alcohol

Sir ALFRED BOSSOM (Maidstone, Con.) asked on August 1 if the Minister would request the Medical Research Council to investigate and report on the conditions under which the consumption of moderate amounts of alcoholic drinks, such as port, sherry, and whisky, was preferable to the prescription of drugs and medicine, in view of the possible implications so far as the prescribing of medicines under the Health Service is concerned. Mr. VAUGHAN-MORGAN replied "No." Practitioners were already in a position to judge in particular cases the relative merits of medication and dietary measures.

Quarantine for Dogs.—The Minister of Agriculture is satisfied that to reduce the quarantine period for dogs or to rely on inoculation against rabies would be an unjustifiable risk.

Flame-resistant Textiles.—The British Standards Institution are well advanced in preparing both a British Standard for flame-resistant fabrics and also a specification for methods of testing flame resistance.

Cost Per Patient.—The average cost of maintaining a patient in hospital in Scotland in 1955-6 was £8 18s. 7d. a week. In 1950-1 it was £6 17s. 8d.

Universities and Colleges

UNIVERSITY OF OXFORD

The Henry Goodyear Scholarship for 1957 has been awarded to Dr. Ann Gaynor Taylor; the Theodore Williams Scholarship in Anatomy to Michael John Gatfield Harrison (Magdalen College); and the Radcliffe Scholarship in Pharmacology to Paul Michael Riisager (Oriental College).

UNIVERSITY OF CAMBRIDGE

The following candidates, having received the degree of B.Chir. on June 28, 1956, had conferred upon them the degree of M.B. on June 29, 1957:

H. J. Davies, G. R. Fraser, J. J. Key, K. D. Austin, J. A. Bessell, R. Carlisle, B. W. K. Fayle, J. F. Harrison, A. M. C. Jennings, W. McConnachie, W. R. Moore, J. L. Reed, A. J. Watson, H. J. O. White, D. W. Downham, R. S. Hole, D. P. Mullan, P. C. Barrington, I. I. Gaston, F. R. Hildborne, N. S. C. Rice, M. H. M. Dykes, T. A. Fox, E. R. Roberts, J. C. F. Townsend, C. G. Waters, C. Hunnybun, B. E. Shaw, S. G. Taylor, W. D. Waller, S. G. Elkington, C. J. Farrer, B. Lomax, D. A. Swales, M. G. Williams, P. W. M. Copeman, J. K. Dauncey, T. G. Evans, M. A. R. Freeman, D. A. Chamberlain, G. B. Gasson, J. R. Sandford, P. G. Watson, E. G. Wooster, J. M. Cairns, G. Cohen, M. L. Fenner, D. A. Gilchrist, T. R. Preston, F. F. Richards, A. J. Salsbury, R. F. Tuckett, M. R. Colwill, D. J. Fairclough, C. J. B. Hundley, N. C. R. W. Reid, M. J. V. Smith, R. E. C. Altounyan, J. R. Batchelor, J. D. M. Richards, R. M. Wainwright, J. B. B. Milne, R. V. Stephenson, N. Wright, C. W. Arthur, M. J. P. Furniss, P. McCormack, J. T. Mainwaring, R. Murphy, A. D. G. Nicholas, M. Slapak, Jean R. C. Bain, Jean McL. Thompson, A. G. Dawrant, J. D. Stirland.

The following candidates had the degree of B.Chir. conferred upon them on July 4, 1957:

R. B. Cole, D. A. Crockford, D. C. Dumonde, M. W. Haslett, C. H. Nourse, R. A. N. Petrie, H. R. M. Roberts, J. H. Li. Bland, T. R. P. Cullinan, O. G. Franklin, A. J. Levi, J. A. Morgan-Hughes, C. E. R. Thompson, C. B. S. Wood, M. J. Abolton, P. R. Butler, W. R. Gibson, P. C. Heal, J. S. Lyon, M. J. O. Massey, C. D. Plows, J. H. W. Shaw, J. C. Mackenzie, J. E. Utting, W. J. Cliff, N. W. Karunaratna, G. W. Knox, J. W. B. Palmer, R. O. S. Sims, P. N. Awdry, B. S. Cox, A. M. Hall-Smith, B. E. Lee, P. J. S. Murray, M. A. Newton, R. J. L. Potts, M. J. S. Scorer, W. A. B. Smellie, J. M. Woodhead, P. Cannon, P. N. Dixon, A. M. Fisher, J. H. Gervie, F. B. Gibberd, R. B. Goldschmidt, D. B. Grant, K. B. Hallam, R. C. G. Hughes, J. R. Jacobs, S. F. Kuvlin, J. N. Stenhouse, S. Clutterbuck, C. C. Cory, T. J. Davenport, R. A. S. Gilchrist, B. A. Latham, A. A. Akiwumi, G. E. Sowton, D. A. Nightingale, D. R. Parry, D. W. Potts, A. P. Sheldon, P. R. Smith, B. Le G. Waldron, J. J. McL. West, D. H. Morgan, M. Parsons, T. C. Daru, J. L. Gedy, J. R. Lang, H. J. Lloyd, M. B. R. Mathalone, J. A. Mathews, I. Smith, J. D. Wyatt, A. J. Edwards, R. H. Herniman, A. W. Gentles, I. McD. Jessiman, M. C. Johnson, J. B. Nichols, M. Taggart, R. Banerjee, J. V. F. Catto, D. R. Dunkerley, A. E. Holmes, B. J. King, J. E. Robinson, D. M. Smith, E. S. Chessier, H. Ludman, D. C. R. Stephens, D. W. Barkham, D. I. K. Evans, J. M. Kirk, M. N. Morgan, I. B. Shine, G. D. Stainsby, J. P. Wilson, Sonia R. Dias Bandaranaike, Anne W. Peryer, Enid Wheldon, June M. Wilby, Elma P. Wyatt, Katharine E. Cuthbert, Margaret S. Davies, Anne S. Hill, Edith G. A. Kerr-Wylie, Jill M. Knight, Mrs. Joan M. Maurice-Smith, Mary J. Silver, C. F. Allenby, P. A. F. Chalk, J. M. E. Dunn, A. W. Galbraith, R. J. Jarrett, H. P. Ozer, P. Francis, K. K. Ho, G. L. Zeitlin.

Dr. A. P. Waterson has been elected into an official Fellowship of Emmanuel College, with tenure from October 1, 1957, on appointment as an Assistant Tutor and as Director of Studies in Medicine.

UNIVERSITY OF EDINBURGH

At a Graduation Ceremony held on July 17 the following degrees and diplomas were conferred:

M.D.—R. Brown, M. F. Oliver, J. A. Owen, W. W. Park, P. D. Stewart.

Ph.D.—In the Faculty of Medicine: D. L. Gardner, M.B., Ch.B., M.R.C.P., E. A. Harris, M.B., Ch.B., M.R.C.P., Margaret M. A. Holzbauer, M.D., J. N. Mansbridge, H.D.D., H. Smith, B.Sc.

M.B., Ch.B.—O. Ajayi-Obe, Frances C. Bailey, J. H. Barber, H. G. S. Battersby, E. D. Baid, P. Beaglehole, M. R. Bewsher, G. Birchall, J. A. Birkbeck, J. B. McK. Black, I. A. R. Brown, P. W. Brown, N. T. A. Byam, F. N. Campbell, J. M. B. Carr, Dorothy Child, Joyce C. Clapperton, J. H. Cochran, Margaret W. Coleman, G. F. N. Collins, Patricia E. McH. Curran, W. Dodd, Jean M. D. Dott, Heather M. Phyllis M. Fulton, A. M. G. Evans, D. C. Flenley, A. M. Forbes, Phyllis M. Fulton, A. M. G. Evans, D. C. Flenley, A. M. Forbes, Phyllis M. Fulton, I. H. Gravelle, F. Harcus, D. N. Harkness, J. D. A. Henshaw, J. H. J. Higgins, Audrey D. Hill, Margaret J. Hutchinson, R. Hutchinson, P. Johnson, D. A. R. King, W. K. Kirkwood, H. MacG. Kohler, Dorothy Lee, A. B. Leys, Nesta E. Lloyd, J. R. Macaulay, Mollie J. McDowall, A. B. Macintyre, A. D. MacKenzie, J. MacKinnon, Jean McLean, D. M. Macleod, H. B. Macleod, H. Macmaster, W. R. MacRae, Margaret McL. Manderson, A. G. Meikle, Margaret J. Millar (née Howarth), P. R. Monk, G. M. Morley, M. Murchison, D. Murray, J. A. Murray, Clair Nelson, H. O. Nicholson, R. H. W. Park, C. Parker, Jean M. Parsons, A. Paterson, G. M. Paterson, H. M. K. Peddie, P. C. Phellips, J. K. Phillips, H. Pullen, J. B. Rae, D. O. C. Rapier, Joyce E. Richardson, Mary M. Roberts, A. A. Russell, D. F. Scott, R. S. Scott, J. H. Shelley, H. Simpson, D. J. Sinclair, G. Slavin, Frances Smith, W. A. Souter, W. M. Steel, Brenda M. Stewart, J. B. Stewart, D. G. Strachan, P. Sutherland, Elizabeth M. Swanson, B. Tammes, R. C. Teifer, D. E. L. Temple, G. M. Thomas, V. P. Varma, J. Wightman, A. M. Wilkie, R. J. Wilson, M. Woodliff.

DIPLOMA IN PUBLIC HEALTH.—J. C. Brannen, I. F. Craik, I. B. C. Eckford, G. I. Forbes, A. K. Ganguly, C. W. G. Irvine, P. Khanjanashidi, Mairi H.

UNIVERSITY OF BRISTOL

Dr. W. J. P. Duff, Dr. L. A. Faigan, and Dr. G. L. Higgins have been appointed Demonstrators in Pathology.

Dr. R. W. Spencer (Tutor in Clinical Pathology), Dr. H. Summers (Lecturer in Physiology), and Dr. T. C. Williams (Demonstrator in Pathology) have resigned their appointments.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on July 11 Colonel J. M. Shah (Karachi) was admitted to the Fellowship, having been elected as a Member of twenty years' standing.

The Hallett Prize was presented to Dr. R. Y. Calne, of Guy's Hospital Medical School, and the Begley Prize to Dr. Sybil Birtwistle, of Liverpool University.

Diplomas were granted, jointly with the Royal College of Physicians of London, as follows:

DIPLOMA IN CHILD HEALTH.—R. C. Higgs, K. F. Tugwell, J. H. Stephenson, S. P. Khatua, B. Prasad.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—N. S. Dixit, M. D. T. Najera, J. A. Najera Morondo.

Professors and Lecturers for the ensuing year were appointed as follows:

Hunterian Professorships.—Mr. B. B. Hickey, one lecture on malignant epithelial tumours in the Sudanese; Mr. J. P. Reidy, one lecture on observations on 300 treated cases of cleft lip and palate; Mr. A. K. Basu, one lecture on chronic Bengal splenomegaly and associated states of portal hypertension; Colonel R. A. Stephen, one lecture on malignant testicular tumours; Mr. A. J. H. Rains, one lecture on biliary obstruction in the region of the porta hepatis; Mr. R. B. Welbourn, one lecture on the surgical aspects of adrenocortical disorder; Mr. A. G. Jessiman, one lecture on hypophysectomy in the treatment of breast cancer; Mr. W. W. Davey, one lecture on the surgery of anastomotic ulceration; Mr. D. A. Macfarlane, one lecture on cancer of the adrenal cortex; Mr. J. P. Hopewell, one lecture on the hazards of uretero-intestinal anastomosis; Mr. J. F. Silva, one lecture on old dislocations of the elbow; Mr. G. F. Murnaghan, one lecture on the mechanism of congenital hydro-nephrosis; Dr. Sydney Thomson, one lecture on molluscum sebaceum and its surgical significance.

Arris and Gale Lectureships.—Mr. H. R. S. Harley, one lecture on the development of the sinus venosus type of atrial septal defect; Dr. D. H. M. Woollam, one lecture on the experimental approach to the problem of the congenital malformations; Mr. I. P. Todd, one lecture on the physiology of rectal sensation and its relationship to disease.

Erasmus Wilson Demonstratorships.—Dr. G. T. Allen, Dr. R. A. Goodbody, Dr. B. C. Morson, Dr. L. W. Proger, Dr. H. G. H. Richards, and Dr. J. B. Walter, one demonstration each.

Arnott Demonstratorships.—Miss Jessie Dobson, Dr. A. A. Barton, Professor R. J. Last, Dr. R. McP. Livingston; Mr. P. A. Ring, and Dr. F. Stansfield, one demonstration each.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

On July 5 the following candidates were admitted to the Licence in Medicine and Midwifery of the College:

H. A. Alfandary, A. B. E. Bryan-Brown, M. T. Brown, C. J. J. H. G. Burns, T. K. Cheah, R. R. Muir-Cochrane, E. S. De Hoedt, M. I. Essack, B. P. Geoghegan, M. J. Gill, G. S. H. Horner, T. W. Jefferies, H. Lautsch, R. D. Leeming, J. G. M. Ling, B. N. C. Littlepage, M. M. Marks, K. H. Meabur, B. A. Molony, D. R. Moody, P. Murphy, J. D. McCafferty, E. I. MacSorley, Y. Nerman, M. O'Brien, J. N. O'Hanlon, E. F. Orli, M. E. Owen, K. Paszkowska, S. L. Peltz, Z. A. Plisko-Dubinski, M. Rose, J. M. Rosenthal, B. S. Schml, M. J. Sherry, W. Z. Sniegocka, J. O. Sodipo, M. F. Stranc, I. Swiestowski, V. A. A. Winston.

FACULTY OF RADIOLOGISTS

The Fellowship examination of the Faculty in May was conducted simultaneously in London, Australia, and New Zealand. The following candidates have been admitted to the Fellowship: In London, P. E. Bodkin (London), A. M. H. Fisher (Oxford), K. E. Halnan (London), L. Langton (Birmingham), P. E. S. Palmer (Southern Rhodesia), J. G. Pearson (Edinburgh), F. M. Ramsay (London), S. D. Roberts (Melbourne), J. G. Sowerbutts (London), P. D. de Villiers (South Africa), I. Yentis (London). In Sydney, M. D. Begley (Adelaide), W. S. C. Hare (Victoria), K. W. Mead (Brisbane), K. W. Mowatt (Queensland), M. G. Pinner (Canberra). In Dunedin, J. H. Stewart (Auckland), P. W. Wishart (Tauranga).

The admission of Fellows was conducted in Australia and New Zealand by Dr. Whately Davidson, the President of the Faculty, who was the visiting examiner together with Dr. John Bromley. This is the second time that the examination has taken place in Australia, and the first time in New Zealand.

Lack, H. C. Lindsay, Mary I. McArthur, R. D. G. MacLennan, J. L. McLetchie, Catherine H. Mair, G. A. Scott, M. S. Warwick, Leila M. Watson, A. V. Wells.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—R. V. K. Alwa, J. C. Barua, M. C. P. Chetty, H. Currie, K. K. Das, N. S. Dhillon, D. N. Gupta, I. A. Hashimi, M. K. R. Jayachandran, M. R. Khan, G. Kuppaswamy, G. Y. McCrick, J. A. McLaren, N. K. Menon, R. S. Nagie, E. L. Szlamp, Susan Benjamin, M. H. Myint.

¹Awarded gold medal for thesis. ²Commended for thesis. ³Passed with honours. ⁴In absentia.

The following scholarships, etc., were awarded in the Faculty of Medicine: *Ettles Scholarship in Obstetrics and Gynaecology*, *Medicine*, *Buchanan Scholarship in Obstetrics and Gynaecology*, *Mouat Scholarship in the Practice of Physic*, and *Murchison Memorial Scholarship in Clinical Medicine*, D. C. Flenley. *Scottish Association for Medical Education of Women Prize*, *James Scott Scholarship in Obstetrics and Gynaecology*, and *Dorothy Gilfillan Memorial Prize*, Phyllis M. Fulton. *Beane Prize in Anatomy and Surgery*, *Keith Memorial Prize in Systematic Surgery*, *Lawson Gifford Prize in Obstetrics and Gynaecology*, *Annandale Gold Medal in Clinical Surgery*, and *Royal Victoria Hospital Tuberculosis Trust Gold Medal*, I. B. Macleod. *Murdoch Brown Medal in Clinical Medicine*, A. G. Meikle. *Graduate Research Fellowships*, G. D. Forwell, D. C. Jessup, A. Peters, R. Shearman. *Graduate Research Scholarships*, Christina A. Fulton, J. A. Hodgson, E. W. Horton, J. F. Lamb, Margaret A. J. Moffat, R. M. Macrae, B. I. Tyson. *Graduate Travelling Scholarships*, R. H. Girdwood, J. Richmond. *Lauder Brunton Medal and Prize in Pharmacology and Therapeutics*, E. W. Horton. *William Leslie Prize in Medicine*, A. Doig. *Greig Medal for Tropical Medicine*, D. N. Gupta. *Wellcome Prize and Medal in the History of Medicine*, and *Ross-Inkester Medal in Public Health and Social Medicine*, W. J. Irvine. *Wightman Prize in Clinical Medicine*, W. A. Souter.

UNIVERSITY OF LONDON

The following candidates at the London School of Hygiene and Tropical Medicine have been approved at the examinations indicated:

ACADEMIC POSTGRADUATE DIPLOMA IN PUBLIC HEALTH.—W. H. Allen, G. L. Balgobin, F. Bauhofer, R. L. Bell, D. W. Bookless, J. A. D. Bradfield, T. N. N. Brennan, T. C. L. Brown, Carmel Cachia, A. C. Camm, S. P. Caruana, J. C. Chakrabarti, J. K. Chakravarti, D. W. Christensen, J. P. Crowdy, S. E. Cupples, W. O. Davies, Aileen P. Dring, J. V. Dyer, D. E. Evison, J. M. Ferguson, C. Gopalan, Gabriele Gramiccia, M. C. Gupta, P. G. Haigh, J. M. Holden, C. Hooja, F. T. Hunt, L. B. Hunt, B. L. Kapoor, Mairad M. Lillott, I. R. Lindsay, H. R. Maltows, A. Manoharan, A. Winifred M. Markham, K. D. Mason, Florence L. O'Rourke, W. A. Paddon, R. H. Peries, R. P. Rajakone, D. W. Rankin, D. K. Ray Chaudhuri, W. T. Richardson, Louise M. C. Rienks, E. Robinson, C. Runciman, R. N. L. Sansonnens, K. S. Seal, W. Sinclair, P. K. Sylvester, Sara Syrop, D. G. Trott.

ACADEMIC POSTGRADUATE DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—M. Aslam, P. D. Farjo.

ACADEMIC POSTGRADUATE DIPLOMA IN APPLIED PARASITOLOGY AND ENTOMOLOGY.—M. Y. Ali, A. El M. El S. Badawi, C. L. E. Bent, W. R. Bransby-Williams, T. Lees May, B. McMillan, A. A. Narasimhan, R. J. Wood.

ACADEMIC POSTGRADUATE DIPLOMA IN BACTERIOLOGY.—A. S. Akhtar, Elizabeth H. Asheshov, G. I. Bartow, J. M. S. Dixon, D. R. Gamble, S. Ghosh, S. Gilani, S. P. Lapage, I. Macadam, J. K. Sarkar, L. P. Spence.

^{*}Awarded a mark of distinction.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examinations indicated:

M.D.—H. D. Cheetham, R. I. Green, J. B. Lynch.
CH.M.—C. R. Helsby.
Ph.D.—In the Faculty of Medicine: E. J. Clegg, M.B., Ch.B., M.B., Ch.B.—Margaret Baron, J. J. Carson, J. R. W. Jones, J. Tracy, L. Adamson, A. Animeshaun, J. F. Archer, P. Arrowsmith, J. R. Bennett, P. R. Blenkinsop, P. F. J. Bunting, J. L. Carter, Vera J. Capey, C. Cheyne, Doreen Clark, W. G. Clayton, R. P. Coates, D. Cohen, J. D. H. Craig, J. C. Craig, E. J. Evans, P. I. Frank, H. Frood, Patricia B. Daymond, R. Dittman, A. E. J. Evans, G. Gordon, M. S. Gottlieb, R. F. Gilmore, W. I. M. Goudrick, A. C. Gordon, R. J. Harrison, M. A. Graham, June S. Grant, J. Hajioff, C. M. Harris, R. J. Harris, M. A. Hill, D. A. Jones, B. A. G. Kimmins, R. M. Kinney, J. F. Moorhead, Marina E. A. Lewis, Jean A. Mellors, G. L. Mills, J. F. Pryce, A. L. R. Reader, Marguerite M. Regan, Jean C. Le Riche, M. K. D. H. J. G. Reader, Marguerite M. Regan, Jean C. Le Riche, M. K. D. H. El-Rifi, Isabella Sanderson, G. J. Santer, F. A. D. Walkden, K. Walker, Lesley F. Thomas, Margaret A. Tongue, J. A. D. Williams, Passed in separate subjects: G. F. Birch, Sybil Birtwistle, R. D. Gardner, and June W. Guy (surgery and obstetrics and gynaecology); P. S. Carter, R. L. Goynne, Colette C. Green, and E. V. Tetteh-Lartey (medicine and obstetrics and gynaecology); J. H. Wright (medicine and surgery).
DIPLOMA IN PUBLIC HEALTH.—Frances Allan, Anne L. J. Cusack, G. W. Danger, L. H. Duthie, T. L. Hobday, P. G. Holt, Marie T. Hyde, Brenda Jones, A. L. Kirkland, Margaret M. Lewis, Dora Marren, J. E. O'Malley, D. C. Pattison, D. P. W. Roberts, W. G. Timmis, Mary P. K. Williams.
DIPLOMA IN RADIOLOGY.—Radiodiagnosis: J. M. Brown, Audrey Couch, R. W. Galloway, K. Grainger, C. R. Locker. Radiotherapy: A. Bhattacharyya, H. J. Hughes, T. Nopparat.
^{*}With second-class honours. ^{*}Distinction in surgery. ^{*}Distinction in obstetrics and gynaecology.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications (uncorrected) in England and Wales in the week ending July 27 were as follows, with the figures for the previous week in parentheses: paralytic 137 (105), non-paralytic 123 (84), total 260 (189). Total cases in Scotland were 13 (3), Northern Ireland 26 (14), and Eire 2 (5).

The main centres of infection continued to be in the Midlands and Kent. In Warwickshire 33 cases were reported (Birmingham C.B. 8, Coventry C.B. 16), in Worcestershire 14 (Worcester C.B. 7, Droitwich R.D. 3), in Staffordshire 12 (Stoke on Trent C.B. 3, Wolverhampton C.B. 2, Leek U.D. 2), and in Lincolnshire, Lindsey 15 (Lincoln C.B. 14). In London 21 cases were reported; not more than 2 were in any one metropolitan borough. Notifications continued rather high in Kent 32 (Maidstone M.B. 3, Faversham M.B. 3, Malling R.D. 3, Tonbridge R.D. 5). In Hertfordshire 9 cases were reported (Hitchin U.D. 4, Stevenage U.D. 2), and in Essex 16 (Colchester M.B. 4). Of the 12 cases reported in Devon, 4 were from Axminster R.D. In the North, Yorkshire West Riding had 13 cases (Leeds C.B. 5, Bradford C.B. 3) and Lancashire 11 (Liverpool C.B. 4).

The 26 cases in Northern Ireland included 15 cases in Belfast, 4 in County Antrim, and 3 in County Down.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1948-56 are shown thus -----, the figures for 1957 thus ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest fluctuations in the notifications of infectious diseases in England and Wales, during the week ending July 20, were decreases of 639 for measles, from 13,417 to 12,778, 84 for whooping-cough, from 1,661 to 1,577, and rises of 131 for scarlet fever, from 413 to 544, and 56 for acute poliomyelitis, from 133 to 189.

The largest falls in the incidence of measles were 141 in Lincolnshire, from 706 to 565, 130 in Nottinghamshire, from 523 to 393, and 116 in Norfolk, from 421 to 305, and the largest rise was 70 in Kent, from 701 to 771. A small increase in the incidence of scarlet fever was recorded in most regions; the largest rise was 29 in Lancashire, from 51 to 80. The largest variations in the local trends of whooping-cough were a rise of 33 in Kent, from 137 to 170, and a fall of 41 in Essex, from 105 to 64. 2 cases of diphtheria were notified, being 1 fewer than in the preceding week.

The number of notifications of dysentery was 480 and was 15 more than in the preceding week. The largest returns were Lancashire 140 (Blackburn R.D. 36, Liverpool C.B. 22, Manchester C.B. 11, Whiston R.D. 11), Yorkshire West Riding 78 (Leeds C.B. 23, Pontefract M.B. 11), Durham 54 (Seaham U.D. 18, Blaydon U.D. 14, South Shields C.B. 10), London 28, and Warwickshire 20 (Birmingham C.B. 11).

The largest outbreak of food-poisoning involved 63 persons in Norwich C.B.

Week Ending July 27

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 564, whooping-cough 1,445, diphtheria 3, measles 11,623, acute pneumonia 172, dysentery 353, paratyphoid fever 4, typhoid fever 1.

Medical News

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending July 20 (No. 29) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 163 great towns in England and Wales (London included). London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Royal Medical Benevolent Fund.—The twenty-first annual meeting of the Royal Medical Benevolent Fund was held in London on July 31. The hon. treasurer, Mr. F. A. JULER, presenting the accounts, said that last year there had been an excess of income over expenditure of £912, but a depreciation in the market value of the Fund's assets of the order of £20,000. Thanks to various legacies, the Ladies' Guild capital funds were increasing. Dr. R. COVE-SMITH, the hon. secretary, said that nine of the 105 new cases awarded grants during the year were already in receipt of National Assistance, so that the amount of help which could be given by the Fund had to be limited to 10s. 6d. a week. With sufficient funds in hand, it might be possible to remove some of those individuals from the sphere of National Assistance and provide them with an income more in keeping with their previous standard of living. However, in present circumstances that was not possible and the most that could be done was to augment with pocket money the National Assistance grant. The only way to achieve this would be by increasing income, and for that a large number of new subscribers was necessary. The most useful method of subscription was by deed of covenant covering seven years. The Fund had more than a thousand of those, and in 1956 there were 342 new covenants and it was hoped that the 2,000 mark would soon be reached. Tribute was paid to Mr. E. C. PENNEFATHER, full-time secretary of the Fund for nearly thirty years, who has now retired. Mr. R. M. HANDFIELD-JONES, chairman of committee of management, who presided at the meeting, said that Mr. Pennefather inspired loyalty and affection in his staff and that the honorary officials had valued not only his services but his friendship. Officers elected were: president, Sir Henry Tidy; hon. treasurer, Mr. F. A. Juler; hon. secretary, Dr. T. Anwyl-Davies; committee of management, Mr. G. H. Bateman, Mr. G. J. O. Bridgeman, Mr. E. A. Crook, Dr. C. B. Dansie, Dr. T. F. Fox, and Dr. T. Anwyl-Davies.

Medical Research Council Awards.—The Medical Research Council has made the following travelling awards for 1957-8.—*Rockefeller Travelling Fellowships in Medicine:* Dr. J. BUTLER, senior registrar, medical professorial unit, Queen Elizabeth Hospital, Birmingham; Dr. W. I. CRANSTON, assistant to the regius professor of medicine, University of Oxford; Dr. D. A. HEATH, lecturer in pathology, University of Birmingham; Dr. S. P. MULDOWNY, university tutor in medicine, St. Vincent's Hospital, Dublin; Dr. W. L. NICHOLAS, lecturer in zoology, University of Liverpool; Dr. G. R. WEBSTER, senior lecturer, department of chemical pathology, Guy's Hospital Medical School. *Lederle Travelling Fellowship in Medicine:* Dr. A. M. DAWSON, registrar, department of medicine, Postgraduate Medical School, London. *Dorothy Temple Cross Research Fellowship in Tuberculosis:* Dr. H. P. LAMBERT, registrar, University College Hospital, London. *Alexander Pigott Wernher Memorial Travelling Fellowships in Ophthalmology and Otology:* Dr. R. P. GANNON, medical officer, Royal Air Force Acoustics Laboratory; Dr. D. M. MAURICE, scientific staff, M.R.C. Ophthalmological Research Unit, Institute of Ophthalmology, London; Dr. J. S. SPEAKMAN, resident in ophthalmology, Toronto General Hospital, Toronto. *French Exchange Scholarships in Medical Science:* Mr. B. L. SILVER, research scholar, University College, London; Dr. CONSTANCE E. WORK, first assistant, department of chemical pathology, University College Hospital Medical School, London. *Lilly Foreign Fellowships:* The Eli Lilly Company of Indianapolis, U.S.A., have also selected the following two candidates, nominated by the Medical Research Council, for Lilly Foreign Fellowships administered by the company: Dr. L. J. P. DUNCAN, lecturer in therapeutics, University of Edinburgh; Dr. R. F. MAHLER, lecturer in therapeutics, University of St. Andrews.

Dangers of Compressed Air.—Special measures to protect the health of men who work in compressed air are detailed in draft regulations published this week (the Work in Compressed Air Special Regulations, 1957). Individuals or organizations may make representations upon them before August 29 to the secretary, Ministry of Labour and National Service, 8, St. James's Square, London, S.W.1.

Blood Transfusion Award Offered.—The committee of the Oliver Memorial Fund intend making their annual £50 award to a British subject whose original work or services in blood transfusion are considered to be notable. The committee welcomes applications, and also communications drawing attention to suitable candidates, before September 30. They should be sent to the Honorary Secretary, Mrs. F. E. BEDBOROUGH, 105, New Park Avenue, London, N.13.

Welfare of Sick Children.—A committee studying the arrangements hospitals make for the welfare of sick children has invited evidence from a wide range of professional and other organizations and hospitals. Appointed by the Central Health Services Council, its chairman is Sir HARRY PLATT, and the other medical members are Professor NORMAN CAPON, Mr. CHARLES GLEDHILL, Dr. F. M. ROSE, Dr. W. P. H. SHELDON, and Dr. E. TYLDEN.

Squibb Foundation.—A report from New York last week announced the forthcoming establishment of a Squibb Foundation. The first reference in London to this event was that made by Dr. J. G. SCADDING at the close of the symposium on fungous diseases held at the Institute of Diseases of the Chest (see p. 348). Dr. Scadding said that the symposium had been sponsored by Messrs. E. R. Squibb and Son, Ltd., the pharmaceutical manufacturers. Although still at an early stage in its planning, it is understood that the new Foundation will exist to finance symposia, support medical and scientific research, publish scientific reports, and assist postgraduate studies on certain pharmaceutical and scientific subjects. Further details will be issued in due course.

Lord Verulam has become president of the Central Council for Health Education on the resignation of Lord BOYD-ORR. Lord VERULAM is also president of St. Mary's Hospital Medical School.

London University.—Dr. S. D. ELEK, reader in bacteriology at St. George's Hospital Medical School, has been appointed to the chair of bacteriology tenable at that school. Dr. Elek graduated from St. George's in 1940, later obtaining the M.D., D.P.H., and Ph.D. The title of reader in pharmacology in the University of London has been conferred on Dr. J. B. E. BAKER in respect of his post at Charing Cross Hospital Medical School. Dr. F. R. JOHNSON, lecturer in anatomy at Sheffield University, has been appointed reader in anatomy at the London Hospital Medical College; Dr. P. H. SPENCER-SILVER has been appointed reader in anatomy at the Middlesex Hospital Medical School.

Midwifery at Dundee.—Dr. MARY G. COYLE has been appointed to a lectureship in midwifery in St. Andrews University at Queen's College, Dundee.

Honorary Degree.—At a degree congregation at Birmingham University on July 6 the honorary degree of Doctor of Laws was conferred on Mr. FRANK BARNES, F.R.C.S., by the Vice-chancellor, Dr. ROBERT AITKEN. Mr. Barnes graduated from London in 1902, and later became lecturer in osteology and lecturer in operative surgery at Birmingham University.

Professor Robert Walmsley, Bute professor of anatomy at St. Andrews University since 1946, has been appointed Master of St. Salvator's College for three years from September 30.

COMING EVENTS

Chartered Society of Physiotherapy.—Annual congress, September 19-21 at St. Pancras Town Hall, London, N.W.1. Medical practitioners are invited to all lectures and demonstrations. Details from the secretary of the society, Tavistock House (South), Tavistock Square, London, W.C.1.

Postgraduate Course in Pathology.—The Association of Clinical Pathologists is arranging a series of week-end courses from November, 1957, to March, 1958. These courses are intended primarily for pathologists of consultant or S.H.M.O. status, and will be held in London. Programmes are obtainable from the secretary, Association of Clinical Pathologists, Maida Vale Hospital, London, W.9.

Seventh International Cancer Congress.—July 6-12, 1958, at the Royal Festival Hall, London. Papers should be submitted before October, 1957. Further details from the secretary-general, Seventh International Cancer Congress, 45, Lincoln's Inn Fields, London, W.C.2.

NEW ISSUES

British Journal of Ophthalmology.—The new issue (Vol. 41, No. 8) is now available. The contents include:

STUDIES ON DEVELOPING RETINAL VESSELS. V. MECHANISM OF VASO-OBLITERATION. (A PRELIMINARY REPORT.) Norman Ashton, Clive Graymore, and Christopher Pedler.
OBSERVATIONS ON PHOTOCHEMICAL REACTIONS IN LIVING EYES. R. A. Weale.
FURTHER STUDIES ON THE DISTENSIBILITY OF THE EYE. E. S. Perkins and J. Gloster.
A MODIFICATION OF THE SMITH INDIAN TECHNIQUE OF INTRACAPSULAR CATARACT OPERATION. M. S. Niranjan and M. C. Maudgal.
BENIGN CALCIFYING EPITHELIOMA. D. St. C. Roberts.
ELECTRICAL CATARACT PRODUCED BY A 240-VOLT CURRENT. J. A. N. Lock.
CONGENITAL PTERYGIUM. Manmohan Malhotra.
NEW APPLIANCES. B. W. Rycroft.
TWO NEW SYNECHIA KNIVES. Frank W. Law.
CORRESPONDENCE.
BOOK REVIEW.
NOTES.
OBITUARY.

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked •. Application should be made first to the institution concerned.

Friday, August 16

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. N. Lloyd Rusby: clinical demonstration.

APPOINTMENTS

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, London, W.C.—Margaret E. Barton, M.B., B.Chir., and Marcel Kinsbourne, B.M., B.Ch., M.R.C.P. House-physicians; Myrtle E. Mitchell, M.B., B.S., House-surgeon; H. T. Thomas, M.B., B.Chir., Resident Officer to the Neurological and Neurosurgical Department; Nora E. Casey, L.R.C.P.&S.I., Assistant Resident Medical Officer, Tadworth; Maatje V. Buhrmann, M.B., Ch.B., D.P.H., D.P.M., Part-time Registrar to Department of Psychological Medicine.

LIVERPOOL REGIONAL HOSPITAL BOARD.—J. G. Neville, M.B., B.S., M.R.C.P., D.P.M., D.C.H., Consultant Child Psychiatrist, Alder Hey Children's Hospital; G. P. Egan, M.D., D.P.M., Consultant Psychiatrist, Liverpool Psychiatric Day Hospital, Croxteth Road, Liverpool; C. A. Hopkins, M.B., Ch.B., M.R.C.P., recently appointed Tuberculosis Medical Officer to East Liverpool Group, has been re-designated Assistant Chest Physician.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Blackadder.—On July 30, 1957, at Edinburgh, to Jean, wife of Eric S. Blackadder, M.B., Ch.B., D.R.C.O.G., 29, Grange Loan, Edinburgh, a brother for Mark.

Scott.—On July 13, 1957, to Mrs. Mary Helena (formerly Davies) and Jack Scott, Greenways, The Balk, Walton, near Wakefield, a daughter—Jane Kemp.

DEATHS

Gates.—On July 23, 1957, Mabel Emily Gates, M.D., of Stanmore, Ridge-wood, Uckfield, Sussex, late of Exeter, Devon.

Gordon.—On July 24, 1957, in hospital, London, Francis Jervis Gordon, M.R.C.S., L.R.C.P., aged 76.

Hewat.—On August 3, 1957, at Edinburgh, Andrew Fergus Hewat, M.D., F.R.C.P.Ed., F.R.F.P.S.

Jones.—On July 17, 1957, in hospital, Walter Paul Jones, M.D., of 2, Talbot Road, Carshalton, Surrey, aged 84.

Knight.—On July 19, 1957, at The Orchard, Hungerford, Berks, John Iles Francis Knight, M.R.C.S., L.R.C.P., late of The Down House, Blandford, Dorset.

McKenna.—On July 24, 1957, Francis Hector McKenna, M.B., B.Ch., of 89, Eyhurst Avenue, Elm Park, Romford, Essex.

Musson.—On July 20, 1957, at 15, Blackstone Road, London, N.W., John Orrett Musson, M.R.C.S., L.R.C.P., formerly of 19, Chichele Road, London, N.W.

Oswald-Smith.—On July 20, 1957, Harry Oswald-Smith, M.D., of The Lodge, Rushall Place, Tunbridge Wells, Kent.

Robinson.—On June 22, 1957, at the General Hospital, Singapore, Harold Humphreys Robinson, M.D., D.P.M., aged 36.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Diagnosis and Prognosis of Amyloid Disease

Q.—By what methods can a presumptive clinical diagnosis of amyloid disease be confirmed? Please indicate the value of the Congo red test in this connexion. What is the prognostic significance of a positive diagnosis?

A.—The Congo red test is very useful in confirming a clinical impression of amyloid disease. With the usual routine a positive diagnosis should not be made unless 90-100% of the injected Congo red solution has been removed from the blood in one hour. The more elaborate Congo red test, performed by plotting the concentration of the dye in the blood at various times after injection, is of the more sensitive but more complicated to perform. The removal of Congo red from the vascular system depends on the amount of amyloid deposited in the tissues, and the Congo red test may be negative if only small amounts are present. A positive result usually indicates hepatic involvement, for this organ provides the largest store of amyloid tissue.

If the Congo red test is negative and there is strong presumptive clinical evidence of the disease, biopsy must be done. Aspiration liver biopsy is particularly valuable, as hepatic involvement is usually diffuse, and, if the liver is involved, amyloid material will be seen. Biopsy of the gums is a safe and easy method, but negative results are not uncommon in the presence of definite amyloid disease. If albuminuria points to renal involvement and the diagnosis cannot be established by any other method, kidney biopsy should be performed either by the needle technique or, if this is not possible, by open surgical exploration.

Positive diagnosis is essential, for the presence of amyloidosis demands renewed efforts at control of the primary disease process. If the underlying condition is cured the amyloid deposits will regress. Tuberculosis is the condition most often associated with amyloidosis, and chemotherapy or surgical treatment may be needed. Rheumatoid arthritis or surgical treatment may be needed. If brought under control the amyloid will disappear. If the patient with amyloidosis does not die of the primary disease, the usual cause of death is secondary contracted amyloid kidneys and uraemia. Progressive amyloidosis is usually fatal within two years of diagnosis.

Tinnitus after Fenestration for Otosclerosis

Q.—Following a unilateral fenestration operation for otosclerosis, the middle ear became infected and there is a persistent fistula (not now discharging) leading from the middle ear to the external ear. Tinnitus has now developed in this ear. What is the cause and how should it be treated? Is it a frequent complication of fenestration?

A.—Tinnitus is common in otosclerosis. About half the cases find it a nuisance. Improvement of the hearing by operation or the use of a hearing-aid may mitigate its severity, as after such measures outside sounds seem intensified.

As the question stands, it suggests that infection coincided with the operation, and it may be that increased deafness

was noticed then. This is important, since labyrinthitis might have occurred, causing inner-ear changes and irreversible hearing loss. Suspicion that this was the case would be aroused were the tuning-fork in Weber's test to be referred to the unoperated ear and not heard at all in the operated ear. Such a case could not be helped by treatment to the ear. If, however, the infection occurred some time after successful fenestration, there is a possibility that the perforation has cancelled out the gain in hearing from the operation, and so allowed the tinnitus to become noticeable. Closure of the perforation might restore the hearing enough for the tinnitus to be partially masked by external sounds. This possibility should be tested by covering the perforation with a small prosthesis: a pledget of cotton-wool moistened with liquid paraffin could be used. If successful this method could be continued, but the prosthesis would need changing monthly. Permanent closure might be achieved by cauterizing the edges of the perforation with trichloroacetic acid, or a myringoplasty (i.e., a skin graft) might be done.

Infection of the middle ear is a rare primary complication of fenestration, an incipient cold being the usual cause. After healing, a successfully fenestrated ear is no more susceptible to infection than a normal one. Most perforations heal if the infection is eliminated.

"Dry Socket"

Q.—What is the pathology of the so-called "dry socket" following the extraction of a tooth? Is antibiotic cover recommended at the time of an extraction in a patient who has had a series of dry sockets?

A.—"Dry socket" is osteitis of the alveolar process following the extraction of a tooth. During the act of extraction repeated rocking movements may have to be performed, and these can crush the bone and occlude its vessels. By the same action pathogenic bacteria may be distributed into the tissues of the socket from any existing infected area. The probability of the complication is increased by greater density of the bone, mechanical difficulties due to the shape of the tooth, and the presence of acute infection.

The crushing of bone can often be avoided by cutting away sufficient bone to permit easier delivery of the tooth or by dividing the tooth and removing the roots separately. In the case of a person who has had a series of dry sockets for which no cause is apparent the provision of antibiotic cover is recommended. It would also be reasonable to seek radiographic evidence of any mechanical difficulties to be anticipated and avoided, and to inquire into the possibility of constitutional reasons for the undue liability to infection.

Auricular Paroxysmal Tachycardia

Q.—A woman of 30 with frequent attacks of auricular paroxysmal tachycardia has been successfully controlled with quinidine, in a dosage of 0.2 g. three times a day, for the last three months. However, her platelet count has fallen from 170,000 to 90,000 per cubic mm. in the course of six months. Quinidine has therefore been stopped. (1) Is thrombocytopenia a common complication of quinidine therapy and what is its prognosis? (2) What treatment is advised for the tachycardia now? (This patient is also intolerant of digitalis, vomiting after 0.6 to 0.8 mg. of digitalis.) (3) In general, for how long is it advisable to continue giving quinidine to cases of paroxysmal tachycardia?

A.—(1) Thrombocytopenia and thrombocytopenic purpura are rare complications of quinidine therapy. Recovery occurs when administration of the drug is stopped.

(2) Prevention of attacks of auricular paroxysmal tachycardia is often difficult, but simple measures such as the avoidance of precipitating factors should not be forgotten. These factors are said to include fatigue, anxiety, overeating, indigestion, excessive smoking, and excessive consumption

BY

Answer

Michel André (1941) showed that those clinical features of myelodysplasia which differentiate it from familial perforating ulcer of the foot are principally bony abnormalities due to diasthesis of the spinal cord, the absence of a familial incidence, the early onset of symptoms, and a predisposition to sensory spinal nerve root disturbances of the syringomyelic dissociation type, though the last-named are not normally very severe.

Hicks (1922) confirmed that familial perforating ulcer of the foot is an independent morbid entity. His patients comprised several members of one family. Hicks was unable to reconcile these symptoms with those of any hereditary or nervous disease or any other disease known to give rise to perforating ulcers. There was some close resemblance with syringomyelia. "The disease is hereditary

FIG. 1.—Genealogical tree of Family De B. The proband is II 7.

in type. The chief symptoms are perforating ulcers of the feet, fulgurant pains in various parts of the body and deafness."

Thévenard (1942) compared the cases reported in the literature with his own observations. Because of the almost total absence of amyotrophy and motor disturbances and the involvement of the upper and lower extremities, he had strong doubts about the relationship of his syndrome with lumbar syringomyelia. Even to-day the problem is not entirely settled, as there are the familial cases observed by Barraquer-Ferré and Gispert-Cruz (1943) with atypical syringomyelia. In one case the findings at necropsy included a huge cavity in the lumbar enlargement of the spinal cord, the spinal parenchyma being reduced to a thin layer. Unfortunately, the specimen was mislaid and not studied histologically. Again, the case just described (that of the De B. family), in which ulcers and mutilating lesions of the extremities coexisted with a classic familial form of syringomyelia, is not the only one of its type, for identical cases have been reported by Mankowsky and Czerni (1933).

Status Dysraphicus

As signs of status dysraphicus are frequently observed in families or subjects affected with ulcers of the extremities, we shall merely mention the syndrome in passing. There are families, such as those described by Tocantins and Reimann (1939) or Murray Jackson (1949), with numerous dysraphic symptoms. The parents of the generation with "anaesthetic" mutilating lesions of the extremities described by Nagib Taleb (1950) showed symptoms of status dysraphicus and marked inbreeding. The patient affected with mutilating lesions of the extremities in Case I of Velluz, Coirault, and Causse (1955) showed a coccygeal dimple, a shortened frenum of the prepuce, a double urethral meatus, trophoedema of the lower limbs, asymmetry of the breasts, a pigmented hairy mole on the right flank, and pigmented naevi on the back. The mother was affected with trophoedema and perforating ulcer of the foot. Case II of these authors concerned a patient with bilateral Dupuytren's contracture, a coccygeal dimple, congenital absence of the xiphoid process, and pigmented naevi on the back. On the other hand, there are cases in which the symptoms of status dysraphicus are quite few in number.

It may be held that ulcers and mutilating lesions of the extremities, status dysraphicus, syringomyelia, and other similar ectodermal dysplasias are all related, being but dysontogenetic variants. Even though symptoms of status dysraphicus be absent or so mild as to be within the limits of normal variations, detailed anatomical study of verified cases of sarcolumbar syringomyelia may unintentionally provide evidence pointing in this direction. In our case concerning the De B. family, we, like Jughenn, Krücke, and Wadulla (1949), were able to detect in the spinal cord twisted and spherular neurofibromata along the vessels accompanying the ependymal canal and the base of the anterior sulcus, as well as aberrant neuroglial brushes in the posterior columns and hypertrophy involving the collagenous fibres of the pia mater and spinal nerve roots.

It has yet to be established that these "minimal" malformations do not occur in all regions. That they were observed in the spinal cord and its coverings was due to the fact that they are readily detectable in this region, where they are crowded into a small space. The same remark applies to the spinal ganglion. It is extremely difficult to detect similar rudimentary malformations in a sole of the foot which has undergone changes due to suppurating ulcers. This has only been done accidentally when removing material for biopsy. Our pathological investigation has been based on exploratory probing rather than a methodical study of the actual substrate.

Anatomical Data

Before 1949 the delineation of an independent disease was based on clinical data alone, save for the case reported by Gastou (1895), which was not of the familial type, and the valuable but unusual case described by the Barraquers anatomically by Jughenn *et al.* (1949). Their case concerned a 32-year-old woman with indolent ulcers, spontaneous fractures, acrocyanosis associated with vasospasm, camptodactyly of the little finger (as in status dysraphicus), symmetrical ankylosis of the metacarpophalangeal joints of the thumb, malformations of the teeth and palate, numerous pigmented naevi, obesity, and scanty menses. The father showed ulcers and amputation of the toes, bilateral Dupuytren's contracture of the hands, and symptoms of status dysraphicus with syringomyelic dissociation in the lower limbs. One sister presented endocrine disturbances, ulcers, and fractures similar to those seen in the patient. In addition, the two sisters showed marked circulatory disturbances due to paroxysmal acro-asphyxia. A younger sister was affected with diencephalic obesity.

It is because of the circulatory disturbances in the extremities that the paper by Jughenn *et al.* (1949) bears the title: "Contribution to the study of a Familial Syringomyelia: Anatomical and Clinical Studies on a Neurovascular Familial Dystrophy of the Extremities." They say, "Being to begin with is that syringomyelia may be positively ruled out as a substrate of this syndrome." It is an interesting point that there were slight structural changes, as those in status dysraphicus, as well as gliosis and perivascular fibromatosis. The dorsolateral nuclei of the ventral cornua of the lumbosacral portion of the spinal cord showed tigroidosis, indicating a corresponding peripheral lesion, but the spinal ganglia and the distal portion of the autonomic nervous system were not studied. The peripheral changes involved both the vessels themselves (parietal changes and proliferation of the small arteries to the point of obliteration, thromboses rendered permeable again) and the vasa nervorum; hence the areas of segmental demyelination and proliferation of the white substance of Schwann. The skin and muscles showed a mixture of atrophic and hypertrophic lesions.

The authors concluded that these cases should be classified somewhere between the myelodysplastic and tropho-vascular syndromes, possibly along with Kehrer's group of

"hereditary universal acrodystrophies." They believed this term to be questionable, however, as the disease is not merely "acral," but also involves the mid-portion of the foot and the entire distal portion of the segments.

The Peripheral Nervous System

In this way the paper by Jughenn *et al.* focused the problem on the peripheral nervous system—though the lesions of the spinal cord which are evidence of the effects of the disease were not overlooked. Denny-Brown (1951) deserves credit for laying his finger on the primary degeneration of the spinal ganglia and thus broaching a new subject: that of the "polyganglionic and radicular hereditary diseases." The case studied by Denny-Brown and McArdle concerned a member of the family previously described by Hicks (1922). In his anatomical study Denny-Brown (1951) described changes in the spinal ganglia, the posterior columns of the lumbar portion of the spinal cord, the posterior nerve roots, and the peripheral nerves. He also drew attention to an amyloid degeneration of the blood vessels (secondary, in his opinion) and to deposits of some hyaline substance, other than amyloid, in the ganglia. Of three cases observed in members of the De B. family, two also showed clinically central deafness, and in the seven years' duration which we followed up this family after our paper was published in 1939 one of the members developed classical syringomyelia.

In our case we too observed lesions of the ganglia and nerve roots, much less severe lesions of the nerve trunks, and more marked lesions of the peripheral nervous system. The capsules of the ganglia, the perineurium, and the blood vessels showed deposits of a hyaline material staining differently from amyloid substance. Examination of the nerves, skin, muscles, and aponeuroses revealed marked rarefaction of the axis cylinders and fibrosis of the perineurium, subintimal proliferation of the smaller arterioles, and lesions of the muscles of the type caused by neural atrophy. Thus the pathological basis to the condition may extend from an involvement of the nerve trunks, ganglia, and roots, as described by Denny-Brown, to the peripheral nerves, and particular stress might be laid on the effects of these changes on the vascular networks.

So far, the family studied by Hicks and the De B. family have been the only families in which the totality of clinical symptoms described by the English authors was observed. To our knowledge, no other case has since been verified and reported in detail. One of the cases described by Nagib Taleb (1950) is assumed to have been confirmed, but we do not know whether it has been published. The unusual case reported by Girard, Mazare, and Devic (1953) was marked by severe changes of the posterior roots and the trunk of the sciatic nerve, but there were no lesions of the spinal cord, with the possible exception of some slight changes in the posterior columns.

The cases observed by Hicks and by Denny-Brown and McArdle are of value in that they show that there is a hereditary polyganglionic radicular disease giving rise to the clinical picture of ulcers and mutilating lesions of the extremities.

Neuro-ganglio-radicular Changes

The case reported by Denny-Brown and our own case are pure forms of hereditary polyganglionic radicular disease. Should most, if not all, of the familial cases with the lesions under consideration be similarly classified? The problem was stated clearly by Thévenard (1953), who, when discussing pure sensory forms of the disease, wrote: "It may be that this merely is a very early and completely silent stage, but there is no reason for assuming that this sensory dystrophy cannot persist unchanged throughout the entire life of the subjects affected. The problem can only be solved by prolonged observation of these families." As regards the parieto-amyotrophic lesions and suggesting "cases marked by transitional lesions and suggesting Charcot-Marie atrophy have been reported." He went on to review the cases of Charcot-Marie atrophy associated

with perforating ulcers of the foot reported by Oppenheim, Halliday and Whiting, Puussepp, Alajouanine, Sicard and Scherer (quoted by van Bogaert, 1953), and by Denny-Brown and England (1952). To these we can add the recent case of a family described by Barraquer-Ferré and Barraquer-Bordas (1953). In all these families perforating ulcers of the feet appeared in characteristic, if not severe, cases of the peroneal neuromuscular atrophy of Charcot, Marie, and Tooth.

Familial perforating ulcer of the foot may, however, be the first indication of a progressive hereditary degenerative disease of the spinal cord; in other words, the clinical symptoms of the neuro-ganglio-radicular lesion may have advanced to a stage beyond that of all the symptoms of disease of the spinal cord. Thus a painless lesion of obscure origin appeared in the same toe in possibly monozygotic twins at the ages of 10 and 11. X-ray examination revealed partial dislocation of the second phalanx and rarefaction of bone. The children had never been able to walk normally and their psychomotor development had been retarded at an early stage of life. At the age of 12, however, they had increasing difficulty in walking and the legs showed incipient signs of becoming thinner, especially on the left side. At the age of 14 the twins showed the picture of Friedrich's ataxia (Fig. 2), accompanied by distal amy-

FIG. 2.—Genealogical tree of Family N.

trophy, impairment of temperature and pain sense, loss of deep sensibility, indolent symmetrical ulcers of the feet, trophic disturbances of the nails, subungual excoriations, exfoliative keratosis of the palms, and callosities on the dorsal surfaces of the second interphalangeal joints of the fingers. The clinical picture was that of amyotrophy with severe involvement of the posterior columns. There was an extreme impairment of deep sensibility, involving all four limbs, though the degree of ataxia was not proportional to the severity of these disturbances (Boudin and Djindjian, 1951).

The trophic disturbances in the upper limbs mainly implicated the skin, the hair, and the nails, but minute ulcers were seen to appear on the tips of the fingers.

In these twins, then, the ulcers and mutilating lesions of the extremities appeared prior to the degeneration of the spinal cord, an observation which justifies Thévenard's previous reservations.

These two cases show another characteristic feature—namely, that the disease was associated with oligophrenia, as described by Passouant, Vallat, and Temple (1951).

These findings are important in that they are the converse of those stressed by Denny-Brown and England (1952) and by Barraquer-Ferré and Barraquer-Bordas (1953), another

FIG. 3.—Genealogical tree of Family Leb.

instance of which we ourselves have observed. In another family (Leb.) concerning which Troch and Cleen (1953, personal communication) wrote a brief preliminary report, the neuro-ganglio-radicular changes were the last to appear in a long sequence of degenerative lesions of the spinal cord and cerebellum. This Leb. family (Fig. 3), studied since 1922, developed diseases such as heredo-ataxia or Charcot-Marie-Tooth's neuromuscular atrophy (C.N.A.) at various stages of

FIG. 4.—Mutilating acropathy of one of the patients from Family Leb.

life, and at the time of writing the eldest son is bedridden, ulcers and mutilating lesions of the extremities (Fig. 4) having been superimposed upon the degeneration of the spinal cord, cerebellum, and nervous system (van Bogaert, 1951).

Related Conditions

Some of the cases in these two clinical groups with ulcers and mutilating lesions of the extremities bear a resemblance to status dysraphicus (including syringomyelia and neurofibromatosis), others to hereditary degeneration of the spinal cord. These conditions appear in young subjects, the average age of onset being 14 (Thévenard, 1953).

With Jughenn *et al.* (1949) we believe it should be stressed that some of these cases are allied to vascular disturbances of the extremities, themselves possibly reflecting a disorder of the peripheral nervous system, and in any case aggravating the course of the disease. We have found no evidence to suggest that the disease was congenital in any of our cases; nor did the onset occur during the first two years of life. A recent case (Eyckmans, Radermecker, and van Bogaert, 1956), so far as we know the only case of this type to have been reported in the literature, was characterized by severe mutilating lesions of the extremities, resulting in extensive necrosis of the four extremities at the age of 42. This case is of interest in view of the appearance of a necrotizing lesion at the tip of the nose, and the fact that an ulcer appeared in a little finger when the patient was 2 years old, followed by spontaneous amputation of this finger after sepsis had continued for a few months, ulceration of a toe, going on to spontaneous amputation at the age of 3, etc. In addition to spontaneous mutilating lesions of the nose, extremities, and ears, there were areas of atrophy of the skin with cyanosis, and symmetrical telangiectases in the buttocks and anterior surface of the thigh. In addition to mild lesions due to myositis fibrosa in the extremities, this patient also showed a syringomyelic sensory dissociation of the type observed in ulcers and mutilating lesions of the extremities. We shall not enter into a discussion of the lesions of the skin, a subject on which there has been no agreement (poikiloderma? Pick-Herxheimer acrodermatitis atrophicans? cutis marmorata? special vascular disease of the

skin?). A case of this type compels us to reconsider the problem from the point of view of the peripheral neurovascular disturbances, previously stressed.

Osteolysis

Finally, there are cases in which osteolysis of the extremities proceeds without spontaneous or surgical amputation from suppurating lesions and without any trace of indolent torpid ulcers. In such cases the lesion is confined to a dissolution of the bones, with sheath-like, sausage-like, or lorgnette-like contractions of the fingers and toes. There are no neurological disorders and the trivial sensory disturbances observed may be attributed to thickening of the skin and keratosis or atrophy of the epidermis. The muscular atrophy seen in these cases may be arthrogenic. The patients affected show endocrine disturbances: the skin is delicate in some cases, parchment-like, glossy, scaly, dry, and wrinkled. The hands are soft and pudgy, the joints loose, and the nails small and brittle. Owing to the contraction of the fingers and toes, the skin folds up "like an accordion" over the affected bones. This withered skin of the extremities is accompanied by atrophy of the dental alveoli, and a tendency towards gynecomastia, kyphosis due to osteoporosis, and changes of the hair and nails. These patients give the impression of having aged prematurely. A certain number of these cases have been collected by Leger and Ducroquet (quoted by Meunier, 1950) and a sporadic typical case was reported by Meunier (1950).

We have previously attempted (van Bogaert, 1953) to classify such patients into certain groups. What Brugsch has described as "acromicria" is undoubtedly related to this disorder, but this is especially so in the cases reported by Harnasch (1950) and Laroche and Hochfeld (1950), the tubero-hypophysial disturbance being particularly marked in these cases. This particular form of familial dystrophy was described by Hozay (1953), who stressed the early inhibition of growth and the non-mutilating osteolysis of the extremities, with malformation of the face.

We have observed this syndrome in a brother and sister. Here, however, the osteolysis of the extremities appeared at such an early stage that miniature extremities were implanted on a body relatively well developed and proportioned (Fig. 5). The undersized portions subsequently under-

FIG. 5.—View of the back of the brother's hands.

went trophic changes, involving both the bones and the soft tissues. The parents emphasized the fact that the hands and feet of the brother and sister were similar to those of their children up to the age of 3 years and 6 months. At that time the digits became flexed; "not only," they added, "did the fingers stop growing, but subsequently they also decreased in length." The arrest of growth and reduction in size occurred independently: the shrinkage of the bones was not accompanied by the elimination of sequestra through the ulcers. The disease involved the four extremities from the onset. Ulcers did not appear until later, when they showed themselves in friction areas on the soles of the feet, resulting from a faulty position of the twisted stump in the shoes. These traumatic ulcers were painful. They healed within one month. This extraordinary smallness and flaccidity of the hands had its counterpart in a surprising adroitness: the girl could wash up, and the boy was able to roll his cigarettes. They walked about on these

miniature feet, the tiny toes of which continued to be identifiable although reduced to the size of nipples. The reduction in girth and length extended cuff-like as far as the lower third of the forearm, and we are not acquainted with any disease in which arms and forearms as muscular as those of adults are provided with the wrists and hands of a child of 2. The nose and ears had undergone less marked changes in shape. The affected extremities showed no vascular disturbances; the pulsations disappeared on palpation of the arteries. The changes of the skin were a mixture of paper-like atrophy, keratosis, and bands of cyanosis. The nails had been reduced to a thin film and their surfaces corresponded with the size of fingers and toes.

Obviously osteolysis of the extremities had taken on such a grotesque appearance in these patients because it had occurred in infancy. There is no doubt, however, that the other endocrinopathic and trophic changes of the soft tissues elsewhere described and particularly stressed in adults had also occurred in this brother and sister. These endocrine changes, however, are inconstant, for both primary and secondary sex characteristics in the brother and sister described by Hozay (1953) showed a development in keeping with their age.

Changes of the skin, muscles, and vessels as well as the endocrine constitution have not been taken into account in adopting the term acro-osteolysis.

Conclusions

Ulcers and mutilating lesions of the extremities are due to affections of the spinal ganglia, of the spinal nerve roots, and, to a certain extent, of the peripheral nerve trunks and networks. The pathological lesions may predominate in any of these structures. Neurological manifestations are accompanied by changes in the vascular system of variable severity, in the pathogenesis of which several factors probably are operative.

The disease is hereditary in some cases; other forms either bear a resemblance to myelodysplasia in the broad sense of the term or to hereditary degeneration of the spinal cord and cerebellum. The disease may be observed in an isolated state or it may constitute an initial or late stage of hereditary degeneration.

It may be congenital and appear very early in life, be accompanied by extensive and complex lesions of the skin, and be associated with only slight neurological disorders (syringomyelic dissociation of the lower extremities), though of a type similar to that usually observed in young patients.

On the other hand, there are cases of non-mutilating familial acro-osteolysis showing endocrine anomalies, without neurological disturbances, but associated with changes of the soft tissues. Up to now, these cases have not been definitely classified from the clinical point of view.

PERIPHERAL ARTERY GRAFTING

DESCRIPTION OF AN OPERATION

BY

PETER MARTIN, V.R.D., M.Chir., F.R.C.S.Ed.

Lecturer in Surgery, Postgraduate Medical School, Hammersmith; Surgeon, Chelmsford Hospital

AND

H. GAYLIS, Ch.M., F.R.C.S.

Assistant Lecturer in Surgery, Postgraduate Medical School, Hammersmith

During recent years there has been increasing experience of the surgery of the aorta and great vessels. Reconstruction of these with a variety of different substances has achieved considerable success, but there is not yet unanimity of opinion on the best material to use. In general an end-to-end anastomosis is used in these vessels. That so many different materials have proved successful is probably due to the large diameter of the anastomosis and the rapid rate of blood flow. In the peripheral vessels, where the diameter of an end-to-end anastomosis is smaller and the blood flow slower, thrombosis is common. Many consider that there is only a limited use for peripheral grafting, particularly when atherosclerosis is the cause of the condition requiring treatment (Fontaine *et al.*, 1952; Rob and Eastcott, 1953). Since the introduction of the end-to-side technique of anastomosis, first suggested by Kunlin *et al.* (1951) and later modified by Cockett (Linton and Menendez, 1955), the outlook in peripheral grafting has improved.

During the past 10 years we have inserted 78 peripheral grafts in the lower extremities, most of them for the treatment of atherosclerosis obliterans, and on the basis of this experience we have drawn certain conclusions.

Materials Used for Peripheral Arterial Reconstruction

Synthetic Materials.—Although many synthetic substances are available, the only material that we have used for peripheral arterial replacement is polyvinyl alcohol sponge. This substance has been used on six occasions; all the prostheses functioned initially, but only one, an end-to-side anastomosis between the aorta and the common femoral artery, remains patent. In our experience polyvinyl alcohol prostheses, though successful in the aorta and iliac vessels,

do not appear to be suitable for use in the peripheral vessels. Eversion of the material in anastomoses of small diameter is difficult, thrombosis is common, and sinus formation has occurred with secondary haemorrhage. We no longer use polyvinyl alcohol prostheses in reconstruction of the limb vessels.

Autogenous Vein Grafts.—These have certain obvious advantages. An autogenous vein graft is readily available, and the long saphenous vein can conveniently be obtained through the incision used to expose the femoral artery. The graft is sterile, it survives transplantation, and the necessity for an arterial bank is obviated. Contrary to what is often stated, we have not experienced technical difficulties with the anastomosis. A disadvantage of a vein graft is that where a long segment of artery has to be replaced a sufficient length of vein of adequate calibre is not always available, and in the region of the knee-joint the long saphenous vein is often of narrow diameter. It is, of course, essential that the direction of the vein should be reversed so that the valves do not obstruct the arterial flow. Although transplanted veins dilate from the unaccustomed higher arterial pressure, we have seen no ill effects from this. In some they may regain their normal diameter, possibly from hypertrophy or from deposition of a layer of mural thrombus, or perhaps a combination of both.

In general, autogenous vein is valuable to bridge arterial defects caused by trauma or by excision of arterial segments infiltrated by malignant tumours. In atherosclerosis, when

thrombosis may be extensive, a sufficient length of vein of adequate diameter is seldom available.

Arterial Homografts.—Arterial homografts preserved either by freeze-drying or storage in saline to which antibiotics have been added are most generally useful. If freeze-dried they can be stored indefinitely. Their disadvantage is that an artery bank is necessary and that suitable donor material is scarce.

Grafting in Obliterative Arterial Disease of the Lower Extremities

(a) Atherosclerosis

Incipient or Established Gangrene.—Except in patients with massive gangrene of the foot or leg, no limb should be considered for amputation until an arteriogram has shown that a grafting procedure is impossible. Gangrene of a toe or of the dorsum of the foot can be induced to separate, with subsequent healing of the tissues by a graft; by such means we have saved a limb from amputation in a man of 79 with severe coronary disease.

Rest Pain.—In the absence of local sepsis rest pain is a symptom of impending gangrene which will usually occur within six months of its onset. Sometimes rest pain occurring after a recent arterial thrombosis will ease, with a period of conservative treatment as the collateral circulation develops, but more often the pain persists and gets more severe, and a grafting operation should be done if anatomically possible.

Intermittent Claudication.—This is the commonest symptom of atherosclerosis. Numerous therapeutic methods for relieving this symptom have been tried with varying success. Sympathectomy is of questionable value, because, although the skin blood flow is augmented, the blood flow to muscle is not significantly improved. Since the introduction of grafting procedures it has become possible to re-establish arterial continuity and thus restore the blood flow to both skin and muscle to a degree not achieved by any other method. Patients whose livelihood is jeopardized or whose activity is severely restricted are accepted for operation provided they have no serious coronary disease. Mild claudicants are not accepted, because their symptoms may remain stationary and in some cases may even improve considerably with the development of further collaterals.

Fig. 1 is the left femoral arteriogram of a man aged 54 suffering from bilateral femoro-popliteal arterial thrombosis. Two years previously a bilateral lumbar sympathectomy was done because of calf claudication and coldness of the feet. The operation did not relieve the claudication, but the feet became warmer. On his second admission in July, 1956, he complained that he could not walk more than about 50 yards and he was forced to relinquish his job. Fig. 4 is a pre-operative digital plethysmograph of the right great toe, showing the blood flow of the skin to be 5 ml./100 ml./min. A

FIG. 1

FIG. 2

FIG. 3

Fig. 1.—Composite left femoral arteriogram (pre-operative). Femoro-popliteal segment thrombosed, with numerous collaterals around the thrombosed segment. Superficial femoral artery is site of diffuse atheroma. Fig. 2.—Composite left femoral arteriogram (post-operative). Graft extends from common femoral artery to distal popliteal artery, indicated by arrows. Interruption of continuity of contrast medium, indicated by interrupted lines, was because of mistiming in first exposure. Note disappearance of collaterals in relation to thrombosed segment (Fig. 1). Fig. 3.—A composite femoral arteriogram showing thrombosis in a femoro-popliteal bypass graft. The proximal (P) and distal (D) anastomoses are still patent.

by-pass graft was inserted in each leg. Fig. 2 is the post-operative arteriogram. A month after discharge he was able to walk without pain and his feet were warm. Fig. 5 is a post-operative digital plethysmograph of the right great toe. The blood flow is 20 ml./100 ml./min.

(b) **Embolism.**—In some late cases of embolism grafting, if feasible, should be undertaken.

(c) Thrombo-angitis Obliterans

Thrombo-angitis obliterans is a disease predominantly of small vessels. Grafting is therefore not possible except in the rare case when the disease affects a major artery only.

FIG. 4.—Venous-occlusion plethysmograph of right big toe before operation on reflex heating. Blood flow, 5 ml./100 ml. per min.

FIG. 5.—Venous-occlusion plethysmograph of right big toe on reflex heating post-operatively. Blood flow, 20 ml./100 ml. per min.

venous fistulae, on the other hand, can seldom be treated surgically, because they are often multiple, small, and diffuse, occurring not only in soft tissues but in bone also.

Aneurysms

Peripheral aneurysms, though not as dangerous as abdominal aneurysms, are prone to the same complications. They may rupture or thrombose, or give rise to pressure effects. Localized aneurysms should be excised even though symptomless, and continuity should be restored by grafting. The diffuse tortuous dilatation associated with atherosclerosis seldom ruptures and is better left alone and reviewed periodically.

Grafting in Atherosclerosis of the Lower Extremities

Dible (1956) has shown that atherosclerosis of the lower extremities is a disease of major vessels and hardly ever affects the smaller arteries of the foot. Although the disease is generalized, thrombosis is often segmental, and in our experience 50% of cases are anatomically suitable for grafting, though the indications for grafting do not arise in more than about a third. In many instances the femoro-popliteal artery is the only artery thrombosed, although, when the rest pain occurs or gangrene threatens, obstruction of one or

FIG. 6.—Femoral arteriogram showing extensive thrombosis. Most of the popliteal artery is thrombosed and the peroneal artery is the only patent artery in the leg. A graft was inserted from the common femoral artery to the small segment of popliteal artery indicated (P).

more of the tibial vessels is usual; nevertheless, in many the distal part of the popliteal artery remains patent. This is fortunate, for if blood under sufficient pressure can be delivered through a graft into this patent segment gangrene may be prevented or localized even if two of the three main vessels below the knee are thrombosed. Fig. 6 is an arteriogram of such a case. A graft was inserted with success (Figs. 7, 8, and 9), though the patient has since had to undergo amputation, presumably from advancing disease, for at the time of amputation the graft was patent.

Arrangement of the Graft

A graft may be anastomosed either end to end or end to side to the host vessel. In arterial injuries the results of resection and end-to-end grafting are good because usually the vessel is healthy.

In atherosclerosis of the limb vessels, however, the results of resection and end-to-end grafting have been disappointing, with a high incidence of immediate or early post-operative thrombosis. There are several factors predisposing to failure. In arterial thrombosis the artery distally may be so small that an efficient end-to-end anastomosis with a graft is difficult to construct. Furthermore, every method of suture causes some narrowing of the stoma, and to this is added the inevitable oedema which accompanies healing. Reduction in the size of the stoma is of little consequence in large vessels such as the aorta or common iliac artery, but in smaller vessels, such as the popliteal, especially when there is a thickened intima, an adequate stoma is difficult to fashion. Resection of the thrombosed segment is unnecessary; it can be difficult, tedious, and harmful, as during exposure of the artery important collaterals may have to be sacrificed, and, should the graft thrombose, more harm than good would result. Also the artery is often adherent to the adjacent vein, which is liable to injury and subsequent post-operative thrombosis. Lastly, the long skin incisions required for excision of the thrombosed arteries heal slowly and mild wound infections are not uncommon.

Dissatisfaction with the results of resection and end-to-end grafting in peripheral obliterative arterial disease has led us to adopt the bypass type of operation described by Kunlin *et al.* (1951). In this procedure the thrombosed artery is left *in situ* and a bypass graft inserted and anastomosed end to side to the host artery proximal and distal to the affected segment. There are many advantages of this method. Few if any collaterals are disturbed; in fact, the graft acts as an additional collateral, and should subsequent thrombosis occur no harm will have resulted. The size of the anastomosis is not limited by the diameter of the host artery, and the most suitable area free of calcification can be chosen.

The end-to-side technique has been criticized on the grounds that this type of anastomosis causes turbulence and thus predisposes to thrombosis (Rob and Eastcott, 1953). It is difficult to refute this contention, but it could as justifiably be argued that such turbulence would retard thrombosis rather than initiate it.

Factors conducive to intravascular thrombosis are slowing of the blood stream and intimal irregularity. In a streamlined vessel the periphery of the blood stream is almost stationary, and in the presence of any intimal abnormality, such as that produced by an anastomosis, thrombosis is apt to follow. If turbulence is present this sluggish zone of blood does not exist, and it would therefore appear that thrombosis might be retarded or prevented. The proponents of the "turbulence-thrombosis" theory may express the view that turbulence resulting from an end-to-side anastomosis injures the intima and that this initiates thrombosis. But throughout the circulation arteries originate as natural end-to-side "anastomoses," and at the origin of the great vessels from the aortic arch, where the angle of branching is acute and where blood is delivered at high pressure, turbulence should be pronounced. The stresses imposed at these sites might be thought to produce intimal

damage and thus predispose to thrombosis. In fact, the incidence of thrombosis here is far less than that at the femoro-popliteal junction, where the blood flow is laminar. To add further support to the contention that turbulence retards clot formation one may draw an analogy with clot formation *in vitro*: blood in a container will clot less readily if agitated than if left undisturbed.

It has also been said that after end-to-side anastomosis the altered haemodynamics results in a reduced blood flow through the graft, varying with the angle of branching and amounting to 10-30% (Szilagyi *et al.*, 1956).

The theoretical disadvantages of the end-to-side anastomosis have not been borne out by results and appear to be outweighed by the practical disadvantages of the end-to-end anastomosis.

From a study of more than 300 arteriograms of the lower extremities affected by atherosclerosis we have been impressed by the relative infrequency with which thrombosis affects the common femoral and distal half of the popliteal arteries as compared with the superficial femoral and proximal half of the popliteal arteries. So vulnerable are the superficial femoral and proximal popliteal arteries to thrombosis that any reconstruction limited to this segment of artery, though at first successful, is liable to subsequent failure from thrombosis elsewhere in the vessel. For this reason we believe that when any part of the femoro-popliteal artery is thrombosed, in however short a length, the minimal graft to be used should extend from the common femoral artery above to the distal popliteal artery below if this is patent, as it usually is (Martin, 1957). Incidentally, and fortunately, at both these sites access to the host artery is easy.

Operation

Age is no contraindication to grafting provided there are no complicating medical conditions. If the patient will tolerate a major amputation he will tolerate a grafting operation.

Anaesthetic.—It matters little what anaesthetic is used provided no significant fall in blood pressure occurs during or after the operation. A fall in blood pressure may precipitate thrombosis, not only in the diseased vessels of the affected leg but also in the coronary or cerebral arteries or in the contralateral limb, so often themselves the site of atherosclerosis. A severe fall in blood pressure may occur when the circulation is restored after completion of the anastomosis. This may result from three factors—blood loss from the anastomosis, reactive hyperaemia in the limb, and the entry of metabolites into the general circulation, causing a vasodepressor action. The anaesthetist should be prepared to replace any blood lost by rapid transfusion, if necessary using a transfusion pump.

Operative Technique

The operation can be done as a synchronous combined procedure, thus considerably reducing the operating time (Owen and Rob, 1956). The patient is placed in the lateral position with the affected limb uppermost. The lower limb is kept straight and the patient's position is maintained by sandbags placed on either side of the abdomen and straps. The affected leg is elevated on a wooden table placed on the operating table over the contralateral limb.

The skin is prepared from the umbilicus to the ankle. One surgeon faces the inguinal region and the other the popliteal fossa, each with his own assistant on the same side. Having applied skin towels to isolate the operative fields, one surgeon first exposes the popliteal artery through a longitudinal incision centred over the popliteal fossa. The artery is palpated for patency and suitability for end-to-side anastomosis and is tested for evidence of retrograde blood flow. When this has been determined the other surgeon exposes the common femoral artery through a longitudinal skin incision and similarly palpates the vessel for the presence of atheromatous plaques and patency. The arteriogram will of course give a strong lead to the best site for anastomosis, but palpation of the vessel is the most accurate guide. In the inguinal incision the common femoral, superficial

femoral, and profunda femoris arteries are exposed and all their branches are preserved; in the popliteal incision the distal half of the popliteal artery and its branches are similarly treated.

While the dissection is proceeding an assistant prepares the graft. Although on occasion we have used autogenous saphenous vein, we prefer a freeze-dried arterial homograft. Inclusion of the external iliac artery in the donor graft provides a larger vessel and one of sufficient length, and in end-to-side anastomosis the disparity in size between the diameter of the graft and host artery is not of importance. The graft is soaked in water for 20 minutes to reconstitute its physical properties, for it may easily be fractured if it is manipulated before it is properly softened. All branches are ligated at their origin with fine silk, but if some branches have been cut flush, leaving no stump to tie, a stitch passed through the adventitia and media will control subsequent bleeding. A solution of heparin in saline (1 in 1,000) is then injected into the graft to test for leakage.

A tunnel in which the graft will subsequently lie is then made between the upper and lower incisions along the course of the femoral artery. The index finger of one hand is carefully insinuated in a downward direction through the inguinal incision and deep to the sartorius muscle, where there is a good plane of cleavage, and the index finger of the other hand is passed upwards through the adductor hiatus. Each finger is advanced as far as possible along the course of the femoral artery, but they will not meet. The intervening distance is tunnelled by means of an adult-sized bronchoscope that is long enough to extend from the proximal to the distal incision.

A long pair of biopsy forceps is then passed through the bronchoscope. The jaws of the forceps grasp one end of the graft, which is then pulled through the bronchoscope, taking care to avoid rotation. The bronchoscope is then withdrawn, leaving the graft in position. When suitable sites of anastomosis have been determined, the graft is put under slight tension and the surplus is excised to prevent subsequent tortuosity. Each end of the graft is then prepared for anastomosis in the following manner.

The adventitia is carefully and completely removed for a distance of about 1 in. (2.5 cm.). This is important, for, during the suturing, threads of adventitia may be drawn into the lumen and predispose to thrombosis. It is not necessary to remove the adventitia of the host artery, because the suturing is always done from the graft to the host artery so that the diseased intima is pushed against the media by the point of the suture needle and not separated from it, as it may easily be if the needle is passed in the opposite direction. The removal of the adventitia of the host artery, too, may result in excessive bleeding from the anastomosis. The end of the graft is cut longitudinally with scissors for about $\frac{1}{4}$ in. (2 cm.), is splayed open, and the corners are trimmed. Arterial clamps are then applied to the host artery above and below the site chosen for anastomosis and to must be perfect, and bulldog clamps are ideal. If a bulldog clamp is not adequate for control of the common femoral artery, then a Crafoord clamp applied as lightly as is consistent with haemostasis may be used, or, alternatively, a soft rubber tourniquet. A longitudinal incision about $\frac{1}{4}$ in. (2 cm.) long is then made in the host artery, started by scalpel and completed by fine straight scissors. It is not necessary to excise an ellipse of artery. Occasionally a partially detached plaque is encountered or a piece of intima becomes impunctured. The lumen is then intermittently irrigated with heparin while the anastomosis proceeds.

Two sutures of 00000 arterial silk are inserted close to each other through the apex of the graft, the ends being tied on its outer aspect (Fig. 7). Each needle is then inserted from within out through the host vessel at the corresponding end of the incision and tied. The base of the graft is sutured to the host vessel in a similar manner (Fig. 8). An over-and-over continuous everting suture on both sides, beginning at the

base of the graft, completes the anastomosis (Fig. 9). The suturing should always begin at the base, as this is the only difficult part of the anastomosis. Before the final stitch is tied heparin solution is injected into the graft to displace any contained air which might conceivably produce air embolism when the clamps are released.

FIG. 7.—Two everting mattress sutures are inserted at base and apex of graft. Needles are inserted from graft to host artery so that diseased intima, if present, is pushed against the media and not separated from it as might occur if needle is passed in opposite direction.

FIG. 8.—Mattress suture at apex of graft should be tied before the continuous suture is begun. This step has been omitted for sake of clarity.

FIG. 9.—Anastomosis has been completed by tying the continuous everting suture to the corresponding end of the apical mattress stitch. The bulge or "cobra head" effect in graft is a usual finding when clamps are released after end-to-side anastomosis.

When the anastomosis has been completed the anaesthetist prepares for a rapid blood transfusion. The clamps are then released one by one, first those on the smaller branches, and then those on the distal popliteal artery, proximal popliteal artery, the profunda femoris artery, the superficial femoral artery, and finally the common femoral artery. This allows a gradual rise of arterial pressure within the graft, and the haemorrhage from the suture line is much reduced. Leakage will almost certainly occur but should not be arrested by immediate suture. A swab placed firmly over the anastomosis for three to five minutes and kept in position by temporary approximation of the skin will generally produce complete haemostasis. If this fails, a stitch or two tied over a small free muscle graft will seal any remaining leaks.

When all bleeding has stopped and the blood pressure is satisfactory, the wound is closed by stitching deep fascia and skin separately.

Post-operative care.

All patients are given phenindione, starting on the day of operation and continuing for three weeks. The prothrombin index is maintained at about 50%. Penicillin and streptomycin are administered for five days. The patient is allowed out of bed on the fourteenth day.

Results and Discussion

The conclusions which form the basis of this paper are derived from two series of cases—one early series of 20 patients operated on between 1946 and 1955, and a later series of 31 cases started early in 1956. The results have been very different in the two series.

In the first series, autogenous vein grafts were used exclusively. In 15 patients the anastomosis was end to end above and below, and in five either end to side above and below or end to end above and end to side below. In none of these cases did the graft extend from the common femoral artery above to the distal half of the popliteal artery below; in all a short segment of thrombosed vessel was either excised or bypassed. Further, in the end-to-side anastomoses the technique employed did not allow of such a wide stoma as that described above and used in the second series. All

the patients were suffering from atherosclerosis and all were male. Their ages ranged from 46 to 72 years. Of these 20 patients, only eight (40%) were discharged from hospital with patent grafts. Three grafts (15%) were patent at the end of one year and only one remained patent after three years.

In the early part of 1956 it appeared to us that bypass grafts by an end-to-side technique should only be used to leave the thrombosed vessel intact and to preserve collaterals. At the same time it was decided that the shortest, and in fact the only, bypass graft to be used would be one extending from the common femoral artery above to the distal half of the popliteal artery below, because of the less frequent involvement of these arterial segments by atherosclerosis; the superficial femoral artery and proximal half of the popliteal artery are so prone to progressive thrombosis that we felt that this part of the arterial tree should always be excluded even if the thrombosis is limited. In this latter series 88 bypass grafts were inserted in 50 patients. Polyvinyl alcohol sponge prostheses were used in six patients, autogenous vein grafts in five, and arterial homografts in 47. All were performed for atherosclerosis. Thirty patients were male and one female. The ages ranged from 49 to 79.

Thirty operations were performed for intermittent claudication and 28 for incipient gangrene. Of the six polyvinyl alcohol prostheses, only one remained patent six months after operation. Two thrombosed before discharge from hospital and one six weeks later. In two patients secondary haemorrhage occurred—one from infection and the other from an undetermined cause. In the first case, that of a man aged 68 in whom a bypass operation had been performed between the common femoral and popliteal arteries, a secondary haemorrhage occurred on the fifth post-operative day at the proximal anastomosis. *Staphylococcus aureus* was cultured from the wound. The defect in the anastomosis was sutured, but two days later a further haemorrhage followed which necessitated ligation of the external iliac artery. The leg became gangrenous, and the patient rapidly deteriorated and died. The graft was patent at post-mortem examination. In the second patient, a man aged 38, haemorrhage occurred at the proximal anastomosis a month after discharge from hospital. Armed with the experience of the former case, no attempt was made to suture the leak, but the entire prosthesis was removed and successfully replaced by an arterial homograft.

Of the 58 arterial homografts used two thrombosed immediately after operation, probably from technical errors, four thrombosed before hospital discharge, and four between ten weeks and eight months later. Forty-eight grafts were patent two to eight months after operation.

Of the five autogenous vein grafts inserted, three were patent six to eight months after operation. One thrombosed before hospital discharge and the other six weeks after discharge. In the patient in whom the early thrombosis occurred an arterial homograft was inserted at a later date. This graft, too, thrombosed before hospital discharge, possibly indicating a marked immunological reaction in the host.

Although the follow-up period is short a comparison can nevertheless be made between the end-to-end and end-to-side anastomoses. In the first series 60% thrombosed before hospital discharge and in the second series only 24%. In the second series, in which long bypass grafts only were inserted, 82% were patent two to eight months after operation. Owing to the small number of autogenous vein grafts used in this series it is not possible to make a comparison with the arterial homografts, but we have no reason to believe that they are inferior.

In the assessment of patency of the grafts subjective evidence was not taken into consideration, because many patients with arterial thrombosis may improve with bed rest alone. Patency was assessed mainly by the presence of pedal pulses. In a few cases these were not palpable because of pre-existing thrombosis between the graft and the ankle. In such cases patency was confirmed either by

and toxæmic signs develop, these signs usually respond rapidly to resumption of progesterone. When oedema or excessive weight gain has occurred during cessation of progesterone, acetazolamide or mersalyl can be given with progesterone to produce a more rapid result.

Results of the Progesterone Trial

Between January, 1951, and September 30, 1956, there have been 7,156 deliveries at the maternity hospital. Figures earlier than January, 1951, cannot be included, as the hospital was then housed in different premises. Prior to the introduction of the experimental scheme in June, 1955, the quarterly incidence of toxæmia had varied between 6.2% and 11%, giving an average of 9% for some 5,307 deliveries. This 9% incidence of toxæmia is similar to that for local maternity hospitals. The first progesterone-treated patients were delivered in September, 1955, and in the third quarter of 1955 the incidence of toxæmia fell from 7.2% to 3.9%, with further declines in subsequent quarters to 2.5%, 1.9%, 1.0%, and 1.3% (see Chart). Prior to the introduction of the scheme there were 12 deliveries for every toxæmic patient, whereas after its introduction there were 47.6 deliveries for every toxæmic patient.

The 141 patients seen with symptoms between the 16th and the 28th week of pregnancy have been delivered. Of these, four were transferred to other hospitals and nine did not attend to report the effect of the test dose. Of these nine, two subsequently aborted and there was one maternal death, with stillbirth, from antepartum and post-partum haemorrhage and toxæmia. Twenty patients with symptoms not relieved by progesterone were delivered, of whom one developed toxæmia. Of 109 patients treated with progesterone, five developed toxæmia and there were two stillbirths (one hydrocephalic monster and one disproportion). Two of these five toxæmic patients were receiving 50 or 100 mg. of progesterone respectively on alternate days at the time of onset of toxæmic signs, and the remaining three had temporarily ceased taking ethisterone. It should be noted that all five cases, as soon as they developed toxæmia, came under the care of the consultants, and no more progesterone was administered. They were treated with bed rest, sedation, and low-salt diet, but in three of these five cases the blood pressure rose higher when progesterone or ethisterone was discontinued.

TABLE II.—Weight Gain Before and After Progesterone (13 Cases)

No.	Weight Gain in 4 Weeks Before Progesterone		Weight Gain in 4 Weeks After Progesterone	
	lb.	kg.	lb.	kg.
1	6½	2.9	4	1.8
2	8½	3.6	5½	2.5
3	7	3.2	4½	2.0
4	7½	3.4	3½	1.6
5	6	2.7	5	2.3

7	7½	3.4	5	2.3
8	6	2.7	4½	2.0
9	10	4.5	6	2.7
10	7	3.2	7	3.2
11	7	3.2	7½	3.4
12	7½	3.4	8½	3.9
13	8½	3.9	1½	0.7
Average	7.4	3.36	3.1	1.4

Decreased Weight Gain on Progesterone Therapy.—Hamlin (1952) has stressed the importance of excessive weight gain during the middle trimester as an early toxæmic sign. It is significant that patients with progesterone-responsive symptoms and an excessive gain in weight before the 28th week show a decrease in weight gain when the symptoms are controlled with progesterone. Among the 109 treated patients were 13 whose weight gain during the four weeks immediately before treatment was 6 lb. (2.7 kg.) or over. In every instance the weight gain during the first four weeks after the commencement of treatment was less than before treatment (Table II).

Limitations of Progesterone Therapy in Toxaemia

Progesterone therapy is essentially prophylactic and effective only if started during the early symptomatic stage and before the onset of signs. In treated patients, should toxæmic signs develop when progesterone is temporarily withheld (owing to failed attendance or improvement in symptoms), a return to progesterone usually effects a rapid amelioration of signs. On the other hand, should patients not under progesterone treatment develop toxæmic signs, even massive doses of up to 300 mg. of progesterone given intravenously usually prove ineffective and the toxæmia takes its uninterrupted course.

It may be argued that this method of treatment, dependent on symptoms alone, is unreliable, and that neurotic patients may receive progesterone therapy needlessly. However, with experience it was easy to distinguish between symptoms due to a specific cause—for example, headache after being involved in a road accident—and those due to pregnancy.

There appears to be a minority of patients who develop toxæmia although symptom-free during the middle trimester. In this series the incidence of toxæmia was reduced under the progesterone scheme from 9% to 2.1%, but in this 2.1% were included some patients who did not report any symptoms during the middle trimester. Again, in retrospective interviews with mothers who had previously suffered from toxæmia, 7% stated that they had remained symptom-free during pregnancy (Dalton, 1954). It is suggested that the development of toxæmia in this minority without a symptomatic stage may be due to a sudden catastrophe of the placental circulation—embolism, thrombosis, or concealed haemorrhage—which causes placental infarction and an abrupt reduction in placental output of progesterone. It seems that one is unable to prevent such fulminating cases of sudden onset with progesterone therapy.

Discussion

Considerable supporting evidence is available to demonstrate the importance of progesterone in the maintenance of pregnancy. Robson and Paterson (1937) have shown that convulsions, acute toxic conditions, and finally death can be produced experimentally in rabbits by depriving them of the luteal or gonadotrophic hormone during the latter part of pregnancy, and that these effects could be prevented by injections of gonadotrophic hormone or progesterone. Nelson *et al.* (1951) found that the high foetal mortality in rats fed on a diet deficient in vitamin B₆ could be avoided by the administration of progesterone and oestrone. Similarly, Nelson and Evans (1953) showed that rats bred on a protein-free diet have a 90–100% foetal mortality, which can be overcome by injections of progesterone and oestrone. Lyons (1943) has demonstrated that pregnancy can be maintained in rats oophorectomized and hypophysectomized after conception if progesterone and oestrone are artificially supplied. The work of Nelson, Lyons, and others has further demonstrated the importance of the ratio of progesterone to oestrone. The fact that animals receiving high doses of oestrone showed an increased foetal death rate suggests that this occurs when there is insufficient progesterone to balance the oestrin available.

LACTATION AND HEREDITY

BY

IAN G. WICKES, M.D., M.R.C.P., D.C.H.

Paediatrician, North Middlesex Hospital

AND

M. P. CURWEN, M.A.

Statistician, St. Bartholomew's Hospital, London

In recent years investigations have shown that only about 50% of our babies are breast-fed for three months (Hughes, 1948; Dummer, 1949) and that the cause of failure is unknown in about one-half of the cases (Robinson, 1943; Royal College of Obstetricians and Gynaecologists, 1948). Although a wide variety of environmental factors are known to affect the duration of breast-feeding, yet basically the outcome will often depend upon the initial adequacy of the lactation—that is, the quantity and quality of the milk produced. Hytten (1954a, 1954b, 1954c, 1954d, 1954e) has pointed out that this may be genetically determined. We have found only four papers which make any attempt to assess the effect of heredity upon human lactation; their results, together with our own, are summarized in Table I.

TABLE I.—Relation Between Mother's and Daughter's Breast-feeding Performance: Comparison Between Published and Present Series

	Mother a "Good Nurse"		Mother Not a "Good Nurse"	
	No.	Proportion with Daughters who are "Good Nurses"	No.	Proportion with Daughters who are "Good Nurses"
Bunge (1900)	237	53%	147	1%
Winternitz (1922)	115	61%	15	73%
Robinson (1939)	81	76%	19	53%
Pfändler (1949)	217	83%	118	49%
Present series	397	60%	63	43%

* In each series the relationship in question is between the mother and one specified daughter (the propositus). Widely differing criteria of a "good nurse" have been used (see text).

Bunge accepted a woman as a good nurse only if all her children (with a few specified exceptions) had been fully breast-fed for nine months, but Winternitz was less rigorous and used only three months' breast-feeding of one specified daughter as a criterion. Neither appeared to recognize the cardinal difficulty of distinguishing between environmental and hereditary effects. On the other hand, Robinson and Pfändler both concluded that the association they demonstrated was the result of environmental factors, though Pfändler believed also in a genetic one. We have tried to throw further light on the problem by investigating the capabilities of two generations of women and also by means of a twin study.

Present Investigation

The investigation included 943 women who first attended an antenatal clinic (A.N.C.) in Edmonton between April, 1952, and June, 1953. It will be convenient to refer to these women as the "subjects." Whenever the word "mother" is used it will refer to the subject's mother; the mother-daughter relationship is that between the subject's mother and the subject. The "current" infant is the one born to the subject after the pregnancy for which she attended the A.N.C.

Omissions.—As a criterion of successful breast-feeding applicable to the current infant we chose the maintenance of uncomplimented breast-feeding of a single normal infant for eight weeks. The reason why we chose this period was

It has long been recognized that toxæmia is frequently associated with beriberi, and in these cases both diseases are susceptible to the administration of vitamin B₆. Hamlin (1952), in Australia, has reduced the incidence of toxæmia by recognizing excessive weight gain as an early sign of toxæmia and by impressing on such patients the importance of lowering their weight by a high-protein, low-carbohydrate, and high-vitamin diet. The importance of the protein and vitamin in Hamlin's work, and the vitamin B₆ in treatment of beriberi cases, is corroborated by the work of Nelson and his colleagues, who found that pregnancies in rats bred on a diet deficient in protein and vitamin B₆ could be maintained only with progesterone. I have already demonstrated the value of the administration of progesterone in the treatment of toxæmia in its early symptomatic stage.

From this it would appear that there is a close connexion between progesterone, protein, and vitamin B₆ in the maintenance of pregnancy. On the one hand, Hamlin has reduced the incidence of toxæmia with a high-protein and high-vitamin diet, and, on the other, the administration of progesterone achieves a like result, while Nelson and others have shown the close connexion between both treatments in their experiments on rats. If the role of progesterone is similar in humans and in rats it would suggest that protein and vitamin B₆ play an important part in the production of progesterone in the body. Should this be so, would it not explain the enigma of the success of vitamin B in the toxæmic beriberi cases and its failure when applied in the prophylaxis of toxæmia in Britain? Does it not also explain the success of Hamlin's slimming diet in Australia and its failure when applied here? The essential element for success in each instance is sufficient dietary protein, which in this country is lacking. The prohibitive cost of a high-protein diet for the average mother in Britain compels her to resort to a low-protein, low-carbohydrate diet for reducing her weight in pregnancy.

Conclusion

Toxaemia of pregnancy is one of the greatest dangers both to the pregnant mother and to the unborn child. Its aetiology is still unknown, and whatever light can be thrown on this subject may help towards eliminating this serious condition. Evidence is produced that lack of progesterone may be one of the important factors in the causation of the disease, and the prophylactic treatment with progesterone seems to have achieved worthwhile results in its first year of experimental operation by reducing the incidence of toxæmia from 9% to 2.1%.

This preliminary study has certainly yielded interesting and encouraging data, and it is hoped that similar trials will be instituted elsewhere, for the subject obviously merits further study.

Acknowledgments are due to Mr. J. V. O'Sullivan for facilities for the progesterone prophylactic scheme; to Dr. D. D. Reid for statistical assistance; to British Drug Houses Ltd. for assistance in the supply of progesterone; to Dr. Margaret M. Sweeney for assistance in scrutiny of records; and to Mr. Nariman S. Bamji for help in the preparation of this paper.

that most of the women brought their children to the post-natal clinic (P.N.C.) at or after the eighth week. There were, however, 88 who attended earlier, and these had to be omitted from the main analysis. This number could have been reduced by taking a shorter period than eight weeks, but this would have been unrealistic, as many unexplained failures of lactation take place in the second month. These 88 women were probably not representative of the main group, but a separate analysis showed that their omission was unlikely to have biased our results. The total number of omissions from the main analysis is given in Table II.

TABLE II.—Causes of 210 Omissions from Main Analysis

Stillbirths or abortions	51
Neonatal deaths or major congenital deformities	14
Twins (pairs)	13
Inadequate information given at P.N.C.	11
Attended P.N.C. before the eighth week	88
Failure to attend P.N.C.	33

At their first visit to the A.N.C. the women were asked a number of questions, the most important being, "Were you breast-fed?" and, if so, "For about how long?" Women who did not know the answers were given the opportunity to ask their mothers and reply at their second attendance.

At the P.N.C. particulars of the duration of breast-feeding were recorded in reply to the questions: "When did you first give the bottle regularly?" and, "When did you completely give up breast-feeding?" There is often an interval of several weeks between these dates, and at any given time the proportion of partly breast-fed infants may be of the order of 10% of the whole series. For most of this analysis we have concentrated our attention on the wholly breast-fed infants. In asking questions about the breast-feeding of other members of the family no such distinction was practicable. In referring to the previous generation we have simply used the criteria "breast-fed" and "not breast-fed," although a large majority of those in the former group claimed that breast-feeding lasted at least three months.

Mother-Daughter Analysis

After making the deductions referred to above there remain 733 women for the main mother-daughter analysis. Of these, 316 (43%) were primiparae. The mothers of these women can be divided into four groups: (1) those who breast-fed all their children, (2) those who breast-fed some, (3) those who fed none, and (4) those for whom no information was available. Table III shows the percentages of daughters who maintained complete breast-feeding of the current infant for at least eight weeks.

TABLE III.—Relation Between Mother's and Daughter's Breast-feeding Performance

Mother's Performance*	No.			Percentage of Daughters Breast-feeding for 8 Weeks†		
	Total	Primip.	Multip.	Total	Primip.	Multip.
1. All children breast-fed	397	180	217	60	62	58
2. Some " "	125	47	78	51	47	54
3. No " "	63	26	37	43	42	43
4. No information of breast-feeding	148	64	84	41	47	37

* The mother's performance is judged by whether, according to her daughter, all, some, or none of her children were breast-fed, no length of time being specified.

† The daughter's performance is judged by whether, after the pregnancy which brought her into this survey, she maintained uncomplimented breast-feeding for eight weeks.

The trend of the percentages for groups 1, 2, and 3 suggests that there may be a genetic factor involved in successful breast-feeding, but before accepting this conclusion it is necessary to exclude the possibilities (a) that the relationship is a spurious one which might be explained by some extraneous difference between the groups, and (b) that the factor at work is an environmental rather than a hereditary one.

There are many factors—social, medical, and obstetric—that have at one time or another been thought to influence

breast-feeding performance. It has not been our intention to confirm or refute these theories; we asked questions about some of these factors for the sole purpose of ensuring that the groups of women with different family histories of breast-feeding were comparable in regard to other factors which might have influenced their breast-feeding. The factors shown to be evenly distributed between groups 1, 2, and 3 are: age; parity; social class (Registrar-General); standard of housing (assessed by health visitor); stage of pregnancy at first antenatal attendance; full-time work during pregnancy; general health before pregnancy; complications of pregnancy, delivery, and puerperium; place of delivery (three hospitals or at home); birth weight of infant; length of stay in hospital.

Factors of possible importance that we did not record were weight and physique, and we cannot rule out the possibility that many of our poor lactators of group 3 are simply the small, poorly built daughters of similar mothers. Such a hypothesis, however, would not conflict with the one we are investigating, although it might throw a different light upon it.

Attitude to Breast-feeding

We attempted to throw some light on the reasons for early failure of lactation by asking women their views on breast-feeding at the first antenatal attendance. In addition, primigravidae were asked their mothers' views. It is not to be expected that many women will express hostility towards breast-feeding at an A.N.C., and it is perhaps surprising that even as many as 38 (5%) did so. The relation between the breast-feeding performance and the attitude is given in Table IV.

TABLE IV.—Relation Between Subject's Attitude to Breast-feeding at Her First Antenatal Clinic and Her Subsequent Performance

Subject's Attitude to Breast-feeding	No.	Proportion Breast-feeding for 8 Weeks*
In favour	599	55%
Doubtful	19	42%
Against	38	32%
Not known	77	51%

* See note to Table III.

If the attitude of these women is analysed according to the performance of their mothers, we find that 3.7% of those in group 1 (good breast-feeders) had daughters who were hostile, compared with 8.8% and 7.7% in groups 2 and 3. Taking these figures in conjunction with Table III, we see that at least a small proportion of the mother-daughter association can be accounted for by the daughter having formed her views on breast-feeding in the light of her mother's experience. It might be argued that all the association could be accounted for in this way if we were able to get an unbiased assessment of the subject's views at the A.N.C. But this does not seem likely: if the subject's attitude antenatally were the sole factor, we would expect the performance of the 38 who were bold enough to express their hostility at the clinic to do much worse than Table IV suggests.

The primigravidae in the series were asked whether their mothers had "strong views" on breast-feeding. None reported strong views against. The proportion strongly in favour was higher in the mothers with a good performance, but there is no evidence, as is shown in Table V, that the

TABLE V.—Relation Between Mother's Attitude to Breast-feeding and Daughter's Performance (Primiparae Only)

Mother's Attitude to Breast-feeding	No.	Proportion of Daughters Breast-feeding for 8 Weeks*
Strongly in favour	139	55%
No strong views	142	55%
Mother dead	36	56%

* See note to Table III.

mothers' views had any effect on their daughters' performance. The evidence given in Table V is probably the best we have in favour of the hereditary hypothesis.

Significance of Milk Yield in First Week After Delivery

During the course of the investigation Sydw (1952) published a paper showing that the duration of breast-feeding was to a large extent determined by the yield of milk at the end of the first week after delivery; his figures, together with those of Hytten (1954c) and our own, are shown in Table VI.

TABLE VI.—Relation Between Milk Yield and Duration of Breast-feeding

	< 200 ml.	200 ml.—300 ml.	300 ml.—400 ml.	400 ml.—500 ml.	500 ml.—600 ml.	600 ml. +
Sydow (1952):						
6th-day yield	68	334	620	363	193	261
No. of cases						
Breast-feeding at 2 months	56%	93%	95%	95%	95%	98%
Breast-feeding at 6 months	22%	58%	64%	69%	72%	75%
Hytten (1954c):						
7th-day yield	< 300 ml.	300 ml.—450 ml.	450 ml.—600 ml.	600 ml. +		
No. of cases	35	41	31	18		
Breast-feeding at 3 months	26%	46%	58%	78%		
Present Series:						
7th-, 8th-, or 9th-day yield	< 15 oz. (425 ml.)	15 oz.—20 oz. (425 ml.)	20 oz.—25 oz. (567 ml.)	25 oz. +		
No. of cases	30	54	45			
Breast-feeding at 2 months	20%	48%	64%			

The publication of Sydw's paper suggested that we might usefully include a similar study in the present investigation. Test weights were therefore carried out on the seventh, eighth, or ninth day on 129 of the babies born in two hospitals and who were included in the survey; to the amount of milk taken by the infant was added the weight of residual milk expressed after each feed by means of a simple breast-pump. It was not possible to make the series a consecutive one; nor were Hytten's rigorous methods used—for example, for ensuring that the breast was entirely emptied. But any possible bias or inaccuracy thus introduced can hardly have been linked with the hereditary factors which it has been our primary object to investigate. In comparing the three series in Table VI it must be borne in mind that different criteria were adopted for inclusion in the series and for determining the duration of breast-feeding. Absolute differences are therefore to be expected; the common feature is the striking correlation. The early milk yield is evidently a most important prognostic sign.

How can this be related to the family history? Unfortunately our series is not large enough for a full analysis. All we can do is to show, in Table VII, that there is no close association between the mother's performance and her daughter's yield.

TABLE VII.—Relation Between Mother's Breast-feeding Performance and Daughter's Milk Yield on 7th, 8th, or 9th Day

Mother's Breast-feeding Performance*	No.	Percentage Distribution of Test Weigh		
		< 15 oz. (425 ml.)	15 oz.—20 oz. (425 ml.)	20 oz. + (567 ml.)
1. All children breast-fed	71	23	42	35
2, 3. Not all children breast-fed	28	29	39	32
4. No information	30	20	43	37

* See note to Table III.

Such difference as there is between group 1 and the combined groups 2 and 3 is in the expected direction, but it is certainly not statistically significant, nor is it large enough to make it likely that all the daughter's genetic potentiality (if it exists) is manifested in the early yield. The importance of these observations is discussed later.

Discussion

There are great difficulties in the way of demonstrating the existence of genetic factors in lactational performance. For a knowledge of the breast-feeding performance of the first generation we have to rely on the memory and honesty

of women being interviewed 20–30 years later. We have not overcome this difficulty, but we have, unlike previous investigators, minimized one of its chief dangers by putting our questions to our second generation at the beginning of their pregnancy. This eliminates an important source of possible bias; in particular the primigravidae, who formed almost half our series, had to answer the questions in ignorance of their own lactational powers. The genetic influence of the father is obviously even more difficult to assess than that of the mother, for it involves going back another generation. If both parents contribute equally to the lactational ability of the daughters, as in dairy cattle, then in confining ourselves to the mothers we cannot expect such a clear-cut result as if we had been able to take the fathers into account.

But the greatest difficulty in all these studies is that of separating environmental from hereditary influences. Family traditions are probably as firmly rooted in matters concerning the rearing of children as in any other human activity. We have already shown how we have tried to rule out the possibility that the association we have demonstrated is primarily an environmental one, by analysing such factors as social grade and attitude. We cannot pretend that our arguments are conclusive; we have eliminated some of the more obvious possibilities, but many of the factors that go to make up family tradition are too elusive to be caught in the net of an investigation of this sort.

Additional evidence is supplied by our confirmation of the findings of Sydw and of Hytten that the outcome of a lactation is usually determined at its outset, and by our twin study (to be published). Unfortunately only a few pairs of identical twin mothers were obtainable and the numbers were too small for firm conclusions to be drawn. Nevertheless, comparison with the performance of fraternal twin mothers showed a greater correlation between the identical pairs. We therefore feel that a good case has been made for the importance of the genetic influence.

We did not set out to investigate the mechanism through which heredity might operate. In the field of dairy research (Johansson, 1950; Mahadevan, 1951) it is now believed, following on the experience gained with artificial insemination, that the heritability of total yield is low (about 20%), whereas the inheritance of butter-fat content is high and easily bred for (Edwards, 1955, and personal communication). That the former may also be true in the human field is suggested by the findings in Table VII, in which no correlation is shown between the mothers' performance and the daughters' early yield; but we have not investigated the daughters' output of butter-fat. If this were genetically determined then presumably there would be a consistent pattern throughout lactation and between successive lactations. Hytten (1954a) has in fact shown that after the first week the level of fat content is remarkably stable and characteristic for each individual mother but may vary from lactation to lactation. This latter observation was based on a study of only six women with two lactations; a larger series might reveal greater consistency. There is certainly scope for much more work here.

There are, of course, other ways in which genetic factors might determine lactational performance. For instance, the duration of breast-feeding must be affected to some extent by the storage capacity of the breast, and there may be other aspects—for example, hormonal—of "staying-power" which are open to genetic influence. The work of Engel (1941, 1947) and of Hytten (1954b) on the functional glandular capacity of mammary tissue requires further development. Heredity might also act in a non-specific manner by affecting the mother's ability to stand up to stress. Hypogalactia might be increasing for the same reasons as other psychosomatic disorders (Halliday, 1948).

The importance of heredity at any one time is determined by the extent to which genetic factors have previously been operative. In the days when artificial feeding was extremely hazardous the ability to breast-feed was a condition of survival. In those circumstances subsequent lactational

failure would be more likely to be due to environmental than to inherited causes. In recent years bottle-feeding has become almost as safe as breast-feeding, and a generation of bottle-fed babies has grown up to perpetuate this trait. Hence genetic factors might well be responsible, in part at least, for the rising incidence of bottle-feeding, and they probably now contribute much more towards lactational failure than was the case when potentially poor lactators were eliminated by natural selection in infancy.

Theoretically selective breeding might counteract to some extent the above effects, for, as any film-goer and magazine-reader must know, modern society applauds the well-developed feminine bust. This, however, is not the only characteristic that makes a man choose a mate, and, even if it were, it must be realized that the large breast does not necessarily contain the greatest amount of functional glandular tissue.

Changing fashions in infant feeding have undoubtedly contributed to the decline in breast-feeding. Insistence on exclusive breast-feeding for six months has resulted in inevitable failure and abandonment in many cases, but the "new" vogue for early introduction of solids may serve to eke out an inadequate lactation for longer. No other mammals have demanded so much from the breast as we have.

In the final analysis it is impossible to separate heredity and environment. Genetic factors would be expected to play a part in the lactational ability of all women. It is therefore the result of the interplay between heredity and environment which determines the success of a lactation. The safety and facility of artificial feeding in modern society mean that environmental factors, such as social conditions, appear to control breast-feeding when in fact they may be merely marginal ones which tip the scales against the breast in a constitutionally poor lactator. According to Hytten, one-third of all women are doomed to fail to produce enough nourishment to support the average infant above a weight of about 11 lb. (5 kg.). Even if glandular inadequacy is largely genetically determined, this does not preclude the discovery of a remedy which could overcome the deficiency. Until one has been found, it may be of some consolation to a mother, genuinely and bitterly disappointed by her failure to feed her baby, to learn that it may well have been due to inborn deficiencies outside her control; she deserves to be spared the unkind suggestion that is sometimes made that she could have fed her baby for longer had she tried.

Summary

An investigation is described in which 943 women (43% primigravidae) were asked at the antenatal clinic about the breast-feeding performance of their mothers. The method of feeding adopted by these women was recorded when they subsequently attended the post-natal clinic.

The principal finding was that of 397 women whose mothers were "good" breast-feeders, as defined for the purposes of the comparison, 60% succeeded in maintaining uncomplemented breast-feeding for eight weeks, compared with 43% for the 63 women whose mothers were not "good" breast-feeders.

This association appears to be independent of environmental factors and of the mental attitude of the mothers and their daughters.

In a small series it was shown that the milk yield at the end of the first week is positively correlated with the duration of lactation.

Absolute proof of the influence of heredity is lacking, but the mother-daughter association and the evidence of a twin study (briefly referred to) point to the probability that genetic factors significantly contribute towards lactational failures, 50% of which are otherwise unexplained.

The possible role of heredity and the mechanism of its application in the declining incidence of breast-feeding is discussed.

A large number of people have been involved in this investigation and we are grateful to all of them for their help. In particular, the main part could not have been attempted without the active co-operation of Dr. D. Regan, area medical officer of Edmonton, who kindly put the resources of his organization at our disposal. Of his assistants, Drs. A. Goggin and M. Brown supervised the completion of the forms at the antenatal and post-natal clinics; Miss H. Bridge, non-medical supervisor of midwives, Miss S. Briggs, superintendent health visitor, and Miss R. Saunders, deputy chief clerk, all worked hard to ensure that the requisite details concerning the confinement and housing were collected and inserted and that the forms, after completion, were dispatched to the staff of the Statistics Department, St. Bartholomew's Hospital, to whom we are also grateful for keeping the records and transferring the data on to punched cards. Our thanks are also due to Mr. K. A. K. Hudson and Mr. A. W. Purdie, who permitted us to investigate the 24-hour yield in some of the patients admitted under their care, and to Miss A. L. G. Hammond and Miss H. Stephenson, superintendent midwives, for their part in obtaining this information.

PNEUMONIA AND BRONCHIAL VESICULATION ASSOCIATED WITH HERPES ZOSTER WITH REFERENCE TO OTHER VISCERAL ASSOCIATIONS OF ZOSTER

BY

R. H. ANDREWS, M.D., M.R.C.P.
Consultant Chest Physician, Isle of Thanet and
South-East Kent

Of the rarer manifestations of herpes zoster a motor paralysis of the same spinal or cranial nerve distribution as the skin lesion is the one most often recorded and, on anatomical grounds, the easiest to explain. Certain visceral associations have been described with very suggestive clinical features—for example, abdominal pain and gastro-intestinal haemorrhage with a tenth thoracic zoster (Porteous, 1947); dysuria and increased frequency of micturition with a second and third sacral zoster (Chesterman, 1932)—but there has not as a rule been any conclusive evidence of the specific nature of the visceral lesion. Thus one reads differing opinions regarding the existence of visceral zoster. Kinnier Wilson (1954), while quoting various reports of the condition, considers it to be a doubtful entity, and notes that Head (1910) found no sign of pleural, peritoneal, or other visceral damage in 394 cases of zoster. On the other hand, Gais and Abrahamson (1939) record that out of 137 cases of herpes zoster 42 had visceral symptoms, and Dubois (1926) reported a case which seems

indisputable—vesiculation of the mucosa of the bladder being observed, by repeated cystoscopy, to run an identical course with the skin eruption of a second and third sacral zoster.

The illness, being self-limiting and relatively benign, is unlikely to provide opportunity for pathological examination of the affected organ, and endoscopy may give the only support for a diagnosis of visceral zoster. In the following case consolidation of the lung was followed by a typical intercostal zoster and the appearance of vesicles on the bronchial mucosa.

Case Report

A male clerk aged 63 had been in good general health, but for two years had experienced a retrosternal gripping pain on exertion, relieved by resting and eructation. He had had a slight cough for many years, and attributed this to smoking. In mid-May, 1955, he developed a fever with right pleuritic pain, and his doctor noted signs of consolidation in the right lung. The fever and physical signs disappeared slowly during the next four weeks, showing no obvious response to sulphonamide, penicillin, or chloramphenicol, and he was referred to the chest clinic on June 15 in view of an abnormal chest x-ray picture.

On examination he looked well and the only abnormal findings were impaired percussion note and air entry over the right lower lobe. There were no added sounds and his blood pressure was 170/90. On screening the right side of the diaphragm appeared high and sluggish and the barium swallow normal.

Films taken on May 20 had shown dense opacity in the right mid-zone and right lower zone which appeared to be due to consolidation of the lower and middle lobes. There were also calcified lesions at both lung apices and the right hilum, with calcification in the ninth and tenth thoracic vertebral spaces. Further films on June 23 and July 14 showed progressive clearing of the opacity, and when he was last x-rayed, on November 10, the right lower zone was quite clear, although the right costophrenic angle remained obliterated. The apical lesions were unchanged.

He was unable to produce any sputum, and one's initial assessment was that he had old apical tuberculosis and a recent lobar pneumonia which was resolving so slowly as to make bronchoscopy advisable. Within a fortnight of his first examination at the clinic, however, and within six weeks of the onset of his illness, he developed the typical erythematous stage of a left fourth thoracic zoster and the investigation was postponed until the eruption (Figs. 1 and 2) had progressed through vesiculation to scab formation.

Bronchoscopy (July 16).—The palate, pharynx, larynx, trachea, carina, and left bronchial tree appeared normal. The right middle and lower lobe bronchi also looked normal, some watery secretion being aspirated and found negative for tubercle bacilli. The orifice of the right upper lobe bronchus was reddened and three small glistening vesicles were seen on the anterior wall. The mucosa around these vesicles was particularly inflamed and they could not be removed by suction.

The patient declined a further bronchoscopy a fortnight later and returned to work feeling perfectly well. It was ultimately learnt that he had died suddenly on January 3, 1956, and that a post-mortem examination had shown a myocardial infarction which was regarded as the cause of death. Apart from the apical tuberculous lesions no abnormality was noted in the lungs.

Other Reports of Pulmonary Changes with Herpes Zoster

Of the 42 cases of Gais and Abrahamson, 7 had symptoms referable to the chest. In each of these the zoster was intercostal, but only one showed a radiological abnormality; five, however, had abnormal signs in the form of a pleural rub or rales. Herbeuval *et al.* (1950) collected 16 consecutive cases of intercostal zoster, and three of these had radiological evidence of pulmonary consolidation (which they aptly called "pneumopathie zostérienne"). Brain (1932) and Thursby-Pelham and Floyer (1944) have noted a pleural rub directly underlying an intercostal zoster; and Lingemann (1953) reports that zoster may be followed by an effusion into an artificial pneumothorax or be associated with an exacerbation of pulmonary tuberculosis.

Discussion

It is generally agreed that the basic lesion of herpes zoster is in the posterior root ganglion or corresponding cranial ganglion and that the virus is neurotropic in behaviour. Thus, to accept any visceral complication as primarily due to the zoster virus one should require the affected organ to be innervated via the same neural segment as the area of eruption and that the sequence of events should be closely related in time.

One difficulty in suggesting an association between intercostal zoster and a lung lesion is that the lungs originate from a pharyngeal outgrowth and cannot be related to any thoracic segment. On this ground one might expect pulmonary manifestations to occur rather with zoster of the vagus nerve, but although various authors—for example, Ergström and Wohlfart (1949) and Negus and Crabtree (1943)—have described this condition, with vesiculation of the pharynx, larynx, and sometimes of the external auditory meatus (via the auricular branch of the vagus), they do not appear to have searched for changes beyond the larynx.

However, the pulmonary autonomic plexuses do receive fibres from the second, third, and fourth thoracic sympathetic ganglia and it is thought that the cells of Dogiel in the posterior root ganglia may bring the somatic afferent neurones into relation with those of the sympathetic system travelling via the posterior nerve roots and the white rami communicantes. There are also fibres connecting the pulmonary plexuses of the two sides (Cunningham's *Text-book of Anatomy*, 1951), and one can thus postulate a neural connexion between the lung and the skin supplied by the second, third, and fourth thoracic nerves on the same or opposite side. Here it is interesting to note that in Head's series the

Figs. 1 and 2.—Skin eruption at time of bronchoscopy which showed bronchial vesiculation.

zoster virus appeared to show a marked predilection for segments having a sympathetic-nerve connexion.

The peripheral lesion of zoster is an inflammation and vesiculation of skin or mucosa associated with degenerative changes in underlying nerve endings, and one might expect any lung complication to be due primarily to such changes, plus oedema, in the bronchial mucosa resulting in pulmonary atelectasis. Personal communication with several thoracic surgeons suggests that bronchial vesiculation is an unusual finding, and it seems reasonable to associate it with the zoster in this case—coinciding as it did with the typical skin lesion.

It is less reasonable, however, to consider that the pulmonary consolidation was a specific manifestation of zoster because it affected the middle and lower lobes whereas the vesiculation was in the upper lobe bronchus; moreover, the onset of the pulmonary episode did not coincide with that of the eruption but preceded it by over a month. The incubation period of herpes zoster is said to vary from 7 to 24 days.

Possibly the pneumonia was a predisposing factor in the manner suggested by Spillane and White (1939), who noted a tendency for patients with angina of effort to develop zoster in the distribution of their cardiac pain—the supposition being that irritation of posterior root ganglion cells by stimuli from a diseased organ might result in trophic changes resembling zoster or, alternatively, in these cells becoming devitalized and susceptible to attack by the zoster virus. This might be compared with anterior poliomyelitis affecting a previously injured limb. Parsonnet and Bernstein (1939) also discussed the association of heart disease and zoster. Wilson considers that all zoster, even those apparently secondary to another disease, are due to an infection with the specific virus—that is, not in some cases to a purely trophic change.

Conclusion

Admitting that both pneumonia and zoster are common and could easily coincide, earlier reports do suggest—and this case would support the suggestion—that visceral disease can be directly connected with zoster; and the practical implication, as stressed by Loiseau (1953), is that one should always question the state of any organ in the same neural segment as the eruption.

In most cases it might be practicable to make only a brief physical examination and inquiry regarding symptoms, but with an upper thoracic or vagus nerve zoster it would be a simple precaution to have the chest x-rayed to exclude an unsuspected carcinoma or tuberculous lesion of the lung.

Summary

A case is described in which pneumonia was followed by intercostal herpes zoster and bronchial vesiculation, and the possible connexion between these lesions is discussed.

Visceral disease in association with herpes zoster has been reported on various occasions, being sometimes probably itself a specific manifestation of the virus infection but at other times perhaps a predisposing factor.

One should consider the health of organs having the same nerve root supply as the superficial eruption.

I thank Dr. W. G. Sutcliffe, who referred the case to me; Mr. C. E. S. Oxley, who performed the bronchoscopy; and Dr. G. B. Forbes, who supplied the post-mortem findings.

PROLONGED LABOUR A CLINICAL TRIAL OF CONTINUOUS CAUDAL ANALGESIA

BY

G. TREVOR JOHNSON, M.D., F.F.A.R.C.S.
M.R.C.O.G.

Consultant Obstetrician and Gynaecologist, Park Hospital, Davyhulme, Manchester; formerly First Assistant, Department of Obstetrics and Gynaecology, King's College, University of Durham

A first stage of labour exceeding 48 hours in duration due to discoordinate action of the uterus and cervix has a sinister reputation for both mother and foetus. The stillbirth rate attributed to this condition is more than four times that encountered in uncomplicated vaginal delivery. The major causes are foetal injury from ill-advised attempts to expedite vaginal delivery, intrauterine infection (McCredie-Smith *et al.*, 1956) by organisms within the upper vagina, and foetal anoxia from placental failure (Johnson and Clayton, 1955). The potentially anoxic foetus, in such labours, is sometimes further endangered by post-maturity (Stewart and Bernard, 1954) and pre-eclampsia, both of which depress placental efficiency (Walker and Turnbull, 1953).

There is no general agreement about the management of prolonged labours of this type, and treatment largely depends upon the judicious use of sedatives to ease the pains of labour and assist dilatation of the cervix, intravenous fluids to control maternal dehydration and ketosis, and, more recently, antibiotics (McCredie-Smith *et al.*, 1956) to prevent intrauterine infection. Some authorities have advocated uterine stimulants (Theobald *et al.*, 1956), and others claim that certain drugs have a relaxing effect upon the cervix (Gill and Farrar, 1951). In some instances, however, these latter techniques may exaggerate the abnormal uterine behaviour (Jeffcoate, *et al.*, 1952; Embrey and Garrett, 1955).

The serious wastage of foetal life attributed to prolonged labour has resulted in the more frequent use of caesarean section (Baird, 1955) as a speedy and less traumatic means of salvaging these infants, but unfortunately the maternal risk of this procedure increases steadily with the preceding length of labour, especially when this has lasted for more than 48 hours (Marshall, 1949).

More recently, claims have been made for the therapeutic application of continuous caudal analgesia to this problem (Arthur and Johnson, 1952; Johnson, 1954; Ball and Chambers, 1956; Youngman and Lloyd, 1956). This technique interrupts the autonomic visceromotor nerves of the cervix, and allows the dilating powers of the body of the uterus to have unopposed action upon a paralysed cervix and pelvic floor musculature. At the same time it has been pointed out that this method

restores the impoverished placental circulation which is encountered in a long first stage of labour by a vasodilatation effect upon the decidual vessels, following the interruption of their vasomotor nerves (Johnson and Clayton, 1955).

Although well-documented series of cases have been reported in which continuous caudal analgesia has accelerated the course of labour, there is a need for more convincing evidence that this technique speeds dilatation of the cervix and reduces the need for caesarean section, to which ends this study has been devised.

Design of Investigation and the Clinical Material

The clinical trial has been planned to draw a comparison between the therapeutic effect of two distinct methods of treatment upon the course of a prolonged first stage of labour. Sustained paralysis of the visceral autonomic nerve supply of the cervix and the mixed somatic nerve supply of the pelvic floor musculature by continuous caudal analgesia has been compared with an orthodox method of sedation with morphine and intravenous glucose-saline to control dehydration and ketosis.

The patients admitted to the clinical trial are shown in Table I. There was reliable evidence that all these had been in labour for at least 48 hours, from discoordinate action of the uterus or cervix, and without evidence of cephalopelvic disproportion.

TABLE I.—Clinical Material (A Comparison of the Two Groups of Patients)

	Caudal Series	Control Series
Average age (years) ..	27.8	25.2
Primigravidae ..	20	18
Multigravidae ..	3	3
Average duration of pregnancy (weeks) ..	40.7	40.7
Pre-eclampsia ..	7	6
Eclampsia ..	1	0

Maternal distress ..	11	6
Foetal ..	0	2
Multiple pregnancy ..		
Position of presenting part:		
Occipito-anterior ..	4	8
" lateral ..	10	7
" posterior ..	8	6
Breech ..	1	0
Cervices less than half dilated on admission to trial ..	19	18
Cervices more than half dilated on admission to trial ..	4	3
Total cases studied ..	23	21

Pre-eclampsia: Blood pressure exceeding 140/90 mm. Hg at the onset of labour.
 Genital infection: Maternal temperature rise of 1° F. on one or more occasions during the course of labour.
 Maternal distress: A pulse rate of 100 a minute, sustained or recurring, during the course of labour.
 Foetal distress: A pulse rate of 160 or more or 100 or less at any time during labour, with or without meconium staining of the liquor amni.

The precise state and dilatation of the cervix were determined by vaginal examination when the patient was admitted to the investigation. No patient was admitted unless the cervix had reached at least one-third dilatation by 48 hours without significant progress in the preceding 12 hours. A clinical assessment of the predominant pattern of uterine dysfunction was made when the patient was admitted to the clinical trial, together with a note of any concurrent maternal or foetal complication.

The treatment adopted for individual cases depended upon a random method of selection, modified by equalizing the two groups according to maternal age, parity, and the presence or absence of such complicating factors as pre-maternal or foetal distress, genital infection, or pre-eclampsia. A table was prepared at the beginning of this investigation, and the allocation of a patient to one or other method of treatment was read from it, after each patient had been admitted to the trial.

Patients designated for the first method of treatment were known as the "caudal series" and those for the other the "control series."

The final comments and conclusions are based on the duration of treatment required to effect delivery in 44 prolonged labours, by one or other method, the progress of labour after six hours of treatment, and the need for caesarean section.

Management

Caudal Series.—Continuous caudal analgesia was induced with 40 ml. of 1.5% piperocaine hydrochloride ("metycaine") injected into the sacral canal with a sterile malleable needle. The technical minutiae have been described by Hingson and Edwards (1943), with a more specific account of its application to the problem of prolonged labour by Johnson (1954). Analgesia was maintained for approximately six hours, with intermittent half-hour injections of 15 ml. of piperocaine hydrochloride. Each patient was nursed lying on her side, and bilateral analgesia was maintained by turning the mother on to her opposite side after each injection.

Control Series.—A subcutaneous injection of morphine, $\frac{1}{2}$ gr. (16 mg.), was given at the onset of treatment, together with 1 litre of 5% glucose-saline, given by slow intravenous drip. Response to treatment was assessed in both series of patients by comparing alterations in dilatation of the cervix after a period of six hours of treatment.

Results of Caudal Series

Twenty-three patients were treated with continuous caudal analgesia, and the final conduct of delivery depended upon its effective aid in dilating the cervix after an initial six-hour period of treatment (Table II).

TABLE II.—Response to Approximately Six Hours of Treatment

	Complete Dilatation of Cervix in 6 Hours	Progressing Dilatation of Cervix in 6 Hours	Non-dilatation of Cervix in 6 Hours	No. of Patients

Stillbirth or neonatal death	1	—	—	1	—	—

in anticipation of vaginal delivery, and all these were delivered in an average of 9.5 hours from the onset of treatment without loss of foetal life. The three remaining patients proved refractory, and were delivered by caesarean section, all the infants surviving. Analgesia was continued

for a further six hours in this particular group, to prove its inability to dilate the cervix, and to justify a more radical approach to caesarean section in this type of case in the future.

Results of Control Series

In this category there were 21 patients, who were collectively similar to patients in the caudal series, and the results are compared in Tables II and III.

Three patients were delivered within the six-hour period of starting treatment compared with 11 in the caudal series. One patient delivered herself spontaneously, and the other two required delivery by forceps.

Ten more patients displayed sufficient progress to continue sedative treatment. This consisted of morphine, or its derivative, the total dose and frequency of administration depending upon individual response to the discomforts of labour and the clinical judgment of the individual obstetrician. The final method of delivering these 10 patients is shown in Table III and compared with similar cases in the caudal series. Three patients delivered themselves spontaneously, and the remainder required assistance. These 10 patients were delivered in an average of 18.7 hours from the onset of treatment. The longest treatment-delivery interval was 43.5 hours, and this infant was lost from intrauterine infection.

The third group of eight patients were all delivered by caesarean section, performed for progressive non-dilatation of the cervix after at least six hours of treatment, but the optimum time for intervention was always decided by the individual obstetrician concerned. The average treatment-delivery interval in this group was 15.4 hours.

Comparison of the Two Series

Progress of Labour.—The ability with which continuous caudal analgesia facilitated dilatation of the cervix compared with traditional methods of treatment is demonstrated by Table II. The cervix became fully dilated in 11 of the patients in the caudal series during the first six hours of treatment, and nine more patients showed sufficient progress to justify persisting with the treatment. All of the latter became fully dilated within an average of 3½ hours of supplementary treatment, the longest caudal block in the whole series being 13 hours from the onset of treatment. Only three patients became fully dilated during the first six hours of treatment in the control series, and 10 more showed progressing dilatation of the cervix in the same time interval. The latter required a mean of 12.7 hours of supplementary treatment to achieve complete dilatation of the cervix, with a range of 3 to 40 hours. Continuous caudal analgesia failed completely in three further patients, all of whom were delivered by caesarean section, but the progress of labour became arrested in eight of the control series and caesarean section was eventually required to complete delivery. The difference between the two series is statistically significant.

TABLE IV.—Mean Duration of Treatment for All Patients Achieving Vaginal Delivery

	No. of Patients	Treatment-Delivery Interval
Caudal series	20	7.7 hours
Control "	13	15.1 "

Difference of means = 7.4 hours. $t = 3.5$; $m = 42$; $P < 0.002$. The individual variations in the length of labour, to the last complete hour, from the time of admission to the clinical trial to delivery, were as follows: Caudal series: 6, 5, 9, 1, 5, 8, 4, 11, 6, 8, 10, 9, 6, 6, 7, 13, 9, 3, 6, 6. Control series: 6, 2, 3, 43, 9, 17, 15, 13, 17, 14, 24, 12, 20.

Duration of Labour (Table IV).—The accelerating effect of continuous caudal analgesia is summarized above. All the patients in the caudal series who achieved vaginal delivery did so in a mean of 7.7 hours of treatment, compared with 15.1 hours for a similar group in the control series. The difference between these means is 7.4 hours, and this is a highly significant figure.

Caesarean Section.—The need for caesarean section arose in three patients in the caudal series compared with eight in

the control series. The difference between these figures gives a value, $P < 0.08$ (by an exact method), which is not significant in itself, although suggestive. When considered with the other findings, however, this result may well be interpreted as anticipating a clear difference in a larger series.

Discussion

There are many complicating factors in a prolonged labour, such as age, parity, maturity, pre-eclampsia, foetal distress, and the general maternal condition, all exerting their individual effect on uterine behaviour or the planning of treatment. This is especially true of foetal and maternal distress, which are common deciding factors leading to caesarean section. As this paper draws a comparison between two methods of treating a prolonged labour, every effort has been made to distribute these factors as equally as possible between the caudal and the control series (Table I). The chief failure is in the caudal series, which is loaded unfavourably by a larger number of distressed infants at the onset of treatment who might have been delivered by caesarean section but for the favourable influence of caudal analgesia upon placental action (Johnson and Clayton, 1955). There was also a preponderance of patients with hypotonic inertia in the caudal group, but it is likely that these would have lengthened rather than shortened the average duration of labour in the caudal series.

The major object of this investigation has been to decide whether the duration of the first stage of a prolonged labour can be significantly shortened by interrupting the autonomic nerve supply of the cervix, in support of the previous tocodynamometric studies by Reynolds (1954), who showed that the normal dominating influence of fundal contractions was undisturbed and frequently enhanced by this technique, especially when uterine action had been deficient.

One additional, and important, effect is the complete obliteration of the pains of labour. This allays maternal anxiety and the production of adrenaline, with its depressant effect upon uterine action.

Upon this basis continuous caudal analgesia is a desirable means to expedite the course of a delayed first stage of labour, with a favourable effect upon the disturbed placental function encountered.

The preponderance of forceps deliveries and malrotation of the foetal skull in the mid-cavity of the pelvis has always been one of the criticisms levelled against caudal analgesia. This is attributed to the complete motor and sensory paralysis of the birth canal and the interruption of the stimuli which initiate maternal expulsive efforts. This criticism is borne out by the results achieved in the present study, but, so far as prolonged labour is concerned, this relative disadvantage is heavily outweighed by an increased need for caesarean section in patients treated conservatively.

Although it is wise to point out the possible difficulties of caudal analgesia, the frequently favourable outcome following its therapeutic application to discoordinate uterine action amply justifies a method which is simpler and considerably safer than performing a caesarean section upon a patient who has been in labour for several days.

With scrupulous attention to details of technique, and avoiding overdistension of the bladder in the early days of the puerperium, we have not experienced any serious post-analgesic sequelae attributable to caudal analgesia, which has been induced satisfactorily in the large majority of patients upon whom it has been attempted in the past six years.

Summary and Conclusions

The use of continuous caudal analgesia for the primary relief of labour pains has justifiably been received with little enthusiasm by British obstetricians owing to the technical difficulties and possible complications of the method. On the other hand, its therapeutic application to the problem of discoordinate uterine

action is a sound application of regional anaesthesia which is based upon the existing knowledge of the autonomic nerve supply of the genital tract.

Compared with orthodox methods of sedation, caudal analgesia can accelerate the course of a delayed first stage of labour and lessen the need for caesarean section or mutilating vaginal operations to expedite the course of labour. However skilfully these latter operations are performed, each imposes a greater maternal risk than caudal analgesia, the dangers of which have been unjustifiably exaggerated. A close collaboration between the anaesthetist and obstetrician is fully justified to substantiate the claims for its efficacy in these special circumstances.

It might reasonably be argued that the favourable outcome of labour in the caudal series arose from the omission of the morphine which was administered to the control series. The experiment was designed, however, to give an answer in terms of therapeutic expediency rather than exact physiological mechanisms, and its results in such terms are conclusive.

This paper is deliberately concerned with patients who have been in labour for more than two days, which is the accepted definition of prolonged labour; but experience has shown that in future practice the method should be given serious consideration before this time has elapsed, to avoid the increased hazard of uterine infection and placental failure, or the extra risks of a caesarean section performed late in labour, should this ultimately prove desirable.

The personal interest and support of Professors Harvey Evers and E. A. Pask are gratefully acknowledged, together with the generous co-operation of the obstetricians at Princess Mary Maternity Hospital, who made this study possible. I am also indebted to Professor S. D. M. Court and Dr. G. Knox, of the department of child health, for their help in planning this investigation, and the presentation of statistical data.

According to the 1956 annual report of Manchester's medical officer of health, Dr. C. METCALFE BROWN, the outbreak of poliomyelitis in Manchester last year produced the largest total of cases, 321, ever recorded there. Of the eight fatal cases, seven were adults. Special tests showed that two other virus infections were present at the same time, one of these being Coxsackie virus, so that it is impossible to say with certainty how many non-paralytic cases of poliomyelitis were correctly notified. The paralytic cases numbered 93. In 20 households more than one case of the disease occurred: in three houses three non-paralytic cases in each house, in a further 12 houses two non-paralytic cases, and in the five remaining houses one paralytic and one non-paralytic case.

INFLUENCE OF HIGH-PROTEIN DIETS ON LIVER-FUNCTION TESTS IN KWASHIORKOR

BY

A. A. KINNEAR, M.D.

AND

P. J. PRETORIUS, M.Med. (Paed.)

From the Departments of Chemical Pathology and Paediatrics, University of Pretoria, Pretoria, South Africa

In a previous publication (Kinnear and Pretorius, 1956) liver function was evaluated in 107 consecutive cases of kwashiorkor. Of the tests used, albumin levels were found to be constantly low while bromsulphthalein retention was significantly high in 84% of cases tested. Thymol turbidity, thymol flocculation, serum colloidal gold, serum colloidal red, total serum bilirubin, and van den Bergh reactions were shown to have no diagnostic or prognostic value. It was also found that bromsulphthalein retention was significantly higher on admission in those patients who later died.

The composition of the diets and assessment of the clinical findings have been discussed elsewhere (Brock *et al.*, 1955; Pretorius *et al.*, 1956).

The Chart shows no significant statistical difference in the ability of the various diets in increasing the speed of production of albumin. Similarly, no statistically significant differences in the return to normal of the other liver-function tests could be demonstrated between the diets.

For these reasons it is proposed to treat all the cases as one group, and we report here the influence of a high-protein diet on serial liver-function tests in 107 consecutive cases of kwashiorkor. Albumin and globulin were estimated in a further 84 cases, while bromsulphthalein retention was estimated in 51 cases.

Liver-function tests were performed on cases of kwashiorkor on admission. They were repeated twice weekly for variable periods up to three weeks.

The methods used have already been discussed (Kinnear and Pretorius, 1956).

Results

Serum Albumin.—Table I shows the changes in concentration of serum albumin over varying periods of time. There is a steady upward trend, which in the cases of the Borden mixture seems to be better than the other diets (see Chart). However, the Borden cases would appear to be less severe cases of the disease, as their initial albumin values were about 2 g. per 100 ml. as compared with ± 1.5 g. per 100 ml. for the other diets. The different high-protein diets showed strikingly similar improvement of the serum albumin concentration in the groups studied.

Serum Globulin.—The value of 2.29 g. per 100 ml. on admission (Table II) is within the normal range for American children given by Kagan and Stern (1955). The steady increase in globulin values during treatment with high-protein diets confirms the findings of Trowell *et al.* (1954). No one diet gave better production of globulin than another. The prognostic value of total serum globulin is limited because of the many factors which influence its concentration in the plasma. Its extrahepatic origin makes its value as a liver-function test doubtful, but it undoubtedly plays a part in the mechanism of some of the flocculation tests of liver function.

Thymol Turbidity and Flocculation.—It has been shown that thymol turbidity and thymol flocculation tests have no diagnostic or prognostic value in kwashiorkor (Kinnear and Pretorius, 1956). We found that 21% of clinically cured cases showed thymol values which changed from negative to positive during the course of the disease, while 11% of clinically cured cases showed an elevated thymol turbidity test during

Regression lines for serum albumin after treatment with various high-protein diets. S.A.D.M. = Dried skimmed milk without vitamin supplement. S.A.D.M. + V.S. = Dried skimmed milk with vitamin supplement. C₂ = Casein formula with vitamin supplement. C₃ = Casein formula without vitamin supplement.

the whole period of treatment. The reason for the change from normal to positive is obscure, but lipids have been implicated in the mechanism of the thymol test (Recant *et al.*, 1945). Table III shows an initial low total serum lipid concentration which rises rapidly during the 3–14 days of treatment and then tends to fall again. The change-over point for the thymol tests from negative to positive generally fell within the 2–15 days period, and it is tempting to postulate a relationship between the positivity of the thymol test and the elevated serum lipids. However, the protein-lipid interrelationships of the thymol test are not as simple as this, and the rise in total lipids was a general phenomenon and not confined to those cases which showed a change of thymol test from negative to positive. Also the globulins tended to rise with time, and the influence of gamma-globulin on the thymol and other flocculation tests is well known. Table IV shows that treatment with the high-protein diet had little effect on the thymol turbidity test. Thymol flocculation tests followed the pattern of the thymol turbidity tests.

Serum Colloidal Gold and Serum Colloidal Red Tests.—Only four cases showed abnormal gold and red tests on admission, and a further four cases developed positive gold and red tests during treatment. A high-protein diet did not cause these tests to revert to normal. All eight cases, however, showed inverted albumin/globulin ratios during the period of treatment. **Van den Bergh Reaction and Total Serum Bilirubin.**—All cases on admission showed a negative direct van den Bergh reaction and all the serum bilirubin estimations were within the normal range. No deviations from this were noted during treatment with a high-protein diet.

Bromsulphthalein Retention.—Too few cases on the individual diets were subjected to the bromsulphthalein test to assess the effect of different high-protein diets on the test. All the results were therefore combined. All cases were normal at three days and the retention became less as treatment progressed (Table V). No differences could be found between the various diets. The fall of concentration of bromsulphthalein in blood is a function of several factors other than excretion to the bile. Extrahepatic removal (Cohn *et al.*, 1947, 1948), intrahepatic storage (Eberhard and Grafe, 1953; Shore and Zilversmit, 1954), and duodenal reabsorption (Lorber and Shay, 1950) may all play a part. Alteration of the circulatory dynamics of the liver seems to

affect bromsulphthalein abstraction, but the mechanism of abstraction is not simple, and, in fact, contradictory (Culbertson *et al.*, 1951; Bradley *et al.*, 1952; Heineman *et al.*, 1952). It appears, however, that the liver is capable of removing a definite proportion of the bromsulphthalein injected (Myers, 1949; Casselman and Rappaport, 1954), with the hepatic artery and the distribution of blood in the arterial bed holding key positions in the abstraction of bromsulphthalein from the blood (Andrews, 1955).

It has been suggested that the fat-laden liver cells of kwashiorkor compress the sinusoids, with resultant low abstraction of bromsulphthalein (Gillman and Gillman, 1951). Bromsulphthalein retention was normal within three days in 84% of cases, and coupled with this was the finding of elevated blood fats also at three days. It is tempting to postulate a liver source for the elevated blood fat. With the relief on tension in the liver cells and consequent decompression of sinusoids a better blood supply would give more efficient abstraction of bromsulphthalein from the blood. Evidence from liver biopsies tends to make the clearing of fat from the liver cells a slow process (Trowell *et al.*, 1954); however, there is often no correlation between structural changes in the liver and functional efficiency as judged by current liver-function tests.

Elucidation of the bromsulphthalein test is under investigation in this laboratory, using bromsulphthalein clearance as index (Kinnear and Pretorius, 1957).

Summary

Groups of kwashiorkor patients were treated with high-protein diets of different composition. The effect of these different diets on serial liver-function tests was assessed.

No difference in efficacy in returning liver-function tests to normal could be found between the various diets tested.

We are indebted to Professor J. G. A. Davel for clinical facilities and financial assistance. Acknowledgment is made to the Williams-Waterman Fund for the Combat of Dietary Diseases, Research Corporation, New York, for financial assistance. One of us (A. A. K.) is indebted to Dr. W. Horner Andrews, of St. Mary's Hospital, London, for stimulating discussions on the bromsulphthalein test.

ANTIHAEMOPHILIC GLOBULIN DEFICIENCY ASSOCIATED WITH A CAPILLARY DEFECT

BY

B. M. FESSEY, M.B., B.S.
Junior Hospital Medical Officer

AND

M. J. MEYNELL, M.D., M.R.C.P.
Clinical Pathologist

Department of Clinical Pathology, General Hospital, Birmingham

A report by Ingram (1956) of a case of multiple haemostatic defects in a female prompted us to record the following examples in a brother and two sisters. Our cases, although less prolific in abnormalities than Ingram's, are of interest in that they conform to a pattern described by others (see Table) of an increased bleeding-time and defective thromboplastin generation due to antihemophilic globulin deficiency. We feel that these cases constitute a distinct entity which until now has been included in the omnibus terms "von Willebrand's disease" and "pseudohaemophilia." The low antihemophilic globulin level emphasizes the need for differentiation.

Case 1

A youth aged 17 had a tendency to bleed excessively. This was discovered following circumcision when he was 3 months old. He has always bruised easily and has had spontaneous purpuric rashes. He bleeds readily from nose and gums. There is a history of joint haemorrhage in the knees and shoulders. Following swelling of the left knee aspiration of the joint produced blood only. Persistent haemorrhage following this necessitated transfusion. He had had two teeth extracted at 7 years of age and bled for seven weeks. Again he had to be transfused.

Laboratory Findings.—Red blood cells, 5,270,000 per c.mm.; haemoglobin, 96% (14.3 g. per 100 ml.); colour index, 0.91; white blood cells, 8,800 per c.mm. (polymorph neutrophils 72%, polymorph eosinophils 2%, lymphocytes 20%, monocytes 6%); platelets, 342,000 per c.mm.; serum proteins, 7.23 g. per 100 ml. (albumin 3.72 g.; globulin 3.51 g.); plasma fibrinogen, 0.2 g. per 100 ml. Blood group O, Rh positive, phenotype CCDee, which in all probability corresponds to the genotype CDe/CDe. Tourniquet test positive. Bleeding-time—Ivy's (Ivy *et al.*, 1941) method—22 minutes. No capillary abnormality was demonstrated. Clotting-time—Lee and White's (1913) method—at 37° C., 11 minutes. Prothrombin time (Quick's method, using human brain extract), 12 seconds (control, 12 seconds).

Prothrombin consumption index (Dacie, 1956), 88% (normal, 0-40%). Thromboplastin generation test (Biggs, Douglas, and Macfarlane, 1953): The patient's plasma with control platelets and serum showed defective thromboplastin generation. The patient's platelets with control plasma and serum showed normal thromboplastin generation, thus excluding a functional platelet defect such as Glanzmann's disease. Assay of antihæmophilic globulin (Pitney, 1956), 20% of normal. There was no evidence of a circulating anticoagulant. The test for plasma antithromboplastin (Biggs and Macfarlane, 1953) was negative.

Family History.—There was no history of abnormal hæmorrhage in other members of the family apart from Cases 2 and 3, described below. Father and mother: all tests, including thromboplastin generation, were normal. A sister of Case 1, aged 14, is alive and well: all investigations were normal. A sister aged 2 is Case 2. A sister (Case 3) died at 11 months.

Case 2

This girl, aged 2, has bled profusely after minor injury since birth. She bruises easily and has frequent nose-bleeds. She recently fell and cut her cheek. Following admission to hospital her hæmoglobin was found to be 30% and she had to be transfused.

Laboratory Findings.—Red blood cells, 5,560,000; hæmoglobin, 86% (12.8 g. per 100 ml.); colour index, 0.77; white blood cells, 14,500 per c.mm. (polymorph neutrophils 28%, lymphocytes 61%, monocytes 10%); platelets, 342,000 per c.mm. Films show anisocytosis, poikilocytosis, hypochromia, and slight polychromasia. Tourniquet test positive. Bleeding-time (Ivy's method), 20 minutes. Tests to demonstrate capillary abnormality were not attempted because of the patient's age and lack of co-operation. Clotting-time

Case	Sex and Age	Author	Personal History	Family History	Bleeding-time	Clotting-time	Prothrombin	Capillary Fragility	Abnormal Capillaries	Prothrombin Consumption	Antihæmophilic Globulin	Other Investigations

Blood failed to correct defect in known hæmophilias. No anticoagulant demonstrated

* Report published after this paper was submitted. Other less well documented cases have been described by: Koch and Schultz (1952); Verstraete and Vandenbroucke (1955); three cases, one son and two daughters of same family; Soulier, Larrieu, and Warville (1955); 2 females and 1 male, all unrelated; Schulman, Smith, Erlandson, and Fort (1955); 3 males and 3 females.

(Lee and White's method at 37° C., 10 minutes. Prothrombin time, 12 seconds (control, 12 seconds). The thromboplastin generation test showed defective generation with the patient's plasma. With patient's platelets and control plasma and serum, generation was normal—that is, no functional platelet defect. No circulating anticoagulant was present. Blood group B, Rh positive, phenotype CcDe, which in all probability corresponds to the genotype CDe/cDe.

Case 3

This child, a girl who died in 1949 at the age of 11 months, was not investigated by us. The following is a summary of the notes kindly supplied by Dr. J. M. Garvie. The patient was admitted to the Manor Hospital, Walsall, on October 9, 1949, with a history of bleeding from the throat for several hours. She had always bruised easily and had had a similar hæmorrhage at the age of 3 months. On admission there were bruises over the limbs and head, and fresh blood was exuding from the base of the tongue. Eleven days later she developed offensive stools and went steadily downhill, dying on November 7.

Laboratory Investigations.—October 10: red blood cells, 3,250,000 per c.mm.; hæmoglobin, 65% (9.7 g. per 100 ml.); white blood cells, 17,600 per c.mm. Platelets plentiful. Bleeding-time, 12 minutes. Clotting-time, 15 minutes. October 20: red blood cells, 3,500,000 per c.mm.; hæmoglobin, 70% (10.4 g. per 100 ml.); white blood cells, 11,000 per c.mm. Bleeding-time, 10 minutes. Clotting-time, 10 minutes.

Post-mortem Findings.—Enlarged cerebral ventricles with thrombosis of the surface vessels of the brain. Congested lungs. Large pale liver. Patchy ulceration in the small intestine. Cause of death, toxæmia following gastro-enteritis.

Discussion

About 25 years ago von Willebrand described a hæmorrhagic diathesis in 16 females and 7 males of one family in the Åland Islands, off the coast of Finland. Since that time a fairly extensive literature has arisen. The disease occurs in either sex and has one constant laboratory abnormality—namely, a prolonged bleeding-time. About 50% give a positive tourniquet test. The disease, which consists of a capillary defect with failure of normal contractility, or should be differentiated from hereditary thrombasthenia or Glanzmann's disease. The latter is due to a functional platelet defect which gives rise to a characteristic pattern of abnormalities: (1) increased bleeding-time; (2) positive tourniquet test; (3) defective clot retraction; (4) defective prothrombin consumption; and (5) defective thromboplastin generation, using the patient's platelets.

The abnormalities found in the condition we describe are:—Capillary defect: increased bleeding-time, positive tourniquet test, and purpura. Antihæmophilic globulin deficiency: may or may not have increased clotting-time, easy bruising, hæmarthrosis, defective prothrombin consumption, and defective thromboplastin generation.

It is obvious that differentiation of this group is of great importance to the patient, since management is influenced by the antihæmophilic globulin deficiency. Fresh plasma or blood should be used when surgery is contemplated and bleeding excessive. Generally speaking, the antihæmophilic globulin deficiency must be fairly mild, since most of the cases described have either a normal or slightly prolonged clotting-time.

We wish to thank Dr. Garvie for referring both patients to us for investigation and allowing us to use his notes on Case 3.

CONGENITAL HAEMOLYTIC ANAEMIA COMPLICATED BY MEGALOBlastic ANAEMIA OF PREGNANCY

BY

M. I. DRURY, M.D., F.R.C.P.I.

Visiting Physician

AND

FRANK GEOGHEGAN, M.D.

Pathologist

National Maternity Hospital, Dublin

Megaloblastic anaemia of pregnancy in association with a hæmolytic anaemia is rarely found. A search of the available literature suggests that only Davidson (1952) has described it. In his report of a case in which a megaloblastic anaemia of pregnancy was superimposed on a pre-existing microspherocytic anaemia he comments on the surprising rarity of this finding in view of the greatly increased requirement of hæmatin agents such as folic acid which must necessarily follow the sustained overactivity of hæmatopoietic tissue in chronic hæmolytic anaemias.

We have observed a similar case over a period of three years; a report of the case is given below.

Case History

A 2-para aged 32 attended the antenatal clinic at the National Maternity Hospital on February 3, 1953. Although her family doctor had given her iron in large doses she was very anaemic and was admitted to hospital. She gave a history of diarrhoea and complained of sore tongue. The spleen was enlarged.

On admission her blood count was as follows: hæmoglobin, 2.5 g. per 100 ml.; erythrocytes, 1,040,000 per c.mm.; leucocytes, 5,120 per c.mm. Sternal marrow showed a well-defined megaloblastic hyperplasia. Treatment was by transfusion (packed cells) and folic acid, 20 mg. intramuscularly daily. There was a reticulocyte response with a peak at 11% on the seventh day, following the institution of folic acid therapy. Re-examination of the sternal marrow on the 10th day after admission showed conversion to normoblastic erythropoiesis. A test meal (histamine) on March 4 showed achlorhydria. While the peripheral blood picture demonstrated a sustained improvement for 25 days after admission to hospital (Hb, 10 g.; R.B.C., 4,000,000), a transient deterioration followed. At the time the reason for this setback was not apparent. It now seems certain that a mild exacerbation of the hæmolytic anaemia occurred at this period.

Between the 25th and 50th days of observation the erythrocyte count did not rise above 3,700,000, but on the 76th day it was 4,200,000 and the hæmoglobin was 11.6 g. per 100 ml. On the 84th day (May 2) the patient was delivered of a living male infant weighing 7 lb. 9 oz. (3.4 kg.). She did not present herself for examination until seven months

after delivery, although she had been asked to remain under supervision. She was found to have marked splenomegaly, and a screening test on her blood showed a reticulocytosis of 10%. On December 12 the findings were as follows: Hb, 11.6 g.; erythrocytes, 4,576,000; packed cells, 39 vols.%; M.C.V., 85 cubic microns; M.C.H., 25 μ g.; M.C.H.C., 30%; plasma bilirubin, 2 mg. per 100 ml.; reticulocytes, 6.1%. Further investigations on January 13, 1954, included direct and indirect Coombs tests; these were negative. Tests for cold agglutinins, Ham's test, incubation fragility, and the

four months of pregnancy the blood count remained reasonably good. The findings at subsequent examinations are summarized in the Table.

Date (1954)	Blood Findings										Therapy
	Gestation (Weeks)	Hb (g./100 ml.)	R.B.C. (mill.)	P.C.V. (vols.%)	M.C.H.C. (%)	Retic. (%)	Bilirubin (mg./100 ml.)	Marrow	Fragility		
25/5	22	8.7	2.08		37.8	3.4	1.2	Normo.			2 pints (1,140 ml.) whole blood 2 pints (1,140 ml.) packed cells Folic acid started
15/6	25	4.5	1.26	12	37.5	0.2	0.9				
22/6	26	5.5		15	36.6	1.8		Megalo.			
26/6	26					8.8		Normo.			
28/6	27	9.6		31	31	4.5					
24/7	31	9.7	3.0			8.0					Haemolysis begins 0.5% NaCl
30/8	36	10.8	3.6	31	35	4.8	1.2				
4/9	37	11.5	3.3	32	30	8.8					Readmitted to hospital
12/9											
10/10											
21/10											
11/12											Delivered, living infant, pseudohermaphrodite, survived one week

On December 11 there was well-marked microspherocytosis, and a further osmotic fragility test on that day showed haemolysis commencing at 0.58% NaCl, complete at 0.4%. The patient was advised to have a splenectomy, and this was performed on January 24, 1955 (Mr. E. O'Malley). Before operation the direct and indirect Coombs tests were repeated with a variety of test sera with negative results. The sternal marrow showed normoblastic erythropoiesis and the plasma bilirubin pre-operatively was 2.2 mg. per 100 ml. Histopathological examination of the spleen supported the clinical diagnosis. A suspected accessory spleen removed during operation proved to be a regional lymph node in which there was intense haemosiderosis. Recovery was uneventful, and on the patient's discharge from hospital on February 18 her blood count was as follows: Hb, 15.7 g. per 100 ml.; erythrocytes, 5,240,000; packed cells, 47 vols.%; M.C.H.C., 33.6%; leucocytes, 5,120;

reticulocytes, nil; bilirubin, 0.6 mg. per 100 ml.; platelets normal. This improvement in the blood picture was maintained, and in July she became pregnant again.

Her progress was followed with keen interest, but during the entire antenatal period the haemoglobin level did not fall below 13 g. per 100 ml. In February, 1956, there was a transient erythrocytosis. On April 24 she was delivered of a living male infant weighing 6 lb. 2 oz. (2.8 kg.). There was a mild thrombophlebitis in the puerperium which responded well to anticoagulant therapy, and on May 14 she was discharged. At the time of writing she remained well.

The patient has one brother and a sister living. So far, only the sister has presented herself for investigation. No evidence of congenital haemolytic anaemia was found in her blood.

Summary

The case is reported of a patient in whom congenital haemolytic anaemia was twice complicated by megaloblastic anaemia of pregnancy. Following splenectomy a third pregnancy was successfully completed without anaemia being evident at any stage. The rarity with which this combination has been reported is commented upon.

We wish to thank Professor Sir Stanley Davidson for his kindness in examining one of the sternal marrow films from this patient. We acknowledge also the co-operation of the staff of the department of pathology, the Mater Misericordiae Hospital, Dublin, and the technical assistance of Mr. C. J. Conway, pathology department, the National Maternity Hospital, Dublin.

Medical Memoranda

Subcutaneous Emphysema Occurring After Labour

Subcutaneous emphysema occurring during or immediately after labour is rare (Reckitt, 1922; Charbonnet, 1925). Simmons described the first case in 1784. The majority of cases have occurred in young primigravidae following a prolonged or difficult second stage, and in whom there has been no demonstrable pre-existing pulmonary disease. The mechanism of causation is obscure. The condition has been reproduced experimentally by injection of air through the buccal mucosa (Watson, 1885). It is probable that most cases are due to intrapulmonary alveolar rupture with passage of air along the perivascular sheaths to the mediastinum. The condition has been reported to follow hard and prolonged labour (Faust, 1940), to follow easy labour (Wiland and Crowder, 1951), and to follow labour complicated by bronchopneumonia (Roth, 1943).

CASE REPORT

The patient was a primigravida aged 21. The last period was on February 16, 1955, and the expected date of delivery November 23, 1955. Her blood was group B, Rh-positive. She was 64 in. (162.5 cm.) tall and weighed 101 lb. (45.8 kg.) when 12 weeks pregnant. The external pelvic measurements were normal. The antenatal period was uneventful, the maximum recorded blood pressure being 120/70 mm. Hg. There was no albuminuria or oedema. At the 36th week x-ray examination confirmed that the head was engaged. At the 38th week her weight was 122 lb. (55.3 kg.).

On November 23 the patient was given a routine medical induction of castor oil, 2 fl. oz. (60 ml.) by mouth, followed by an enema saponis and hot bath. Vague uterine contractions were noted eight hours later; these continued irregularly during the next 24 hours. At 1.30 a.m. on November 25 strong regular (1:15) uterine contractions were noted. At 3 a.m. 100 mg. of pethidine was given intramuscularly, and this dose was repeated at 7.30 a.m., at which time the contractions were strong and regular (1:10),

the cervix was dilated three fingerbreadths, and the patient was tired and distressed. At 2 p.m. the cervix was fully dilated and the membranes were ruptured artificially, whereupon she started to bear down vigorously. At 3.45 p.m. the head was on the perineum and the patient was still bearing down extremely vigorously with little progress. At 4.45 p.m. the soft tissues of the introitus were noted to be small, tight, and unyielding. The perineum was infiltrated with 20 ml. of 1% procaine hydrochloride and a wide right medio-lateral episiotomy was performed. At 4.50 p.m. she complained of pain in the right chest. At 5.5 p.m. she was delivered spontaneously of a vigorous 6½-lb. (2,950-g.) male infant. At 5.10 p.m. a slight swelling of the right side of the face was noted. The placenta and membranes were delivered intact by fundal pressure at 5.30 p.m.

On November 26 a gross crepitant swelling of the face, especially in the periorbital regions, and more marked on the right side, was observed. This crepitant swelling extended into the right supraclavicular fossa, both infraclavicular fossae, and the entire upper anterior chest, again most marked on the right side. Pitting oedema of the right arm, forearm, and hand of non-crepitant type was noted. The patient was not cyanosed and did not complain of cough, dyspnoea, or dysphagia. Her temperature was 98° F. (36.7° C.), and pulse 88.

A diagnosis of subcutaneous emphysema was made. Clinical examination of the chest revealed symmetrical expansion. The percussion note was normally resonant, and the cardiac and hepatic areas of dullness were elicited. The breath sounds were vesicular throughout and no adventitious were detected in any zone.

During the next 48 hours the crepitant swelling became more marked. No symptoms were elicited apart from a diminishing non-pleuritic type pain in the right chest. The patient was, however, much distressed by her bizarre and grotesque facial appearance.

Her pulse and temperature were recorded twice daily for the next 12 days. The pulse varied between 84 and 92 for the first seven days of the puerperium, settling to 74 by the tenth day. The maximum recorded temperature was 98.6° F. (37° C.) on the evening of the third day.

By the tenth day no subcutaneous crepitation could be elicited in any zone, and the pitting oedema of the right arm had resolved.

I wish to thank Miss M. A. Ridgley for her interest in the case and Dr. W. H. Callander for confirming the clinical signs.

Avulsion and Rupture of the Tendo Calcaneus after Injection of Hydrocortisone

A cross-country runner aged 33 had been suffering from gradually increasing pain about the insertion of the tendo calcaneus for over nine months when he first sought advice on April 23, 1955. He had done no running for some months. There was no swelling of the tendon or round it, but there was tenderness in front of the upper part of its insertion, which seemed consistent with a diagnosis of chronic tendo calcaneus bursitis.

As it continued to get worse, on May 14 hydrocortisone acetate (25 mg. in suspension in 1 ml.) was injected into the painful region. This was followed by some relief of pain, and further injections were given on June 11 and July 9. On each of these occasions 50 mg. was injected, half on each side of the tendon. A little of the fluid was seen to run up in the paratenon on the second occasion, but when the point of the needle was in actual tendon tissue no fluid could be forced in.

After the third injection he felt complete relief and resumed training without apparent ill effect. On July 30, while running gently on smooth ground, he felt the tendon tear suddenly, but had no pain, and he limped home. There was an obvious gap, and the tendon was operated upon the next day.

Findings at Operation.—The superficial part of the tendon was found to be avulsed from the calcaneum. The deep part was ruptured about 1½ in. (3.8 cm.) above the heel, and a longitudinal split joined the two lesions. The avulsed part resembled a cast of the posterior surface of the calcaneum. Its lower margin was smooth and sharply defined, and it was drawn up and tucked into the gap in the deep part. There had been very little bleeding, and there was no scarring or other evidence of past or present inflammation. The tear in the deep part was obviously recent and a little frayed.

As a transverse incision above shoe level had been used, it was not possible to inspect the bursa or the back of the calcaneum effectively even by curving the incision downwards. Repair was carried out with stainless steel mattress sutures, the deep and superficial parts being overlapped and stitched together. No attempt was made to suture the avulsed part direct to the calcaneum, but it was tucked into position.

A short walking-plaster was continued for 7½ weeks, after which normal use was encouraged. Three months after the operation the lower part of the tendon was still much thickened, but not tender or painful, and the patient resumed cross-country running.

COMMENT

Whatever caused the original pain, it had been unchanged in character for about nine months. Chronic pain and swelling in the tendo calcaneus are common in long-distance runners, who usually recover in a few months whether they continue to run or not. Pain about the insertion is much less common, and is usually ascribed to calcaneal bursitis. It is aggravated by running and forces the sufferer to stop. If this patient's pain was due to bursitis it may have been secondary to a lesion of the tendon at its insertion. There was, however, at no time any pain or swelling at the back of the calcaneum.

The unusual nature of the avulsion leads to a suspicion that the final phase was influenced by the injections. The suspension may have been injected into a space, actual or potential, between the superficial and deep layers of the tendon, and absorbed slowly because of the relatively avascular nature of the tissue. Gonzalez (1953b) reported that remnants of the drug were still present in the tissues three weeks after it had been introduced at operation.

Avulsion appears to have been going on for some time. Simultaneous repair may have been hindered by the hydrocortisone. Experimental evidence of its effects on tendon healing is rather conflicting. Gonzalez (1953a) reported that local hydrocortisone did not affect repair of cut tendon sutured at a distance. Carstam (1953) stated that the tensile strength of repairs in dogs was not affected if firm apposition was maintained, but if apposition failed the repair was weaker than in controls. Berkin (1955) confirmed that neither cortisone nor hydrocortisone affected tendon union. Strict comparison with experiments in small animals may be vitiated by a slow rate of absorption in such a large tendon.

Progressive weakening of the attachment of the superficial part of the tendon would evidently increase the strain on the deep part, which would rupture under a stress insufficient to injure a normal tendon.

Reviews

FLUID BALANCE

Fluid Balance Handbook for Practitioners. By William D. Snively, jun., M.D., and Michael J. Sweeney, M.D. Illustrations by Kathleen Calhoun. (Pp. 326+xix; illustrated. 51s.) Oxford: Blackwell Scientific Publications. 1956.

Clinical Recognition and Management of Disturbances of Body Fluids. By John H. Bland, M.D. Second edition. (Pp. 522+xvii; illustrated. 80s. 6d.) Philadelphia and London: W. B. Saunders Company. 1956.

Fluid Balance Handbook for Practitioners sets out to provide a readable explanation of the physiological control of electrolyte and water balance which can be understood easily by practising physicians and surgeons who lack time and the inclination to assimilate the considerable literature referring to this subject. In general the authors have succeeded in this object, but, as so often happens with books of this type, simplification has tended to over-simplification in some of the more intricate branches of the subject. Thus in the section on "acid-base imbalances" the authors have deliberately confined themselves to describing the respiratory control of carbon dioxide and the bicarbonate-carbonic-acid buffer system; such a one-sided description of the complex and diverse methods by which the reaction of the internal environment is sustained is unfortunate. In the section on treatment they recommend that replacement and maintenance therapy should be based on the body surface area and not the body weight of the patient, which is in line with recent thought and is thoroughly sound. The requirements for treatment are calculated by rule-of-thumb methods without reference to plasma electrolyte concentrations. Nine different solutions are described, one of which is for oral use only, which seems unnecessarily elaborate. The book is lavishly illustrated with diagrams and line drawings of varying degrees of relevance and usefulness. Some illustrative case histories are given and there is a bibliography of 106 references, only two of which are to British publications, and one of these was published in 1831-2. The literary style and presentation of this book are such that it is more likely to appeal to the Admass than to intelligent members of a learned profession. It can safely be recommended to those who prefer to swallow the pill of science painlessly and with plenty of synthetic jam.

Clinical Recognition and Management of Disturbances of Fluid Balance is in complete contrast. It is an exhaustive and well-written monograph of eighteen chapters on every aspect of the theory and practice of replacement therapy. A bibliography of 633 references is given, the references being at the end of the chapter to whose subject they are relevant. The difficult subject of the control of hydrogen ion is explained carefully and well. There are chapters on electrolyte alterations in hepatic disease, in diseases of the circulation, in the aged, in diabetes mellitus, in suprarenal disease, in injuries to the head, and in diseases of the central nervous system. The illustrations by diagram and line drawing are excellent. This comprehensive work is one which anyone who has much to do with the treatment of electrolyte disturbances would be glad to possess.

WALTER H. H. MERIVALE.

FRACTURES

Outline of Fractures Including Joint Injuries. By John Crawford Adams, M.D., F.R.C.S. (Pp. 248+vii; illustrated. 27s. 6d.) Edinburgh and London: E. and S. Livingstone Ltd. 1957.

There are many short books on fractures, and anyone who adds to their number can do so justifiably only if he can write with exceptional clarity and is gifted with very sound judgment. Works of this sort are, as the author of this one says, usually "intended primarily for the medical student and for the practitioner who seeks a knowledge of general principles . . . and for the physiotherapist." This is very proper, because everyone has so much to learn nowa-

days that short, precise books are more necessary than ever. Mr. Adams's little volume on orthopaedics was very good; this companion *Outline of Fractures* is superb. It is beautifully produced and written with felicity. He knows his subject so well that he can be brief without being too dogmatic and is aware of what in recent developments is worth mentioning. There are no references but a few historical footnotes; there might well have been more. The illustrations are excellent. Half-tone pictures, line drawings, and diagrams are used for the right purposes, with the result that a good deal of writing is saved. Thus fourteen injuries of the ankle are illustrated on two pages (214-15), and yet there is a story to be read with enjoyment, not merely a tedious synopsis.

Every now and then a short book appears which is a model of its kind. This is one of them, and its popularity ought to be such as to encourage the author and publishers to make plans for a second edition. The cost of books is becoming a burden. Here is one of some 240 pages, elegantly printed, and costing only 27s. 6d. This is good value.

H. J. SEDDON.

CYTOLOGY OF EFFUSIONS

The Cytology of Effusions in the Pleural, Pericardial, and Peritoneal Cavities. By A. I. Spriggs, D.M., M.R.C.P. (Pp. 71; illustrated. 42s.) London: William Heinemann Medical Books Ltd. 1957.

It would appear that most cytologists employ the Papanicolaou method of staining for cell identification. Some, however, have used haematoxylin and eosin or methylene blue, and a certain number—for example, Cardozo—have preferred Romanowsky stained films. This last procedure has also been adopted by Spriggs, as shown in this monograph. Romanowsky-stained films will appeal especially to haematologists, but appearances in films stained by other methods are more satisfactory for comparison with malignant cells seen in paraffin sections from the primary lesion. These are usually stained by haematoxylin and eosin. A certain amount of difficulty in diagnosis may arise in some effusions owing to the similarity in appearance between mesothelial cells desquamated from the serous membrane and certain types of malignant cells—particularly in adenocarcinoma. His published results show that Spriggs has had marked success with the Romanowsky technique; of 103 consecutive cases of malignant pleural or pericardial effusion 71% had positive reports and 29% could be regarded as "false negatives." There were no false positive reports.

Considerable care is required in the preparation and staining of films by the Romanowsky method, and a chapter of the book is devoted to a detailed account of the technique recommended by the author. A good description of the appearances of the various types of cells seen in effusions, both innocent and malignant, is given. The book is well illustrated. The majority of the figures are in black-and-white (a few are not very convincing), but the coloured drawings, originally due to the work of an artist, are excellent. In addition there is a useful bibliography.

The cytological examination of effusions is important in medical diagnosis, and this book should be of considerable assistance to those interested in this branch of laboratory work.

J. BAMFORTH.

TEXTBOOK OF PHYSIOLOGY

Medical Physiology. Edited by Philip Bard. Tenth edition. (Pp. 1421+xxiv; illustrated. £5 5s.) London: Henry Kimpton. 1956.

This is the tenth edition of *Macleod's Physiology and Biochemistry in Modern Medicine*. The book does not set out to be a textbook of "applied physiology": clinical data are invoked only when they illustrate well-founded principles. The title assumes that physiology serves medicine by solving fundamental problems, not necessarily of immediate practical importance, by acquainting the student with their real importance, and by imbuing him with the value

of experimental evidence. It is the largest textbook (in bulk and number of pages) on the subject in English. Clearly printed on good paper and with good illustrations, its cost at 5 guineas is on the American scale of values. It has a good index and a first-class bibliography, particularly of original papers, with, however, the common tendency to stress those of the North American continent. The literary style is good, being unhurried and uncrowded. The editor seems to have achieved success in imposing some sense of this lack of urgency upon his fellow contributors, thereby making it delightfully readable.

The outstanding parts are the sections for which the editor has been responsible. That on the central nervous system is the best account in any textbook and worth the whole cost alone. The chapter on temperature control is well balanced, and the joint account by Bard and Bazett of the cardiovascular system and that by Schmidt of respiration are quite outstanding in clarity and in the art of omission. On the other hand, one expects to find more reference to genetics, immunity, and prenatal development than a single index reference to placental hormones and a good account of the Rh factor. In developing the *corpus sanum* for the *mens sana*, this seems unfortunate. The day is past when these areas of physiology can be loculated as branches of pathology or zoology having no relation to normal function.

The supreme quality of this book, in the reviewer's opinion, is that it enables the student to see the wood despite the trees.

A. ST. G. HUGGETT.

HALSTED OF JOHNS HOPKINS

Halsted of Johns Hopkins: The Man and His Men. By Samuel James Crowe, M.D. (Pp. 247+ix; illustrated. 37s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1957.

The profession and science of medicine owe much to enlightened laymen who, in their wisdom, have listened to and acted upon the advice of far-sighted medical advisers. We have an excellent example in this country in the Nuffield Foundation. This book describes the development of the Johns Hopkins Hospital, which by the terms of the university donor's will was to be an integral part of the university programme. By this means a high standard of medical training was assured. It is generally admitted that this foundation has had an immense and beneficial effect upon medical education in America, and indirectly in other parts of the world. It was through the generosity of Johns Hopkins that the forward-looking ideas of Dr. Patrick Macaulay achieved a great fulfilment.

Dr. Crowe here tells the story of the gradual development of the surgical side of this great experiment, which was guided by the brilliant but slightly eccentric genius of William Stewart Halsted. Halsted's surgical achievements are well known. His remarkable technique, his originality, his wide catholic outlook all fitted him to train young surgeons. This book shows that he also possessed a wonderful flair for picking out men well fitted to organize particular departments of surgery. What other school has turned out in one generation such renowned names as Harvey Cushing, Walter Dandy, Hugh Hampton Young, and Samuel James Crowe? In this small volume the reader will find many fascinating details about the life and work of Halsted and his brilliant assistants.

Within a few hours of completing the book Dr. Crowe was taken ill with an attack of coronary thrombosis which proved fatal. Dr. Alfred Blalock has written a foreword in which he gives an appreciative account of the author.

ZACHARY COPE.

PHYSICS IN PHYSIOLOGY

Physical Methods in Physiology. By W. T. Catton, M.Sc. (Pp. 375+xi; illustrated. 42s.) London: Sir Isaac Pitman and Sons Ltd. 1957.

Physiology is so rapidly becoming the province of the physicist and physical chemist that any book aimed at making

the physical principles involved in the study of physiological phenomena more easily understood by those physiologists who have been trained in less rigorous disciplines must always be welcome. This is a small book, so that the reader must not expect to find detailed accounts of any specific methods of study; instead he will find a clear and simple (if rather condensed) exposition of the physical theory underlying certain experimental approaches in physiology. For example, the student of the vascular circulation will find an adequate account of the theory of fluid flow in tubes, of the physics of elasticity, and so on. The subjects covered are blood, circulation, respiration, muscle, nerve, and heat exchanges. The author writes well and obviously understands what he is writing about. In general, it can be said that the book will be very useful to those who work on the vascular circulation, since the methodology here involves physical principles that are not always well understood by the worker in this field; and it is in this chapter that the author has taken pains to be thorough. It seems doubtful whether the chapters on muscle and nerve will help workers in these fields, since they must of necessity be familiar with the theoretical background of their subjects. To the advanced student these chapters might be an adjunct to the textbooks were they up to date and well documented. In both these respects, however, they are painfully deficient; references to work later than 1951 are conspicuous by their rarity, while the total number is less than one would expect to find in a textbook for medical students. These chapters give the impression of having been hastily compiled from one or more modern textbooks with some supplementary information obtained from reviews.

HUGH DAVSON.

CORONER'S DUTIES

Jervis on the Office and Duties of Coroners with Forms and Precedents. Ninth edition by W. B. Purchase, C.B.E., M.C., M.B., D.P.H., and H. W. Wollaston. (Pp. 565+xxiv. 84s.) London: Sweet and Maxwell Ltd. 1957.

For anybody who wants to know or for professional reasons has to know anything about that ancient and curious English institution the coroner, the information is all there to be found in *Jervis on Coroners*. How coroners managed before its first edition was published in 1829 taxes the imagination when you see the wealth of material contained in the ninth edition.

This ranges from the history and jurisdiction of the coroner through the various complications leading to and during the inquest, and through an illuminating chapter on the law of homicide to such practical problems as the design of mortuaries with post-mortem accommodation. As an illustration of the practical and human approach to what might at first sight appear to be an arid subject it would be hard to beat the editors' appreciation of the qualities required in a mortuary site, which should be "quiet and pleasant and should, if possible, be near the coroner's court. The use of council yards associated with dumps or building materials, etc., should be avoided. A poor site can, however, be improved at little cost by the use of screens of shrubs, flower beds, or flowers in tubs." Pathologists may wonder whether Appendix VIII, where this appears, was included in some earlier editions.

Doctors will appreciate the chapter on "medical matters." In twenty pages there are covered such important and widely differing problems as when, where, and by whom post-mortem examinations should be made and who is entitled to be present, the problem of cremation and corneal grafting where death has been or may be reported to a coroner, when and how medical evidence at inquests is given, and the fees to which a medical witness at an inquest is entitled. And the doctor is reminded that in the witness box in the coroner's court, as in other courts, he cannot claim privilege from being caused to disclose what he has learned in the strictest professional confidence.

PERIODIC DISEASE

A little-understood disorder, or group of disorders, which goes by the name of periodic disease, has recently been the subject of a monograph by H. Mamou.¹ Its opening sentences (here translated from the French) are as follows:

"Periodic disease is a chronic disorder, often beginning during infancy, sometimes affecting several members of the same family and showing at times a hereditary character.

"It evolves over the course of many years, lasting sometimes throughout the whole of a life-time, and reveals itself clinically by acute paroxysmal episodes whose essential characteristics are that they are recurrent, obstinate, and incurable. These acute, transitory crises can be grouped under three headings:

"Joint syndrome, which is generally characterized by acute arthritis with effusion.

"Abdominal syndrome, producing a true, recurrent, benign, acute peritonitis.

"Febrile syndrome, which is particularly of a pseudo-malarial type but can also mimic any of the known types of fever.

"Between crises, the patient recovers in an astonishing way and his general state appears to suffer relatively little from these incessant episodes."

The condition is particularly associated with the name of H. A. Reimann, who in 1951 published a review² of the disorder and has since made a number of studies of the various syndromes embraced by it. Episodes are said to last a few hours or days and recur in cycles, often with striking regularity in seven or multiples of seven days. Periodic peritonitis occurs especially in Jews, Armenians, and Arabs,¹⁻³ is hereditary, and is characterized by sterile inflammation. Individual episodes mimic acute appendicitis or other abdominal emergencies, so that victims of the disorder are often submitted to laparotomy. Those subjects with joint manifestations suffer from recurrent attacks of arthritis with effusion into the joints, a condition variously known as intermittent hydrarthrosis or palindromic rheumatism.⁴⁻⁶ The joints are not permanently damaged. A third main group consists of those patients who suffer from periodic fever, of which an example was recently published in this *Journal*.⁷ This was a patient with recurrent attacks of fever for five years, for which no cause could be

found and which no treatment influenced. The treatments were diverse and consisted of sulphonamides, penicillin, chloramphenicol, chlortetracycline, streptomycin combined with isoniazid, cortisone combined with anti-tuberculosis drugs, quinine, arsenicals, antihistamines, chlorpromazine, thyroid, codeine phosphate, oestrogens, testosterone, and, finally, hypnotherapy—"but her state remained unchanged."

In addition to these main syndromes, other illnesses have been thought to belong to the same general group of periodic diseases. Among blood diseases periodic neutropenia is the best-known example,⁸ but thrombocytopenia, Henoch-Schönlein purpura, and haemolytic anaemia may all present in a cyclical form. Cyclical vomiting of children has been put into the same general category.⁹ Certain cases of recurrent angioneurotic oedema may fall into the same group. Familial periodic paralysis is possibly another example; in this disease an interesting discovery has been made that a great increase of secretion of aldosterone is associated with episodes of paralysis.¹⁰ Retention of sodium may be the primary factor which sets in motion the characteristic chain of events in an episode of periodic paralysis.¹¹ Recently M. D. Milne, R. C. Muehrcke, and I. Aird¹² have reported two cases of primary aldosteronism, one of which had suffered from severe periodic paralysis for many years.

One interesting possibility to explain the aetiology of some of these examples of periodic disease is that the patient becomes sensitized to one of his own metabolites or secretions. B. Zondek and Y. M. Bromberg¹³ described 47 cases of endocrine allergy in women, in which the clinical manifestations were diverse and included asthma, vasomotor rhinitis, angioneurotic oedema, migraine, and abdominal pain with vomiting and diarrhoea. In haematology, auto-immunization is well recognized, and in many instances the clinical manifestations pursue a recurrent course which is sometimes related to season. For example, W. H. Crosby and H. Rappaport¹⁴ have surveyed the clinical features in 57 cases of autoimmune haemolytic anaemia and find that there is a marked seasonal variation in the occurrence of haemolytic crises, there being an exceptionally low incidence

during the months of May, June, and July. In the field of thyroid disease I. M. Roitt and colleagues have shown¹⁵ that the serum of patients with Hashimoto's thyroiditis contains an antibody to extracts of normal thyroid. It appears possible that the methods used by these and other workers on thyroiditis might be profitable if applied to the study of the various syndromes grouped together as periodic disease.

The use of the term "periodic disease" introduces a problem in semantics. As soon as we give a condition a definite name we imply a certain uniformity in the clinical manifestations and a pathological process which is common to all sufferers from the disorder. It is quite different if we talk about periodic diseases, recognizing that periodicity may be due to entirely different factors in different circumstances. Adopting this more tentative approach, we can recognize that Reimann, Mamou, and other students of these periodic conditions have fulfilled a useful function in bringing them together in the hope that information gained about one group of them may throw light on the others. Indeed, Reimann himself is not far from this viewpoint in his latest article¹⁶ when he writes: "For the present, the disorders grouped as periodic disease may, at least, be extricated from other recurrent ones for the purpose of study. They may be unrelated entities, but, regardless of their disparate nature, it is tempting to classify some, most or all of them as different facets of a syndrome dependent upon or provoked by a single obscure underlying rhythm. They have as unifying bonds similar regular cycles of recurrence, combinations and substitutions of features, a genetic aspect, ineffectiveness of therapy and an unknown cause. It may offend tradition and disturb complacency, but a nosologic rearrangement, new names and a different point of view sometimes stimulate enough thought to cast light on a mystifying problem."

PROSTITUTION

Reports in the newspapers and questions in Parliament have recently drawn attention to the growth of prostitution in Stepney, a borough in east London. Its occurrence in the West End has also been commented on from time to time. These disagreeable features of the London scene, and the inquiries of a Royal Commission soon to report on the subject, have resulted in the last few months in mental health workers being asked about their views on the causes of prostitution.

⁵ *Women of the Streets*, ed. by C. H. Rolph, 1955, London.

Half a century ago Lombroso regarded prostitution in women as the equivalent of crime in men. If he was right, we should expect to find many varieties of prostitute and many combinations of causes, both psychological and social. Unfortunately, less is probably known about prostitutes than about criminals, since few are seen by psychiatrists in hospitals or penal institutions. The late Sir Norwood East,¹ with his immense experience of all sorts of offenders, suggested that "prostitution depends on personality rather than personality upon prostitution." In the search for such personality factors the question is sometimes asked why more women do not become prostitutes, and to do this immediately reveals the weakness of earlier explanations that prostitution is due merely to laziness, to being oversexed, to poverty, or, more recently, to being sexually frigid; for these apply to many women who never become prostitutes. If present, they must be combined with other qualities, and the same may be said of subnormal intelligence. Prostitution is one of the few occupations open to the mental defective, and there seems no doubt that there is still a steady recruitment of defective prostitutes, though social workers are generally agreed that they see fewer to-day. In a remand home for juvenile girls T. C. N. Gibbens² saw a small number of immigrant Irish or Cypriot mentally defective prostitutes brought up in primitive and morally debased homes in which prostitution was almost familial; and there are English equivalents. More might come from studying those features which distinguish the prostitute from other women.

Havelock Ellis was the first to draw attention to the frequency of homosexual practices between female prostitutes. East was inclined to regard this as the result of lack of affection in their heterosexual lives: nowadays we tend to ask if it may not be the cause of it. E. Glover,³ in his detailed review of psychopathological features, stressed the regressive nature of the behaviour reflected in other features of the personality. The sexual frigidity reported by many prostitutes is not peculiar to them, but Glover thought that in them it was due to unconscious homosexuality, and unconscious antagonism to the male and jealousy of him. Frigidity is far from universal among prostitutes, and some seem to show sado-masochistic attitudes, especially perhaps in relation to their pones or "protectors." Their behaviour, too, seems designed to prove to themselves that sexual emotions have no value—a sort of inverted puritanism.

Another approach to the origin of prostitution is to study it in young girls before many social forces or habituation have had time to operate, and while their development can still be studied accurately. Gibbens⁴

found that 5% of 400 girls examined in a remand home for juveniles aged 14-17 were prostitutes at the time of their arrest, and another 5% of 200 who were followed up took to prostitution in the next few years. Nearly all the girls were sexually experienced or promiscuous and often "on the run." The rarity of prostitution in such wayward girls in itself points to the existence of some emotional predisposition. Three groups were distinguished. The largest was composed of highly intelligent (average I.Q. 125) but very unstable girls; half of them attempted suicide at some time, and many of them had overt homosexual interests. Their background had been extremely traumatic, leaving a tendency to hostility and resentment which disturbed all their relationships. A feature common to all the prostitutes was that they had a thinly veiled hostility to men and fear of being dominated by them. This was also a feature of other girls who seemed in danger of future prostitution—mercenary girls whose lack of feeling allowed them to be contemptuous gold-diggers, and girls who associated with coloured men because they found them less possessive and dominating than white men. Menstrual irregularity, which is rare in wayward girls, was also a feature of the prostitutes. When these young prostitutes were followed up, it was found that most of them gave up prostitution quite readily and many had successful and valuable careers; several became nurses. This raises the question whether prostitution is not usually, like crime in men, a transitory event. Kinsey⁴ insists that "a very high number of the females who engage in such activities do so as a minor adjunct to their regular occupations." The important problem may be why some persist.

Social forces cannot fail to be important in prostitution, and they are emphasized by Mrs. Wilkinson⁵ in her study of London prostitutes. Her most valuable contribution to the psychology of the prostitute concerns the ponce, whom she shows to be actively chosen by the prostitute and faithfully maintained in spite of quarrels and prison sentences. The procurement of prostitutes, like the seduction of homosexuals, is now regarded as of less aetiological importance than used to be thought. It is clear too that, just as the homosexual prostitute is not always very strongly homosexual, the sexual predisposition of the prostitute may not need to be strong to make her succumb to social pressures. Prostitutes have a strong feeling of "us girls" and form a subculture which thrives on the disapproval of society. In this subculture a girl can steal from her best friend and cheat her of her love-partner. This lack of persistent relationships seems elevated to a principle, and it must offer a haven of refuge to those who are incapable of normal or persistent relationships.

The existence of intellectually brilliant young prostitutes is a reminder that throughout history many famous women have been prostitutes or near-prostitutes. The passive, receptive sexual role, and the conventionality which our society imposes upon women, make it difficult on the one hand to detect the nature of their sexual perversions and on the other hand to examine dispassionately the phenomenon of female rebellion or originality. The scores of books on prostitution are, as Kinsey remarks, out of proportion to its sexual, if not its social, significance. With the increasing awareness of the intimate interaction of culture and personality in its production, some progress may be made. And it is increasingly apparent that this will include a close study of the prostitute's client, who keeps up the demand.

TROPHIC LESIONS IN NERVOUS DISEASE

Trophic lesions in the limbs and extremities may result from a variety of lesions of the nervous system. In patients with long-standing disease of the lower motor neurone (as a consequence, for instance, of poliomyelitis) the affected limb may become blue and cold and sometimes swollen, while the skin eventually becomes shiny and atrophic. When the sensory pathways, and particularly those subserving pain sensation, are also affected, trophic lesions may be much more severe, giving rise to chronic ulceration and in certain cases to gross disorganization of bones and joints with extensive mutilation. In all disorders of this nature it is still doubtful how much of the destruction results from repeated painless trauma and how much from loss of nutrition of the tissue owing to damage of autonomic fibres and, secondarily, of blood supply. The peripheral ulceration and deformity seen in the neuropathic form of leprosy is all too familiar in countries where the disease is endemic, while a condition more familiar in Great Britain is the insensitive, scarred, and brawny hand, with perhaps a Charcot's arthropathy at the elbow or shoulder, seen in patients with chronic syringomyelia. In tabes dorsalis, too, perforating ulcers of the soles of the feet and swollen, flail joints in the lower limbs are common. Severe destructive changes of this degree are rare in sporadic cases of polyneuropathy, but here too the hands and feet may be cold, brawny, and swollen and may sweat profusely, while in cases of peripheral nerve lesions, such as severe compression of the median nerve in the carpal tunnel, similar skin changes and even ulceration may occur in insensitive areas.

Less well known is the curious group of disorders to which Dr. L. van Bogaert draws attention in the opening pages of the *Journal* this week. In these the clinical

⁷ Denny-Brown, D., and England, A. C., *A.M.A. Arch. Neurol. Psychiat.*, 1952, 67, 1.

picture is suggestive of a lumbosacral syringomyelia, often occurring in more than one member of a family. Among the many titles used for this group of conditions are Morvan's syndrome, hereditary perforating ulcer of the foot, neurotrophic atrophy, and acro-osteolysis. In many cases of this type the disease gives rise to one or more perforating ulcers of the feet, with blueness and coldness of the limbs, and this may be followed by extensive ulceration, leading to bony destruction and mutilation. On examination the clinician usually finds extensive peripheral loss of pain and temperature sensibility, affecting the lower limbs particularly, but often the hands and arms as well. Whereas in certain cases of this type histological studies have shown cavitation in the central areas of the lumbar spinal cord, like that of syringomyelia, or else an anomaly of cord development or myelodysplasia resulting from incomplete closure of the neural tube, the work of D. Denny-Brown¹ has suggested that in most such cases the primary lesion is in the posterior root ganglia and that the condition is best referred to as "hereditary sensory neuropathy." When occurring in a young child the condition may present as an apparent congenital indifference to pain,² which was discussed in these columns earlier this year,³ but testing will reveal that the insensitivity is peripheral in distribution, unlike the rare cases of "pain asymbolia" which are relatively unaffected by painful stimuli applied to any part of the body.⁴ The fact that deafness is almost always found in patients with sensory neuropathy suggests a close relationship between this disorder and the "heredopathia atactica polyneuritiformis" of S. Refsum.⁵ Since Morvan's description in 1833 was of a disease occurring in a group of fishermen in Brittany, it is of interest to note that C. Andrade⁶ has recently described a form of peripheral neuropathy, shown histologically to be due to primary amyloidosis and giving trophic lesions and pain loss in the lower limbs, which was endemic in the fishing village of Povoia de Varzim in Portugal. In other words, there seem to be many different degenerative neurological syndromes which differ in detail but have as a common feature genetic determination, perforating ulcers of the feet and other trophic lesions leading to mutilation, and peripheral sensory loss affecting principally pain and temperature sensation. The fact that changes of this type occur in certain families with peroneal muscular atrophy⁷ and Friedreich's ataxia suggests that hereditary degenerative neuropathy may be another of those hereditary degenerative disorders of the nervous system which may sometimes occur alone in pure form, but may on other occasions be combined with other member diseases of the "hereditary ataxia" group in various combinations.

Finally, there are the disorders believed to be due to disturbances of the autonomic nervous system which give rise to trophic lesions in the extremities. The swollen, cyanosed, and burning hands and feet of the infant with pink disease are well known to every paediatrician; while in some cases the condition is attributable to mercury poisoning, in others the nature of the neuropathic disturbance remains unknown. Little, too, is known about the aetiology of causalgia, of the post-

traumatic Raynaud phenomenon, and of the shoulder-hand syndrome, though the relief experienced in each of these conditions after sympathectomy suggests that a disturbance of the autonomic nervous system is responsible. Causalgia takes the form of an intense burning pain and hyperaesthesia in the distribution of a peripheral nerve (usually the median or sciatic), and usually follows an injury to the nerve. The post-traumatic Raynaud phenomenon generally follows a non-specific injury to the upper limb or else occurs in workers who use vibrating tools; the hand may become cold, swollen, hyperhidrotic, and intensely painful. The condition is closely related to the shoulder-hand syndrome, in which a similar painful swelling of the hand is associated with a pericapsulitis of the shoulder-joint. The latter condition, which may follow upon trauma or cardiac infarction, may, if severe, result in atrophy and decalcification of bones of the extremity (Sudeck's atrophy). Clearly much remains to be learned about these curious conditions. Indeed, the entire range of trophic disorders occurring in neurological disease and their prevention are worthy of study, for they may be a serious cause of disability.

FALSE ADMISSIONS OF PATERNITY

Most lawyers in Great Britain are well aware nowadays that paternity can be positively excluded if the putative father's blood group is genetically incompatible with that of the child. An unusual case heard recently in the Scottish Court of Session is reported in our medico-legal column this week (p. 417). But magistrates cannot compel a mother in affiliation proceedings to submit herself or her child to a test, and in consequence the court often has to come to a decision on incomplete evidence. However much the putative father may ask for a test, which, if he is falsely accused, will give him something like a 50% chance of conclusively clearing himself, the court cannot order one to be made. In practice no court draws an inference adverse to the mother if she refuses to submit to a blood test for herself and her child when invited by the putative father's advisers to do so.

A recent report¹ from the U.S.A. points to some anomalies, which might also be found in Britain. L. N. Sussman and S. B. Schatkin, of New York, persuaded the parties in proceedings for affiliation in the United States to submit themselves to blood tests after the putative fathers had admitted paternity and the equivalent of affiliation orders had been made against them. The investigators observe that obtaining the co-operation of the parties after their cases were completed was understandably difficult. Nevertheless they were able to make tests on the parties in 67 cases, and these showed that in no fewer than six cases the putative father who had not disputed paternity could not have been the father of the child. The investigators state that in the United States most men involved in paternity suits do not contest the charge, and it is only those who do so who are privileged by the law of many states to request blood

¹ Sussman, L. N., and Schatkin, S. B., *J. Amer. med. Ass.*, 1957, 164, 249.

tests to sustain their denial. They comment that the result of their investigation shows it to be in the interests of justice that a blood test should be ordered in every case where paternity is in issue, so that even a putative father who from whatever motive is prepared to admit paternity, or is deceived into doing so, will at least not be held to be father of a child who, unless the highly improbable event of a suitable mutation has occurred, cannot be his own. They conclude that the demonstrated unreliability of admissions of paternity should be drawn to the attention of the proper authorities.

Whatever may happen in the U.S.A., no change is likely in England. When a putative father is prepared to accept responsibility for a bastard, the mother's corroborative evidence is essential here before an order can be made, whether he admits paternity or not; and, even if abstract justice requires the exclusion of such error as can be excluded by blood tests, it is difficult to imagine that Parliament in the interests of justice would interfere to make that exclusion compulsory.

SANITATION AND POLIOMYELITIS

A patient with poliomyelitis may excrete in one gramme of faeces enough virus to infect one million monkeys.¹ Half the patients are still excreting virus after three weeks, and some continue to excrete it up to twelve weeks. Since many rivers, streams, and ditches in Great Britain, as in other countries, are polluted by human excreta, it is a wise precaution to advise parents to keep their children away from them when cases of poliomyelitis are occurring in the area. Medical officers of health in many districts have found it advisable this summer to give this warning, and to emphasize that hygiene in the home may help to prevent the disease. Flies are known to be capable of carrying faecal material contaminated with virus, so that measures to destroy them and to prevent any reaching food are well worth carrying out assiduously. Yet the curious fact remains that sound evidence is still lacking that poliomyelitis is mainly a water-borne or food-borne disease, like dysentery, for instance, or food-poisoning, though a recent study² in the U.S.A. suggested a connexion between cases of the disease and a water supply contaminated with excreta from lavatory pans. Careful studies have shown that the virus is usually spread by close contact, and that the path of its spread, when it can be traced, is sometimes quite narrow.³ How wide or narrow this path of infection may be is still disputed,⁴ but observers seem to be agreed that poliomyelitis is what has been called a family disease. Spread of infection within a family is so rapid that when a case is detected all the other members of the household are normally found to give serological evidence of infection. Transmission beyond the bounds of the family seems to be principally by personal con-

tact at work—as doctors in particular know⁵ from the additional risks they run—or at play from child to child in gardens and streets.

As well as advocating hygiene in the home, early reporting of feverish illness, and moderation in exercise, some form of segregation of contacts is generally held to be desirable, a period of three weeks being suggested.⁶ A final point worth considering is whether people should be advised to stop bathing off the shore of a seaside resort where cases are occurring. If sewage containing poliomyelitis virus is pumped into the sea and it comes into contact with bathers, there would seem to be some risk of disease being thus transmitted. No outbreak of poliomyelitis has been tracked down to this particular source, and it is probably a reasonable inference that the risk of infection, at present, is exceedingly slight. But while coastal resorts continue to grow, and more and more people take seaside holidays, England is fast becoming a jewel set in a sea not of silver but of sewage. A thorough study of this public health problem seems overdue.

PINK DISEASE

Even to those enjoying normal colour vision the aetiology of pink disease is evergreen. Presenting in infancy, of self-limited duration, and rarely recurrent, it appears to be commoner in some regions than in others. Such features as cold, pink extremities, pain, misery, trophic changes, profuse sweating, sudaminal rashes, tachycardia, hypertension, constipation, and dysuria appeared to E. Feer to be due to a disordered vegetative nervous system.⁶ Others have pointed to the possible aetiological role of such insults as measles, maternal deprivation, and mercury. Impressed by some resemblances to mercurial poisoning, J. Warkany and D. M. Hubbard⁷ successfully demonstrated abnormal amounts of the metal in the urine of infants with pink disease, and this has been confirmed repeatedly. But infants may ingest mercury without absorbing mercury in any form. Some "mercurial pinks" have responded to dimercaprol, many have not, and some have responded although they excreted no mercury before, during, or after treatment. Others have successfully survived treatment with mercury before, during, and after the condition. Hypersensitivity to mercury has been postulated to explain why so few infants receiving mercurial medicines develop pink disease. Yet the infants of Warwickshire, according to A. Holzel and T. James,⁸ ingested mercurial powders five times more frequently than those of Manchester, but had less than a quarter of the latter's incidence of pink disease; other,

less likely, mercurial medicines were not considered by them. Because of concern about the possible aetiological role of the metal it was withdrawn from popular "teething powders," and prescriptions have decreased. According to T. Colver⁹ a rapid fall in the consumption of mercury by Sheffield infants has been paralleled by a decreased incidence of pink disease, though the fall in incidence of the disease appears to date from 1951, whereas mercury-free teething powders became freely available in 1954. A reasonable case against the use of mercury exists, however, and there are less harmful and equally efficacious remedies for the fretful or infected child.

In a paper entitled somewhat prematurely "Pink Disease, Its Nature, Prevention and Cure" D. B. Cheek and C. S. Hicks¹⁰ recorded that deficiency of water and salt occurred in this condition, and they ascribed this to stress hypoadrenocorticism. According to them the chain of events is that water moves into the cells, with resultant cell turgor and cerebral oedema, shown by irritability and photophobia. Haemoconcentration explains the high haematocrit, raised serum protein, tachycardia, hypertension, stagnation, anoxia of the peripheral organs, and constipation. Heat regulation is impaired and compensatory sweating takes place. Administration of salt, water, and deoxycortone resulted in dramatic improvement. As the authors said, "The theory was found to apply almost suspiciously well." The electrolytic and therapeutic findings were not reproduced in Melbourne¹¹ or in the more temperate United Kingdom. Further work by Cheek¹² confirmed the occurrence of oligoemia and hypochloroemia and the limited value of salt and deoxycortone. He considered that steroid studies provided evidence of hyperadrenocorticism in pink disease, and he quoted experimental evidence for his belief that hypokalaemia also existed. The basic upset appeared to be the loss of water and chloride, but replacement of these was not curative.

Workers investigating apparently unrelated aetiological theories may sometimes find they share common ground, and Cheek¹³ has wedded his ideas to those that blame mercury. The result is attractive, and would be more so if all pink disease were undoubtedly due to this metal. He now believes that the renal tubules of the hypersensitive child are damaged by mercury; rejection of water and chloride results in an initial diuresis, and total volumes of body water and chloride are impaired. The resultant oligoemia and hypochloroemia initiate the resultant chain of events described above. The kidney gradually succeeds in conserving water, but loses salt until spontaneous remission begins. A possible increase in metabolic rate is suggested to explain the increased sweating, which Cheek believes to be unsurpassed in any other disease. The electrolyte content of the sweat is low, as in heat stress, but the volume is so great that the total loss of electrolyte in this way is high. Some would say the sweating of phaeochromocytoma was even greater, and D. Hubble¹⁴ and D. G. Vulliamy¹⁵ have found that the two conditions have much in common. The clinical picture of phaeochromocytoma results from the action of sympathetic amines, and according to J. W. Farquhar

and colleagues¹⁶ they may be excreted in excess in pink disease. These authors consider the possibility of pink disease being the result of a central disorder of sympathetic control and are thus in accord with Feer⁶ and D. Leys.¹⁷ Why should the sympathetic nervous system be deranged? Here some would agree with Cheek's original conception of response to stress. Perhaps like a number of other conditions pink disease may result from the conjunction of a constitutional factor and an environmental stress. Of the latter mercury may be the most important and is best not given. Deficiency of salt and water, when present, should be remedied, but symptomatic relief of the child's distress is more likely to follow the skilful use of an autonomic blocking agent.¹⁸

DRUGS FOR PRIVATE PATIENTS

A Bill to amend Section 38 of the National Health Service Act, 1946, was presented by Mr. John Hall and Mr. Ronald Bell on July 31. The amendment sought reads as follows:

"Notwithstanding anything contained in section thirty-eight of the National Health Service Act, 1946, every private patient of a registered medical practitioner shall, as from the passing of this Act, be entitled to be supplied with drugs and medicines and prescribed appliances pursuant to the said Act, on the same terms as patients who are registered with a medical practitioner who provides general medical services under the said Act."

It is satisfying to see this aspect of Association policy receiving this degree of support. The arguments in favour of allowing patients to enjoy benefits of any part of the N.H.S. are well known and need not be repeated here. Apart from any argument, the public was promised this before the appointed day. But the drafting of the Act made it possible for the politician to take refuge from an action that might be politically unsafe. Members of the Association who are especially interested in the Association's policy of free drugs for private patients can support it by urging their M.P.s to see that Mr. John Hall's and Mr. Ronald Bell's Bill gets a fair hearing.

PRINCIPAL AT BANGOR

Mr. R. C. Evans, F.R.C.S., has been appointed principal of the University College of North Wales, Bangor. One of the most experienced mountaineers in the world, Mr. Evans played a prominent part in the 1953 Everest expedition, when Hillary and Sherpa Tensing reached the summit. Two years later he led the expedition which climbed Kangchenjunga for the first time. Now aged 38, Mr. Evans qualified with the Oxford degree in 1943, and after serving in the R.A.M.C. took the F.R.C.S. in 1949. In 1956 he received the honorary D.Sc. from the University of Wales. At present Mr. Evans is working as surgical registrar with the United Liverpool Hospitals (Royal Southern Hospital). He will give up medical practice when he takes up his new duties next year. At Bangor he will have the pleasure of living within sight of the Snowdon range, where he gained his first experience of mountaineering.

CONGRESS OF NEUROLOGICAL
SCIENCES

[FROM A SPECIAL CORRESPONDENT]

The First International Congress of Neurological Sciences was held in Brussels on July 21-28. It was opened by the Belgian Minister of Health in the presence of the King of the Belgians. The president of the congress was Dr. P. VAN GEUCHTEN (Brussels) and the secretary-general Dr. L. VAN BOGAERT (Antwerp). All the scientific meetings were held in the spacious Palais des Beaux-Arts. The congress evolved in the following way. The First International Congress of Neurology was held in Berne in 1931, and subsequent meetings were held in London, Copenhagen, Paris, and Lisbon, so that this became the sixth international congress of neurology. Before the war the International League Against Epilepsy was formed, and this association was due to hold its fifth international conference. This year was also the time for the third international congress of neuropathology, the fifth congress of neuroradiology, and the fourth international congress of electroencephalography and clinical neurophysiology, and for the first time there was an international congress of neurosurgery. About two thousand members attended the congress, of whom about half were neurologists. The largest contingents came from Great Britain, the United States, France, and Germany, but the international nature of the meeting was upheld by members from Chile and Japan, from Venezuela and Yugoslavia, from Poland and Peru. This year also witnesses the centenary of the births of Sherrington, Horsley, and Babinski, to all of whom homage was paid respectively by Dr. RAYMOND GARCIN (Paris), Dr. ERNEST SACHS (Newhaven), and Sir GEOFFREY JEFFERSON (Manchester).

Extrapyramidal Surgery

A joint meeting of all the disciplines, dedicated to the memory of Sir Charles Sherrington and devoted to the study of extrapyramidal pathology, was held on July 22 under the directorship of RAYMOND GARCIN. Modern surgical methods in the treatment of Parkinsonism were reviewed, particularly the destructive procedures directed to the globus pallidus. This subject was again discussed at the neurosurgical congress, with particular reference to stereotaxic methods. There is already one surgeon in the United States who has operated on 450 Parkinsonian cases. Everybody was convinced that chemical pallidectomy has something to offer in certain carefully selected patients, but the procedure is by no means simple, nor is it always effective, and it carries risks of such complications as hemiplegia or aphasia; it may indeed be fatal.

On July 23 there was a joint meeting to discuss states of consciousness in neurology under the directorship of Sir Geoffrey Jefferson. The first paper was read by WILDER PENFIELD (Montreal) and largely centred round the centrencephalic system within the higher brain stem, including the diencephalon and mesencephalon. The following thirty-one papers were devoted to such varying aspects of the problem as electroencephalographic studies in the anaesthetic state, and altered states of consciousness following traumatic damage to cerebral white matter and in liver coma. Unfortunately, the value of some of the papers was lost through a failure to define precisely what was meant by consciousness.

On July 24 there was a plenary session of the sixth international congress of neurology on disseminated sclerosis and demyelinating diseases under the directorship of HOUSTON MERRITT (New York). This was opened by G. H. MONRAD-KROHN (Oslo) and was followed by speakers from widely scattered countries. Many papers, both at this meeting and at another being held at the same time, were devoted to the experimental production of demyelination. Much work on allergic encephalomyelitis has been carried out, though nobody has yet produced disseminated sclerosis

in the experimental animal. Among other matters that emerged were the following. Disseminated sclerosis and cervical spondylosis have now been found in combination in a number of patients, including some cases at necropsy. The level of gamma-globulin is raised in the active phases of disseminated sclerosis (which is closely tied to the finding of a positive Lange curve) and the level can be reduced to normal by giving A.C.T.H. One claim was made that A.C.T.H. given over a period of three years appeared to have achieved some therapeutic success, and a similar claim was made for repeated blood transfusions. It also became apparent that disseminated sclerosis is not completely unknown in such countries as India. Geomedical studies are being carried out in many countries, including Hungary, Argentina, and Brazil. There seems to be no doubt that disseminated sclerosis is commoner in colder climates, the incidence in the northern United States being much higher than that in the deep south.

The international congress of electroencephalography and clinical neurophysiology met on five days, during which over two hundred papers were read. These were largely devoted to electroencephalography. The impression grew that neurologists and neurosurgeons are tending to divorce themselves from electroencephalography and it is passing more into the hands of psychiatrists. This is unfortunate, but it would certainly seem that electroencephalography is evolving to a point where a full understanding is likely to be beyond the ability of most practising clinicians, in sharp contrast, for example, to electrocardiography.

The international congress of neuropathology was held on three days and there were more than a hundred communications on a very wide range of subjects, some of a highly technical nature. The first international congress of neurosurgery was held on three days. One morning was devoted to a discussion on the use of hypothermia, under the directorship of E. H. BOTTERELL (Toronto), and an afternoon was devoted to the study of supratentorial angioma, under the directorship of H. OLIVECRONA (Stockholm). The fifth international congress of neuroradiology was held on three days, and on another occasion there was a joint meeting with neuropathologists to discuss the pathology of ionizing radiation, under the directorship of W. HAYMAKER (Washington).

In addition to the discussions on limited subjects there were many scores of papers on unrelated matters, and in many cases a chairman was reduced to reading a short summary of a group of papers.

Neurology Fragmented

A round-table conference met on July 27 to discuss "Neurology at the Cross-roads." This was opened by Sir FRANCIS WALSHE (London), who was followed by G. H. MONRAD-KROHN (Oslo), G. SCHALTENBRAND (Würzburg), I. S. WECHSLER (New York), and MACDONALD CRITCHLEY (London). The speakers' main theme was the unfortunate way in which the "neurological sciences" are becoming fragmented. In the international congresses held before the war the various disciplines were all represented under the general heading of "neurology." It was felt that the present tendency to break away was likely to have unfortunate results and that if neurologists were not careful they might be reaching the stage of the expert in lumbar puncture or even in the right, as opposed to the left, plantar response. A comparison was made with cardiology, where there seemed to be no tendency to divide the subject into groups of cardiac physicians, surgeons, pathologists, and electrocardiographers. Although there was a good deal of destructive criticism there were few suggestions on the treatment of the problem, but the four older speakers clearly had a nostalgia and a desire to return to the old type of conference with the term "neurology" being all-embracing. It would seem, however, that this is unlikely to occur.

The Belgian neurologists must be congratulated on a triumph of organization. For the inveterate monoglot the portable earphones and the rapid translation of all papers

into four languages was a great advance over the days when it was impossible to follow three out of four communications. It is probably true to say that most people felt that at the end of the conference any thirst for neurological knowledge was left largely unslaked. All the publications were printed *in toto*, so that there was little need to hear them spoken, but it was generally felt that it would have been better to have had fewer communications and more time for discussion.

POLIOMYELITIS VACCINE

MINISTRY OF HEALTH STATEMENT

The following statement in the form of question and answer was issued by the Ministry of Health last week:

Q.—Who advises the Minister on polio vaccination?

A.—The Medical Research Council and its expert committees, including one dealing with safety tests; and the Joint Committee on Poliomyelitis Vaccine, which sits under the chairmanship of Lord Cohen of Birkenhead. The Joint Committee includes virologists and immunologists who have special knowledge of polio problems.*

Q.—What are the Government's intentions as to the import of vaccine?

A.—All the present evidence is that the British vaccine is superior, in both safety and effectiveness. The main difference is that it does not include the virulent Mahoney strain of virus, which was at first tried in this country on an experimental basis and was abandoned, and which in 1955 was responsible for an accident which led to a number of cases of paralytic polio in vaccinated children in the United States.

Suggestions are sometimes made that the import of Salk vaccine now could reduce the incidence of polio this year. That is not so. Assuming that the safety tests to which British vaccine is subjected were applied, these would take about three months. To this must be added the time needed for the inoculations to be given and to take effect. In the average case polio vaccine takes up to two months to give protection.

There is a constant exchange of information, both through the World Health Organization and direct with other countries, including Canada and the U.S.A. We have been considering for some time and have now decided on the dispatch of a special team to Canada and the U.S.A. to investigate the desirability of obtaining further supplies of vaccine, against any outbreak next year, by the manufacture overseas of British type vaccine. In addition the team will discuss with the appropriate authorities the present position regarding the safety and potency of Salk vaccine. Again it should be emphasized that this cannot have any bearing on supplies of vaccine this year. In the long term the principal supply of vaccine will be drawn from this country in view of its unrivalled record of safety.

Q.—Why does the Government allow the import of small quantities of Salk vaccine?

A.—Because we do not wish to exercise a rigid control over individuals who have been sent gifts of small quantities for family use, the Customs have been authorized to release small packages of vaccine provided it is clear that a doctor has taken responsibility for injection, having been told by us that the vaccine does not necessarily conform to the standards of safety and efficacy required of the English

*The members of the Joint Committee on Poliomyelitis Vaccine are:—Members of the Central Health Services Council: Lord Cohen of Birkenhead, Sir Russell Brain, Dr. C. Metcalfe Brown, Professor R. Cruickshank, Dr. W. V. Howells, Dr. W. P. H. Sheldon. Member of Scottish Health Services Council: Dr. J. Riddell. Other Members: Professor S. Alstead, Professor A. Sir Samuel Bedson, Professor C. H. Stuart-Harris, Professor A. Bradford Hill, Professor J. W. Howie, Professor H. J. Seddon, Professor E. T. C. Spooner, Dr. G. W. H. Townsend, Professor G. S. Wilson, Professor Wilson Smith, Professor Wilfrid Gaisford, Professor J. L. Henderson, Dr. H. N. Rose.

vaccine. The number of packages dealt with in this way has been quite small—33 in May, 48 in June, and 58 in July. There may also be a little brought in by travellers for the use of their families. These arrangements apply only to small quantities for private use and not to the import of large batches for the vaccination programme under the National Health Service, since that would imply a degree of responsibility for its safety and efficacy which, in the light of the expert advice received, the Government has so far felt unable to accept.

Q.—Why should not supplies of vaccine be concentrated in those areas which are suffering from outbreaks of polio?

A.—Since vaccine is distributed as it becomes available, there is no reserve. Therefore diversion to places where the incidence of polio is highest could be done only at the expense of other areas. But, with polio infection widespread in the country, any area is at any time liable to suffer an outbreak. It would therefore be difficult to justify a reduction in the supplies of vaccine available to areas where for the time being the incidence of the disease is low, particularly since the protection given by the vaccine takes up to two months to develop. Indeed, vaccination is not generally regarded as a suitable emergency method of checking a local outbreak of polio which is under way; and, as the Joint Committee on Poliomyelitis Vaccine recognized and the World Health Organization pointed out as recently as July 24, it may even in certain circumstances be advisable to suspend vaccination for a time if an outbreak is particularly intense.

Q.—How much vaccine has been issued and what is the Government's programme?

A.—Including Scotland, enough has been issued for two doses for over 1½ million children. Further batches are in continuous production, and one sufficient for another 160,000 children is going out next week. In accordance with the advice received from the Joint Committee on Poliomyelitis Vaccine, which sits under the chairmanship of Lord Cohen of Birkenhead, priority is being given to children up to 10, who are by far the most vulnerable group. The incidence of the disease is highest in the lower age groups. In the two most recent years the incidence rate of paralytic attacks was in the 0-4 age group three times, and in the 5-9 age group more than twice, what it was in the 10-14 age group. Best results can therefore be expected to come from concentrating vaccination on the children under 10 years of age.

The number of children born between 1947 and 1954 who registered last year was 1,910,000, or 30% of those eligible. A second chance is now being given to the parents of children in this group who did not put their names down last year. Children born in 1955 and 1956 have just been given the opportunity of being registered, and in England and Wales so far only a little over 300,000, or about 23% of those eligible, have had their names put down. The vaccination of the children originally registered should be completed this autumn. Local authorities will then go straight on to this year's registrations. Then the question of further registrations can be considered. In this very unpredictable field, and bearing in mind the complexity of the necessary testing procedures—the standard of which must be maintained—the time when batches will become available cannot be forecast with any exactness, and a more detailed programme of future progress is therefore not possible.

Q.—Why has British production been so small?

A.—The production of a safe and effective vaccine involves some of the most complicated processes ever undertaken in this field. When the plans were first announced in January, 1956, they were based on estimates of production provided by two firms. One of these firms has produced over 2½ million safe doses of vaccine and is now in the process of expanding its capacity by 50%, and the Ministry would like to pay a tribute to them. The other firm experienced a number of initial difficulties but is now expected to come into production in September or October. Barring

the unforeseen, we can therefore look forward to a steady expansion of supplies.

Q.—What is the present incidence of poliomyelitis? Is this a bad year?

A.—The total number of cases notified since January—including the figures for the week ended August 3—is 2,366, and of these 1,412 were of the paralytic type. This total was exceeded in 1950, when at this time a total of 2,591 cases had been notified, of which 1,863 were paralytic. The majority of paralytic cases recover completely. The weekly total for the week ended August 3 was 260 cases (141 paralytic). This total was exceeded in the corresponding week in 1950 (367), 1953 (297), and 1955 (307). It is not possible to forecast what the incidence of the disease will be during the rest of the year; but so far as we have gone it is somewhat above average this year, but so far less than 1950. The incidence of the disease is widely scattered through the country. For example, eleven areas reported more than 5 cases in the week ended August 3. Certain areas may be reporting a high incidence now, but other widely separated areas may be affected in coming weeks. It is not possible to predict when a local outbreak will occur.

CONGRESS OF NUTRITION

[FROM A SPECIAL CORRESPONDENT]

The fourth International Congress of Nutrition was held in Paris on July 26–August 1 under the presidency of Professor E. F. TERROINE. It was chiefly concerned with the influence of nutrition on lactation, reproduction, the skin, the digestive flora, and old age, though there were other communications on widely differing aspects of nutrition.

Nutrition and Old Age

M. COPPO (Modena) distinguished senescence as physiological from senility as pathological, and his remarks were concerned only with senescence, though he admitted that the boundary between the two was difficult to define. The only nutritional feature of old age that differed from youth was the reduced calorie requirements, these gradually falling as age advanced. There were no marked differences in the need for proteins, carbohydrates, fats, or vitamins between the young and old, though Coppo showed that blood levels of vitamin C were lower in old people living alone or in almshouses than in those who still lived with their families. He was convinced that longevity was dependent to a large extent on nutrition, but refused to be drawn on the role of lipids in cardiovascular diseases.

The speakers who took part in the discussion included L. HARRIS (Cambridge), who believed that extra milk should be provided for the aged to counteract the osteoporosis. An objection raised to this was that calcium would be laid down in the aorta and kidney. I. NITZULESCU (Bucharest) felt that the diet of old people should be frugal and regular, though the tendency to obesity must be resisted. "We are as old as our membranes," he said. J. V. G. A. DURNIN (Glasgow) produced evidence to show that the absorption of food in old men was the same as in young men, the only function of the body, he believed, that did not "run down" with advancing years.

The effect of nutrition in childhood on the longevity of an individual was discussed in view of the experimental findings that some undernutrition in young rats allowed them to live longer. The application of this to man was felt to be impracticable.

J. MACDONALD (California) said that in the U.S.A. all persons over 7 years old had at least one atheromatous plaque, whereas such tribes as the Bantu in South Africa got no such lesions. This, he felt, might be a reflection on nutrition, but he was uncertain of the course to adopt to prevent it. One school of thought believed a high-protein, low-fat, low-calorie diet with adequate essential fatty acids would delay cardiovascular catastrophes, while another

advocated a *laissez-faire* policy towards the diet so long as the body weight was kept down.

Nutrition and the Skin

Reviewing nutrition and the skin in man, H. M. SINCLAIR (Oxford) pointed out that the skin reflects in various ways many nutritional disorders. The generally accepted symptoms of pallor, coldness, acrocyanosis, and pigmentation seen when calories were deficient and the classical skin lesions when vitamins A and C were deficient compared with the controversial lesions that might be due to a shortage of the essential fatty acids. These substances, which were compounds containing one or more double bonds, were considered by Sinclair to be essential to the well-being of skin, though evidence for this in man was difficult to obtain. Certainly in experimental animals the skin was markedly affected in the absence of essential fatty acids. The intentionally provocative nature of this review had its reward in that an interesting discussion followed, and the majority of the speakers supported Sinclair's views on the importance of the so-called essential fatty acids.

Bread and Fish

There were many interesting papers apart from the main reviews. One was given by R. S. HARRIS (Massachusetts) on bread. Detailed analyses had been done on samples of bread bought in the shops of twelve countries. The findings were placed in order of amount of the constituent found, and this showed that at the top of the list came bread from Finland, which had been enriched with milk. It is felt that it is desirable to add milk to the bread. Surprisingly at third place in the list of twelve was rye bread from Denmark. No British bread was examined.

A. HORVAT (Zagreb) found a high incidence of goitre in schoolchildren on a Croatian island despite the relatively high consumption of fish. There was a low intake of vitamin A, and in a controlled study the goitres of children receiving extra vitamin A daily for three months were found to have decreased by almost half in this time, showing that thyroid enlargements might not be due solely to a disturbance of iodine intake.

Many findings on deficiency of protein were presented. The French school in Dakar, and notably A. Raoult and J. Sénécal, are very active. The emphasis on protein deficiency as a cause of kwashiorkor seems to be shifting to the idea that it is due to an imbalance of protein and possibly other constituents in the diet. Several speakers described attempts to find one biochemical change that would assess the extent of this form of malnutrition, but it does not seem that any great success has yet been achieved.

Fats

The nutritional value of intravenous fat emulsion was assessed in some experiments carried out by B. S. M. LEVENSON (Washington, D.C.). Fat was given intravenously in addition to food by mouth and later isocaloric amounts of the fat were given orally. It was found that the infused fat emulsion had a calorie- and protein-sparing ability that was roughly equivalent to that of intravenous glucose and oral fat, which showed therefore the usefulness of infused fat emulsions.

Points of practical clinical importance came from the work of M. BARTCHENKO (Kiev) and A. GREIG (Glasgow). The former found that not only do cheese, yeast, and sour milk increase the protein and fats in human lactation, but the point was made that isolated foods such as fruit juices, and in particular blackcurrant juice, also had this beneficial effect on maternal mammary secretion. GREIG found in mice that excessive calcium carbonate in the diet led to a hypochromic anaemia because the carbonate had acted as an antacid and by neutralizing the gastric hydrochloric acid had diminished the amount of iron in absorbable form. Therefore there might be a danger to patients maintained for long periods on an antacid regime unless an iron supplement was given.

Preparations and Appliances

A STANDARD DIATHERMY CYSTOSCOPE

Mr. E. W. RICHES, M.S., F.R.C.S., surgeon and urologist, the Middlesex Hospital, writes: A further addition has been made to the standard cystoscopic instruments

previously described (Riches, 1955). It is based on Frank Kidd's diathermy cystoscope (1925), which was designed for the destruction of large papillary tumours of the bladder at a single session. The use of that instrument over many years has given convincing evidence of its value, but it suffers from the drawbacks of having a small field of vision and in particular a small irrigating channel. Moreover, its bakelite construction makes it fragile and has been found unnecessary.

The present instrument (see Fig.) consists of a metal tube of size 52 Bé (26 Ch) terminating in a stainless-steel ball electrode size 48 Bé (24 Ch); the distal 1.5 cm. next the ball electrode is insulated by plastic material. At the proximal end is a fixed male terminal directed towards the same side as the ball and fitting the standard diathermy cable supplied for bladder electrodes, resectoscopes, and haemostatic forceps. Proximal to this is a single large-bore irrigating inlet on a rotating collar; the standard three-way stopcock supplied for rotating cystoscopes and biopsy forceps fits it, and no change is necessary when substituting one instrument for the other. The obturator, telescope, and faucet are locked in position in the same way as those of the cystoscope, and are easily unlocked by aligning the two short vertical posts. The unlocked telescope with an angle of view in water of 64 degrees covers a field of approximately 1½ inches (3.8 cm.) when the electrode is placed in contact with the tumour. The same faucet is used as for the cystoscope; a bladder syringe fits it internally or a Freyer's evacuator externally, making periodic removal of debris possible. The volume of irrigating fluid passing through the sheath around the telescope is, however, such as to render long periods of coagulation possible without removal of the telescope.

A new spark-proof switch is provided for the lighting circuit; it incorporates a condenser which by damping the circuit precludes all chance of overloading the lamp when the diathermy is switched on. The same switch without the adapting fork can be used for the standard cystoscope, and should be used for the resectoscope.

With this instrument it is possible to destroy cystoscopically large papillomata or papillary differentiated transitional-cell carcinomata of low-grade malignancy. It is desirable that biopsy of all bladder tumours should be performed, but if the cystoscopic appearances suggest that diathermy destruction is possible it is our practice to take the biopsy and proceed at once to coagulation. The effective irrigation system usually allows any bleeding from the biopsy cut to be quickly checked. Donovan (1950) has pointed out that the diathermy current destroys the tumour by pro-

ducing heat coagulation throughout its extent, and that the heating effect increases with the size of the electrode. Although influenced by other factors, the depth of coagulation is roughly equivalent to the diameter of the electrode, which in this case is 8 mm. It is possible with this cystoscope to coagulate and evacuate the bulk of the tumour, leaving a hard core to which deep and prolonged coagulation can be given. This takes time to separate, and after a bladder tumour has been so flattened the slough may not separate for from four to six months. At the end of a year

the area can usually be detected by a white area surrounding a small central pit.

Treatment by coagulation diathermy will not destroy solid infiltrating tumours, which should be treated by excision or irradiation. Tumours situated close to the internal meatus cannot be reached by this cystoscope; they are better treated by a resectoscope or panendoscope fitted with a fore-oblique telescope.

The instrument has been made by the Genito-Urinary Mfg. Co., Ltd., and I am particularly indebted to Mr. A. E. Bean for the improvements he has made in the optical system.

LAMINECTOMY RETRACTORS

Mr. K. F. HULBERT, consultant orthopaedic surgeon, Dartford Group of Hospitals, writes: The usual type of self-retaining laminectomy retractor has several shortcomings. In fat people the blades are often not deep enough to reach to the depths of the lumbo-sacral wound; the mechanical

efficiency of the apparatus is such that great manual strength is required to open the blades wide enough, and the blades slip too easily.

A laminectomy retractor (see illustration) has been made for me by Messrs. A. L. Hawkins and Co. Ltd., 15, New Cavendish Street, London, W.1. It is an adaptation of a Kirschner wire calliper and tightener with adjustable blades that can be made to any design and are removable. The blades are of two or more prongs, the ends being sharp to avoid slipping and deep enough to reach to the depths of the wound. Retraction is obtained by turning the screw without great manual effort.

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

British Medicine Abroad

SIR,—Having worked during the latter years of the war for the British Council in Turkey, I can confirm all that appeared in your leading article (*Journal*, August 3, p. 281).

Until the Medical Department of the British Council initiated its activities in the countries of the Middle East, little was known in that part of the world about British medicine. On the other hand, Germany used its commercial houses to conduct propaganda, and Bayer Products were the best agents that Germany could have had for extolling that country's achievements in medical and allied sciences. Slowly the influence of the British Council gained ground, aided by the establishment of a medical library and information service and the gradual development of the *British Medical Bulletin* into the now well-known series of research symposia, and the achievements of Britain in the field of medicine became accepted. There followed a heavy demand for British books, pharmaceuticals, instruments, hospital equipment, and so forth. Turkish doctors wanted to study in Britain instead of Germany, Austria, France, Switzerland, as in the past. But now the tide has turned and we are displaced with detriment to ourselves. Germany has regained her position and the U.S.A. has become the medical Mecca.

It may be argued that as medical men we should not concern ourselves with what happens beyond the white cliffs of Dover. But this is a specious and dangerous argument, since we are all involved in the survival of Britain. Decline of our prestige and our exports will affect every individual in this country whatever his profession. I once heard an American colleague in an after-dinner speech praise the British Council for teaching foreign students English so that they could read American books and study in his country.

More funds for the display of British medical journals in the British Council's reading-rooms and for their inclusion in specialist exhibitions would be welcome, but even more valuable would be positive action by the Government to make possible their purchase by would-be subscribers in countries where lack of sterling at present makes this impossible: Israel, Turkey, Indonesia, Pakistan, and now India. The Americans are already doing this; the fact that Britain cannot afford to do as much as they do should not be an excuse for doing nothing.—I am, etc.,

London, W.C.1.

W. C. W. NIXON.

Blood Group Chimeras

SIR,—Dr. F. Marsh (*Journal*, July 6, p. 44) postulates that the Rh (D) type of mother may influence whether or not her Rhesus-negative daughter in later life would produce antibodies if exposed to the D antigen by pregnancy.

In 1952-3, following earlier suggestions independently made to the National Blood Transfusion Service by Professor Rogers Brambell and Mr. N. A. Mitchison, a study was made of the maternal grandmothers of children suffering from haemolytic disease of the newborn.¹ In the words of Professor Brambell: "The essence of Burnet's marker concept seems to be that the organism cannot produce antibodies to antigens to which it is exposed sufficiently early in its development. Assuming that the maternal blood group antigens, as well as antibodies, can reach the foetus, the young should never be able to develop antibodies to either its own or its mother's antigens. Thus an Rh-negative child of an Rh-positive mother should never be able to form anti-Rh, whereas an Rh-negative child of an Rh-negative mother should be able to do so. Is this the explanation of the erratic reaction to Rh-immunization of Rh-negative people?"

If Professor Brambell's suggestions were correct, provided no other factors were involved, then: (1) there should be an excess of D-negative maternal grandmothers among children with haemolytic disease due to anti-D, and (2) there should be an excess of Rh-positive maternal grandmothers amongst normal Rh-positive children born to multiparous Rh-negative women who fail to produce anti-D antibodies. In 1953¹ the results of four laboratories were pooled and the D type of 113 maternal grandmothers of affected children was studied. They were found to have precisely the calculated number of Rh-positives and Rh-negatives expected. Two other similar studies^{2,3} have been reported, and in none was there any significant deviation from the normal expectation.

On the other hand, Owen *et al.*² suggest that their evidence on a smaller series of cases supports the idea that Rh-negative daughters of Rh-positive mothers are relatively tolerant to immunization if the absence of antibodies is used as the criterion of tolerance. However, they failed to take into account the ABO groups of the Rh-negative wife and Rh-positive husband.

In any attempt to answer the problem of why some Rh-negative women married to homozygous D/D men fail to become immunized, the protective effect of ABO differences between husband and wife, now well established, must be taken into consideration. Furthermore, as shown by Murray,⁴ the Rh genotype of the foetus, whether CDe/cde or cDe/cde, also influences the immunization. Murray's studies suggest the D antigen in combination with E is more antigenic than with C. From the literature it would appear, therefore, that to investigate the suggestion which Dr. Marsh has revived it is necessary to determine the ABO group of the husband and wife and to genotype the husband as well as Rh type the wife's mother. The discovery of a solitary grandmother, as hoped for by Dr. Marsh, will not answer this fascinating problem.

So far as the development of immunological tolerance due to exposure to foreign red cells is concerned, the literature contains confirmation⁵ that the foetus can bleed into the mother, but the reverse phenomenon of maternal haemorrhage into the foetus has not yet been recognized so far as we are aware.

The detection of such a flow in either direction is not easy, the difficulties in each case being different. With foetal haemorrhage into the mother odd agglutinates in a field of free cells are observed (the mixed field picture) when the mother's red cells are tested with certain antisera. However, with flow in the reverse direction—i.e., from mother to child, while the volume of foreign red cells may be similar, it is less diluted and therefore the mixed field picture may be overlooked, especially if the results are not observed microscopically. Reading all grouping results microscopically and investigating mixed fields to exclude accidentally mixed samples, chimeras, etc., may lead to observations that the foetus can at times receive some of the mother's red-cell antigen. This would seem to be a necessary step in the recognition of the concept of immunological tolerance developing by such a mechanism.—We are, etc.,

Routine Ergometrine

Sir,—In your otherwise admirable leading article (*Journal*, August 3, p. 280) commenting on the Ministry of Health's *Report on Confidential Inquiries into Maternal Deaths in England and Wales*,¹ one passage calls for comment. After asking the question, "Is death from obstetric haemorrhage preventable?" you state: "The assessors were of the

opinion that in antepartum cases half of the deaths could have been prevented and in the post-partum group that 90% of the mothers should not have died." After stressing the need for "an experienced obstetrician and anaesthetist," you go on to say: "Perhaps when ergometrine is given routinely with the delivery of the baby these tragedies . . . will no longer appear in maternity reports." This speculation is dangerous, and, taken literally, suggests that in a dictatorship death from post-partum haemorrhage could be abolished by decree. The need for obstetric skill and experience in the management of labour when ergometrine is given routinely with the delivery of the baby is increased, as it carries a risk to the baby as well as new hazards to the mother if used by attendants not fully aware of them.—I am, etc.,

South Shields.

Priority in Poliomyelitis Immunization

SIR,—The natural change in poliomyelitis from a condition affecting infants to one infecting an ever-increasing proportion of young healthy and active adults deserves the most careful consideration in framing our policies and attitudes over the priorities in relation to the present programme of immunization. In this group of the population young doctors and nurses appear to be an especially vulnerable section, and every summer we hear and read of more and more doctors dying from the effects of poliomyelitis. If this fact is accepted, then there is an urgent need for this section to be given extra protection by means of immunization. I would urge the Ministry and the representatives of our profession to consider this as a measure of urgency, and take steps to provide some priority measure of protection to young doctors and nurses who are liable to come in contact with cases of poliomyelitis.—I am, etc.,

Beckenham, Kent.

JOHN FRY.

Early Sign of Parkinsonism

SIR,—The early symptoms of Parkinsonism have been recently discussed in your *Journal* (June 29, p. 1541). May I draw the attention of your readers to a new manoeuvre which I have found useful in eliciting the early Parkinsonian tremor and in differentiating it from the other types of shaking phenomena?

The patient, in a sitting and relaxed position, is asked to squeeze strongly with one of his hands the examiner's hand, while his other hand rests freely in his lap or is held outstretched in front of him. With the patient trying to squeeze the doctor's hand the latter is carefully watching the other hand of the patient without attracting his attention to the real purpose of the manoeuvre. In Parkinsonian patients the free hand promptly begins to shake in a typical "pill-rolling" character, revealing or confirming the diagnosis. This sign appears to be especially valuable in early cases, when the disease often remains unilateral. I have also observed the "unmasking" value of this sign in patients whose tremor has been successfully controlled by adequate doses of ethopropazine hydrochloride or by diethazine hydrochloride or any other agent. Such cases may present no evidence of any spontaneous tremor, but the "contralateral sign" described above is usually positive.

In a number of cases of familial tremor, alcoholism, hyperthyroidism, multiple sclerosis and cerebellar diseases, general paresis, psychogenic "functional" tremor, and tremor in Wilson's disease that I have been collecting for a forthcoming publication, the "contralateral tremor sign" has been absent, thus helping to differentiate them from the Parkinsonian type of tremor. I would be grateful for the observation of others who may apply this test to various cases of rare tremors.—I am, etc.,

Osawa.

VICTOR SZYRYSKI.

Tropical Pulmonary Eosinophilia

SIR,—Although many parasites and also mites have been suggested as causative factors in tropical pulmonary eosinophilia, I have seen no mention of amoebiasis in the article by Dr. Rosemary Davies on this subject (*Journal*, 1956, 2, 1470) or in the correspondence which followed (*Journal*, January 19, p. 166; May 11, p. 1119; and July 20, p. 161). Working under the somewhat sketchy conditions of a small station hospital in Somalia during 1944-5, I admitted a number of East Africans and Somalis suffering from bronchospasm, with an eosinophilic blood picture. During routine investigation nearly all proved to be carrying *Entamoeba histolytica* in either the active or cystic stages. On questioning, all had a recent history of bowel upset and some were still passing blood and mucus when admitted. Treatment for the amoebiasis was started with emetine HCl 1 gr. (65 mg.) daily, and the dyspnoea as well as any bowel symptoms usually ceased on the fourth or fifth day.

Unfortunately, I had neither time nor facilities for extensive follow-up, but there were not the readmissions one would have expected should the treatment have been unsuccessful. Recently I saw in Liverpool an Aden Arab suffering from "asthma," which failed to improve with routine hospital treatment. He had been in hospital a short time previously with "enteritis." Although no *E. histolytica* had been found on that occasion, and his eosinophil count was only 8%, he became so ill that I felt a trial of emetine was justified. There was the usual improvement by the fifth day, and the patient was fit for discharge at the end of the course.—I am, etc.,

Liverpool, 17.

H. M. BLAQUIERE.

Dyspareunia

SIR,—Dyspareunia at the introitus is common in the newly married, and may sometimes be found even months or years after the wedding. If untreated, it will often lead to mental disharmony or even deeper mental upset. In dealing with this condition I have found that the application of "xylocaine gel," 2% (Duncan, Flockhart), intended originally for analgesia of the urethra, is most useful.

After cleansing and drying the area, the jelly is applied liberally round the vaginal introitus and a further amount injected through the hymeneal orifice by means of the special nozzle supplied with the tube. In most cases the hymen can then be stretched without difficulty either digitally or with graduated dilators. This technique is also useful for girls who wish to have the hymen stretched premaritally with or without the fitting of a contraceptive cap. In cases where the hymen is so rigid that incision becomes necessary, or a hymeneal band across the vagina requires excision, application of the jelly before injecting a local analgesic, as suggested by Green-Armytage,¹ will be found very helpful.—I am, etc.,

London, W.1.

Compulsory Powers Over Mental Patients

SIR,—Dr. C. R. Birnie (*Journal*, July 27, p. 234) strikes a timely note of warning about the proposed alteration to the Mental Treatment Acts. I am surprised that so little notice has been taken of the potential changes by the profession. Doctors would be well advised not to accept the responsibility of using compulsory powers for admission, and I hope they will take action before it is too late. Patients may be admitted to hospital on the contributory evidence of relatives and friends. These same relatives and friends may deny their statements when the patient recovers. I have seen this happen. As an independent referee in the form of a magistrate sees these statements in a reception order and can verify them, there is some protection for the doctor. In the future there will be none. The patient when he has recovered will proceed to take action in the courts against the doctors concerned, and the doctors may

find it difficult to prove their impartiality. We can look forward to the day when the doctors have had "Mrs. Jones put away, poor soul." Then the council for liberty, equality, and fraternity, or what you will, will proceed to take notice, and possibly action, with highly undesirable notoriety for the doctors concerned. No, there must be legal safeguards.—I am, etc.,

Smethwick.

JAMES SHAW.

Reticulohistiocytosis

SIR,—In my letter on the above subject (*Journal*, July 13, p. 103) I should have referred to the remarkable case published by George Graham and A. G. Stansfeld.¹ In their case, before the patient died, the front wall of his chest collapsed. I have only seen this happen in one other case. This was a young man, a patient of Dr. H. C. Lauber.² I think it is highly probable that this case was in some way allied to Graham and Stansfeld's case.—I am, etc.,

London, N.W.1.

Dangers of Cigarette-smoking

SIR,—In spite of my very real respect for Sir Ronald Fisher, I fear that the principal value of his letter (*Journal* August 3, p. 297) is its demonstration of the limitations of pure statisticians as against medical statisticians in dealing with this type of problem. The essential need is to decide not only what is statistically probable but was it medically probable; a hypothesis which does not qualify in both ways is not easily tenable.

(1) Sir Ronald suggests that the relative immunity of women as compared with men, in spite of the phenomenal increase in their consumption of cigarettes, makes nonsense of the theory that the increase in smoking has a causal relationship to the increase in lung cancer. What he ignores is that there are many conditions in which there is a marked difference in incidence between the sexes. Excluding those in which the difference is purely anatomical, it would seem that endocrine, metabolic, and sex-linked genetic factors may produce relative immunity or susceptibility to various diseases, and it is by no means improbable that this wide difference in lung cancer incidence might be accounted for in some such way.

(2) It is obviously proper to consider whether the relationship between lung cancer and heavy smoking might be due to some common cause, but it is difficult to discover such a cause which is medically probable. The genotype hypothesis is, in the light of present knowledge, somewhat far-fetched and hard to reconcile with the improved apparent outlook of heavy smokers who give up smoking. The hypothesis that a pre-cancerous condition with chronic irritation produces an urge to smoke heavily is reasonable on the face of it, but rather less so when one realizes that if the hypothesis is true the condition must, in many cases, have existed in late adolescence or early adult life, 25 years before the development of detectable cancer. Again, if it is mainly the already doomed who smoke heavily, how can they escape their doom by giving up cigarettes unless the development of cancer is due to the joint effects of the pre-cancerous condition and the smoking?

(3) It is becoming generally realized that the social and environmental factors which produce or foster disease not only influence the course of the disease but influence each other. In this context a "causal relationship" is not necessarily the direct one which Sir Ronald seems to think is meant; it may be, but it may equally be the subtler one of disturbing a delicate equilibrium between a number of factors. Perhaps smoking pulls the trigger of a gun which has been loaded by diesel fumes, coal smoke, chromosomes, or "improvers" in flour; perhaps it helps to load the gun so that something else pulls the trigger. This sort of relationship certainly seems the most probable, but, even so, smoking remains significant.

It is suggested that since smoking is under grave suspicion the prudent man will cut down his cigarette-smoking, at least until more is known and the cigarette is either exonerated or deprived of its sting. In human terms, as

distinct from those of pure statistics, it is hard to see that this is a "catastrophic and conspicuous howler." If the M.R.C. were advising the Government to start a nuclear war or proposing the abandonment of something which had long been accepted as an essential nutrient, this strong language might be justified. As it is, the proposals will affect only the income of shareholders in cigarette-making firms, and even this might be of small importance if there were, among the confirmed addicts, a simple shift from the cigarette to the pipe. The warning "Since there is doubt, be cautious" is certainly better medicine than the injunction "Go on at full speed till the danger is proved beyond doubt."—I am, etc.,

Colchester.

JOHN D. KERSHAW.

SIR,—In a letter (*Journal*, July 27, p. 236) Dr. John Landon remarks upon the failure of Professor Bradford Hill and Dr. R. Doll to find a difference in the incidence of lung cancer between smokers who inhale and those who do not. A possible reason for this may be that the deposition of droplets of smoke upon the bronchial epithelium is dependent upon their having grown to a certain size by the absorption of water vapour rather than upon the deep inhalation of the smoke.

It is a familiar observation that cigarette smoke changes in colour from blue to white if it is held in the respiratory passages for a second or two. This is due to the scattering of light by the droplets becoming less dependent on wavelength as they increase in size. A theoretical investigation of the mechanism of growth, which is being prepared for publication, suggests that particles in the smoke drawn from a cigarette require to spend about a second or longer in a humid atmosphere at body temperature before they can grow large enough to settle upon the bronchial epithelium. The longer the droplets are held in the warm, moist atmosphere the larger will they grow and the greater will be their chance of making contact with the epithelium. On the other hand, droplets which are either expelled in under a second, or are rapidly inhaled into the alveoli, cannot make contact with the epithelium; in the first case they are too small to deposit, and in the second case they will deposit in the alveolar regions and be speedily removed by the lymph stream and the blood.

It is therefore suggested, on the hypothesis that contact between smoke particles and the bronchial epithelium is necessary to cause cancer, that a habit of drawing smoke into the upper respiratory channels and retaining it there for more than a second is the one which correlates with the incidence of the disease. Casual observation of cigarette smokers has confirmed the existence of this habit, which might not be generally regarded as "inhalation"; deep inhalation, carrying the bulk of the smoke to alveolar regions, would be carcinogenetically less effective.—I am, etc.,

London, W.C.1.

C. N. DAVIES.

Mass B.C.G. Vaccination

SIR,—Dr. T. M. Pollock (*Journal*, July 6, p. 21) paints a gloomy picture of primary tuberculosis in adolescence as a justification for mass B.C.G. vaccination at the age of 10. Yet the most striking feature of the improved tuberculosis position in the United Kingdom is the great reduction of mortality and morbidity in children and young adults. I am qualified to speak only for the part of the United Kingdom in which I work, but here the trend has been quite spectacular. In County Tyrone (pop. 132,000) 96 people died of tuberculosis in 1948, 13 of whom were in the 0-5 age group. In 1956 11 people died of tuberculosis, and one of these was in the 24-45 age group. The remaining 10 deaths were distributed between middle-aged and elderly patients. Thus the total mortality in 1956 was less than the mortality in the 0-5 age group in 1948. Tuberculosis mortality, therefore, in children and young adults has disappeared and tuberculosis morbidity among them is so low that the Dungannon

Chest Hospital now is almost a geriatric unit. This situation has arisen from the application of the modern treatment of tuberculosis, with a consequent reduction in the number of circulating tubercle bacilli in the community, and from a diligent search for active cases. B.C.G. vaccination, so far as possible, has been most carefully avoided.

It could be argued that fewer children and young adults in County Tyrone are contracting primary infections, and, although no large-scale tuberculin survey has been carried out, there is no reason to doubt that we have now many more negative tuberculin reactors than there were in 1948. Nevertheless, occasional primary infections must still be occurring, and, since there are so many more apparently vulnerable young people than there used to be, the individual case ought to be the same as before. But exactly the case is true: not only has tuberculosis become rare in children and young adults, it has also become less severe. Tuberculous meningitis has virtually disappeared and has been replaced by pleural effusions and minimal pulmonary lesions. On the other hand, tuberculosis in the middle-aged and elderly remains just as destructive as it has always been and is the main therapeutic difficulty.

The great paradox of the recent behaviour of tuberculosis is its rapid disappearance from, and amelioration in, what has always been thought to be the most vulnerable section of the community, and its persistence unchanged in the middle-aged and elderly, who, by virtue of having overcome a childhood primary infection, have been traditionally regarded as being relatively immune. The acquisition of resistance has never been a guarantee, or even a modestly efficient protection, against tuberculosis, and far too much importance has been attached to primary infection and the age at which it occurs. What is important is that infection should occur at all, and even the most fervent believer in B.C.G. would not attempt to say that vaccination can prevent infection. It is becoming increasingly obvious, therefore, that it is the tuberculin-positive and not the tuberculin-negative population which is in need of attention and that the dangerous tuberculous lesions of adolescence and early adult life, which formerly were common, were the result of repeated exposure to infection and not to any especial hazard of primary disease.

These facts have made nonsense of mass vaccination of children wherever it has been practised. The Danes believe that mass vaccination has controlled tuberculosis in their country, but in the Netherlands it has been controlled just as well without it. In Sweden the wisdom of applying mass vaccination is at last being questioned,¹ and this is not only because there is now little childhood tuberculosis in Sweden but because any beneficial effect of the hundreds of thousands of vaccinations which have been performed there cannot be clearly demonstrated. If the policy which Dr. Pollock recommends is adopted, no immediate damage will be done, apart from the usual crop of tuberculous lesions which B.C.G. notoriously provokes and which the devotees of vaccination so notoriously ignore. The main danger of advocating the mass vaccination of children is that it directs attention to a problem which no longer exists and postpones the solution of the real problem, which is the presence of destructive, infectious tuberculosis in the middle-aged and elderly. It would be unfortunate if a method of preventing tuberculosis which has never proved effective elsewhere, and which is already falling into disrepute in Scandinavia, were applied on a wide scale in Britain. If, in fact, tuberculosis in children and young adults is still common in Britain, it ought not to be any more difficult to eradicate than it has been in County Tyrone.—I am, etc.,

Dungannon, Co. Tyrone.

E. F. JAMES.

Natural Background Radiation

SIR,—The leading article on natural background radiation (*Journal*, July 6, p. 34) contains the following statement: "... the background radiations to the body tissues of

inhabitants of spas are unlikely to differ greatly from the average for other parts of the country." There could be exceptions in spas such as Lacco Ameno and Lurisia in Italy, and Oberschlema and Braubach in Germany, where the radioactivity of the water is very high—1,146, 1,141, 826, and 4,000 millimicrocuries per litre respectively. In such spas the amount of radon in the air may also be so high as to represent a risk for those submitting to the water-cure, and especially for the staff. The point is, in my opinion, worthy of investigation as one of scientific and practical interest.—I am, etc.,

Naples.

M. PACELLI.

Nocturnal Enuresis

SIR,—Dr. G. Kagan in his letter (*Journal*, July 20, p. 161) describes a new method of treating enuresis simpler than hypnosis, which consists of the administration of methylpentynol carbamate ("oblivon-C") and which is specific for nervous tension. I notice that Dr. Kagan includes in his cases an age-group 0-5. No child is considered enuretic unless it fails to attain full control of micturition by the age of 5.

Enuresis is not due to nervous tension only, although this is present in every case to a certain degree. No drug will have any effect of providing the support and sympathy from the parents which the poor enuretic so badly needs, and of preventing the administration of punishment, which nowadays tends to be mental rather than physical. So many parents adopt an attitude of hopelessness accompanied by nagging that the child becomes morose and introverted. A distinction has to be made between the congenital and acquired type, which is of recent origin. The acquired enuresis is produced by a strong emotional stress in a person who was ordinarily continent. Congenital enuresis is found in the following cases: mental defectives; borderline intelligence; improper habit training; emotional immaturity; conflicts related to sexuality or aggression. In some instances it represents a form of aggression against the parents or against the world in general. Often it signifies an appeal for dependence on the basis of being a childish, passive, helpless person. The bedwetting serves a function of pleading for love or for mercy on the basis of his helplessness. He virtually tries to make himself a baby to avoid responsibility or to get out of a difficult situation.

The two short histories given by Dr. Kagan are of acquired enuresis, each of 12 months' duration and not difficult to cure. No drugs will be effective in congenital enuresis; these require prolonged re-education and hypnoanalysis. Hypnosis will help the enuretic child with his anxiety, inferiority, and depression, and give him hope, which no drug can do. The two- and three-months follow-up periods mentioned by Dr. Kagan are not sufficient to be certain of the permanency of the cure. Hypnosis in acquired enuresis is a very simple and effective method. The case mentioned in my paper (*Journal*, June 8, p. 1323) became dry after the first session and has remained so now over 18 months. Drugs in this case were ineffective. A case of congenital enuresis in a boy aged 13 took over 12 months to get right with hypnotherapy.

Many drugs have been recommended for the treatment of enuresis; they have to be given in large doses with unpleasant and undesirable side-effects, without effecting a cure. There is no such a thing as a safe drug, and this holds good for methylpentynol carbamate. Its effect is similar to alcohol, and many motorists got themselves into trouble by taking it. The M.R.C. handbook on alcohol says that its effects are that "it facilitates escape from reality and feelings of weariness, encourages day-dreaming, wish-fulfilment and a general regression towards the earlier and more primitive levels of childhood and infancy." This last effect is obviously undesirable in the treatment of enuresis.—I am, etc.,

London, S.E.25.

A. FRY.

ventricular fibrillation by acting as ectopic foci, or by allowing re-entry. Mild infective illness commonly precedes cot death, and it is suggested that such deaths are due to susceptibility of the infant's heart to develop myocarditis with electrical failure. The lesions may not be demonstrated after death, as they may be too few to be included in routine sections of heart muscle, or as cardiac arrest has occurred at a very early stage when the enzyme systems responsible for electrical activity are damaged and there has not been time for histological changes to develop.

Cot deaths appear to be due not to overwhelming infection but to mild infection with associated myocarditis and electrical failure. Myocarditis is a fairly common phenomenon in infectious disease, and it is clear that few cases develop the conditions producing cardiac arrest. Further work on the problem might well be directed towards the incidence of myocarditis in infections in infants and its effect on the electrical function of the myocardium.—I am, etc.,

Brisbane, Australia.

D. A. HENDERSON.

Hospital Confinement

SIR.—I should like to agree most heartily with all that Dr. H. D. Forbes Fraser said on this subject (*Journal*, July 20, p. 159). In addition to his points, I would also say that a number of abnormalities occur less often at home than in hospital: not only with regard to infection and breast-feeding, but in the labour itself. From my experience (of only a few years) I am sure that delay in the second stage and post-partum haemorrhage are less common at home; and even the "normals" are more normal, the mother regarding labour as a natural occurrence and not fraught with abnormal possibilities.

There is another point which is often raised, and which I should like to answer. That is the question of where the mother herself would like to have her baby. Until she has had one baby in hospital and another at home she does not know, although she may think she does. But nearly every woman who has tried both is emphatic that if she has any more she will have them at home. I have many patients who are now very glad that they were unable to obtain a hospital bed. I am of course referring only to those women who would not be admitted to hospital for either medical or social reasons. I would add that (with proper antenatal care) I do not consider primiparity a medical reason on its own.—I am, etc.,

Hazel Grove, Ches.

M. G. SMITH.

The Forgotten Thomas Splint

SIR.—Although in regular touch with civilian colleagues, until I read the letter of Mr. G. P. Arden (*Journal*, July 13, p. 101) I had not realized that the Thomas splint is being forgotten, and that ambulance services are advising the use of the long Liston splint for first-aid treatment of fractured femur. Surely this retrograde step must be stopped, for the latter appliance has no virtue. The long Liston splint was condemned early in the Kaiser's war, and this may be read in the official *History of the Great War*.¹ Your correspondent emphasizes what Sir Heneage Ogilvie has reiterated frequently since the second world war, that the lessons of a last war are regularly forgotten in the following peace, and must be painfully relearned in the next. The medical histories of wars bear witness to this.

The Thomas splint does all the long Liston splint cannot do, and immobilizes the fracture in extension. Extension has been shown to be of value in controlling the haemorrhage at the fracture site, and so shock. As Ogilvie has pointed out, it is possible for the whole of the patient's life blood to drain into the tissues of the thigh, without any evidence of external haemorrhage, in a fractured femur transported without splinting. It is regrettably a fact that this can and does happen from time to time, even to this day. A short distance to hospital does not justify a fracture sent there without adequate splinting.

In my time the Thomas splint was drilled into us, not in the medical school as such, but in the medical unit of the O.T.C. If such units are less well supported by medical students now, it appears that the medical school itself should teach this important procedure. The Thomas splint is taught to all at the R.A.M.C. Training Establishment, with its additional modifications like the Tobruk splint to the senior, junior, and National Service medical officers' courses at the Royal Army Medical College. This splint has proved itself, and till a better comes along, if ever, must be regularly taught to and used by all concerned with the management of fractures of the lower limb. If it appears a complicated procedure, it is not so to the practised, and to a well-trained team its application is only a matter of minutes. Many medical practitioners up and down the country who have served in one or both of the great wars may be, like myself, surprised that the Thomas splint, which was in their experience so efficient and worth while, may tend to be forgotten. Let us not put the clock back again and lay ourselves open to the rebuke, "Do we ever learn anything?"—I am, etc.,

London, S.W.1.

Toxic Effects of Meprobamate

SIR.—In view of the recent correspondence on the toxic effects of meprobamate I should like to report another case where one tablet of "equanil" 400 mg. produced a generalized intense erythema within an hour or two of taking it. The patient was a woman of 50 with a menopausal depressive state; and it is interesting to note that, though extremely agitated about it at the time, she had completely forgotten about it when I tried to check the details with her (probably because her condition subsequently required hospital admission). The rash subsided within 24 hours on treatment with promethazine hydrochloride and local application of calamine. The patient's previous treatment had been with phenobarbitone or butobarbitone with stilboestrol.—I am, etc.,

London, E.4.

HELEN WAGSTAFF.

Post-operative Apnoea

SIR.—Several causes of post-operative apnoea have been propounded of late, and one is that it is due to excess of carbon dioxide from some cause. Following an appendicectomy using thiopentone, curare, nitrous oxide-oxygen sequence with controlled respiration, it was observed that apnoea persisted after atropine and neostigmine had been injected, the soda-lime canister still being in circuit. Reaction to tracheo-bronchial irritation, which was at first present, eventually disappeared. Rapid examination of the canister, which had been filled pre-operatively with fresh "durasorb," showed that it was cool and the inside of the outer casing bone dry. Some 5 ml. of water was placed in it, controlled respiration continued, and normal respiration was soon established. Re-examination of the canister showed that it had now become warm.

It would appear from these observations that durasorb is short of water and requires its addition for efficient absorption of carbon dioxide. This fact had previously been suspected, otherwise the case might have been confused with a "neostigmine-resistant curarization."—I am, etc.,

Birkdale, Lancs.

POINTS FROM LETTERS

Talcum Powder and Abdominal Examination

Dr. J. D. O. POOLE (Rhayader, Radnor) writes: When palpating the abdomen I have found it of some advantage to apply a light sprinkling of toilet powder to the area. The use of talcum powder for the purpose of facilitating massage is well known, but it occurs to me that its use in the way referred to is not generally appreciated. I have found it particularly useful in abdominal examination of the gravid uterus.

Obituary

A. FERGUS HEWAT, M.D., F.R.C.P.Ed., F.R.F.P.S.

With the sudden death on August 3 of Dr. A. Fergus Hewat the Edinburgh medical school mourns the loss of a man who for more than a generation was known and respected by hundreds of medical students now scattered at home and abroad. He was 73 years of age.

Andrew Fergus Hewat was born in Edinburgh on June 1, 1884, the son of Archibald Hewat, a distinguished actuary, and was educated at Edinburgh Academy and at Edinburgh

University, where he graduated M.B., Ch.B. in 1907. He was elected a Member of the Royal College of Physicians of Edinburgh in 1911, becoming a Fellow of the College three years later. In 1935 he was elected a Fellow of the Royal Faculty of Physicians and Surgeons of Glasgow. After graduating he held the posts of house-surgeon and house-physician at the Edinburgh Royal Infirmary, and later was senior resident medical officer at the Royal Hospital

for Sick Children, Edinburgh. Subsequent appointments included those of resident medical officer at the convalescent home of the Royal Infirmary, clinical assistant and tutor at the Royal Infirmary, physician to the New Town Dispensary, clinical assistant to the Royal Victoria Dispensary for Diseases of the Chest, and assistant to the lecturer in pathology and bacteriology at the Surgeons' Hall. During this period he took the L.M. at the Rotunda Hospital, Dublin, in 1910. Subsequently he became a lecturer in the Edinburgh postgraduate vacation course. In the first world war he served with the R.A.M.C. as a specialist physician at the Royal Victoria Hospital, Netley, being mentioned in despatches. After the war he returned to Edinburgh, and was appointed assistant to the professor of tuberculosis in the university and assistant physician at the Royal Infirmary, where he ultimately became consulting physician, and physician to the Kingscroft Hospital, Barnton.

When the British Medical Association held its Annual Meeting at Edinburgh in 1927, Fergus Hewat was the local honorary secretary of the Meeting, under the presidency of Sir Robert Philip, and demonstrated his competence in administration. At the Cardiff Meeting of the Association in the following year he served as a vice-president of the Section of Medicine. His old school, the Edinburgh Academy, claimed his loyal attention, and he was elected president of the Academical Club in 1955, a post he continued to hold until his death. For many years he served on the kirk session of St. Cuthbert's parish church, where his family had a long association. He also gave his services to the Royal College of Physicians of Edinburgh in many of the notable ways, first as secretary, then as curator of the College laboratory, and later as president during 1943-5. After vacating the chair he was appointed a trustee of the College, and for some years had been the senior trustee.

Dr. J. K. SLATER writes: There can be few who felt more keenly the passing of the old order of things with the advent of the National Health Service than Fergus Hewat. He was essentially a physician of the old school, unaccustomed to thinking in terms of "notional sessions," but adjusted to the erstwhile distinguished role of "honorary physician," of which people of his day were justly proud. Students,

young and old, loved him and could never return to Edinburgh without a visit to one who seemed to be ageless; many, indeed, recalling an earlier happy occasion when Fergus and his charming and kindly wife had been their hosts at dinner, an outstanding event being the year when his clinique won the residents' Rugby cup. His generosity was immense and for those he liked knew no bounds. Long years ago Sir Robert Philip, his chief, said in my presence, "Hewat, you must become impersonal." He never did, but those who knew him best respected all the prejudices which, in fact, in the scheme of things were unimportant. The late Professor Edwin Bramwell, to whom Hewat was assistant physician for many years, regarded him affectionately as the most loyal and enthusiastic colleague with whom he had been privileged to work, and the two as a team always attracted large numbers of students. Writing did not come easily to him, but his occasional papers always showed the same careful preparation and accurate observation which characterized his whole attitude to life. His opinion was highly valued by family doctors. At one stage in his career tuberculosis was a major interest, and he was a founder member of the Tuberculosis Trust of Scotland, yet essentially he remained a general physician. As a teacher his style was didactic and perhaps inclined to suffer from over-conscientious preparation, but the popularity of his lectures and the large size of his ward clinics were always eloquent tributes to the regard in which the students held him.

Since retirement from hospital practice Fergus Hewat had been mainly engaged in insurance work, and he loved his duties as principal medical officer to the Scottish Life Assurance Company. A short time ago, in conjunction with Mr. Colin Penn, F.F.A., he published for the Actuarial Society a valuable paper on life assurance underwriting. In a busy and varied life he had two outstanding and inherited devotions, medicine and insurance. His maternal grandfather, Dr. Andrew Fergus, was President of the Royal Faculty of Physicians and Surgeons of Glasgow, a post also held by two uncles, Dr. A. Freeland Fergus and Dr. J. Freeland Fergus. His father, Archibald Hewat, F.F.A., was at one time president of the Faculty of Actuaries. The fraternity of Edinburgh medicine has lost from its number one who for many years had contributed memorably to the events which unfolded. All of us who had been privileged to know the splendid partnership of their marriage will wish solace and comfort to his widow.

Sir DAVID HENDERSON writes: The sudden death of Fergus Hewat has come as a shattering blow and has removed from our midst a Christian gentleman who occupied a most distinguished place in the medical, social, and cultural life of Edinburgh. We were friends from our student days, we both graduated fifty years ago, and we were intimately associated throughout our professional life. I pay my tribute to his memory and accomplishments with deep affection and a sore heart. He perpetuated in himself a medical and professional tradition which came to him from both sides of his family. It is not given to very many people to have three near relatives all presidents of the Royal Faculty of Physicians and Surgeons of Glasgow, and on the other side to have a father who was president of the Faculty of Actuaries and a son of John Hewat, who introduced the time-gun to Edinburgh.

Fergus Hewat was frequently called to serve on committees which, apart from the medical profession, dealt with scholastic, church, and charitable concerns. He was always well prepared, he had something constructive to say, and he had no hesitation in expressing his own view irrespective of whether it coincided or conflicted with the opinion of others. It was that part of his disposition and character which we so fully trusted, because we recognized in him a man of worth and integrity. I knew him well, both as a family doctor and as a consultant physician. He would come at any time, regardless of any personal inconvenience to which he might be put. During the period in which I was physician

superintendent of the Royal Edinburgh Hospital for Nervous and Mental Diseases he acted as my consultant physician, and at all times gave of his best, bringing to bear an unflinching humanistic interest and kindness which all those who depended on him appreciated.

He was a distinguished-looking man, carefully groomed, serious rather, and imbued with a great sense of duty in relation to anything he undertook. He was far more shy and sensitive than most people realized, and he was almost unduly modest in regard to his own attainments. He gave credit for what he himself had accomplished to those great teachers and mentors John Chiene, the Bramwells, Alexander Bruce, Sir Robert Philip. He was intensely loyal to them all, and perhaps it was this feature of loyalty that was the greatest of all his qualities; he was fearless in the support of his principles and his friends. I shall always look back upon him as a man who had those qualities of heart and mind which allow him to be numbered among the great clinicians and teachers of the Edinburgh medical school.

He enjoyed his leisure hours. He liked good company and good books, especially biographies. A day's fishing was entered into with great zest, and he was delighted when he was elected president of the Edinburgh Medical Angling Club. He was equally delighted when, as an old Academy boy, he was elected president of the Edinburgh Academical Club. His annual holidays in the Highlands and in the English Lake District were always a source of much delight. I cannot conclude this short note without recalling with gratitude the gracious hospitality of his parents in their home in Eton Terrace, and his own charming, happy family life which he shared so generously with so many others. Such unforgettable memories are sacred. At this time our thoughts and sympathy are with his widow, who throughout their life together has been so devoted.

Dr. J. SHARP GRANT writes: Others will write of Fergus Hewat's place in medicine and of his skill in his specialty, but I would like to say a few words on the Fergus Hewat whom I knew as a young man when I acted as his house-physician in the Edinburgh Royal Infirmary before the last war, and in so doing I believe I shall be speaking for many of my contemporaries who acted in a similar capacity.

Fergus Hewat was at his best, both as a man and as a clinician, in the company of young doctors who were making their way in the world. His manner was brusque, but never unkindly. He was tolerant of human failings, but entirely intolerant of humbug, carelessness, or laziness, especially if a patient was affected. He never omitted a word of praise to his house-physician if he carried out some clinical task particularly well. Self-seeking and intrigue were anathema to him, and this soon became apparent to any young doctor who had inclinations in that direction. I believe that Fergus Hewat became better acquainted with his assistants than any other chief of his time, one reason for this being that he always appointed as housemen young men keen on their work and in whom he took a general interest. By the time one's term as house-physician ended a bond of friendship had been forged which remained unbroken, and the affection with which he was regarded by so many of his assistants in later life was proof of this. The grief that overcame him when any of his young men were lost during the last war was very deep and genuine, and I well remember being with him on at least one such occasion.

He will be remembered by us all not only as a great doctor and a worthy representative of the Edinburgh school of medicine but also as a good and kindly man who by his wise counsel and guidance did much to help the young doctor to attain success in his chosen profession.

E. M. ELMHIRST, T.D., M.S., F.R.C.S.

Mr. E. M. Elmhirst, who was until recently senior surgical registrar at the East Suffolk and Ipswich Hospital, died at his home in Bermuda on August 1. He was 41 years of age.

Edward Mars Elmhirst-Baxter was born on December 18, 1915, and was educated at Wellington College, receiving his professional training at St. Bartholomew's Hospital. He qualified by taking the London Conjoint Diploma in 1939 and in the same year obtained the London degrees of M.B., B.S. Soon afterwards he changed his name to Elmhirst. As a Territorial officer in the R.A.M.C. he was mobilized on the outbreak of the second world war in 1939 and served in the Near East and in Burma. He was the author of a book entitled *Battle First-aid* published in 1942. Released from the Army in December, 1945, he was promoted to major in the Territorial Army two years later, and in 1951 the Territorial Efficiency Decoration was conferred upon him.

Elmhirst obtained admission to the F.R.C.S. in 1948. He held registrar appointments at the British Postgraduate Medical School and the Central Middlesex Hospital before becoming senior surgical registrar at the Hampstead General Hospital in 1951. In the following year he obtained a similar appointment at the East Suffolk and Ipswich Hospital. He became honorary secretary of the East Anglian Regional Registrars Group in 1955. While at Ipswich he took the London higher degree of M.S. in December last year, but consultant status eluded him, and he described his feeling of frustration at his plight, and that of other senior registrars waiting for promotion, in a letter printed in the *Supplement* to the *British Medical Journal* of January 26 this year. By that time he had left England for good and had become a consultant surgeon in Bermuda.

Elmhirst was a first-class surgeon, quietly confident and with a much admired dexterity, and he was always kind and courteous both to patients and to hospital staff. He had an extensive knowledge of pre-Elizabethan heraldry and painting, and had written on these subjects. Only pressure of work made him decline, with great reluctance, an invitation to act as one of the heralds at the Coronation of Queen Elizabeth II. News of his early death came as a great shock to his many friends in Ipswich and elsewhere, and the sympathy of all who knew him is extended to his widow and five children.

R. A. KERSHAW, M.B., M.R.C.P.Ed.

Dr. R. A. Kershaw, assistant chest physician at Worcester Royal Infirmary and the Corbett Hospital, Stourbridge, died of poliomyelitis after a short illness in Little Bromwich Hospital, Birmingham, on August 3, at the age of 36.

Born in Manchester on July 19, 1921, and educated at King William's College, Isle of Man, Robert Arthur Kershaw proceeded to Manchester University, where he graduated M.B., Ch.B. in 1947. During the next three years he held various resident and registrar appointments in general medicine and then decided to specialize in diseases of the chest, obtaining the appointment of registrar chest physician at Sunderland Chest Clinic. In January, 1952, he obtained the diploma of M.R.C.P. of the Edinburgh Royal College and later the same year moved to Worcester. Very soon his sterling qualities were evident to those who had the good fortune to work with him. Doctoring to him was a vocation, not merely a job of work. He applied himself to the service of his patients with untiring devotion, always giving of his best. Courteous, kind, and understanding, he would go to endless trouble to relieve anxiety and suffering, never sparing himself in doing so; he was a good man and a good doctor. With his cheerful manner, even temper, and enthusiasm for new ideas, he was a most stimulating colleague who will be greatly missed by his associates in hospital, public health, and general practice. His work and his family were his life and happiness, and his conscientious devotion to them left little time for other interests. To his widow and two young children, and to his parents, we extend our deepest sympathy.

J. E. BANNEN, M.B., F.F.R.

The news of the death on August 2 of Dr. J. E. Bannen at his new home in Jersey came as a great shock to his friends in Hull and the East Riding of Yorkshire, although it was well known that ill-health was the reason for his retirement 15 months ago. He was 63 years of age.

Joseph Edward Bannen was born on January 18, 1894, and was a medical student at Glasgow University before the first world war. He joined the Cameronians in the first year of the war and saw service in Gallipoli, and from there he was invalided home in 1915. With typical pluck he went back to his university, and graduated M.B., Ch.B. in 1916 at the age of 22. After graduation he again offered his services, and was specialist radiologist to the Southern Army in India from 1917 to 1919.

In 1920 Bannen became assistant to Colonel W. Atkin Thompson, of Hull, who, with great foresight, saw him equipped with the latest x-ray apparatus. "Joe," as he became familiarly known, went to Liverpool two or three times weekly, and there obtained the D.M.R.E. in 1922. One of the first fully qualified consultant radiologists to be attached to Hull Royal Infirmary, he made a great name for himself in his specialty. Later he became partner to Dr. Richard Hermon, also a radiologist. He was elected a Fellow of the Faculty of Radiologists in 1939.

Joe Bannen was an authority on various aspects of radiology, and was the author of a textbook, *The Radiology of Pulmonary Tuberculosis*, published in 1937. He wrote many articles on his subject, not only for the medical press in this country but in America as well. An excellent diagnostician, he was particularly keen on the importance of the clinical history of his cases. As a colleague, his advice was very much appreciated, and his keen sense of humour made him a most delightful consultant. He had a very cheery and philosophical outlook on life, and on his last illness, although he well realized its seriousness. He was chairman of the advisory panel on diagnostic radiology under the Leeds Regional Hospital Board, and president of the Hull Medical Society in 1934. An active member of the British Medical Association, he had been secretary of the East Yorkshire Branch for some time and was president-elect at the time of the second attack of the illness from which he died and on account of which he had to retire. He was a keen golfer, and he liked to go to race meetings and loved a "flutter." He had a considerable knowledge of antique furniture, and a tour of the antique shops of the area was a favourite form of relaxation. His memory will always be cherished by those who were fortunate enough to know him, and the sincere sympathy of the profession in Hull goes out to his widow and family.

Medico-Legal

BLOOD TEST EVIDENCE IN LEGITIMACY PROCEEDINGS

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

In December, 1951, Mr. X obtained a decree of divorce in the Scottish Court of Session on the grounds of adultery of his wife. Her daughter had been born three weeks before they were married, but Lord Guthrie held that the child had been legitimated by the subsequent marriage and granted custody to Mr. X. Mrs. X did not defend the proceedings or contest the issue of custody, and married Mr. Y, with whom she had been committing adultery.

The child was looked after by Mr. X's sister, but in 1957, when the child had reached the age of 9, Mrs. Y brought an action in the Court of Session for a declaration that her daughter had been illegitimate. Her intention was,

¹ *Scotsman*, July 15, 1957.
² *Glasgow Herald*, July 15, 1957.

as she frankly averred in the witness-box, to circumvent the 1951 custody order and get her daughter to come and live in Mr. Y's home. Difficulties had arisen over access while the child was in the care of Mr. X's sister.

The action was heard before Lord Wheatley in the Court of Session on July 12.¹ Mrs. Y claimed that the child's father was a Pole with whom she had been associating before her marriage to Mr. X and who had now returned to Poland. Although Lord Wheatley was satisfied that Mrs. Y had had sexual relations both with the Pole and with Mr. X at about the time the child was conceived, he thought her evidence unreliable. Blood tests had, however, been carried out by two doctors on Mr. X, Mrs. Y, and the child. The doctors' evidence was that unless this was a case of mutation, the chance of which was about 1 in 100,000, the result of the tests excluded the possibility that Mr. X was the father. Lord Wheatley accepted this evidence as sufficient in law to discharge the onus of proof which lay upon Mrs. Y. Lord Wheatley regarded Mrs. Y's failure to contest the child's legitimacy during the 1951 proceedings as a formidable obstacle, and did not regard her explanation that she had not fully understood the effect and repercussions of the custody order. Nevertheless he declared as a result of the blood-test evidence that the child had been illegitimate.

This is the first occasion in Scotland on which a mother has ever sought a declaration that her own child was illegitimate.

Universities and Colleges

UNIVERSITY OF BIRMINGHAM

In Congregation on July 6 the following degrees were conferred:

M.D.—I. S. Howell (with honours), J. Butler, C. Wood.
Ph.D.—*In the Faculty of Medicine*: Esther C. Jones, M.B., Ch.B.—A. T. Bevan (with second-class honours), Sheila M. Alley, J. Anthony, C. Bate, J. H. Bell, T. D. J. Botting, Anne J. Bowman, J. Bradley, K. W. Bramley, P. W. Burden, C. Carlish, P. B. Carpenter, Christine F. Clarke, T. P. Cole, Elizabeth D. Cooper, D. Cresswell, A. Denton, P. J. Edwin, G. Finemore, C. T. Flynn, C. R. Frazer, S. N. Freeman, W. H. S. George, I. M. Ghany, G. Gripton, J. R. Hayes, R. N. Herrington, M. M. Hills, K. L. Hindle, Edward Housley, Ernest Housley, Janet M. Hoyle, Josephine C. Jackson, A. Jones, G. R. Kelman, C. T. Landey, D. H. Lawton, R. A. Lea, Christobel H. Lomax, Marie K. McClelland, Mary B. McDermott, R. McLean, W. A. Marshall, Geoffrey Mills, June Mills, D. C. Mintz, R. G. Mucklow, A. N. Nicholson, W. R. Ostell, Marigold J. Parsons, P. L. Pearson, M. Pendlington, R. Prasad, M. Quinn Hill, A. J. Reeves, Muriel M. Rogers, Edwina E. Rogerson, B. W. Roper, J. G. Rosser, Agnes M. Semple, R. C. Smith, A. R. Sneed, R. B. Somerset, M. S. Spelman, Maxine R. Sunderland, Elizabeth R. Swain, Muriel Tomlinson, J. V. Tranter, Claudine M. Tyson, Margaret Wallace, G. D. P. Wallen, D. C. Watts, D. M. Wayte, G. T. Whitfield, F. R. Wilkes, G. Williams, A. K. Woodward.

¹Distinction in pathology and bacteriology. ²Distinction in paediatrics and child health. ³Distinction in pharmacology and therapeutics. ⁴Distinction in forensic medicine and toxicology. ⁵Distinction in social medicine.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a quarterly comitia of the College held on July 25 the President, Dr. Robert Platt, was appointed the College representative on the governing body of the British Postgraduate Medical Federation, and Professor C. H. Stuart-Harris on the court of Sheffield University. It was announced that the Murchison Scholarship for 1957 had been awarded to David Caton Flenley.

Licences to practise were conferred upon the following 124 candidates who have passed the final examination in medicine, surgery, and midwifery of the Conjoint Board and who have complied with the by-laws of the College:

I. Akinsete, A. A. Akiwumi, C. M. Atkinson, P. J. Banfield, Anne P. Barnes, E. J. Batterham, G. Beaumont, D. G. Beynon, Jane Bingham, D. Bond, J. A. Brayshaw, J. R. Bright, T. R. C. Brodie, D. W. Brook, P. Cannon, Gillian C. Cardy, P. A. F. Chalk, J. D. Clark, P. A. Clark, N. H. Cohen, G. C. Cook, F. C. T. Cooper, J. D. H. Craig, T. R. Cullinan, J. L. C. Daintree, T. C. Dann, G. R. Davies, D. E. Day, M. H. de Groot, R. F. Dorrington, C. Dulake, P. Dure-Smith, V. A. Economides, A. Eisenstadt, L. O. V. Ekpechi, P. M. Ellis, Shirley P. Evans, M. C. Fairweather, Freda Festenstein, D. S. Filer, P. L. Frank, C. R. Frazer, D. Freeman, Joyce Fung, F. O. S. Gamm, F. B. Gibberd, Shirley M. Gittins, J. B. Gornall, Jean M. B. Graham, D. Gray, C. I. Haines, K. B. Hallam, A. M. Harris, J. P. Hewson, H. C. Hollingworth, Mary Hoogewerf, Margaret J. Hill, J. Horton, J. M. Hutchinson, A. E. Ifekwunigwe, I. McD. Jessiman, M. C. Johnson, Patricia H. M. Jones, R. W. Jones, V. R. Keep, J. J. Key, G. W. Knox, M. d'A. Lafoley, S. J. Lam, H. O. Latham, A. J. Levi, A. C. W. Lewis, June M. Lewis, Marny A. Lloyd-Jacob, D. Lovell, B. M. McGibbon, K. A. Mackenzie, J. G. Manson, Anna W. Markowska, W. H. Marshall, M. B. R. Mathalone, J. A. Mathews, J. Miller, M. N. Morgan, P. J. S. Murray, F. J. Nabapiet, B. I. Nwakanma, E. W. R. Oakden, R. O'Neill, H. O. N. Onubogu, H. P. Ozer, M. R. Patel, R. Prasad, B. N. C. Prichard, D. Procter, A. E. Rampling, A. P. Redmond, R. S. O. Rees, M. B. Rees-Jones, P. Robert,

H. R. M. Roberts, Audrey F. Rogers, M. E. Sheard, R. W. Sherwin, T. H. F. Staunton, K. W. Sweeting, J. O. Slingerland, D. C. R. Stephens, L. E. Taylor, M. J. Templer, D. A. H. Thomas, Sally Thomas, Ann K. Trimm, H. M. Tuddenham, J. E. Utting, M. F. Waboso, H. J. Walker, E. J. Walsh, Margaret J. Walton, A. C. Whyte, G. Willett, R. C. Williams, J. M. Woodhead, Elma P. Wyatt.

The following diplomas were conferred jointly with the Royal College of Surgeons of England:

DIPLOMA IN ANAESTHETICS.—M. Ahmad, M. A. Aziz, G. M. L. Baer, Ellen M. T. Baker, S. S. Barker, P. Bennett, Lorna Boyd, Margaret T. Brash, K. S. Camerson, D. Campbell, Yik-On Chan, P. Chandra, Mary Crawford, Patricia Crowther, Lois R. Davidson, F. J. Davis, Elizabeth A. Davison, Judith A. Dewsbury, P. E. Doyle, Phyllis B. D'Souza, P. B. D'Souza, L. J. F. X. Dunkin, J. G. Emery, D. W. Eyre-Walker, G. M. Falconer, H. P. L. Falla, T. R. Farrimond, S. A. Feldman, G. L. Feldmar, A. T. R. Fuller, N. Geffen, Rosemary A. Grange, Jose V. Hall, Kathleen C. Hall, Dorothy E. Harris, Constance C. M. Howie, Elizabeth F. Hurley, Margaret T. Hyde, A. A. Jebouri, Margaret A. Johnson, A. O. Jones, Beryl P. Jones, Elizabeth M. H. Kennett, Philippa F. Keyes-Evans, C. W. Law, Ann B. Lewin, Sheila M. Lightowlers, M. E. Lopresti, W. N. C. McCleery, J. C. MacIntyre, Ursula Michels, J. Milliner, C. M. Miln, J. W. Mostert, P. C. Murphy, H. I. A. Nisbet, C. S. Osen, Mary B. O'Sullivan, Margaret R. Palmer, Tulsi Panikkar, Elizabeth L. M. Perkins, A. Pfeiler, M. W. Potts, F. N. Prior, P. O. Pyic, Norah P. Raitt, J. S. Robinson, W. Rogers, Joyce W. Russell, G. H. Ryder, C. R. Salisbury, S. Sharma, D. A. E. Shephard, K. I. Shimmings, H. H. Siddiqui, K. Singh, K. G. Smith, Mary K. Stedman, B. W. Stein, J. M. Straiton, A. D. Surtees, A. P. Thatcher, S. Thirumalai, J. G. K. Thomas, J. G. Thynsma, C. Todd, G. L. Turnbull, P. J. Verrill, D. Wakely, C. Ward, U. Weerakody, Eileen M. Welcher, J. T. Wheeler, R. M. Whelan, Barbara M. Williams, G. Wilson, A. G. Winfield, Margaret Woods.

DIPLOMA IN CHILD HEALTH.—R. C. Higgs, S. P. Khatua, B. Prasad, J. H. Stephenson, K. F. Tugwell.

DIPLOMA IN INDUSTRIAL HEALTH.—R. L. Bell, T. C. L. Brown, W. T. K. Cody, G. S. Dhalwal, F. W. Ford, J. D. Harte, F. T. Hunt, W. S. Kulesza, Florence L. O'Rourke, D. K. Ray Chaudhuri, W. T. Richardson, C. Runciman, E. R. Steyn, J. G. Trott, H. Walters, J. L. Weeks.

DIPLOMA IN LARYNGOLOGY AND OTOTOLOGY.—S. V. Anand, A. P. Ardouin, M. S. I. Chandra Sekaran, W. N. de Vos, T. P. Diwakar, K. K. S. Goleia, R. Hinchcliffe, R. Irani, K. C. Kasliwal, M. S. U. Khan, J. S. McGrail, K. J. Modi, R. Pandey, T. S. Russell, J. N. McM. Schofield, G. D. L. Smyth, K. L. Ved.

DIPLOMA IN MEDICAL RADIOLOGY.—A. K. Banerji, A. K. Bhattacharyya, J. M. M. Darte, S. Dische, K. S. Holmes, H. F. Hope-Stone, G. A. Newsholme, A. F. Phillips, M. C. Purkayastha, M. Sutton, H. W. C. Ward.

DIPLOMA IN MEDICAL RADIODIAGNOSIS.—A. H. Ahmed, F. O. Brown, J. Colquhoun, D. K. L. Davies, P. J. Fonceca, B. M. Goldsworthy, Pamela N. Harris-Wright, T. D. Hawkins, H. Herlinger, Hia Shwe, M. Ibrahim, J. P. A. Jayasundera, J. A. B. Jones, J. A. Liver, M. R. McNulty, A. R. Manners, J. V. Oocleshaw, A. B. Reed, B. N. Roy, B. P. Royston, D. R. Smith, M. D. Sumnerling, R. G. Thomas, P. R. Ward, A. F. Young.

DIPLOMA IN PATHOLOGY.—D. L. Boardman, W. I. Horne, Marguerite A. R. King, K. Misch, M. G. Muazzam, A. Saleem, B. L. Williams.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—A. C. D. Abdool Raman, I. C. Black, J. J. Bradley, H. G. E. Crane, D. P. Cronin, Ala-Ud-Din Drooby, J. F. Dunn, G. S. Fiddler, R. M. Gabriel, Brenda Grant, R. H. Harris, J. R. Hewitt, W. A. Heyworth, G. M. Jacobides, K. Jones, I. M. Lowit, C. J. Lucas, H. McG. McBryde, P. D. McCarthy, W. E. McGovern, W. McQuaker, B. L. Mallett, H. Merskey, A. G. Mezey, P. A. Morris, A. Morrison, Margaret Munro, D. H. Nimmo, J. Owens, I. G. Pryce, Bridget M. A. Quigley, P. A. Reed, I. M. Rifaat, P. Roughtead, Eileen P. Scanlan, C. S. Sheldon, A. Spellman, R. A. Stamp, F. G. Thorpe, Rene N. D. Weerasinha, F. A. Whitlock, C. E. Williams, P. J. Williamson, A. R. Wilson, J. S. Wright.

DIPLOMA IN PUBLIC HEALTH.—A. G. Alexander, A. C. Anazonwu, P. Brodwin, J. G. E. Collins, A. R. Darlow, W. N. Dunnet, Shirley R. Fine, Frances M. Fisher, H. B. Gibson, Ruth Y. Golder, H. Graham, T. G. Hawley, G. K. M. Khomo, F. H. King, Ann L. Linsell, L. M. Mackey, D. E. Marchant, T. C. H. Mathews, M. D. H. Myhill, P. B. M. O'Reilly, E. H. Osborn-Smith, A. J. Paul, A. Rezler, D. M. Richardson, T. E. Roberts, M. A. Rozalla, A. H. B. Rydon, Ethel M. Wallis.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—N. S. Dixit, M. D. P. Najera, J. A. Najera Morondo.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on August 1, with Sir James Paterson Ross, President, in the chair, Mr. Rodney Smith was admitted as the first Penrose-May Surgical Tutor.

It was reported that Sir Russell Brock would give the Bradshaw Lecture at 2.30 p.m. on December 11, the day of the Annual Meeting of Fellows and Members.

The date of the Provincial Meeting in Cardiff was fixed for Saturday, September 27, 1958.

Lieutenant-Colonel P. D. Stewart was awarded the Mitchiner Medal and Squadron Leader E. R. McGuire the Lady Cade Medal.

A gift of £20,000 from the Coulthurst Trust for the provision of the new library reading-room was reported.

It was reported that the petition of the College for a Supplemental Charter had been signed by Her Majesty the Queen in Council on July 31.

The Handcock Prize was awarded to A. W. Asscher, of the London Hospital Medical School.

Diplomas were granted, jointly with the Royal College of Physicians of London, in Anaesthetics, Laryngology and Otology, Medical Radiodiagnosis, Medical Radiotherapy, Industrial Health, Psychological Medicine, Public Health, and Pathology to the successful candidates whose names are printed above in the report of the meeting of the Royal College of Physicians of London, and in Ophthalmology to R. N. Mellor.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending July 27 (No. 30) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included). London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1957					1956				
	Eng. & Wales	Land.	Scot.	N. Ire.	Eire	Eng. & Wales	Land.	Scot.	N. Ire.	Eire

STILLBIRTHS	202	34	24			189	27	15		

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
§ Includes puerperal pyrexia.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications (uncorrected) in England and Wales in the week ending August 3 were as follows, with the figures for the previous week in parentheses: paralytic 141 (137), non-paralytic 119 (123), total 260 (260). Total cases in Scotland were 9 (13), Northern Ireland 8 (26), and Eire 4 (2).

Coventry, Lincoln, and the Maidstone area continued to be the main centres of infection. In Warwickshire 36 cases were reported (Coventry C.B. 9, Birmingham C.B. 7, Bedworth U.D. 6, Nuneaton M.B. 6, Leamington Spa M.B. 4). Of the 15 cases reported from Lincs (Lindsey), 14 were from Lincoln C.B. In Kent 18 cases were notified (Maidstone M.B. 4, Faversham M.B. 2, Dartford M.B. 2, Beckenham M.B. 2, Strood R.D. 2). In the rest of south-east England notifications continued at a moderate level. In Hertfordshire 14 cases were reported (Stevenage U.D. 6, Hoddesdon U.D. 4), and in Essex 18 cases (Chelmsford R.D. 3, Colchester M.B. 2, East Ham C.B. 2, West Ham C.B. 2). The 18 cases reported from London were spread over ten boroughs, Wandsworth (5) having the highest total.

In Belfast 4 cases were notified as compared with 15 in the previous week.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1948-56 are shown thus - - - -, the figures for 1957 thus —. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest variations in the notifications of infectious diseases were decreases of 1,155 for measles, from 12,778 to 11,623, 132 for whooping-cough, from 1,577 to 1,445, 127 for dysentery, from 480 to 353, and increases of 129 for food-poisoning, from 372 to 501, and 71 for acute poliomyelitis, from 189 to 260.

The largest falls in the incidence of measles were 448 in Yorkshire West Riding, from 1,627 to 1,179, 160 in Kent, from 771 to 611, 131 in Middlesex, from 395 to 264, and the largest exceptions to the general fall were rises of 78 in Norfolk, from 305 to 383, and 59 in Somersetshire, from 218 to 277. The notifications of scarlet fever numbered 564, 20 more than in the preceding week, and there were no large variations in the local returns. The only large fluctuation in the trends of whooping-cough was a fall of 35 in Kent, from 170 to 135. 3 cases of diphtheria were notified, being 1 more than in the preceding week; 2 of the cases were notified in Birmingham C.B.

The chief centres of dysentery were Yorkshire West Riding 71 (Leeds C.B. 31, Bradford C.B. 13), Lancashire 69 (Liverpool C.B. 16, Manchester C.B. 13), Durham 36 (South Shields C.B. 15), Surrey 32 (Frimley and Camberley U.D. 17), and London 25.

The largest outbreaks of food-poisoning were 91 in Kent, Lydd M.B., and 57 in Southampton County, Winchester M.B.

Week Ending August 3

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 475, whooping-cough 1,284, diphtheria 4, measles 9,885, acute pneumonia 167, dysentery 325, paratyphoid fever 6, typhoid fever 6.

Medical News

Asiatic Influenza Vaccine.—A British vaccine against Asiatic influenza is expected to be available to the public in the autumn. It is a formalin-killed vaccine and is at present being prepared in the virus research department of the Wright-Fleming Institute of Microbiology, St. Mary's Hospital, London, under the direction of Dr. F. Himmelweit. The vaccine may give protection for at least several months, but whether a later boosting dose will be necessary is not certain. The development of antibodies in 120 volunteers given the vaccine was comparable to that found in sera obtained from patients convalescent after an attack of Asiatic influenza. Doctors in the Health Service will be able to prescribe the vaccine for their patients so far as it is available.

Educational Experiment.—Something like a controlled experiment in medical education is to be carried out at Johns Hopkins University, Baltimore, with the aid of 2,500,000 dollars from the Rockefeller Foundation. The student will devote most of his first two years in college to the humanities and social sciences, and then do a year of advanced chemistry, mathematics, elementary physics, genetics, and elective subjects. In the following three years a redesigned medical curriculum will take his attention, a rotating internship being held during the last of these years. The university expects to select about 20 students for the special course, while most of its students will continue in the standard course. For a number of years not yet determined the results of the two types of education will be compared. This six-years education is intended to replace one at present lasting eight years, and the experiment is prompted by the need for more doctors in the U.S.A.

Smallpox Vaccination Certificate.—The international certificate of vaccination against smallpox, prescribed by the International Sanitary Regulations, has been revised. The new form requires a doctor to record more precise information for a primary vaccination by providing spaces for recording a second attempt at a primary vaccination if the first is unsuccessful. It will come into use generally on October 1 next, but if stocks of the existing form are used up before then, the revised form may be used instead.

Appointments in U.S.A.—Dr. DERRICK ROWLEY, director of the bacterial physiological department, Wright-Fleming Institute, St. Mary's Hospital Medical School, has been appointed visiting professor in the department of medical microbiology, Stanford University, California, for the academic year 1957-8. Dr. GEOFFREY FURNESS, of the same department, has been appointed visiting lecturer in the department of microbiology, University of Pittsburg, for the academic year 1957-8.

Training of District Nurses.—The Minister of Health has appointed a committee to advise him on matters relating to training of district nurses. Its main task will be to advise on schemes of training and examinations submitted to the Minister for approval by local health authorities. Of the 12 members, four are medical: Dr. A. ELLIOTT (county M.O.H., Kent), Professor A. B. SEMPLE (M.O.H., Liverpool), Dr. D. F. EGAN (principal medical officer, London County Council), and Dr. MARY ESSLEMONT (general practitioner and member of B.M.A. Council), who was nominated by the B.M.A. The chairman is Dr. D. H. INGALL, D.Sc.

Suggestions to Authors.—Under this title the *Biochemical Journal* has published, in the form of a pamphlet, a reprint from a recent number giving advice to authors on how to write their papers. It is obtainable from the Editorial Office (*Biochemical Journal*), the Lister Institute of Preventive Medicine, Chelsea Bridge Road, London, S.W.1, price 1s. 6d. post free.

Professor Alexander Haddow, director of the Chester Beatty Research Institute at the Royal Marsden Hospital,

received the honorary degree of Doctor of Medicine from the University of Perugia while recently participating in a symposium on mammary cancer held at Professor Severi's cancer research division at the Institute of Anatomy. Professor Haddow, who delivered his dissertation in Latin, was the first Briton to be thus honoured by the University of Perugia, which began to grant doctorates "in medicinalibus" in 1321.

Ophthalmological Prizes.—Prizes are offered by the Instituto Barraquer, Laforja, 88, Barcelona, to physicians aged under 40 for papers on ophthalmological subjects. The first prize is 5,000 pesetas (about £43). Full details may be obtained from the institute.

Mass-Radiography Prize.—The Italian Association of Mass-Radiography offers a prize of 500,000 lire (about £285) for an unpublished monograph on "The present and future of the photo-fluorographic diagnosis of tuberculous, cardiovascular, neoplastic, and pneumoconiotic affections, and for the diagnosis of impairments of the skeleton and of the digestive apparatus." Nine typewritten copies must be sent before December 31, 1957, to the Secretariat of the Italian Mass-Radiography Association, via Bertoloni, 26A, Rome, from whom full particulars may be obtained.

Dr. David Harley, president of the Collegium Internationale Allergologicum, is to address the joint congress of the West German Allergy and Ophthalmological Societies to be held in Heidelberg in September.

Dr. T. W. Glenister has been made reader in anatomy in the University of London at Charing Cross Hospital Medical School.

COMING EVENTS

International Congress of Radiation Research.—August 10-16, 1958, Burlington, Vermont, U.S.A. Sponsored by the National Academy of Sciences and the Radiation Research Society, in co-operation with a European committee. Apply before September 10, 1957, to Dr. HARVEY M. PATT, International Congress of Radiation Research, Argonne National Laboratory, Post Office Box 299, Lemont, Illinois, U.S.A.

Ninth International Congress for Radiology.—July 23 to 30, 1959, Munich, Germany. Details from the congress secretary, Dr. V. LOECK, Forsthausstrasse, 76, Frankfurt am Main, Germany.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked •. Application should be made first to the institution concerned.

Friday, August 23

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. N. Lloyd Rusby: clinical demonstration.

APPOINTMENTS

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—P. J. L. Hunter, M.B., Ch.B., D.O.M.S., Consultant Ophthalmic Surgeon, Norfolk and Norwich Hospital Group; R. A. Pargiter, M.B., B.S., D.P.M., Assistant Psychiatrist, Fulbourn and Addenbrooke's Hospitals; C. D. Linton, M.B., Ch.B., D.Obst.R.C.O.G., D.A., Anaesthetic Registrar, Peterborough Memorial Hospital and Annexes; E. M. Dunkley, M.B., B.Ch., Anaesthetic Registrar, United Norwich Hospitals.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Boyd.—On July 10, 1957, at Nicholls Nursing Home, Port-of-Spain, Trinidad, to Dr. and Mrs. B. C. W. Boyd, of Sangre Grande, Trinidad, a son.

DEATHS

Beaton.—On July 28, 1957, in a nursing-home, Aberdeen, William Leslie Beaton, M.B., Ch.B., of The Beeches, Forres, Morayshire, aged 78.
Coutts.—On July 27, 1957, in Jersey, Bernard Fisher Coutts, L.R.C.P.&S.Ed., L.R.F.P.S., of Rosedene, Bent Road, Hamilton, Lanarkshire.
Edwards.—On July 26, 1957, John Alwyn Edwards, M.R.C.S., L.R.C.P., of Colne Cottage, Colnbrook, Bucks, aged 56.
Huggins.—On July 25, 1957, Sydney Penrose Huggins, M.D., of 75, Goring Road, Worthing, Sussex, formerly of High Wycombe, Bucks, aged 83.
Upshon.—On July 24, 1957, at 1 Parkhurst Road, Guildford, Surrey, Hector Marshall Upshon, M.R.C.S., L.R.C.P., Lieutenant-Colonel, R.A.M.C., retired.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

"Elixirs of Life"

Q.—The plant *hydrocotyle asiatica* has been called an elixir of life. It is said to contain a "youth vitamin," and ingestion of the dried powdered leaves or fresh fluid extract is claimed to lead to extreme longevity. On the other hand some botanical books say that it causes both urinary and ovarian irritation. *Sarsaparilla* is also said to possess some property conferring longevity. What is the basis of these claims?

A.—The first plant mentioned is now known as *Centella asiatica* (Urban) (*Hydrocotyle asiatica* L.). References to its application as an elixir of life or its content of youth vitamin are not available, but the material in the form of juice or leaves dried in the shade, known by the names of Manduk-parni (Sanskrit) and (Khad)-brahmi, is mentioned in early works on Ayurvedic medicine of the era before Christ, particularly in works by Charaka and Susruta. Chakradatta, an author of mediaeval times, refers to the rejuvenating action. He says that the drug is pungent and destroys phlegm and bile; that it is used in cough, asthma, fevers, urethritis, as a blood purifier, and is specially recommended in many skin diseases as an application to skin or orally; that it causes redness, warmth, itching, and powdery desquamation of the skin; that it is used as a tonic and rejuvenant; that larger doses cause headache, giddiness, and intoxication; and that it contains a volatile oil and therefore should not be heated. At the present time it is used in India in hair tonics on account of its reputation for restoring the colour of grey hair. It is possible that the desquamation of the skin caused by the drug is the basis of the belief in its power of rejuvenation by renewing the tissues. The plant attracted attention recently because the Madagascan variety was said to be active against leprosy,^{1,2} and its activity was believed to reside in a glycoside (asiaticoside) of the triterpenoid sapogenin, asiatic acid. Investigation of the related plant which occurs in Great Britain, *Hydrocotyle vulgaris* or pennywort, was carried out by Mink.³

I do not think I can better comment on sarsaparilla than to quote from the *United States Dispensatory*, 20th edition, 1918 (p. 980). "The use of sarsaparilla in medicine is an interesting example of the power of superstition to survive the attacks of truth and reason. It was introduced into Europe about the middle of the sixteenth century as a remedy for syphilis, but soon fell into disrepute until revived by Fordyce in 1757. Subsequently it came to be used as an alterative in various other chronic diseases, especially chronic rheumatism and scrofula. There is, however, no reason to believe that it possesses any virtues except as a mild gastric irritant through its saponin content. Its most popular employment is in the form of its compound syrup, which is used as a vehicle especially for mercury and potassium iodide." The plant *Hemidesmus indicus* R.Br. fam. Asclepiadaceae is known as Indian sarsaparilla. There is information about it also in the *United States Dispensatory*.

Treatment of Multiple Myelomatosis

Q.—Have there been any recent advances in the treatment of multiple myelomatosis, and what is considered the best treatment nowadays for such a case? What increase in life expectancy will treatment give?

A.—The most recent advance in the treatment of multiple myelomatosis has been the introduction of the cytotoxic

agents for the control of the more advanced case. Multiple myelomatosis, in contrast to solitary myeloma, is a generalized condition from the outset, but the first lesions may remain localized for a considerable time and therapy is directed to their arrest, thereby delaying dissemination. Local irradiation therapy in moderate dosage often relieves the painful bone lesions for a long time. Later, as the disease progresses, blood transfusions are needed for the associated anaemia. Oestrogens are helpful in encouraging remineralization of the osteoporotic areas.

Amongst the chemotherapeutic agents used for the widely disseminated disease are stilbamidine, 100-150 mg. on alternate days up to four weeks; urethane, 1-6 g. daily for 3 to 12 weeks; intravenous nitrogen mustard, in a total dosage of 20-40 mg. in 4 to 8 injections on alternate days; 2-naphthylamine mustard (C.B.1048; R.48), 100-300 mg. daily for 3 to 12 weeks; and chlorambucil (C.B. 1348), 4-12 mg. daily for 3 to 12 weeks. Of these agents nitrogen mustard and C.B.1348 are the most effective, and there is no doubt that in a proportion of cases they are capable of bringing about considerable symptomatic relief and improvement in the patient's general condition.

It must be borne in mind that multiple myelomatosis is a disease which varies greatly in its rate of progress from case to case. Many years of good health have been observed in the more benign form of the disease. It is difficult to estimate increased life expectancy resulting from these methods of treatment, but the definite impression gained is that in a significant proportion of cases life has been usefully prolonged.

Ethics in Life Assurance Examinations

Q.—If during a medical examination for life assurance purposes I find some condition which I think needs treatment, am I entitled to tell the proposer despite the usual instruction, "It is requested that the results of this examination be not disclosed to the proposer"? What is the position when the proposer is not a patient of the medical examiner?

A.—It is implicit in the first part of this question that the examination for life assurance is being carried out by the proposer's own medical attendant. He would then naturally act in the latter capacity and apply the necessary treatment. If the examiner is not the proposer's own medical attendant, then the situation would appear to be covered by paragraph 7 of the ethical rules for examining medical officers in the B.M.A.'s *Year Book*, 1956-7 (p. 127). This reads as follows: "When in the course of an examination there come to light material clinical findings, of which the attending practitioner is believed to be unaware, the examining practitioner shall, with the consent of the patient, inform the attending practitioner of the relevant details." This rule does not, of course, relieve the examining practitioner of his obligation not to disclose the results of his examination directly to the proposer. It only requires him to obtain the proposer's consent before communicating with the latter's usual medical attendant.

Post-traumatic Epilepsy

Q.—A man was hit on the head and suffered a closed depressed fracture of the parietal bones. At operation his condition was unsatisfactory, so that only the broken pieces of bone were removed. He was given antibiotics and made a good recovery. Four months later, however, radiographs show that the inner table is depressed about half an inch (1.2 cm.). He is without symptoms. (1) Does the likelihood of later irritative phenomena necessitate a second operation to elevate the bone? (2) Has the use of antibiotics led to any decrease in the incidence of post-traumatic epilepsy so that more conservative treatment is justifiable in cases of brain injury?

A.—The questioner does not state whether or not the dura mater and cerebrum beneath the fracture were lacerated. Such laceration would lead to a cerebral

scar, which always carries a risk of post-traumatic epilepsy. Indeed, even without dural and cerebral laceration fibrosis in a contusion beneath a depressed fracture may itself become an epileptogenic focus. The answer to the first part of the question is therefore that it is the cerebral damage sustained at the time of injury rather than pressure from bone fragments that causes "later irritative phenomena"—that is, epilepsy—though clearly gross depression of a wide area of skull, or depression of small fragments into lacerated cerebrum, could be responsible for continuing local injury from ischaemia or for further scarring and thus increase the risk of epilepsy.

In answer to the second part of the question, since the fracture in the case described was a closed one the question of infection does not arise. In general it was expected that the reduction of infection after penetrating brain wounds following the introduction of the sulphonamides and antibiotics would decrease the incidence of post-traumatic epilepsy. But, while the mortality from such wounds has been greatly reduced, the incidence of epilepsy remains high, about 50% of these patients having one or more fits at some time after injury.

Treatment and Prognosis of Psoriasis

Q.—What is now regarded as the most effective treatment of psoriasis? Has this led to any improvement in prognosis?

A.—Other things being equal, the most effective treatment of psoriasis is to reside in a warm, sunny, and equable climate and to indulge in free exposure to sun and light and air. The epidermal aspect of the psoriatic reaction appears to be a breakdown in adjustment to climatic environment.

In so far, however, as psoriasis is a constitutional reaction it is always an individual problem particularly susceptible to endocrine and emotional influences. The impact of the psoriasis itself upon the psyche is very important. In general, the less psoriasis a patient suffers the less susceptible he is; and, for the reason stated above, the patient should know that his psoriasis can almost invariably be completely cleared in an average of three weeks. All these points bear on prognosis, and especially is this true of the treatment of a first attack of psoriasis. If it is cleared in three weeks it may leave no more impression on the skin and the mind than the rash of measles.

In the British climate an effective treatment consists of a daily tar bath (liquor picis carbonis, 4 fl. oz. to 20 gallons—114 ml. to 90 litres) followed by exposure to ultra-violet light in near-erythema dosage. This is followed by the application of a dithranol paste to the affected parts, the whole being covered with stockinet dressings. The treatment should be conducted in a hospital clinic.

Various vitamin therapies, especially with cyanocobalamin (vitamin B₁₂), probably by exerting an influence on epidermal metabolism, are often helpful, but in the present state of our knowledge remain empirical. Often in these cases there are other medical conditions needing treatment, as with all constitutional ills.

Treatment of Pyorrhoea

Q.—Have there been any recent advances in the treatment of pyorrhoea, and what is now regarded as the best treatment for it?

A.—The treatment of pyorrhoea, in which infected pockets surround the teeth, is essentially the elimination of these pockets. This may be achieved either by extraction of the teeth or by causing recession of the gums to occur. With shallow pockets thorough scaling and polishing of the teeth to remove all calculus (especially calculus within the pocket), and scrupulous oral hygiene by the patient to remove food debris from around the teeth immediately after every meal, will result in shrinkage of the inflamed gums as the inflammation resolves. With deeper pockets it may be impossible to keep them clean enough to allow much permanent reduction in the degree of gingival inflammation,

and here gingivectomy may be indicated to remove the outer wall of the pockets. It has not been shown that any form of systemic treatment is effective in the elimination of these periodontal pockets.

The recent advances in treatment have been mainly in technique, but, in addition, with severe cases more attention is now paid to reducing the mechanical stress which the teeth with their depleted supporting bone have to bear. This may be achieved by grinding to adjust the bite, or by some form of splinting of the teeth to provide mutual support. It is also more generally recognized now that any form of treatment other than extraction is worthless unless the full co-operation of the patient is obtained in the maintenance of oral hygiene.

NOTES AND COMMENTS

Chronic Cyanide Poisoning.—Dr. A. M. G. CAMPBELL (Clifton, Bristol) writes: Though there is no direct evidence that cyanide is a factor in the production of disseminated sclerosis ("Any Questions?" July 27, p. 247), it was not perhaps made quite clear that cyanide used experimentally can produce areas of demyelination.¹ It has also always proved interesting to me that a number of cases of disseminated sclerosis, which may be more than coincidental, have enlarged thyroids and colloid goitres and the exacerbation of the demyelinating disease is sometimes accompanied by an enlargement of the thyroid. Another interesting fact is the rarity of demyelinating diseases in South Africa and the rarity also of goitre. Whether there is any tie-up between goitre and disseminated sclerosis one cannot say, but the production of goitre by cyanide and its possible effects on the nervous system cannot be completely neglected and might be an indication for further research.

REFERENCE

¹ Lumsden, C. E., *J. Neurol. Neurosurg. Psychiat.*, 1950, 13, 1.

Early Symptoms of Parkinsonism.—Dr. P. L. DESHMUKH (Poona, India) writes: With reference to the query ("Any Questions?" June 29, p. 1541), it would be of interest to mention a case which was diagnosed by me 20 years back. The patient was a woman aged 32 years who complained of insomnia. A fine tremor of the hand was discernible on physical examination. Other investigations were negative. She was treated for hyperthyroidism, hysteria, and debility. Sedatives and hypnotics were used without success. When the patient was brought to me, on questioning about sleep it was brought out that she was excited and restless at night, doing something or the other and disturbing the sleeping household. After the morning tea she used to feel very drowsy and often slept the whole day, except for the meal hour, when she had to be awakened. This inversion of sleep rhythm suggested to me the diagnosis of Parkinsonism. Further development of the disease in the course of the next few years with the appearance of mask face and characteristic rigidity confirmed the diagnosis.

Collected Articles from the "British Medical Journal"

The following books are available through booksellers or from the Publishing Manager, B.M.A. House. Prices include postage.

Emergencies in General Practice (26s. 6d. inland; 26s. over seas).

Refresher Course for General Practitioners, Volumes 2 and 3 (26s. 6d. inland each, 26s. overseas).

Clinical Pathology in General Practice (22s. 3d. inland, 21s. 9d. overseas).

Any Questions?, Volumes 2 and 3 (8s. each).

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: Aitology, Westcent, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the British Medical Journal alone unless the contrary be stated. Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad. ADVERTISEMENTS should be addressed to the Advertisement Director, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. MEDICINAL TREATMENT: ITS AIMS AND RESULTS*

BY

Sir HENRY H. DALE, O.M., G.B.E., M.D., F.R.C.P., F.R.S.

Gideon Delaune came to this country as Apothecary to King James the First's Queen, Anne of Denmark, and soon appeared as a bold and vigorous protagonist in the movement which led to a decision by the King in Council, in 1610, to promote a Bill in Parliament for the creation of a Company of the Apothecaries, separate from the parent Company of the Grocers, which had till then exercised authority over the trade in drugs and medicinal substances as well as over that in the spices and comestibles which we still regard as the proper concern of the grocer. The Grocers' Company was apparently in a position to snub Gideon Delaune, on the ground that, as a foreigner, he was not admissible to the freedom of the City of London or of its Companies. In any case, they were able to exclude him from a meeting of their Court which they called to consider this movement for the secession of their apothecary members, and the Bill proposed for their separate incorporation.

In the event, the prorogation of the Parliament intervened, and prevented this Bill from going any further. When, however, the aggrieved apothecaries took action again in 1614, by the different method of presenting a direct petition to the King for the grant of a Royal Charter, on the analogy of those already granted to the College of Physicians and to the Company of the Barber-Surgeons, the Grocers' Company was unable either to interfere with Delaune's influential access to the King himself, through his attachment to the Queen's household, or—a matter probably of even greater importance for the success of the petition—to prevent his approach to the Law Officers of the Crown, and especially to Sir Francis Bacon. It is suggested that the great Bacon had a rather poor opinion of physicians, and that he was the more ready, on that account, to interest himself in furthering the claim of the apothecaries. That may seem, indeed, to be a strange preference when we remember that Bacon's own physician was no less than William Harvey, who, in due course, was to give the first and still the supreme example of the application, in the field of medicine, of the then new and revolutionary method of advancing all natural knowledge by direct observation and experiment, which had been spreading to this country from the European continent, and the elaboration of which into a new system of philosophy was to be Bacon's own prime interest and greatest achievement. We might have expected, perhaps, to find that this triumphant application by Harvey of principles which Bacon was advocating with such subtlety and

eloquence would have united them in a common enthusiasm. We have no evidence, however, that there was anything more than the professional doctor-patient relation between them, or that Bacon even recognized the tremendous significance of what Harvey was doing. As for Harvey's opinion of Bacon's contribution to the foundation of modern science, Aubrey's gossipy report of it suggests a tolerance, somewhat less than respectful, of the practical experimenter for the merely theoretical organizer or exponent—an attitude, it must be admitted, of which examples can be found even to-day.

A New Structure of Medical Knowledge

We must not lose sight, however, of the dates of such events, in relation to those with which we are here more directly concerned. The new Charter of the Apothecaries was ready for acceptance in 1615, though it was not actually signed till 1617. In 1615 Harvey was only just beginning the progressive exposition of his discoveries, in his Lumleian Lectures to the College of Physicians; and it was not till thirteen years later, in 1628, when Bacon had been dead for two years, that he was ready to present all his evidence, and to deploy the full array of his arguments, in the *De Motu Cordis*. It is to the year 1628, therefore, that we must look for the beginning of a new structure of medical knowledge, built upon a new foundation of experimental science; and, even then, this revolutionary change was to proceed but slowly and intermittently during following centuries, so that it had hardly entered upon its present phase of rapid and still accelerating progress until years so recent that some of us who still survive were already adolescent when it began.

In 1615, therefore, there was hardly any reason even to suspect the coming of so great a change. At that date, and indeed for very many years after it, the formal training of a physician still bore signs in plenty of the earlier association of the practice of medicine with the priesthood. If it included any direct observation of the normal functions of the body, or of the effects of diseases in disturbing them, it was only by the rather casual accident of opportunity. The training was based primarily upon a long and intensive indoctrination with ancient writings, reverently accepted as embodying an orthodox code of medical knowledge, especially the writings of Hippocrates and Galen, together with argumentative interpretations of these by mediaeval commentators.

The statutory obligation of the regius professor of physic at one of our ancient universities at that time

*The second Gideon Delaune Lecture, given on May 14, 1957, in commemoration of the founder of the Society of Apothecaries of London.

was to present these medical scriptures, in lectures delivered four times a week, to students obliged to attend them regularly and to listen to them quietly and attentively. There was, indeed, an additional obligation to perform an "anatomy," and to interpret its demonstration by lectures, once every year; but, in a Grace passed by the Cambridge Senate in 1646 to reinforce this provision, we can find the allegation that "for several years, in order to effect some slight saving, no dissections at all have been made in the faculties of medicine and surgery." We should not expect such a training, which seems to have required eleven or twelve years, to predispose Francis Bacon to any special respect for the physician which it produced; while we should not expect to find, in the physician so trained, any eagerness to embrace the new philosophy, which was claiming to check and to replace ancient doctrines with a knowledge won by direct observation and experiment.

We can hardly suppose that Bacon would have had any detailed knowledge of the function of the apothecary; but, from what he knew of it, it might well have appeared to him to be more congenial to his own principles. For, however trivial and even ludicrous, in the light of our present knowledge, we may find the credentials of almost all the drugs and medicaments with which the apothecaries were then called upon to deal, they were at least actual substances, and not vague ideas. The tests by which the apothecaries endeavoured to control their identity and quality, whatever their scientific value, had at least the character of observation and experiment; whereas the physicians were mainly concerned with ancient speculations, using their ingenuity to interpret diseases and their symptoms in terms of the all-pervasive doctrine of the four bodily humours, and to attribute remedial activities to various drugs and therapeutic procedures, in terms of the same fantastic but reverently accepted dogma.

The Physicians' Attitude

It must not be supposed, however, that the physicians and their College were, at that stage, opponents in principle of the claim of the apothecaries to be separated from the grocers. In that dispute they were prepared to side with the apothecaries, provided that the latter would accept, with their proposed Charter, a set of by-laws drafted in agreement with the physicians. These were to give the apothecaries, on the one hand, an exclusive right to compound, prepare, sell, and distribute the remedies included in the "London Antidotary"—a sort of pharmacopoeia to be compiled by the College of Physicians; but, on the other hand, they were to forbid the apothecary to "visit any sick person for the sake of giving advice," or to "administer medicine except in urgent necessity and imminent danger to life, when no physician can be found." If these by-laws, which were accepted by both parties, had indeed been strictly interpreted and made fully effective, it seems obvious that the function of the apothecaries should have developed into one not greatly different from that which, in years much more recent, came to be recognized as proper to that of the duly qualified dispensing pharmacist.

It would, however, be widely outside the scope of my intention in this lecture to make any attempt to follow the further course of events through which this Society became, in due time, the sponsor of the general practitioner of medicine, and the authority first responsible for testing the qualifications of that key contributor to the effective structure of medical practice in this country. This central achievement of the Society, in its now long history of 340 years, had a prominent place in the fine lecture, forming the first of this series, delivered here a year ago by my dis-

tinguished friend and predecessor in the lectureship, Sir Zachary Cope. Sir Zachary made due acknowledgment of the advantage which he had enjoyed in preparing his lecture through the kindness of Dr. Charles Cameron, who had allowed him the privilege of studying, in page-proof, the new history of this Society which Dr. Cameron had completed in typescript, and had even believed that the corrected page-proof of it was ready to be passed for publication, several years ago. I have myself had a similar privilege through Dr. Cameron's kindness, and have made free use of it, especially in that section of my lecture already given.

If I may here be allowed a slight digression from my own proper subject, I feel that I owe the Society an explanation and apology in this connexion. When Sir Hugh Lett was Master of this Society he appealed to me, as Chairman of the Wellcome Trustees, for financial support for the eventual publication of such a new history of the Society. Sir Hugh handed to me the large typescript draft which had been prepared by the late Dr. Cecil Wall, and which embodied copies of a number of Charters and other historical documents in the Society's archives, of which Dr. Wall had for many years been a devoted student. I think that Sir Hugh believed that, with a moderate amount of editing, the typescript left by Dr. Wall could itself be made suitable for the proposed publication; and the Wellcome Trustees, when I put the matter to them, were willing to provide the necessary financial guarantee. When the material was examined, however, with the aid of the best advice available, it became evident that Dr. Wall's draft had not yet reduced the material which he had collected to anything like the compass or the form which would enable it to be made suitable for publication by any merely formal editing. In the hands of a suitably qualified author, however, it would provide an excellent basis for a new history of moderate dimensions; and I was pleased to find that my friend Dr. Cameron was willing to accept a modest commission to undertake what was not expected to require a great deal of work. Using Dr. Wall's draft, Dr. Cameron was soon able, in fact, to produce what will surely be accepted by the Society, and by readers in general, as an attractive and a most informative account of our history. It would not then have occurred to me, any more than it did to Dr. Cameron, to suspect that the extensive transcripts from documents in the archives which Dr. Wall had included in the material which he left, and which Dr. Cameron had conveniently collected in appendices to his book, could not be accepted as textually exact. Dr. Ashworth Underwood, however, had meanwhile made the advantageous proposal that this new history of the Society should be included in the Publications of the Wellcome Historical Medical Museum; and when the proofs fell into his hands and those of his staff, and the transcripts began to be compared, word by word, letter by letter, with the original documents, they were found to be so full of transcriber's errors that the process of correction is even yet not quite complete. I can only offer to the members and friends of the Society the assurance that when we get what ought to be a definitive history of the Society we shall not only enjoy the reading of the text but shall be able to refer to the supporting documents without fear of criticism from the most exacting historian.

Apothecaries' Original Functions

It is not my purpose, however, to deal further with the general history of this Society, or with the long-drawn-out struggle with the physicians, which eventually won for the licentiates of the apothecaries the function and status of the general practitioners of medicine, instead of that of the preparers and purveyors of drugs. Sir Zachary Cope gave a brilliant survey of that general history in his lecture last year; and I propose to draw attention, more particularly, to some features in the more general history of the medicinal treatment of diseases, in relation to which the original function of the apothecaries was the control, supply, and administration of the remedies which the physicians prescribed.

I think that we should remember what a very large part must have been played in medical practice, at the time when this Society obtained its Charter of incorporation and long afterwards, by the prescription of medicinal treatment and the corresponding supply, with a recognized guarantee of identity and quality, of the remedies which had been ordered. No methods of diagnosis could then have existed, except in the crudest and most superficial sense of recognizing, for example, the presence of a pox or a dropsy; for there was

as yet no real physiology or pathology on which anything better could be based. The physician, and doubtless the apothecary also, as soon as he strayed outside the by-laws which were supposed to restrict his function, could no doubt, then as now, give useful service to his patient by common-sense advice about the regulation of his bodily habits; but morbid symptoms of any kind would inevitably be referred to excess, or defect, or some other kind of perversion, of one or another of the four postulated humours. The first impulse would naturally be to remove the peccant material, either medicinally, by a vomit, a purge, or a clyster, all of a drastic character, or surgically, by bleeding or cupping, or by issues and setons; all available to be tried in turn, of course, or often in combination. These drastic methods had a very long currency; and I think that it was the late Professor A. J. Clark who first pointed out that the doctrine of homoeopathy, which began to be promulgated by Hahnemann in 1810, must even then have had the comparative advantage that, with the almost inconceivably minute dosage which its author eventually advocated, it could, at the worst, do the patient no positive injury.*

Seventeenth-century Materia Medica

Apart, however, from these more drastic remedies and procedures, used with the object of draining off deleterious humours in one way or another, the therapeutic repertory of the physician and the apothecary of the seventeenth century contained an astounding array of materia medica. A large proportion of these were of vegetable origin, their natures and supposed remedial values being set forth in a number of well-known and elaborate herbals. Some of the more fantastic and repulsive, however, were of animal origin, such as the "bezoar stone" (a concretion found in the intestines of certain wild ruminants), "crab's eyes" (apparently not the visual organs of marine crabs, but internal concretions, found on either side of the stomach of the freshwater crayfish), as well as vipers, millipedes (prepared by drowning them in white wine), sheep's tritrites (dung pellets), and so forth. Lastly, there were certain metals and mineral salts, for which it could at least be claimed that several were powerfully active poisons. It would be difficult, of course, to discover any intelligible theory to account for the supposed therapeutic properties of most of this impressive collection of reputed remedies. They must have been given largely on a trial-and-error system; and, of course, if the patient's symptoms showed improvement, or recovery began, the result would naturally, and without hesitation, be ascribed to the treatment.

The case-books of the day must have been full of the records of such treatments, and of facile deductions from their apparent results. I may quote one from Dr. Poynter and Mr. Bishop's scholarly edition of the case-book of Dr. John Symcotts, a seventeenth-century physician practising in Huntingdon, who had Oliver Cromwell among his patients. In February of 1647 he records the case of a certain Mistress Baldwin who, according to his account of her symptoms, would appear to have been suffering from biliary colic with jaundice. After purging and bleeding her, and administering a clyster of tobacco, he proceeds to apply a more gentle and continuous treatment. "All this while," he writes, "I gave her every morning a draught of worm-wood, white wine wherein sheep's tritrites were infused, with a pretty quantity of egg-shells powdered." Later again, "To all this, and the sheep's trittle drink as before, with a dram at least of the powder following; egg-shells powdered one-half, of millipedes (drowned in white wine or aqua vitae and dried) and Gascoyne's powder each half so much—I ascribe the perfecting of the cure, for this brought away abundance of gravel and a good plenty of urine, whereby (thanks be to the God of Heaven) the pains and jaundice were both

*According to Professor Clark's calculation, Hahnemann's indication for the effective dilution of one of his tinctures would have produced a solution containing not more than one molecule of the drug in a sphere of fluid of which the circumference would have been equal to the orbit of the planet Neptune.

eradicated." There seems to be something like a *non sequitur* here with regard to the jaundice, and it is hardly surprising to read that the patient soon relapsed. Then, after further cuppings and clysters, the poor lady is returned to her former routine, with "two spoonfuls of fresh juice of horse dung" added to her daily morning draught; "wherein," records the good doctor, "I respected the colical wind rather than the icterical effect."

Prescriptions such as some of these may perhaps have been specially characteristic of the practice of a physician in the provinces, where, in those days of slow and difficult communication, it would be natural to have recourse to remedial substances which happened to be locally available. He would be ready, for similar reasons, to borrow both materia medica and therapeutic methods from those handed down by tradition to the chatelaines of country houses, or their servants. The same Dr. Symcotts records, for example, a case, in a lady patient, of nose-bleeding—a rather frequent trouble, apparently, in his practice—which had resisted all attempts to stop it until "the cooke-mayd boldly took a cloth wet in cold water and made her sitt upon it." Concerning which expedient the doctor's note comments, as a memorandum, we may suppose, for his own future treatment of this emergency, that "vinegar it may be had been better."

Traditional Nostrums

We should not, I think, be too critical of this readiness to give a professional authority to such homely procedures, however ridiculous most of them may appear. We may remind ourselves that the use of what is still one of the most important of all the symptomatic remedies available to medicine, digitalis, was discovered in the latter part of the following century (1775) by William Withering, as the essential constituent of a cure for the dropsy, which, as he records, "had long been kept secret by an old woman in Shropshire, who had sometimes made cures after the more regular practitioners had failed." And it may be noted that some of the more complicated and expensive remedial mixtures, such as the fabulous mithridate, were also in occasional use in a provincial practice, as well as in that of the London physicians. The mithridate, of the formula which was official when this Society was still in its precarious youth, had evidently acquired a great reputation as a protection against what was then the standing menace of the bubonic plague. Dr. Symcotts records that his important patient, Mr. Oliver Cromwell, "taking abundance of Mithridate to avoid the infection of the plague, cured his pimpled face," and adds a reference to a lady patient in whom its regular use had a similar welcome result.

Mithridate was perhaps the extreme example of a number of these complicated mixtures, often of rare and correspondingly costly ingredients, handed down with innumerable variations over centuries of tradition, with nothing but the cruder kinds of superstition to support their claims to any therapeutic value, but still apparently retaining the confidence of doctors, apothecaries, and patients alike, even long after the period which we are considering. Mithridate was said to have owed its origin, as well as its name, to Mithridates, King of Pontus in the first century B.C. He was supposed to have included in it minute subtoxic doses of poisons of every kind known to him, to protect himself against their actions. (I find it difficult to decide whether the system thus attributed to Mithridates should be regarded as an early adumbration of homoeopathy or of immunology.) In some of its formulae mithridate is said to have required over one hundred ingredients. It was one of the important responsibilities which the early apothecaries shared with the physicians, to supervise its preparation, together with that of other complicated and traditional mixtures, known as diascordium and theriaca.

It is recorded that in 1625 an outbreak of the plague in London caused such a demand for these complex nostrums that some of the normally required ingredients became unobtainable; so that it was necessary to obtain from the physicians a special concession, allowing cinnamon to be

substituted for *Cassia lignea*. There was another reputed "epidemiological antidote," called the "confectio alkermes," the constituents of which, pearl, ambergris, and lapis lazuli, we might suppose to have been chosen expressly for their costliness; and, not unnaturally, the apothecaries found themselves involved in action to prevent the sale of a cheaper counterfeit. There was even stronger reason for them to be watchful of the authenticity of the bezoar stones which were offered; for these, without any imaginable reason, were so highly prized for general antidotal efficacy that the most authentic and potent, obtained from the intestine of a Persian wild goat, would fetch as much as £5 per ounce! And £5 in those days had, of course, several times the purchasing value of even the now almost legendary £5 of the years before the first world war.

Difficult as we may now find it to discover, or even to imagine, any reasonable basis for a belief in the remedial value of such things, it was certainly as sincere and effective as the beliefs in many other superstitions of those days; and it was even more tenacious than some of these. We do not have to go back to the earlier years of the seventeenth-century for evidence of it. Official recognition continued to be given to the merits of a number of these products of a credulous tradition well into the eighteenth century's "age of reason," and even in some cases long after it. The bezoar stone was included in the *London Pharmacopoeia* till 1746, while mithridate and theriaca were retained in the same authoritative compendium till 1788; and even in the latter half of the nineteenth century, when the parents of some of us were already beginning to be frightened by the dangerously rapid progress of scientific knowledge and theory, the *French Pharmacopoeia* of 1866 still included a theriaca, with no fewer than 57 ingredients, and vipers still among them!

Awakening Scepticism

There were signs already, however, fairly early in the eighteenth century that a certain measure of healthy scepticism in such matters was beginning to affect the attitude of some members of the medical intelligentsia. In Dr. William Macmichael's fanciful autobiography of *The Gold-headed Cane*, first published in 1827, you will find a long account—purely imaginative, of course—of a conversation between the learned Dr. Richard Mead and his friends, held in his great library. From internal indications we are supposed to accept this as having taken place about 1727, a century before Macmichael's book appeared. Dr. Freind is represented as having commented, as well he might, on the remarkable advances made by physiology in the half-century between 1620 and 1670, which included, of course, Harvey's publication of *De Motu Cordis* in 1628, his *De Generatione Animalium* in 1651, and the first decade of the Royal Society of London, founded in 1660, three years after Harvey died. *The Gold-headed Cane* proceeds to recall the contribution to this discussion of another member of the circle, unidentified except as one who had "devoted himself more particularly to the study of *Materia Medica*," and who remarks that "it was within the same memorable period that some of our most efficient drugs were either first made known to the world, or first introduced into general use." "It will be sufficient," he continues, "to mention bark, ipecacuanha, mercury and antimony; to which four remedies, if we add opium, it may be questioned whether we should not possess a tolerably complete *Materia Medica*."

We cannot, of course, accept the quotation as having historical authenticity. I find it very remarkable, however, that even Dr. Macmichael himself, writing a century after this imaginary symposium, should have been ready to entertain such a therapeutic heresy, quite apart from the fact that this story imputes it, with evident approval, to a predecessor in the 1720's. For it vividly recalls to me many very similar statements, which I was accustomed to hear as recently as 50 or even fewer years ago, from critical pharmacologists, and even from some of the more sceptically minded physicians of those days. Such men were eager to jettison almost the whole of the traditional empiricism

and irrational polypharmacy still surviving then, and still widely prevalent then among physicians of a less critical habit of mind, who required no sanction for the continued prescription of a particular drug or mixture beyond a vague impression that they had "seen it do good."

If the data were available, however, for a historical survey of the growth of this rationalist movement in medicinal therapeutics, I think that we should find that Dr. Macmichael was not so far wrong in producing an imaginary example of it from the earlier years of the eighteenth century. For we have definite evidence of it, of which *The Gold-headed Cane* also takes note in due course, in the Essay on Mithridatism and Theriaca by the elder Dr. William Heberden, one of the greatest of clinical observers, and therewith a sceptical critic of most of the therapeutics current in his own day. This was published in 1745, when Heberden was still lecturing on *materia medica* at Cambridge, and before he moved to practise in London; and it was so vigorously destructive of the previously unchallenged reputation of these two famous nostrums that it was to lead to their eventual disappearance, as already mentioned, from the *London Pharmacopoeia* of 1788, though they survived much longer elsewhere.

I feel sure, if it were indeed practicable to obtain an authoritative history of therapeutic opinion, that we should find, indeed, that during the eighteenth and nineteenth centuries there had been a number of such partial and tentative approaches to a generally more rational attitude, but that progress in that direction had been at best very slow, and intermittent as well. This slow development is certainly not to be attributed wholly to a blind and conservative clinging to outworn dogmas. We must recognize that, however strong and general might have been a desire for a rationally based therapeutic practice, derived, as Harvey would have said, "not from books, but from dissections," or, as we might amend the phrase for our present purpose, "from experimentally established data," the physiological and pathological knowledge required to provide such a basis did not really begin to become available till the later decades of the nineteenth century. We could claim, indeed, for its final ten years, the 1890's, a very special share in the inauguration of the new therapeutic era, the ever more rapid development of which we are now watching with an excitement verging perhaps on bewilderment.

A Decade of Therapeutic Enterprise

On earlier occasions than this I have already drawn attention to the occurrence, by a curious chance as it may seem, in a single year of that decade, the year 1891, of the discovery and introduction of three new and different kinds of medicinal treatment, each of them rationally based on a special body of experimental evidence, and each of them providing a starting-point for the eventual development of a whole new range of therapeutic enterprise. There was the first treatment in that year of a disease due to a deficiency—the treatment of myxoedema by direct replacement with a thyroid extract, opening the way for all subsequent developments in endocrinal therapy; there was the discovery in 1891 of the antitoxins, giving a new and rapidly effective impetus to immunological treatment, both therapeutic and prophylactic; and there was Ehrlich's early trial, years in advance of its further development, of a new principle in the treatment of infections—a "chemotherapy," aiming at the direct elimination of infecting organisms by specific artificial remedies—when he treated, also in 1891, a few cases of malaria with methylene blue.

The 1890's, as a whole, appear indeed to have been years of intellectual ferment and unorthodox enterprise, in more than one direction; and more than an itch for alliteration, I think, was required to nickname them "the naughty 'nineties." Scientifically they were characterized by a breaking through long-accepted boundaries, and into new territory. The atom, indivisible till then, as its name implied, began to disintegrate with the discovery of the x rays and the rays from uranium. On the biological side this decade saw the

recognition of the viruses, and the discovery, made by Ross with Manson's encouragement, of the mosquito-transmission of malaria; while physiology was stirring in several new directions, to find surprising activities in extracts from the suprarenal capsules and the pituitary body, to unravel the intricacies of distribution and function in the autonomic nervous system. Biochemistry, with all its immense potentialities, was just beginning to assert itself as a separate discipline; and perhaps we should note that, before the century ended, organic chemistry had made a significant step towards a now familiar order of synthetic products, with credentials based on experimental physiology, when it introduced aspirin in 1899. Just after the turn of the century came the first synthesis of a hormone, adrenaline.

Old age, I know, is apt to see the years of its youth through a mist of fallacious memories; and I am prepared for all the discounts which cool reason may demand when, looking back to those closing years of last century, I find the words of a poet coming to mind, in which he recalled an earlier and a different dawn, when "to be young was very heaven."

Of course, I do not suppose that we, who were young then, had any real awareness at the time of what was then, had any clear vision of what was to come. And happening, or any clear vision of what was to come. And I recognize, of course, that any change, dating from that period, in the character of the medicinal therapeutics which is my particular concern in this lecture might be regarded as one of relatively small detail in a great transformation of the whole material and intellectual character of our civilization, as it began to move and expand into its scientific epoch. I do believe, however, that, even in comparison with the remarkable technical advances which the developments in the basic sciences have made possible also in the methods of diagnosis, in functional pathology, and in fact in all departments of medical activity, the medicinal treatment of disease has been the subject of a yet more sudden and a more fundamental transformation since the turn of the century, in that it has undergone a change even in its aims, in the kind of warrant which it demands, and in the kind of results which it expects.

Closing of a Therapeutic Era

We have seen that there had been a long, slow, and intermittent growth of a rational scepticism concerning the claims of most of that therapeutic heritage from mediaeval credulity and superstition with which this Society began its activities. Yet, although before the end of the nineteenth century so much had been eliminated that was fantastic, disgusting, or, at best, useless, there had till then been very few more rationally based remedies to take its place. Some of these, such as cinchona and ipecac, which as we have seen, more critical observers even early in the eighteenth century were reputed to have chosen as examples of drugs having genuine remedial values, had been kept in use indeed; but their specific reputations had been clouded by vague and irrational applications, in spite of the chemical identification of their specific alkaloids. In countries where malaria had disappeared, quinine had been left with a reputation as a general antipyretic, or even as a tonic, presumably on account of its bitter taste; while ipecacuanha had not only become a recognized expectorant, but was widely used in the tropics for the treatment of undifferentiated dysenteries, after the removal of the emetic alkaloids, later recognized as the source of its one specific, antiamoebic activity. And it is not, indeed, until the close of last century, or even until the present one was getting well into its stride, that we can recognize the real ending of a therapeutic era which had been characterized by a sterile scepticism on the one hand, and a complacent, empirical unreason on the other, and can welcome the dawning of a new era, of a rational medication worthy of scientific confidence.

Mention has been made of thyroid gland and the diphtheria and tetanus antitoxins, as pioneer examples of

remedies and prophylactics of the new species, dealing directly with causes. Ehrlich's new chemotherapy had yet to wait till the end of the present century's first decade before it could register its first major therapeutic triumph, with salvarsan; and yet another had to pass, and the first world war to come and go, before the vitamins could claim a comparable success with rickets, and insulin with diabetes mellitus—diseases due to a dietary and a hormonal deficiency, both of them widely prevalent and tragic in their consequences, and till then without any accepted means of effective prevention or treatment.

Accelerating Progress

From that point onwards, the story has, of course, been one of an accelerating progress into this new era of medicinal treatment, with therapeutic applications following ever more closely upon the heels of experimental physiology, pathology, and pharmacology. If we look back to the early years of the century, the contrast between what had then seemed impossible, and what has now become commonplace, gives ground, not yet indeed for complacency, but already, in the light of what has been achieved, for an expectation, to which no real limits can properly be assigned, of what may yet be to come. The centenary commemoration of the birth of Ronald Ross has lent a special interest to the present position of malaria. This one of the great world-plagues had been early in finding fairly effective specific treatment and prophylaxis, in the use of quinine—a chemotherapy, one might say, discovered and applied even long before the malarial parasites or the mode of their transmission were known, and, by Ehrlich's own acknowledgment, the point from which his experimental campaign of chemotherapy took its start. And now it seems impossible to resist the conviction that, with the effective insecticides and prophylactics which research has already made available—research which a world war encouraged rather than hindered—this still predominant cause of death and depressed vitality, for a large section of the human race, could be added to the lengthening list of the diseases which have already been banished, if only the requisite money and man-power could be made available.

The list of the infectious diseases, previously with no effective treatment, which have thus been eliminated or mastered by immunology or chemotherapy, especially since the coming of the sulphonamide derivatives and the antibiotics, has grown to such dimensions, and is receiving such frequent additions, that I cannot mention further examples in detail. I can only ask you to make a retrospective comparison between the present position and that at the beginning of this century, when medicinal treatment was essentially helpless—"expectant treatment" was the familiar phrase—in the face of practically all the common acute infections, with the significant and then recently made exception of diphtheria. And as striking a comparison could be made between the therapeutic possibilities, then and now, in dealing with the diseases due to deficiencies.

I should like to call attention to the development, equally impressive and similarly recent, of rationally based remedies which deal with the symptoms rather than with the primary causes of maladies. Here again we find a new situation, in that the development is keeping ever more closely in step with the advance of knowledge in physiology, pathology, and pharmacology, so that the immediate quest is guided by the aim to deal, no longer just empirically, by blind trial and error, with the overt symptoms as such, but rationally with their proximate causes, as these are progressively revealed by research. An example is afforded by the use of some of the hormones, or of their synthetic analogues, in excess of the normal need—not therefore to replace deficiencies, but to relieve symptoms; and perhaps I may allow memories of earlier research interests of my own to prompt me to mention, in the same connexion, the antihistamines, and the agents which block, or potentiate, the transmission of the excitation across ganglionic synapses, or from motor nerve endings to muscle fibres. And these last are playing their

part, together with the progressive and scientific development of the barbiturates and other anaesthetic and analgesic agents, in the recent remarkable advance in the methods of producing anaesthesia, muscular quiescence, and adjustment of the blood pressure, to meet the needs of surgery. It is obvious, I think, that these improvements, all dependent on a scientifically based medicinal therapeutics, together with the now rapidly improving methods of establishing and physiologically controlling an artificial circulation, are playing essential parts in the dramatically successful extensions of surgery to the heart and its great vessels, and to the other thoracic organs.

Conclusion

I have been making a rather hasty survey, in which has been noted the recent, fundamental, and still progressive change from a medicinal therapeutics which still derived its sanction from a largely irrational empiricism to one which endeavours to follow ever more closely, step by step, the likewise recent development of an aetiology based upon experimental science. The association will certainly continue, and no limit can be rationally predicted to what may further be achieved under its guidance. I do not think that we can doubt the magnitude of the benefit which it has already brought, and will continue to bring, to medicine in its service to the needs of humanity. In its practical applications, however, it will inevitably raise, and indeed may be assumed to be raising already, new problems for medical practice which are likely to create a peculiar difficulty for unspecialized, general practice.

Pharmacology will certainly acquire a growing importance in any effective scheme of medical education. I imagine, however, that its educational aim will have to be increasingly directed to general principles of pharmacological action, in relation to a scientifically warranted therapeutics. For it is hardly to be expected that pharmacopoeias, textbooks, or even annually revised lectures, will continue to keep pace with *materia medica* subject to continual innovation and replacement, dependent for sources of supply, and, to a large and growing extent, for the researches producing the new remedial agents, on large-scale pharmaceutical industry. To enable the optimum benefit for the patient to be obtained from such new therapeutic resources the practitioner will surely need to have a continuing access to some expert and completely independent source of information and advice, on the relative merits and disadvantages of the remedies presented for his choice in so embarrassing and bewildering an abundance, as well as access to the means for a scientific control of the application of many of them. It is one among the needs which we might surely expect a national health authority to be considering, if it were indeed concerned, not merely to settle the terms on which a medical service of some kind can be provided, but to ensure the continuous and progressive improvement of that service, in step with the relevant advances of scientific knowledge and methods, as these become available for its use.

When the All-India Institute of Mental Health was inaugurated at Bangalore in 1954, the Health Minister, RAJKUMARI AMRIT KAUR, emphasized the inadequate facilities for treating mental patients in India. Training facilities, too, were equally poor. The object of the Institute is to train psychiatrists, nurses, and other staff for mental hospitals and to conduct research into problems of mental health and disease. It also intends to conduct surveys in selected urban and rural areas on the incidence of mental abnormality and the biological factors that accompany mental illness. The Institute is divided up into fifteen departments; these include departments of clinical psychiatry, social psychiatry, neurology, radiology, and statistics. In addition to a number of distinguished Indian medical men on the staff, the Institute has, as medical consultant, Dr. W. Mayer-Gross, of Great Britain. Its handbook, recently published, gives details of the courses of study available to postgraduate students.

SUDDEN LOSS OF MEMORY

BY

ALEXANDER KENNEDY, M.D., F.R.C.P.
F.B.Ps.S.

Professor of Psychological Medicine, University of
Edinburgh

AND

JOSEPH NEVILLE, M.B., M.R.C.P., D.P.M.
D.C.H.

Senior Registrar, Joint Department of Psychological
Medicine, Royal Victoria Infirmary and King's College,
Newcastle upon Tyne

The individual who is found wandering or who presents himself at a police station unaware of his identity, his past history, or his whereabouts is a familiar figure in the lay mind which has been reinforced by his frequent appearance in fiction and on the screen. Sudden amnesia is well known in a variety of contexts as occurring after accidents involving head injury, after epileptic fits, in boxers who have been knocked out, after alcoholic intoxication, after sudden personal disasters or bereavements, after stage displays of hypnotism, in battle-exhausted soldiers, in criminals facing arrest, in absconding treasurers and reluctant bridegrooms. Further, it can be induced in normal subjects under hypnosis, and has occurred from time to time in almost epidemic form, the report of one case in the press being the signal for the appearance of several apparently sincere imitators.

Although general opinion thus recognizes that the aetiological factors responsible for an apparently identical clinical feature, a period of amnesia, may be either organic or psychogenic, there is scanty reference in the medical literature to this dual approach to the study of pathological forgetting. Owing to the transient nature of the amnesia, a relatively small proportion of those seen at police stations, casualty clearing stations, hospital accident departments, and doctors' surgeries are referred for detailed psychiatric examination or are, in fact, examined before time and circumstance have either led to recovery or greatly modified the clinical picture.

The object of the present study was to examine the aetiological factors in two series of instances (in all, 74 cases) of abrupt failure of memory with or without loss of personal identity, with a view to establishing the relative importance of organic, psychoneurotic, and volitional factors. As the result of this investigation general conclusions have emerged which seem to us to have practical significance for diagnosis and treatment. In this article the attempt is made to extract from the detailed case material the evidence on which these conclusions may be based.

Previous Investigations

Freud (1904) stated that the primary function of amnesia is that of defence against the admission into conscious thought of traumatic elements involved in a neurotic conflict. An entirely dissimilar view was held by Mott (1919), who, basing his conclusions on patients from the first world war, implicated the factor of organic commotio cerebri resulting from shell-shock. Parfitt and Gall (1944), from their experience of Service men who had not been exposed to front-line hazards, described abrupt loss of memory as a hysterical or malingered evasion of the consequences of

wrongdoing. The hysterical symptom was thus in their view the result of an act of conscious evasion, subsequently forgotten.

The majority of cases of sudden loss of memory reported in the literature are regarded as hysterical. Kanzer (1940), describing a series of 71 cases of "hysterical amnesia" admitted in 1937 to the psychiatric division of the Bellevue Hospital, claimed that the patient who took refuge in loss of memory displayed his basic inadequacy by adopting a childish and ineffective method of dissociating his conscious mental life from the problems demanding solution. Parfitt and Gall also stressed the global psychic immaturity and exhibitionistic dependency of most of their patients, and made a distinction between hysterical amnesia and the "defensive" amnesia found in the neurotic personality. These authors' suggestions echo Gillespie's (1937) division of amnesia into simple malingering and "affective" amnesia; the latter term would appear to be synonymous with Parfitt and Gall's "defensive" memory loss. Several workers have observed that somatic manifestations of tension and anxiety are often exhibited by the amnesic patient. In terms of the theory of the unconscious this could be interpreted as an incomplete conversion with anxiety reaching the conscious level.

Wilson, Rupp, and Wilson (1950) described evidence of perturbation and anxiety in a small number of their series, and Adatto (1949) was impressed with the frequent coexistence of anxiety with amnesia. Kanzer's patients, most of whom were basically reacting against financial and interpersonal difficulties, were often worried by headache, and this symptom was interpreted by him simply as indicating the presence of emotional tension. Abrupt loss of memory, then, is not always a fully effective screen against disabling anxiety. Again, sudden loss of memory tends to be of short duration so that the patient may soon be confronted again with his original difficulties. This is in contrast to the persistent and sometimes impregnable neurotic defences employed by the persistent hysteric, who finds a solution of his conflict in some more permanent disability.

A further point of interest is the tendency of functional amnesia, in the opinion of several observers, to occur in association with demonstrable organic disease of the central nervous system (Kennedy, 1940, 1949; Stengel, 1941, 1943). In some of Kanzer's patients the periods of amnesia followed head injuries and epileptic attacks. Wilson *et al.*, in a series of 59 cases of amnesia, described 15 suffering from organic nervous disease. In this group alcoholic intoxication was a common precipitant of amnesia. In a statistically well-controlled study, Berrington, Liddell, and Foulds (1956) demonstrated that the incidence of previous head injury was significantly greater in patients presenting with amnesia or fugue than in other psychiatric patients. Williams (1947) incriminated epilepsy as an important cause of amnesic episodes in air-crews while flying, and indicated that psychoneurotic factors might contribute towards the production of epileptic amnesia. Williams's work bore out the suggestion, made by Lennox (1943), that cerebral dysrhythmia was an important cause of attacks of loss of memory in patients who, in many cases, had never had convulsions. Despite the attractive psychodynamic interpretations that could be elaborated around individual cases, Abeles and Schilder (1935) pointed to the appearance of short-term amnesic attacks in illnesses as different as cerebral arteriosclerosis and carbon monoxide poisoning, and Buzzard (1897) was probably the first to draw attention to its frequency in disseminated sclerosis.

The plea of sudden loss of memory in criminal actions is quite frequently made, though less often sustained, and Baker (1901) was a pioneer in delineating epileptic automatic behaviour as a valid defence. This view was first given the support of electroencephalography in this country by Grey Walter. Hopwood and Snell (1933) indicated the hysterical or malingered nature of amnesic states in criminals, pointing out that recollection waxed as the need for repression waned. Authorities such as Leitch (1948)

and Davidson (1952) have attempted to distinguish clearly between malingered, hysterical, toxic, and organic amnesic states, but other workers have found themselves forced to admit that clear-cut differentiation is rarely possible (Wilson *et al.*, 1950). Siegal (1951) and Rudolf (1947) have produced evidence that similar transient memory loss can occur in both psychoneurotic and organic disorders.

Theoretical Considerations

In daily life an almost continuous inward process takes place by which a selection is made of the information offered to the senses, in such a way that priority in the field of attention is given to those stimuli which are of immediate interest and use to the individual. That this can occur presupposes the rejection from consciousness or the relegation to marginal awareness of material inconsistent with the preoccupations of the subject at the moment. A man who is walking on a girder high above the ground, for instance, will do so more efficiently and safely if he pays close attention to stimuli from his immediate path and rejects distant appeals to his attention. This mechanism has survival value. At a higher level of nervous integration, the attention required to deal mentally with an abstract problem can be achieved only by the rejection of outside stimuli from consciousness for the time being. This is comparable to the way that the music of a bad gramophone record can be appreciated with an effort by concentrating on its meaning and thus discriminating against the accompanying noise. There is abundant evidence of such a discriminating mechanism at lower levels of nervous activity. The principle necessary for such a system—that is, that one part of the nervous system may react positively or negatively as the result of activity in a distant part—is well established (Sherrington, 1947).

It has been suggested that the clinical manifestations of hysteria may be an exaggeration of normal protective mechanisms (Kennedy, 1940). In time of war, for instance, the soldier must learn to blind himself to some of the realities and dangers of his situation in battle if his efficiency is not to be reduced by anxiety. Under overwhelming or long-continued stress this mechanism of rejection of the not-immediately-useful or the unpleasant may be exaggerated to a pathological extent. Apart from the almost experimental situations of war a process of rejecting sensory impressions, percepts, and memories which are painful or which are inconsistent with the individual's preconceived beliefs or attitudes is a commonplace in the genesis of psychiatric symptoms, and, under the name of "repression," is an essential part of psycho-analytic theory.

Mechanisms of a similar kind have been observed clinically and experimentally at different levels of nervous activity and of human behaviour, and according to the point of view have been called "negative induction" (Pavlov, 1928), "extinction" (Bender, 1952), "non-realization" (Kennedy, 1940), "selective attention" (Mackay, 1952), "discrimination" (McCulloch, 1948), or "selective inattention" (Sullivan, 1956). It is certain that without some such mechanism for excluding from attention stimuli that might detract from efficiency in dealing with any matter in hand it would be impossible for thought and action to be directed consistently towards predetermined ends. Since the capacity to direct the attention towards a goal is essential for normal survival and adaptation, if such a mechanism exists, it might be expected that it would exhibit disorder not only when the individual was under psychological stress but when the nervous apparatus was the subject of disease.

From the psychological point of view, where stress is sufficiently in excess of the individual's constitutional powers of adaptation to give rise to a pathological and intolerable degree of tension, inward flight may be achieved (Kennedy, 1940) either by diverting the attention from the tension-producing subject (flight into activity) or by reducing the amount of attention paid to stimuli generally (flight into non-realization). The latter mental mechanism results in the extinction from the individual's consciousness of the

offending subject, together with a greater or lesser amount of psychologically related material. The result is a loss of awareness of the intolerable memory or situation, which either may be strictly circumscribed to the offending "complex" or may spread to involve the whole of his conscious mental activity, resulting in hysterical stupor or coma. An examination of patients with loss of memory might therefore be expected to throw some light on the conditions, nervous and psychological, which favour or prevent this gross pathological exaggeration or caricature of a normal process which must be in operation at every moment of our waking lives.

Method and Results

Two independent investigations were carried out, one by each of us, giving a total of 74 patients studied in detail.

Series 1 (J. N.).—During a period of three years 21 patients presented themselves with amnesia at the casualty and outpatient departments of the Charing Cross and Fulham Hospitals, at the Royal Salop Infirmary, and at the Royal Victoria Infirmary, Newcastle upon Tyne. All were examined while amnesia was present and a full history was obtained after recovery.

Series 2 (A. K.).—During a period of 15 months 53 persons presented themselves at a London police station or were referred to the Maudsley Hospital. All were at the time unaware of their identity and could not, or would not, tell whence they had come. All were examined for the first time while fully amnesic and the majority were either admitted to hospital for investigation or seen on several occasions as out-patients. In 51 it was possible to take a full history from the patient after recovery from the amnesia, while in two patients who proved to have a gross underlying organic loss of memory the history of the illness was obtained from relatives only.

Investigation of Aetiology

In all the cases it was possible either to arrive at a firm diagnosis of organic nervous disease or to come to a definite conclusion regarding the immediate psychological precipitants. Simple situations relating to marriage, bigamy, debt, financial irregularities, in which there was an element of either fear or conflict, accounted for most of the amnesias. There was a group of patients with a history of previous hysterical illness and of practice in the use of the advantage-of-illness motive. Similar factors were brought to light in some of the patients with demonstrable organic disease, and the amnesia was thus the means of bringing to light the fact that the patient's general adaptation to life had been deteriorating for some time. The following are illustrative of special types:

1. A man of 32 who had walked blindly for several miles before jumping into a pond and who had been rescued by a passer-by. He was calm and helpful but could give no account of himself. Under hypnosis his condition became one of severe agitated depression. There was a history of two previous attacks of depression. His amnesic state was evidently an escape from his psychotic depression, and the idea of suicide had evidently influenced his behaviour in the fugue.

2. An Australian company director who had persuaded others to put up money for a large venture. On doubts being expressed at a meeting about the soundness of his ideas he became abusive and walked out into the street. Picked up as an unknown man, he had been found to be suffering from general paralysis, and for this he was treated in a mental hospital. After improving considerably he escaped, and, in spite of complete amnesia for the period of his illness, obtained work and prospered. His organic illness came to light when he sought advice in this country about the part of his life of which he had no memory. His history, given after the amnesia had responded to hypnosis, was fully confirmed.

3. A young man who was picked up in an exhausted condition by the police. On recovery from the amnesia it transpired that the patient feared that he had murdered his sister. He had in fact attacked her, but she was not seriously harmed. His previous history and the E.E.G. allowed of a confident diagnosis of choroid epilepsy. The epileptic automatism had been

followed by a functional one due to the situation created by his attack of violent behaviour, of which there had been previous examples.

4. A man of 28 with a good work record up to four years previously had been sent to prison for a series of burglaries. He was wanted by the police and had been sleeping in houses which he entered at night in search for food and money. He walked into a police station in an amnesic state. After some discussion his memory returned and he said that he would like to tell the police what he had been doing, serve his sentence, and get a job. On examination, however, there was an early hemiparesis. There was a history suggestive of an attack of encephalitis seven years before. Four years ago he had left a good job and taken to night work because of inversion of his sleep rhythm. The decline in his adaptation to life could clearly be traced to the organic disease.

5. A 17-year-old girl of low average intelligence was brought to hospital by the police, having been found "sleeping rough." At first she exhibited a complete loss of memory extending to ignorance of her identity, but apart from a patchy amnesia for the previous two days her memory returned after a bath and a meal. She had run away to London after a quarrel with her stepmother. To make a living without revealing her whereabouts to her family, and since she "felt that the end of the world had come and things couldn't be worse," she began to accost men in one of the royal parks. Promiscuity seemed initially to gratify her, but after she had been ill-treated and robbed by a gang of men she became severely depressed. During the two days' amnesic period she had evidently been in a state of clouded consciousness, making no effort to obtain food or shelter. In this case a combination of amnesia with a fugue state seems to have acted as a screen against realization of what she had done and against her intolerable depressive thoughts. In this case no useful purpose would have been served by attempting to break down this defence, and, after her memory had recovered in other respects, the matter was not pressed.

The aetiology of the amnesia as ascertained in the 74 cases is summarized in Table I.

TABLE I.—Psychiatric Aetiology in 74 Patients with Sudden Amnesia

	Series		Total	%
	1	2		
Gross organic disease of C.N.S.	8	19	27	37
Major epilepsy	5	4	9	12
Hysterical amnesia without organic disease	10	25	35	47
(a) With previous history of hysteria	6	16	22	30
(b) No previous history	4	9	13	17
Psychopathic personality or very bad employment record	8	7	15	20
Feeble-minded or illiterate	0	2	2	3
Admitted malingering	0	5	5	7
Fugue associated with suicidal attempt	3	3	6	8
Functional psychosis present	3	4	7	10
Depressive state	2	3	5	7
Other	1	1	2	3
Fearing arrest or disciplinary action	3	9	12	16
Senile	0	2	2	3
Under age 12	3	0	3	4

Organic disease was found in 27 patients. The distribution is shown in Table II.

TABLE II.—Varieties of Organic Nervous Disease Found in 27 Out of 74 Patients with Sudden Amnesia

	Series		Total	%
	1	2		
Idiopathic epilepsy	1	4	5	19
Head injury	3	1	4	15
Chronic encephalitis lethargica	1	3	4	15
Rheumatic chorea	1	0	1	4
Disseminated sclerosis	0	2	2	7
Increased intracranial pressure	0	2	2	7
Cerebral syphilis	0	2	2	7
Presenile dementia	1	3	4	15
Hypertensive encephalopathy	1	0	1	4
Freidreich's ataxia	0	1	1	4
Diffuse sclerosis	0	1	1	4
Total	8	19	27	

In some of the patients it was not possible to assign a single aetiology, and organic nervous disease existed in the presence of a clear psychogenic precipitating factor. The overlap of aetiologies is shown in Table III.

TABLE III.—Psychogenic, Organic, Psychotic, and Malingered Amnesia in 74 Cases Showing Overlapping Causes

	Series		Total	%
	1	2		
Convincing psychogenesis discovered but no evidence of organic disease	10	16	26	24
Psychogenesis elicited and organic disease present	6	19	25	23
Organic disease or dementia present	8	21	29	27
Organic disease present but no evidence of psychogenic factors	2	8	10	9
Malingering	0	5	5	5
Psychosis, excluding depression	3	4	7	7
Endogenous depression with hysterical fugue	2	2	4	4
Total	31	75		

The extent to which organic and psychogenic factors contributed throughout the series is shown in the following analysis of 61 patients with sudden amnesia (malingerers and psychotics excluded): psychogenic, 43%; dual aetiology, 41%; organic, 16%.

The sex incidence is shown in Table IV.

Treatment

Amnesia is a condition calling for symptomatic treatment if only to enable a history to be taken from the patient. There is a strong tendency to spontaneous recovery, although this may be much delayed if nothing is done. The method chosen in the two series depended on three factors: (1) The kind of treatment possible in a police station, casualty department, or general hospital ward, where the absence of distracting noise is difficult to ensure. (2) The state of the amnesia and the attitude of the patient to medical aid. The presence of mental confusion, intoxication, or aggressiveness, for instance, made hypnosis or narcotic abreaction impossible. (3) The approach used was that which the individual investigator preferred and felt he could use with success. Thus in Series 1 (J. N.) suggestion with a vehicle was used in 4 out of 21 cases, while it was not used at all in Series 2 (A. K.), where 31 out of 53 patients were treated by means of hypnosis only. It was shown that recovery could be brought about by six main methods.

(i) **Therapeutic Anamnesis.**—Establishing contact with the patient and causing memory to return by encouraging him to extend his history until he realized that he could recall details about himself normally.

(ii) **Hypnosis.**—Amnesic patients are easy to hypnotize if the induction is rapid and amnesic somnambulism rather than light hypnosis is the aim. Sometimes induction is almost instantaneous. Under hypnosis the patient is made to relive known incidents in his past and to produce a sort of running commentary. During this there is usually considerable emotional abreaction with deepening of the hypnosis. When the emotion has subsided the patient is kept talking and told to wake up, when he discovers that he is recounting past events and that his amnesia is at an end.

(iii) **Narcotic Abreaction.**—A great deal of the effect of using intravenous barbiturates is due to suggestion, especially if the patient has the impression that he has been given a "truth drug." There is usually a considerable abreaction, and the patient may relive some event related to his amnesia and realize its significance when the effects of the narcotic have passed. This aspect is increased by the use of methamphetamine.

(iv) **Suggestion, Direct or with Vehicle.**—An impressive approach to the patient may induce recovery almost at once, and the giving of an injection, exposure to flashes of light from a photic stimulator, or the use of faradism to the scalp may act as vehicles for suggestion.

(v) **Direct Discussion.**—This was reserved for shallow hysterics and also for malingerers wanted by the police and "on the run." The process consisted in letting the patient know that loss of memory was a method of evasion fully understood by both doctors and police officers, and that the best course would be to avoid introducing medical and psychiatric complications into a simple matter of law. Where the patient had already been picked up by the police he was then questioned by them *de novo* after a rest, there being no admixture of police and psychiatric procedure.

(vi) **Medical Measures.**—Where the amnesia is associated with a physical disorder affecting the nervous system it is necessary to apply as early as possible any method likely to improve the level of consciousness which carries no undue risk to the patient. The single case of hypertensive encephalopathy responded to the intravenous injection of 50 ml. of hypertonic dextrose alone, while one patient with raised intracranial pressure responded to intravenous sucrose. In the other it was deemed inadvisable to use this method, and the patient recovered his memory under light hypnosis attempted on the principle that if the amnesia can have a dual aetiology it might respond to either physical or psychological treatment.

The mode of recovery of the 74 cases is summarized in Table V.

TABLE V.—Progress and Response to Immediate Treatment of Amnesia

	Series		Total
	1	2	
Spontaneous recovery, immediate or after medical measures	0	3	3
Recovered during therapeutic interview	14	12	26
under hypnosis	0	31	31
Suggestion with vehicle	4	0	4
Recovered after narcotic abreaction	1	2	3
"spontaneous convulsion	2	0	2
Malingering, dismissed with warning	0	3	3
Organic amnesia, no appreciable improvement	0	2	2
Total	21	53	74

Clinical Findings

The majority of the patients were aware of their loss of memory and either complained of this or allowed it to be inferred. In many, personal identity was retained with ignorance of address and locale. The greater number exhibited an attitude of incurious detachment to their disability, although others were distressed or perplexed. It was not possible to separate features of the amnesia itself which indicated an organic or functional cause, and even when the patient's capacity for attention was low the state of consciousness was of small diagnostic value. The discovery of organic nervous disease depended, therefore, on physical signs or on the detailed neuropsychiatric assessment made after memory was restored. In two patients with gross degenerative cerebral disease there was very severe underlying organic loss of memory, yet at the first impression the clinical picture was not unlike that seen in the exhausted patient with a functional amnesia.

A finding common to both series was that the patients were highly suggestible, so that the level and content of the amnesia was readily influenced by the nature of the investigator's questions and by his attitude as interpreted by the patient. This suggestibility in recent hysteria is in contrast to the resistance to suggestion characteristic of patients with functional disabilities which have become well established. As experience grew it became easier to relieve the loss of memory in organic as well as in functional amnesia by direct suggestion. In the second series it was noteworthy that a very high proportion of the patients were

X-ray Examinations.—Barium-meal and follow-through examination carried out elsewhere shortly after the first attack of pain showed the signs of an entero-enteric intussusception of the upper jejunum. Three subsequent barium follow-through examinations were carried out: the first two

of these showed no abnormality apart from some "hold-up" in the upper jejunum; the third demonstrated a pedunculated polyp in the jejunum. Barium enema was negative.

Operation.—At laparotomy on June 29 several small entero-enteric intussusceptions were discovered. These were easily reduced, and in relation to them many polyps were palpated in the jejunum and ileum. The greatest concen-

FIG. 1.—Pigmentation of lips and face in Case 1.

tration of these was in the ileum, about 3–4 ft. (90–120 cm.) above its termination. Twelve of the larger polyps were removed by enterotomy, and a 10-in. (25-cm.) length of ileum, containing a large number of polyps, was resected, continuity being restored by end-to-end anastomosis.

Pathology.—The twelve separate polyps were found on microscopy to be benign adenomata, and the 10-in. (25-cm.) length of ileum was studded with polyps. Thirteen of the latter were comparatively large, and on microscopy were also found to be benign adenomata; there were numerous smaller polyps and sessile tumours which were not sectioned.

Convalescence from the operation was uneventful. The patient has been followed up and seen at three-monthly intervals, remaining symptom-free. On January 1, 1956, sigmoidoscopy revealed a pedunculated rectal polyp, about 1 cm. in diameter, at 12 cm. This was removed with the diathermy snare; microscopy showed a benign adenomatous polyp.

Case 2

A man aged 56 was first seen at Harrow Hospital in December, 1946, when he was admitted as an emergency case with acute intestinal obstruction. He gave a history of several previous attacks of abdominal pain, sometimes associated with the passage of blood in the stools.

First Operation.—In 1937 a polyp had been removed from his rectum at another hospital. On laparotomy an irreducible ileo-ileal intussusception was found which was resected.

The specimen was not examined histologically, but it is recorded that the apex of the intussusception was formed by a collection of polypoid tumours.

He was not seen again at Harrow Hospital until 1954, when he attended the out-patient department complaining of recurrent attacks of abdominal pain accompanied by diarrhoea.

On examination a soft mobile mass was felt in the right iliac fossa. Rectal examination was negative. Sigmoidoscopy revealed melanosis of the rectal mucosa without other abnormality. Barium enema showed some small rounded filling defects scattered along the colon, but the caecum was not clearly shown.

Second Operation.—At laparotomy on December 9, 1954, numerous polyps were felt in the caecum and transverse and descending colon. Near the hepatic flexure were two or three large polyps which were thought to be malignant. The small intestine was examined but no polyps were discovered. Total colectomy was performed and the ileum was anastomosed to the rectum.

Pathology.—The resected specimen consisted of the colon and 3–4 in. (7.5–10 cm.) of terminal ileum. Numerous polyps were present in the colon, scattered along its length. The three largest were sectioned and carcinomatous change was demonstrated in one; the other two were benign adenomata.

Convalescence was uneventful. A subsequent barium follow-through examination showed no abnormality in the small intestine. On October 13, 1955, he was readmitted for further examination, as he was complaining of occasional attacks of abdominal colic since the last operation, of frequent loose motions, and the passage of blood on one occasion. He was examined specifically for the presence of any abnormal pigmentation, and for the first time melanin spots were noted. These were dark-brown and black discrete spots varying from 1 to 3 mm. in diameter. They were most numerous around the eyes, across the bridge of the nose, on the forehead, and on the nape of the neck. They were relatively sparse around the mouth, but there were some dark bluish patches on the mucosal surface of the lower lips and inside the cheeks. The dorsal surfaces of the hands were covered with light-brown and dark-brown spots; the feet were almost free. No pigment spots were present on the arms, legs, or trunk. When he was asked about the pigmentation he said that it had been present all his life and had, in fact, faded since his boyhood, when he recalled having been taken to hospital for advice concerning the dark spots on his face. He had completely lost touch with his family—both brothers and sisters, and two sons—but he could not recall that any of them had suffered from either pigmentation or abdominal pain.

Apart from the pigmentation no abnormality of importance was discovered. Sigmoidoscopy was repeated, but revealed no abnormality other than the rectal melanosis. Examination was repeated early in 1956 with negative findings.

He remained fairly well until August, 1956, when he reported the passage of blood per rectum. Digital examination discovered an obvious carcinoma of the rectum, confirmed by sigmoidoscopy and biopsy.

Third Operation.—At laparotomy on August 10 the rectal carcinoma was found to be extensively invading the sacrum and was irremovable. The ileo-rectal anastomosis was divided and an ileostomy fashioned.

Case 3

A youth of 18 was admitted to University College Hospital in December, 1946, with a history of recurrent attacks of severe abdominal colic over the last three years. These attacks, not related to meals, were sometimes accompanied by vomiting. The attacks had become more frequent and severe in the last three months. The bowel motions were regular and contained no mucus or blood. A younger brother suffered from occasional attacks of pain of the same type.

On examination, apart from slight fullness in the right hypochondrium, no abnormality was found. No pigmentation of the face or lips was noted. A barium meal and follow-through examination showed dilatation of the duodenum with numerous rounded translucencies, particularly of the second and third parts. There was also some dilatation of the upper jejunum.

First Operation.—At laparotomy on December 13 the second, third, and fourth parts of the duodenum were found to be grossly dilated. The upper jejunum was dilated for 2 ft. (61 cm.) and several small solid tumours were felt within the lumen. The lymph nodes in the upper part of the mesentery were enlarged and firm. The rest of the gastro-intestinal tract appeared normal. The duodenum was opened and many polypoid tumours were found arising from the mucosa. One of these was removed for microscopy and the duodenum was closed. Microscopy of the excised tumour showed a benign adenomatous polyp.

In view of his continued symptoms, removal of the polyp-bearing portion of the intestine was decided upon.

Second Operation.—On January 13, 1947, the duodenum and upper 2 ft. (61 cm.) of jejunum were resected together with the head of the pancreas. The distal jejunum was closed and anastomosed to the common bile duct, pancreas, and stomach. At the end of the operation the patient's condition was very poor and he died two hours later.

FIG. 2.—Resected specimen from Case 3. Duodenum and upper jejunum bisected to show the polyps arising from the posterior wall.

duodenal polyps were very large. Microscopy of the larger tumours showed benign adenomata without evidence of malignant change.

Case 4

A woman aged 55 was admitted to University College Hospital on December 9, 1953, complaining of severe abdominal pain of 10 days' duration, associated with vomiting. Over the past two years she had had several similar attacks which had lasted for six to seven days. She had always been constipated, but more so at the time of the attacks. She occasionally passed blood per rectum independently of the attacks of pain. A cholecystectomy had been performed elsewhere in 1936. No relatives were known to have suffered from similar attacks of pain.

On examination she was seen to be very obese. There was tenderness in the right hypochondrium; no other abnormality was found in the abdomen. Small haemorrhoids were seen on proctoscopy, but no abnormality was felt digitally. No abnormal pigmentation of the mouth or lips was noted.

The abdominal pain subsided spontaneously shortly after admission but returned on December 23, and at that time a vague mass, which appeared to come and go, was felt just above and to the left of the umbilicus. This attack was short, but on December 31 severe pain recurred and

on the following day she presented the classical signs of intestinal obstruction with vomiting, distension, and visible peristalsis. A large tender mass could be felt in the left hypochondrium.

Operation.—At laparotomy on January 1, 1954, a jejuno-jejunal intussusception was found about 2 ft. (61 cm.) below the duodeno-jejuno flexure. Reduction was impossible. The intussusception was resected and end-to-end anastomosis carried out. The adjacent jejunum appeared normal, but the rest of the intestine was not explored as the condition of the patient was precarious.

Her post-operative progress was satisfactory until January 13, when she suddenly collapsed and passed a large amount of altered blood per rectum. In spite of immediate blood transfusion her condition steadily deteriorated and she died in a few hours.

At necropsy the end-to-end jejunal anastomosis was sound. A number of epithelial tumours, both sessile and pedunculated, were present for a distance of 1 in. (2.5 cm.) on either side of the anastomosis. Below the anastomosis the small intestine and the colon contained a large amount of dark red fluid blood, but no further tumours were found. It was presumed that the source of the bleeding was one of the remaining polyps.

Pathology.—The resected specimen consisted of an intussusception, the apex being formed by a warty area of mucosa. The epithelium of the intestine involved in the intussusception was studded with numerous oedematous tumours. Microscopy of several of these tumours, and also of those remaining in the jejunum and discovered at necropsy, showed benign adenomata.

Discussion

Cases 1 and 2 are examples of the association between adenomatosis of the gastro-intestinal tract and melanosis of the lips, face, and oral mucosa. Although no pigmentation was noted in Cases 3 and 4 it is possible that it was missed, as we were not aware of the syndrome at the time these patients were seen. The ease with which it may be overlooked is shown by the fact that it was not noticed in Cases 1 and 2 until it was specially looked for with awareness of the syndrome, after the presence of intestinal polyps had already been demonstrated. The possibility of this mistake has been previously pointed out by Wolff (1952). Both these patients were conscious of their abnormal pigmentation; both had previously sought advice concerning it, but neither of them mentioned it until inquiry was made. The first patient (Case 1) subsequently told us that she had been shown to a meeting of the Dermatological Section of the Royal Society of Medicine in 1938, the report of which had been traced (Mitchell-Heggs, 1939).

Diagnosis of small-bowel tumours is usually difficult. Cattell and Colcock (1947) comment that because tumours in this situation are not common they may not be thought of in a patient complaining of mild abdominal cramps or intermittent rectal bleeding. Because of this, any diagnostic aid is useful, and melanin pigmentation is worth looking for in every patient with abdominal pain of obscure origin. Provided that it is borne in mind, it should be easily recognizable. An excellent description of the syndrome has been given by Jeghers *et al.* (1949), and there is little to add to their account; but since familiarity with the condition is not as general as it might be it is worth reiterating some of the features of the syndrome, now usually named after Peutz (Touraine and Couder, 1945).

Pigmentation

Pigmentation is probably present at birth but may not be noticed until early childhood. A case in a patient under 1 year has been reported (Andrews, 1954). Peutz (1921) suggests that the intensity of the pigmentation fades with increasing age and may therefore be less noticeable in older patients. Both our patients (Cases 1 and 2) mentioned this

recession of the pigmentation. Nearly all the reported subjects have been of dark complexion (as were all our four patients), but fair-skinned and fair-haired patients have been reported (Kleitsch *et al.*, 1955; Jones, 1953).

According to Jeghers *et al.* (1949), pigmentation of the oral mucosa is the essential part of the syndrome; the skin may or may not be affected. One of Peutz's cases also showed pigmentation of the rectal mucosa, as did one of our patients (Case 2), but this is uncommon, and melanosis here is, of course, of frequent occurrence apart from this syndrome.

The pigment spots of the mucosa are usually blue-black in colour. They are most numerous on the mucosal surface of the lower lip and cheek, but may be found also on the palate, gums, and the tongue (Jeghers *et al.*, 1949).

The skin pigmentation consists of dark-brown or, occasionally, black spots which remain discrete and do not coalesce. Most of them are about the size of small pin-heads, and they are most numerous around the mouth and in a butterfly pattern below the eyes and around the bridge of the nose. Pigment spots may also be found on the extremities, principally on the dorsal surface of the fingers, as they were in our two patients. Under the hand lens the patches have a stippled appearance which was clearly seen in Case 1. Histological examination reveals a collection of melanin distributed in vertical bands through the epidermis (Sherman and Tenner, 1952). A small biopsy was taken from the lip in our Case 1 in 1938, when she sought advice, requesting the removal of the pigmented spots. Microscopy showed "multiple pigmented cells in the deepest layer of the epithelium and melanophores in the fibrous tissue" (Mitchell-Heggs, 1939).

It is important to distinguish these pigmented spots from ordinary freckles. Clinically this distinction can be made by consideration of: (1) The occurrence in people of dark complexion: freckles occur, as a rule, in fair-skinned subjects. (2) The colour: freckles are a lighter brown. (3) The distribution: freckles of the face are most numerous on the cheeks and relatively sparse around the mouth. In this syndrome pigment spots are most numerous in the areas described above and are not usually found on the neck, trunk, or proximal parts of the limbs. (They were, however, numerous on the nape of the neck in our Case 2.) Freckles are not associated with intraoral pigmentation.

Confusion may arise with the pigmentation of Addison's disease (Tanner, 1951), which may also be associated with abdominal symptoms, but the distribution of the pigmentation and, if necessary, biochemical tests should differentiate the two conditions.

Polyposis

The term "polyp" implies a pedunculated tumour. In these cases, however, many of the tumours are sessile, and would be better described as adenomata, to indicate their epithelial origin and avoid possible confusion with other varieties of tumour. In the Peutz syndrome adenomata are scattered throughout the length of the gastro-intestinal tract, but involvement of the small intestine was present in all reported cases, and this may be regarded as an essential part of the syndrome. The small-intestine adenomata may be in the ileum or jejunum, but are usually more numerous in the latter. Adenomata are found in the colon and rectum in rather over half the cases (Peutz, 1921; Jeghers *et al.*, 1949), and tumours in this part of the bowel may be more numerous than in small intestine, as in our Case 2. This syndrome should not, however, be confused with familial polyposis of the large intestine, where the adenomata are confined to the large bowel. This disease of the colon has been very thoroughly investigated; at St. Mark's Hospital 60 colonic-polyposis families have been studied, but no case has been seen exhibiting the melanin pigmentation here described (C. E. Dukes, 1957, personal communication). Adenomatous polyps have often been found in the stomach of patients with the Peutz syndrome (Jeghers *et al.*, 1949; Tanner, 1951). Ravitch (1948) reports the case of a patient whose whole gastro-intestinal tract from cardia to anus was

studded with polyps; however, no pigmentation was noted in this case. In two of Peutz's patients polyps were also present in the nasopharynx.

The symptoms produced by these tumours have been classified by Olson *et al.* (1951) as: (1) symptoms of obstruction, (2) bleeding, and (3) symptoms produced by local irritability of the intestine. The first symptoms most often appear between 10 and 30 years of age, although the diagnosis has been made in many younger and a few far older patients.

Obstruction, which may be due to obturation of the intestine, but more often to intussusception, causes spasmodic abdominal pain, which may be associated with vomiting. Intussusception in general is rare in adult life, 78% of cases occurring before the age of 1 year (Williams and Williams, 1949), and when it does occur in adults a tumour of the bowel is nearly always the cause. The intussusception tends to be a chronic one, less dramatic than the infantile variety, but it may become acute later.

Frank bleeding is most often due to polyps in the colon, but sometimes the origin is in the small intestine. If ileal tumours are responsible the blood is usually dark red, but jejunal tumours will lead to tarry stools. In many cases bleeding is not severe enough to be noticed but may cause an iron-deficiency anaemia.

Local irritability of the small intestine may lead to diarrhoea, and duodenal tumours often cause symptoms suggestive of a peptic ulcer.

The difficulty of clinical diagnosis has already been stressed. Radiology may be of little help, as the demonstration of polyps in the small intestine is notoriously difficult, although sometimes the typical appearances of chronic intussusception are seen in a barium follow-through examination. Polyps in the rectum can be seen on sigmoidoscopy easily enough and gastric polyps may be seen on gastroscopy (Tanner, 1951), but tumours are not always present in these sites, and, even if they are recognized, do not, of course, indicate involvement of the small bowel.

The only easy way of arriving at a diagnosis is therefore by recognition of the presence and significance of the typical pigmentation, which often obviates the need for repeated investigation of these difficult cases. Jeghers *et al.* (1949) reported that only one person showing the typical pigmentation had been found in whom small-bowel polyposis had not been demonstrated by full investigation short of laparotomy. Wolff (1952) sums up the position when he says, "Dark pigmentation on the mucosa of the lips and mouth in a patient without Addison's disease, and with a history of abdominal pain, strongly suggests polyposis of the small intestine."

Family History

There is a strong tendency for this syndrome to occur in near relatives. Crone and Light (1954) have reported two triplets with the full syndrome; the third showed the pigmentation, but the presence of polyposis had not been demonstrated at that time. However, several apparently sporadic cases have also been reported, and a family history does not appear to be an essential part of the syndrome. No such history was obtained from either of our two patients. Although there was a suggestion that a brother of Case 3 suffered from intestinal colic, no pigmentation was noted in this patient.

The inheritance of familial polyposis of the colon has been very fully worked out (Dukes, 1952a), but it has not been possible to analyse the inheritance of the Peutz syndrome so thoroughly owing to the comparatively small number of known cases. However, it probably follows a similar genetic pattern and is inherited as a Mendelian dominant which is not sex-linked (Jeghers *et al.*, 1949); new cases may occur as a result of gene mutation.

Risk of Malignant Degeneration

The complications of haemorrhage and intussusception have been discussed. The only other important complication

is that of development of carcinoma in a previously benign adenoma. This risk is high and well recognized in the case of familial polyposis of the colon, in which condition the average age of diagnosis of carcinoma is about 35 years, and the ultimate development of carcinoma is almost invariable if the polyposis is left untreated (Dukes, 1952b). Gastro-intestinal polyposis of the Peutz type has

Bailey (present cases)	F 35 M 56	Adenocarcinoma (colon and rectum). Small-intestine tumours not examined microscopically

not in the past been considered so seriously from this point of view. In order to obtain more information on the incidence of carcinoma I have looked through all the published case reports. The Table summarizes those cases where adequate details have been given concerning the distribution and histology of the intestinal tumours. Including our two patients (Cases 1 and 2) this gives a total of 67 patients for analysis. The occurrence of carcinoma of the gastro-intestinal tract is recorded in 16 of them, an incidence of nearly 24%. In 13 of these cases the malignant tumour was situated in the small intestine, an incidence of about 19%. In the remainder the carcinoma developed in the colon or rectum. These figures are startling, especially when it is considered that the recorded incidence of carcinoma would probably be higher if all polyps removed were subjected to routine serial section (River *et al.*, 1956). Vary (1956) also comments that many of these patients die from the effects of multiple intussusception or anaemia and thus do not reach the age of maximum incidence of cancer.

Clearly the polyposis of the Peutz syndrome must be regarded as a precancerous condition.

Treatment

In the past it was agreed that no treatment was indicated in this condition until the need was determined by symptoms, except in the case of colonic polyps accessible to sigmoidoscopic removal. Intussusceptions were treated by emergency operation and at the same time the bowel was examined for the presence of polyps, the larger ones being removed by enterotomy or resection of short lengths of intestine.

Recognition of the precancerous nature of this syndrome raises the question of whether a more aggressive policy should not be adopted. If the patient is known to be suffering from polyposis, should surgery be undertaken in the absence of serious symptoms; or, further, should laparotomy and any further procedure necessary be undertaken on recognition of the pigmentation alone, in the absence of any definite evidence of polyposis? In the case of familial polyposis of the colon, surgery for prophylaxis against cancer is now accepted, and many of these patients are treated by total colectomy, ileo-rectal anastomosis, and control of polyps in the rectal stump by regular sigmoidoscopic examinations. There is clearly a need for similar prophylactic surgery when dealing with the more generalized polyposis of the Peutz syndrome, but if the principle is accepted two questions must be answered—What type of surgery? and When should it be carried out?

In a few cases the polyps are localized to comparatively short lengths of intestine, resection of which is possible, although, since it is easy to overlook small polyps when palpating the unopened intestine, this will not always result in removal of all the tumours. An example of this is provided by our Case 4. If the polyps are more generalized resective surgery is contraindicated by the need to preserve enough small intestine for adequate function. Camp and Lesser (1952) resected half the duodenum, the whole jejunum, and half the length of the ileum without any apparent ill effect, but this must be regarded as exceptional; in general, resection of much shorter lengths of small intestine will result in severe jejuno-ileal insufficiency. Resection of the colon, removal of a short length of small intestine, and ileo-proctostomy are permissible where the colon is extensively involved and only a few polyps are situated in the small bowel, which is occasionally the state of affairs—for example, our Case 2. In other cases some alternative method of clearing the intestine of these dangerous adenomata must be adopted. Such a method has been suggested and carried out by Vary (1956). Briefly, the procedure is as follows.

A 1½-in. (4-cm.) longitudinal enterotomy is made on the antimesenteric aspect of the jejunum about 10 in. (25 cm.) below the duodeno-jejunal flexure. Through this, tissue forceps are passed up the lumen of the intestine and made to

grip the mesenteric border as high up as possible. By a combination of traction on the forceps and pressure from without the jejunum is intussuscepted and made to protrude through the enterotomy opening, so that the mucous surface is facing outwards, and is available for inspection and removal of any adenomata. After reduction the intestine below is brought upwards through the enterotomy in a similar manner and cleared of polyps in turn. The enterotomy is then closed transversely. The process is continued serially down to the ileo-caecal junction or into the colon if necessary. Vary states that this procedure causes little disturbance to the patient and recovery is uneventful. This type of operation appears to be the most practicable method of cancer prophylaxis in this disease, but it is unlikely to be entirely effective, as it is easy to overlook tiny tumours and also because new adenomata may develop in the future. The suggestion that the procedure could be repeated every few years is not likely to meet with general acceptance. Certainly following such an operation, or indeed any operation in this disease, the patient must be kept under observation and re-examined at frequent intervals.

The next problem is to decide when surgery should be carried out. In the 16 patients developing carcinoma (see Table) the average age of diagnosis of malignant disease was 27 years, or, if the three patients with cancer of the large intestine are excluded, 20 years. From these figures alone it might be argued that clearance of the polyps should be undertaken at an arbitrary age of about 18 years. However, exploration at this age might well be negative, since, although this is a congenital syndrome, it appears likely that in many cases the polyps do not develop until a comparatively late age; it is, for example, difficult to believe that the polyps had been present for very long in our first patient (Case 1), as she had no intestinal symptoms at all until the age of 33 years—that is 17 months before her abdominal operation. For the time being, therefore, the question of the timing of the operation must remain unsolved, but it is suggested that where symptoms have been present for more than a few months a clearance of as many adenomata as possible should be carried out along the lines indicated above, or, if an emergency operation is required owing to the occurrence of intussusception, a similar general clearance of polyps should be attempted where the general condition of the patient permits.

To settle the question, an idea of the average duration of symptoms before the development of malignant degeneration is required, and in order to obtain further information it is desirable that all cases of this syndrome should be reported, as only a few cases are likely to be seen by any one group of surgeons. Full details are particularly required in cases complicated by the development of carcinoma. Details of long-term results following prophylactic operations are also necessary in order to assess their effectiveness.

Other Reported Cases

The Table includes only those cases where full details are available. Other patients with the syndrome have been reported by Peutz (1921), Touraine and Couder (1945), Ravitch (1952), Andrew (1953), Andrews (1954), Goldberg and Goldhaber (1954), Bortz and Bethell (1955), Hafter (1955), Horzelowa and Stapinski (1955), Exinger (1956), Klostermann (1956), and Vary (1956). The reason for the exclusion of these cases from the Table is in most instances lack of pathological information concerning the polyps or because the small intestine had been investigated only by x-ray examination and not at operation. With the 67 cases already included in the Table, this brings the total number of reported cases which I have been able to trace up to 80. A further case described by Renyard (1951) is almost certainly an example of the Peutz syndrome, but the description of the pigmentation does not correspond to the typical picture. The two cases described by Cronkhite and Canada (1955), in which gastro-intestinal polyposis was associated with diffuse pigmentation, alopecia, and atrophy of the fingernails, appear to be examples of another syndrome as

the authors themselves suggest. Several other probable examples of the Peutz syndrome have been reported, but since they cannot be regarded as certain they are not listed.

Summary

Four cases of polyposis of the gastro-intestinal tract are reported. Melanin pigmentation of the mouth, lips, and digits was noted in two of these cases, which are considered to be examples of the syndrome described by Peutz (1921).

The essential features of this syndrome are: (a) dark pigmentation of the buccal mucosa of lips and cheeks, and often of the skin of the face and digits; and (b) multiple adenomata of the gastro-intestinal tract with involvement of the small intestine in all cases.

The main symptoms of tumours of the small intestine are intermittent obstruction and bleeding. The difficulties of diagnosis are discussed and the usefulness of the pigmentation as a diagnostic aid is emphasized.

Sixty-seven reported cases of the Peutz syndrome are tabulated. The incidence of malignant tumours is 24%.

The treatment of the syndrome is discussed. Elective surgery for prophylaxis against cancer is justified when symptoms attributable to polyposis are present. Removal of the tumours may be accomplished by serial enterotomies or resection of short lengths of intestine.

I would like to thank Mr. D. R. Davies for permission to publish case reports of two of his patients and for allowing me to see his patients at Harrow Hospital; and Mr. E. K. Martin and Mr. H. R. I. Wolfe for permission to publish case reports of their patients at University College Hospital. My thanks are also due to Dr. Basil Solomon, Mrs. June Treacy, and Mrs. Gerda Holt for help with the translation of the Dutch and German literature, and to Mr. A. Bligh and the staff of the photographic department of U.C.H. Medical School for the photograph.

HYPOPITUITARISM WITH CONSECUTIVE DEVELOPMENT OF DIABETES MELLITUS

BY

A. GRUNBERG, M.D.

AND

J. L. BLAIR, M.D., M.R.C.P.Ed.

Diabetic Centre, St. Catherine's Hospital, Birkenhead

The first convincing demonstration of the importance of the anterior part of the pituitary gland in diabetes mellitus was given in 1931 by Houssay and Biasotti, when they showed that the diabetes which followed pancreatectomy in dogs could be alleviated by hypophysectomy; and the "Houssay dog" formed the basis for a great deal of experimental work in the years that followed. It was also found that if anterior pituitary extracts were injected into dogs thus operated on the diabetes reverted to its former severity. Later, Young (1937) found that administration of pituitary extract to adult dogs for a certain length of time led to the development of diabetes mellitus. The occurrence of hyperglycaemia and glycosuria in a proportion of patients with acromegaly had of course been recognized for many years.

In the last twenty years the role of the pituitary and of other endocrine glands in the aetiology of diabetes has become increasingly obvious, so much so that Hims-worth (1949) declared that diabetes could no longer be regarded as a single entity but as a syndrome. Nevertheless there are many points still not fully understood, among which should be mentioned the part played by the glands of internal secretion in the production of some of the complications of the disease.

The Houssay phenomenon, first described in dogs, has been reported in man on various occasions. In each of these cases pituitary insufficiency has developed in patients known to have had diabetes for a varying length of time; the pathological lesions have been diverse and have included infarction, tumour, and abscess. It is extremely rare, however, for the sequence of events to be reversed, and we have been able to find only one previous report of such a condition.

Case Report

The patient was first seen by us in September, 1953, at the age of 45, when he was referred by his doctor with a request for gastro-intestinal investigations. He stated that

for about ten years he had suffered from recurrent attacks of pain in the epigastrium and right hypochondrium accompanied by vomiting; he also complained of backache for three years, with difficulty in stooping, and a sensation of locking in the small of the back. As he was extremely deaf his wife amplified the history and revealed that since her marriage to him in 1943 she had known that he was sexually underdeveloped. She stated that during their married life her husband had seldom shown any desire for intercourse, and when he attempted coitus he was unable to achieve erection. The patient himself was quite co-operative during interrogation, but seemed unaware of the significance of many of the questions. He did, however, volunteer the opinion that "it was all the result of self-abuse"; he stated that during his middle teens he had occasionally masturbated and had had seminal emissions. This was the only fact ever obtained that might give some hint regarding the duration of the pituitary deficiency.

In 1947 he was examined by an ophthalmologist because of iritis and early keratitis in the right eye, and the blood Wassermann reaction was found to be strongly positive; his brother's W.R. was also positive, and a presumptive diagnosis of congenital syphilis had been made at that time. The patient's wife had known him for about eight years before marriage and thought that "he had always looked much the same." In view of this story he was admitted for endocrinological study.

In appearance the patient looked pale; his face was smooth and hairless, and the skin of the body generally rather dry. No axillary sweating was observed; there was no cutaneous or mucosal pigmentation. Hair was completely absent from axillae, chest, abdomen, and thighs, but a few fine downy hairs were present on the pubic region. Both testes were in the scrotum, but were soft and only the size of a pea; the penis approximated to that of a pre-pubertal boy (see Fig. 1).

The lungs, cardiovascular system, and alimentary system were clinically normal. The blood pressure was 140/80. No neurological abnormality was noted except that the left pupil was a little larger than the right; both reacted to light and on convergence. The fundi were normal. Moderate dorsal kyphosis and an exaggerated lumbar lordosis were present.

Mentally he was a placid, amiable individual, and took little interest in his surroundings or in his own condition. He showed no diffidence in exposing his body for examination.

Radiological and Laboratory Studies.—X-ray examination of the skull showed that the pituitary fossa was normal. The lumbar spine showed generalized osteoporosis with osteoarthritic change between the spines of L3 and 4; there was slight wedging of the bodies of D11 and 12 with minimal osteoarthritic changes; the appearances suggested old fracture. No abnormality was noted in the epiphyses of the long bones. 17-Ketosteroid excretion, 2 mg. a day. Fasting blood sugar, 85 mg. per 100 ml. Glucose-tolerance test, normal (see Fig. 2). Serum electrolytes: sodium, 315 mg.; potassium, 18 mg. chlorides, 640 mg. per 100 ml. Serum cholesterol, 200 mg. per 100 ml. Serum proteins, total 6.1 g. per 100 ml. (albumin 4.2 g., globulin 1.9 g.).

FIG. 1.—Photograph of patient; body hair absent and genitals underdeveloped.

Haemoglobin, 90% (Haldane). Wassermann reaction, strong positive. Meinicke reaction, strong positive. Kepler's test: overnight urine, 720 ml.; 8.30 a.m., 55 ml.; 9.30 a.m., 45 ml.; 10.30 a.m., 58 ml.; 11.30 a.m., 52 ml.; 12.30 p.m., 53 ml.; $\Delta = 2.9$.

FIG. 2.—Results of glucose-tolerance tests.

patient asserted that he now had to shave daily. Objectively, however, one felt that "the wish was father to the thought." Three months later there was still no significant physical change, and after this he was not seen again at the out-patient clinic for almost two years.

In May, 1955, he came to the diabetic centre with the classical symptoms of diabetes mellitus—thirst, polyuria, nocturnal muscle cramps, and loss of weight—which had been present for four months. There was no family history of diabetes. Clinical examination was essentially the same as before, but he was about 10 lb. (4.5 kg.) lighter. The urine gave a strong reduction of Benedict's solution, but no ketones were present. The blood sugar two hours after an average breakfast was 480 mg. per 100 ml. A diet containing 200 g. of carbohydrate was prescribed, with 15 units of soluble insulin (S.I.) in the morning and 10 units in the evening.

One week later the blood sugar two hours after breakfast was 185 mg. per 100 ml. and the urine was sugar-free. He was now placed on insulin zinc suspension (I.Z.S.) 24 units daily. After a further seven days the blood sugar two hours after breakfast was 120 mg. per 100 ml. and the urine was sugar-free. He had had no hypoglycaemic symptoms, but the insulin was reduced to 18 units I.Z.S. Two weeks later the blood sugar was 220 mg. per 100 ml. under the same conditions, and there was no sugar in the pre-breakfast sample of urine. It was not considered necessary to alter the insulin dosage.

During the next three weeks he began to develop attacks of hypoglycaemia but did not report to the clinic as advised. On June 29 he was admitted to hospital in severe hypoglycaemia at 8.30 p.m.; 60 ml. of 50% dextrose was given intravenously with good effect. One hour later he relapsed, but recovered on injection of 20 ml. of 50% dextrose followed by glucose orally. Seven hours later he was again hypoglycaemic and again responded to the intravenous administration of 20 ml. of 50% dextrose. At 10 a.m. on the morning after admission—that is, about 14 hours after the last dose of insulin and two hours after a light breakfast—blood sugar was only 130 mg. per 100 ml. The urine remained sugar-free, without insulin, for the next three days on a diet containing 160 g. of carbohydrate. On July 4 the fasting blood sugar was 160 mg. per 100 ml. with no glycosuria; three hours after breakfast it was 320 mg. per 100 ml. and the urine contained 1.5% sugar. However, in view of the recent severe hypoglycaemia this high figure was not considered sufficient reason for recommencing insulin, especially as there was no clinical evidence of deterioration.

On July 7 an oral glucose-tolerance test showed a typical diabetic curve (Fig. 2). Subsequently a number of investigations previously carried out in 1953 were repeated. 17-Ketosteroid excretion, 1.5 mg. a day. Serum electrolytes:

sodium, 300 mg.; potassium, 17 mg.; chlorides, 590 mg. per 100 ml. Serum cholesterol, 200 mg. per 100 ml. Kepler's test: overnight urine 480 ml.; 9.30 a.m., 40 ml.; 10.30 a.m., 65 ml.; 11.30 a.m., 50 ml.; 12.30 p.m., 45 ml.; A=3.4.

A modified Thorn test was carried out by injecting 50 units of corticotrophin in a single dose intramuscularly on four successive days; eosinophil counts were made hourly for 12 hours on the day prior to this series of injections and four times on each day that the hormone was given, the injection being made at 8 a.m. daily. The details of these eosinophil counts and of a normal control are shown in Table 1. After the second dose of corticotrophin ketonuria

occurred for the first time, though the blood sugar did not show any very significant increase; glycosuria was between 2 and 3% in a 24-hour specimen of urine, having previously been between 0.5 and 1%. Insulin was therefore given in doses of 10 to 15 units before each of the three main meals of the day, and the ketonuria disappeared by the third day of this regime.

Fig. 3 illustrates the result of radio-iodine tracer studies; thyroid function was almost negligible, and the pick-up in the gland was so low that a survey was not feasible. The

FIG. 3.—Radio-iodine tracer studies. ●—● Before thyro-
trophin. ×—× After thyrotrophin.

investigation was repeated after 5 units of thyrotrophin had been injected daily for four days, but no appreciable increase in thyroid function was produced nor was there any change in the clinical condition. Estimation of the B.M.R. before administration of thyrotrophin gave a figure of minus 20%; this test was not repeated after thyrotrophin. Other findings are shown in Table II.

There was no follicle-stimulating hormone or interstitial-cell-stimulating hormone in a 24-hour sample of urine.

TABLE II.—Findings Before and After Administration of Thyrotrophin

	Before	After

" ratio" " " " 51 " ..	0.32%	0.16%
Thyroid clearance rate (litres/hour) ..	0.446	0.07
	1.45	0.61

An intravenous insulin-tolerance test (Fig. 4) showed much increased sensitivity to a very small dose of insulin (0.03 unit per kg. body weight). Twenty-four hours after this dose of insulin the blood sugar was still only 135 mg. per 100 ml.

FIG. 4.—Insulin-tolerance test.

The diagnosis having now been firmly established, we were anxious to study the effect of hormone therapy (a) on the manifestations of the pituitary insufficiency and (b) on the diabetes. It had already been observed that ketosis rapidly developed when corticotrophin was administered, and it was anticipated that this would recur when other hormones were exhibited, and that insulin sensitivity would decrease.

The following regime was begun on October 2; (a) thyroxine, 50 μ g. twice daily, (b) testosterone, 25 mg. twice daily, and (c) cortisone, 12.5 mg. twice daily. Within 48 hours of beginning this treatment the patient complained of some thirst and polyuria, and moderate ketonuria appeared. On October 3 the fasting blood sugar was 300 mg. per 100 ml. On October 4 it was 600 mg. per 100 ml. and 5 units of S.I. was therefore given before each of the three main meals on that day. It was felt that caution was necessary with the initial doses of insulin because of previous experience; but it was soon found that larger doses would be required for control; this was achieved eventually with 40 units of S.I. daily, divided into three doses. Before his discharge from hospital the insulin was readjusted to 20 units before breakfast and 15 units before supper, and the daily carbohydrate increased to 200 g. Thyroxine was discontinued and thyroid extract, $\frac{1}{4}$ gr. (32 mg.) three times daily, substituted for it. Testosterone was reduced to 25 mg. once daily; cortisone was continued in a dosage of 12.5 mg. twice daily. While still in hospital marked improvement was already manifest in the patient's general condition; he became much more alert and interested in his surroundings. The most noticeable physical change was the development of a strong growth of beard.

He subsequently attended the diabetic clinic, at first twice weekly, and later once weekly. The dose of insulin varied between 16 and 20 units a day, and he took 25 mg. of cortisone daily. Apart from growth of the beard, there was little sign of increased gonadal activity, but the pubic hair did show a slight increase in quantity.

He has remained well up to the time of writing apart from one illness, and is at work each day as a canteen manager. In February and March, 1956, he suffered from an attack of infective hepatitis, for which he was admitted to hospital. During this illness cortisone was discontinued and his dietary carbohydrate increased considerably. He was given 16 units

of insulin daily (in two doses). In spite of his large carbohydrate intake, and even though he was kept in bed, he had one severe hypoglycaemic reaction; this developed rapidly about 10 o'clock one evening, and, although the nursing staff gave him some oral glucose, he quickly became unconscious and convulsions occurred. The injection of 30 ml. of 50% dextrose intravenously brought recovery, and he was then able to swallow a further 15 g. of sugar. Analysis of a sample of blood (taken before the injection of dextrose) showed a sugar content of 35 mg. per 100 ml.

Recovery from the hepatitis has apparently been complete, and liver-function tests have not so far revealed any evidence of residual liver damage.

Discussion

In the foregoing description certain points deserve special comment. Firstly, as mentioned earlier in this article, previous reports of the Houssay phenomenon in man have recorded the effects of pituitary failure on a pre-existing diabetes, the chief result being, as would be expected, marked increase in sensitivity to insulin, both endogenous and injected. It is therefore somewhat surprising to find that diabetes mellitus in typical form may occur in a person who shows clear evidence of pituitary hypofunction.

Secondly, the history of this patient indicates that hypopituitarism has been present for probably twenty years and possibly more. In spite of this the diabetes has arisen in circumstances which would appear to be antagonistic to it.

Thirdly, the pituitary insufficiency has apparently declared itself in relation to only some of the other endocrine glands. The thyroid and the gonads show definite evidence of prolonged lack of stimulation by the hypophysis, and, the thyroid has lost its ability to respond to the administration of thyrotrophic hormone.

The results of the therapeutic use of cortisone, thyroxine, and testosterone are of interest. The most striking effect has been the growth of the beard, although this is also frequently observed in cases of primary hypogonadism. Up to the time of writing axillary and chest hair has not appeared, nor has there been more than a very slight increase in pubic hair. The external genitalia have not increased in size and there is still complete absence of libido. The patient's mentality and outlook have improved; he is more active physically and has taught himself to lip-read.

The diabetic state reacted to hormone therapy in the expected fashion. Ketonuria appeared for the first time when corticotrophin was given and was abolished by insulin; it occurred again under the influence of cortisone and was again abolished by insulin. Sensitivity to insulin was also much less than before.

Summary

A case of hypopituitarism is reported in which diabetes mellitus developed after at least twenty years of deficient pituitary function. The clinical findings and laboratory investigations are described, with special reference to the behaviour of the diabetic state under the influence of various hormones.

Our thanks are due to Professor H. L. Sheehan for his helpful criticism and advice; to Dr. Rachel Rawcliffe and the staff of the Group Laboratory, and especially to Mr. R. D. Roberts for the photograph; to the staff of the ward for their unflinching attention to detail in nursing and investigation; and, not least of all, to the patient and his wife for their ready co-operation during what must have been to them a rather tedious procedure.

COARCTATION OF AORTA PRESENTING AS CARDIAC FAILURE IN EARLY INFANCY

BY

J. J. KEMPTON, M.D., M.R.C.P.

Paediatrician, Reading and District Hospitals Group and
Canadian Red Cross War Memorial Hospital, Taplow

AND

DAVID J. WATERSTON, F.R.C.S.

Surgeon, Hospital for Sick Children, Great Ormond Street,
London

Of ten cases of cardiac failure in the neonatal period or early infancy from the Thames valley areas served by the Royal Berkshire Hospital, Reading, and the Canadian Hospital, Taplow, and seen by one of us (J.J.K.) during the last three years, four have been cases of coarctation of the aorta. Each, after a period of medical treatment, was transferred to the Hospital for Sick Children, Great Ormond Street, where resection (D.J.W.) was carried out. This paper is an account of the four cases, with a discussion of the problems and the possibilities of diagnosis and treatment which they have seemed to illustrate. No details of investigations are given, and treatment is described in outline only.

Case 1

A baby boy was first seen in August, 1954, in domiciliary consultation, when 12 days old. Difficulty in feeding had begun on the seventh day, the baby having seemed normal until then. The nurse had noticed that he became breathless after sucking for a few minutes, and had choked over several breast feeds. Apart from feeds his mother said that she had twice woken up in the night and heard him panting. He had regained his birth weight of 8 lb. 2 oz. (3,685 g.). There had been no cyanosis, but both mother and nurse thought he looked a little grey sometimes. The family doctor had observed the breathlessness and suspected a heart abnormality.

On examination he did not look ill, and was afebrile. His respiratory rate varied from 30 to 50 and on sucking rose to 90 in about three minutes. His pulse rate was 140 and regular, the arm pulses being easily felt. Heart sounds were normal with no murmurs. Blood pressure in the right arm was 130/70 mm. Hg; femoral pulses could not be felt. Breath sounds were normal. The liver edge was felt at the level of the umbilicus. Limb movements and reflexes were normal and there was no oedema. He was admitted to the Canadian Hospital the following day.

On admission, in addition to the previous signs, some oedema of the legs was noticed, and there were some rales in the lung fields. He was given digoxin, 0.125 mg. eight-hourly, for three doses, then the same dose daily, and was put on salt-free milk feeds. He quickly improved, the signs of failure disappearing within a week. A systolic murmur became audible in the interscapular region at this time. Blood pressure in the arms rose progressively, reaching 180/90 mm. Hg six weeks after admission. Systolic blood-pressure recordings in the legs varied from 40 to 65 mm. Hg. When 6 weeks old a basal systolic murmur became audible anteriorly. He was transferred to Great Ormond Street on October 19. After transfer there was a further rise in arm blood pressure to a maximum of 220 systolic, and signs of failure recurred, needing an increase in the dose of digoxin. Operation was carried out on October 25.

At thoracotomy the coarctation was found to be at the usual site just below the origin of the left subclavian artery. There was a small persistent ductus arteriosus 3 mm. in

diameter just proximal to the coarctation. This was ligated and the narrowed area of the aorta was excised. The aorta was sutured, using 00000 silk thread. The post-operative course was uneventful, and 17 days after operation the baby returned to the Canadian Hospital, where digoxin was gradually withdrawn and feeding with ordinary dried milk established. He was discharged home on November 29 and has been seen at intervals since. At 2½ years he is a healthy-looking child who seems to be developing well and has no symptoms. There is an indistinct basal systolic murmur.

Blood pressure in the right arm remained raised after operation, and in March, 1955, was 130/90 mm. Hg. No pulse could be felt or pressure measured in the left arm. Systolic pressure in the legs was 90 mm. Hg. Now at 2½ years his blood pressure in the right arm is 110/70 mm. Hg. The pulse cannot be felt at the left wrist and systolic pressure in the left arm is 70 mm. Hg. Pressures in the legs are 95 mm. Hg systolic, and femoral pulses are easily felt.

Case 2

A baby girl was first noticed to have noisy breathing and a tendency to choke over feeds in September, 1954, at the age of 4 weeks, and at the time of the mother's first visit to the welfare clinic. On this account she was referred to the family doctor, who in turn sent her to the children's clinic at the Royal Berkshire Hospital. When seen there at the age of 5 weeks she was a healthy-looking infant with no cyanosis or oedema. However, she had gained only 12 oz. (340 g.) in weight from a birth weight of 6 lb. 13 oz. (3,090 g.). Arm pulses were easily felt at a rate of 130. Femoral pulses could be felt with great difficulty. Breath sounds were normal, but the respiratory rate was 40-50 with a little inspiratory indrawing. The respiratory rate rose quickly to about 100 a minute on feeding. A basal systolic murmur was indistinctly audible both anteriorly and in the interscapular region. The liver edge was palpable 2 in. (5 cm.) below the rib margin. No accurate blood-pressure recordings could be obtained in the out-patient department that day, but after admission to the Canadian Hospital the following day systolic pressures were found to be 210 mm. Hg in the arms and 100 in the legs. She was put on salt-free milk and given oral digoxin, 0.125 mg. eight-hourly for five doses and then the same dose daily. Considerable improvement occurred during the next week, feeds being taken with much less respiratory distress and the liver edge becoming less easily felt. There was some weight gain. Further blood-pressure measurements after admission gave figures in the arms of 190-210 mm. Hg systolic, and in the legs 80-90 mm. Hg systolic.

Thirteen days after admission she was transferred to Great Ormond Street. Operation was carried out on December 6. At operation the aortic arch was found to be hypoplastic, and there was a very large pulmonary artery from which a wide persistent ductus arteriosus opened into the aorta just proximal to the coarctation. A palpable thrill was perceptible just above the aortic valve, but pressure recordings revealed no evidence of aortic stenosis. The ductus was divided and the coarctation excised as in the previous case. On releasing the clamps on the aorta the heart rate slowed, with a very marked decrease in cardiac output. Within one minute ventricular contractions had ceased, and in spite of cardiac massage and all the usual resuscitative measures the baby died.

Necropsy showed extensive fibroelastosis affecting the left ventricle and the aortic valve. The right atrium also showed endocardial fibroelastosis.

Case 3

A male infant was sent to the children's clinic at the Royal Berkshire Hospital in August, 1956, at the age of 6 weeks with a letter from the family doctor describing feeding difficulty and failure to thrive. After taking up to 2½ oz. (70 ml.) of a bottle feed he was said to refuse to

AUG. 24, 1957

suck any more. Birth weight had been 9 lb. 6 oz. (4,250 g.) and at 6 weeks he weighed 10 lb. 3 oz. (4,620 g.). He did not look ill and there was no cyanosis or oedema. Respiration at rest was normal. A feed was watched, and it was seen that he became breathless after two to three minutes. A basal systolic murmur was indistinctly heard in the interscapular region, and the liver edge was palpable at the level of the umbilicus. Breath sounds were normal. Blood pressure in the arms was 160/80 mm. Hg and the femoral pulses could not be felt.

He was admitted to the Royal Berkshire Hospital and given digoxin, 0.125 mg. eight-hourly for four doses and then 0.125 mg. daily. Ordinary dried-milk feeds were given. After digitalization feeds were taken well, and he began to gain weight, reaching 11 lb. 13 oz. (5,360 g.) two weeks after admission. He was transferred to Great Ormond Street, still on his daily dose of digoxin, where, after a period of observation and more investigations, operation was carried out on October 4. At operation there was a small persistent ductus which joined the aorta just proximal to the coarctation. It was ligated and the coarctation excised as in the previous cases. The post-operative course was satisfactory, and after his return home digoxin was gradually withdrawn over a period of two months. He is doing well, though he has had pertussis since the operation. Systolic blood pressures are: arm, 95 mm. Hg; legs, 90 mm. Hg. Femoral pulses are easily felt.

Case 4

This child was born at the Canadian Hospital in September, 1956. He was a large baby with a birth weight of 11 lb. (4,990 g.) and showed signs of cerebral irritation after a difficult forceps delivery. He was kept in the nursery for five days and was at first tube-fed. He was thought to be well and had regained his birth weight on discharge on the eleventh day. Two weeks later his mother took him to see the sister in the obstetric nursery; lactation had failed and bottle feeds were not being taken well. The sister watched a feed and saw that the baby became breathless and had a choking fit after sucking for a few minutes, and so kept mother and baby until the paediatric round later in the day.

On examination then the baby had a good colour and was not breathless at rest. There was no oedema or cyanosis. The liver edge was palpable below the level of the umbilicus. Breath sounds were normal. A systolic murmur faintly audible over the cardiac base was more easily heard between the scapulae. Femoral pulses could not be felt. Blood pressures by the flush method were: left arm 160 mm. Hg, left leg 70 mm. Hg. He was admitted and given digoxin, 0.125 mg. eight-hourly for four doses and then the same dose daily. Nine days later, when signs of failure had cleared, he was transferred to Great Ormond Street, still on a dose of 0.125 mg. of digoxin daily, and taking feeds of an ordinary dried-milk mixture fairly well. However, after admission he again showed signs of failure which did not respond satisfactorily to treatment, and urgent operation was decided upon.

Operation was planned for November 1, but fairly severe pulmonary oedema developed during induction of anaesthesia; operation was deferred and a further attempt was made on November 8. On this occasion cardiac arrest occurred immediately following tracheal intubation. An urgent thoracotomy was performed and the heart restarted after cardiac massage. Further procedures were not attempted at this time, but on November 19 the coarctation was successfully resected after ligating a large persistent ductus arteriosus which entered the aorta proximal to the stenosis. Post-operative progress was uneventful.

After return home digoxin was gradually withdrawn over a period of three weeks. The baby appears to be thriving. Blood pressures four months after operation were: arms 130/85 mm. Hg, legs 85 mm. Hg systolic. Femoral pulses were easily felt.

Discussion

It has been established that coarctation of the aorta is a common cause of cardiac failure in early infancy (Keith, 1956). The incidence of failure itself in babies is hard to assess. The essential early symptoms—breathlessness on sucking, and subsequent choking attacks as the respiratory rate rises—are very likely to be disregarded, and an experienced doctor or nurse may regard the picture as that of mechanical feeding difficulty unless a feed is watched with the chest exposed. The essential physical sign is liver enlargement, and palpation of the liver edge at this age, even when there is much enlargement, is of the same order of difficulty as palpation of the tumour of pyloric stenosis, and requires the same technique and patience. There may be no oedema, no cyanosis, and no chest signs. No murmur may be audible in the early weeks.

Inhalation of milk and gastric contents, together perhaps with early pulmonary oedema, may lead quickly to a picture of respiratory distress with distended chest, costal indrawing, and downward displacement of the liver edge in which the cardiac origin of the illness may be very easily overlooked—may not, indeed, be at all apparent—so that cases are even more likely to be missed if they reach this stage.

Once the basic diagnosis of failure has been made, the diagnosis of coarctation will of course depend on observation of limb pulses and blood-pressure measurements; the latter, whether by auscultation (for which a number of small-sized cuffs are needed) or by the flush method, needs time and a degree of practised skill, and there is a considerable personal error.

Final decision on the type of coarctation present, and the indication for immediate or late operation, will need more detailed investigation in a special centre.

Bonnet (1903) divided coarctation into an infantile developmental type, with hypoplasia of the arch and narrowing occurring before the opening of a persistent ductus arteriosus, and an adult type in which the fibroelastotic process closing the ductus was assumed to have extended into the aortic wall, producing a constriction. This division was accepted by Maude Abbott (1928) and is still sometimes used, though the two separate processes of development are not accepted, and it is well known that the infantile form may be found in adults, and vice versa. Mustard *et al.* (1955), writing with special reference to the first year of life, divided their cases into pre-ductal and post-ductal types, the first approximating to Bonnet's infantile type and having a very high mortality. Previously Johnson *et al.* (1951) had devised a classification based on the state of the ductus arteriosus and its relationship to the stenosis and on the amount of collateral circulation.

It is perhaps best, considering the almost infinite possibilities of abnormality in development from the 12 embryonic arches, not to attempt any exact classification. We can be sure that no two cases will be exactly alike.

Resection of coarctation was first carried out in young adults by Crafoord and Nylin (1945) and Gross (1945, 1950), and there are now a number of published series of successfully treated cases; the subject has been reviewed recently by Campbell and Baylis (1956) and also by Cleland *et al.* (1956), who surveyed 52 cases in patients aged 1 to 55 years, 40 of whom had undergone resection.

Calodney and Carson (1950) reviewed 22 cases diagnosed in infancy, all the patients dying in cardiac failure, and suggested that in some cases operation might be possible. A case successfully undergoing resection at 2 weeks was recorded by Baronofsky and Adams (1954). Mustard *et al.* (1955), of Toronto, described 15 cases operated upon in infancy, the youngest at 11 days. There were five deaths, all cases of "infantile" or pre-ductal coarctation, the remainder having survived and continuing to do well. Nouaille *et al.* (1955) described 15 cases in early infancy, five of which successfully underwent operation. Of 10 patients not operated upon, eight died; but one of the two survivors lost all symptoms after a period of severe failure.

Gross (1953) stated that the majority of these babies can be tided over their period of embarrassment by medical means, and that the best chance of successful operation will come later, between the ages of 8 and 12 years.

Lang and Nadas (1956), reporting nine cases treated medically, also suggested that most of these infants can be managed satisfactorily by medical means, but added that surgery should be performed early if medical management fails.

Though no classification of cases of coarctation is really satisfactory a certain therapeutic grouping appears reasonable. First there will be cases where there is gross abnormality of the arch, often with other anomalies, sometimes with very extensive endocardial fibroelastosis, and in which the deformity is such as to be incompatible with survival. These patients are likely to die within the first few hours or days. A second group will comprise those who have early and severe cardiac failure which proves difficult to control, and who will need surgery as soon as possible if they are to survive. Thirdly, there are those whose symptoms are less severe and more easily managed, and who have a tendency to marked spontaneous improvement after the first few months. Some of these might well be kept under supervision and operated upon later, after the general improvement has occurred and all signs of failure have disappeared. Finally, there is a fourth group of cases in which the early symptoms are slight or absent, and which are unlikely to be recognized in infancy. Retrospective inquiry into feeding difficulties, choking attacks, and breathlessness in the infancy of adults found to have coarctation would be of doubtful value, and, so far as we are aware, has never been undertaken. This group therefore includes all adult cases.

Until recent years this condition in infancy was not thought to be important; if it was of the infantile type death was inevitable, and if of the adult type no symptoms would occur. Reports of larger series, and the individual study of our four cases, would appear to show the importance of coarctation in babies, and our cases seem specially to show the way in which the successful management of this not uncommon condition depends on care at all levels. Cardiac failure in babies presents as feeding difficulty, often developing quickly, after choking attacks, into a cardio-respiratory illness in which the diagnosis becomes very much more difficult and the prognosis very much worse. Early diagnosis before this occurs can result from alertness to the possibility on the part of the family doctor, the midwife, and the nurse. Confirmation of diagnosis and immediate investigation and treatment can be carried out in the area paediatric department. This will consist essentially in really close ward observation and management of feeding, in x-ray screening, and, generally, in digitalization with serial electrocardiograms. Salt-free milk powder will be helpful in some cases. This period of emergency care is followed by more investigation and more detailed assessment in the specialized unit in which resection may be carried out, either at once or later. Later, care of those operated upon and of those in whom operation is deferred after assessment can again be undertaken by the paediatric department and family doctor, and will usually include the gradual weaning off digitalis. Blood pressures may in some cases not return to normal figures for several months after operation, so that continued recordings are advisable.

There is the possibility, mentioned by Gross (1953) and others, that stenosis may occur at the site of resection. Animal experiments, on the other hand, have suggested that growth of the scar may occur. Only time will show. Of more immediate importance is the inescapable impression that many of these babies must die as cases of bronchopneumonia, the real cause of their illness remaining unrecognized.

Summary

An account is given of four cases of coarctation of the aorta presenting as cardiac failure in early infancy. In each case resection was carried out after medical

treatment. There was one death; the remaining three children have done well. The history and presenting features in each case are described in detail in order to show the importance of the recognition of early symptoms and signs in those babies who may appear to be cases of mechanical feeding difficulty or chest infection.

The management of these and similar cases is presented as a combined responsibility.

We wish to acknowledge the part taken by Dr. R. E. Bonham Carter in the care of these cases, and to thank him for much help. These four babies are to be included in a more extensive review of congenital heart disease in infancy, from Great Ormond Street, which is in course of preparation.

CAT-SCRATCH DISEASE

BY

E. HINDEN, M.D., M.R.C.P.

Paediatrician, Whipps Cross Hospital

Cat-scratch disease is an illness which is not well known in this country. It usually presents as a mass of inflamed lymph nodes in the groin, axilla, or neck, which commonly proceeds to suppuration, though occasionally it may resolve. Daniels and MacMurray (1954) present a comprehensive account of the disease, based on 160 cases (including 27 personally observed); Brand and Finkel (1956) describe three cases and give a bibliography of all the others reported to date in this country. The former authors write: "Cat-scratch disease may simulate a wide variety of lymph-node lesions such as tularaemia, infectious mononucleosis, lymphosarcoma, Hodgkin's disease, tuberculous adenitis, lymphogranuloma venereum, and both benign and malignant disease." The following cases illustrate some of these diagnostic pitfalls, showing the need to consider all data, clinical and pathological, in order to reach a correct diagnosis. They also include an unusual familial relationship.

Case 1

A boy aged 2 years 2 months was admitted to hospital on September 1, 1954, from the surgical out-patient department. He had been sent there by his family doctor because of a lump which had appeared in his right groin five days previously. It was neither painful nor tender; it was hard and irreducible; there was no impulse on coughing or disturbance in his general health. It was thought that it might be a hernia with impacted omentum.

At operation later that day the mass was found to consist of enlarged lymph nodes, and it was excised. The histological report on the specimen stated: "Marked reticulo-endothelial proliferation in lymph nodes with a few mitotic figures and a suggestion of granulomatous pattern. I cannot

AUG. 24, 1957

CAT-SCRATCH DISEASE

BRITISH
MEDICAL JOURNAL 445

be certain, but I suspect early tuberculosis." However, no primary focus could be detected either on the limb or on the perineum, the x-ray film of his chest was clear, and the Mantoux test (1:1,000 and 1:100) was negative; his white-cell count was 10,000 per c.mm., with polymorphs 65% and lymphocytes 33%. The wound healed by first intention and he was discharged quite well on September 13. At follow-up on October 12, 1954, and April 12, 1955, the scar was soundly healed and no other glands could be felt.

In view of the negative Mantoux test, the diagnosis of tuberculosis was in doubt and cat-scratch disease was suspected. An attempt was made to obtain the specific antigen, but without success; and there the matter rested for a while. However, the possibility of cat-scratch disease was mentioned to his mother, and she decided to have her domestic cat replaced by another.

Case 2

This patient, aged 10 years 9 months, was the brother of the first patient. He was admitted on November 16, 1955, also with a swelling in the right groin for one week. On examination there was a mass of glands in the femoral triangle, below the inguinal ligament, and also some easily palpable glands of the external iliac chain above the ligament. There was no disturbance of his general health, no focus of infection on the limb or perineum, no other enlarged glands, and his spleen was not palpable. The blood count showed: haemoglobin 86%; white cells, 10,500 (normal differential count); sedimentation rate, 10 mm. in the first hour; Wassermann reaction, negative. The chest x-ray picture was clear. The Mantoux test 1:1,000 was doubtful. The glands were neither painful nor tender.

This child had attended the out-patient department in January, 1951, with a vague story of poor health; the only finding then had been general lymph-node enlargement, and a firm diagnosis was not made. He had also been admitted previously, on September 16, 1954, suffering from abdominal pain, for which no cause was found. On that occasion his glands were not abnormal.

To return to his present admission: it was decided to remove the glands below the inguinal ligament for microscopy. This was done. The report stated: "Commencing destruction of gland pattern. Proliferation of reticulum cells in follicles and sinusoids with foci of eosinophils and neutrophil leucocytes. The appearances are those of an early Hodgkin's disease." Because of this report he was referred to the radiotherapy department of the London Hospital. However, when Dr. Boden examined him he was doubtful of the diagnosis, as there were no other manifestations whatever of nosis, and this time the section was considered to indicate cat-scratch disease. Accordingly he arranged for Professor Barwell, of the department of bacteriology, to try the cat-scratch antigen, and this was markedly positive, raising a papule 10 by 8 mm.; the Frei antigen test was negative. On learning this news the biopsy slide from Case 1 was also sent to the London Hospital; the report stated: "Lymph node showing severe chronic inflammatory changes. A few granulomatous foci are present in this node, but the changes are not sufficiently marked for a definite diagnosis of cat-scratch disease." The skin of Case 1 was also tested, and Professor Barwell reported: "Frei antigen and control, no reaction. Cat-scratch antigen: papule 11 mm. in diameter, positive." It will be realized that the cat which infected the first patient could not have infected the second—it was no longer in the house.

Comment.—Other authors have described familial outbreaks. Daniels and MacMurray (1954) mentioned 12 household epidemics, involving 26 patients, mainly children (no other details are given). Clément *et al.* (1951) report the disease in a child aged 13 and in his mother; Blinski and Kaye (1955) found it in a child of 16 months and his mother; and Philpott *et al.* (1955) describe the cases of twins aged 5 who suffered from it. But in all these examples

the household illnesses were roughly concurrent, so that one animal was responsible for all the cases in each outbreak. In the illnesses here reported, this could not be the case; we must postulate two infected cats in the same house, at different times.

Case 3

A girl aged 14 was admitted to hospital on September 20, 1955, from the paediatric out-patient department. She had been quite well till the previous week, when her right eye became inflamed and sticky, and some lumps appeared round her right ear. She had complained of occasional face-ache during the previous few days, but there was no other symptom or any constitutional disturbance. On examination she did not look ill; she had a right conjunctivitis with some sticky discharge, and many enlarged lymphatic nodes—pre- and post-auricular, jugulo-digastric, and in the anterior and posterior triangles of the right side of her neck. The inguinal glands were palpable, but were not unduly large; the epitrochlear and axillary glands were not palpable; the spleen could be just felt; her right tonsil was enlarged. Her mouth temperature was 99° F. (37.2° C.).

She quickly improved in hospital. Her temperature settled, the conjunctivitis cleared up in a few days with chloramphenicol drops, and the glands subsided. All but one, that is: the pre-auricular gland became enlarged still further and then softened as pus formed. The abscess was opened and curetted by Mr. S. G. Nardell, and the contents were sent for examination. The histological report stated: "Chronic purulent inflammation of caseous tuberculous granulation tissue," but bacteriological examination failed to find tubercle bacilli by fluorescence or Ziehl-Neelsen stain, by Löwenstein-Jensen culture, or by guinea-pig inoculation. Finally the Mantoux test (1:1,000 and 1:100) was negative. It seemed that the diagnosis of tuberculous lymphadenitis was excluded. Skin tests were performed by Professor Barwell, who reported: "Complement fixation tests for antibody to the psittacosis-L.G.V. group of viruses, negative. Skin tests: Frei antigen and control, no reaction. Cat-scratch antigen: tender papule, 12 mm. in diameter, positive."

Comment.—This combination of conjunctivitis and pre-auricular adenitis (Parinaud's oculoglandular syndrome) in cat-scratch disease has not previously been reported in this country, though Professor Barwell (personal communication) informs me he has seen one. It is a rare form of the illness; Daniels and MacMurray (1954) found only two such in their series of 160 cases, but they mention six others. In the familial cases reported by Clément *et al.* (1951) the mother's illness was of this type. These latter writers consider that the virus might be carried to the eye by the patient's own fingers, and not introduced directly by the infecting cat.

Two further patients with this disease have been seen at the hospital within the last 12 months; their illness took the usual form.

Case 4

A boy aged 13 was referred by his family doctor because of a lump in the right axilla. When seen at hospital on March 15, 1956, the mass had been present for two weeks, and was already getting smaller; painful at first, it was no longer and his general health was unimpaired. The lump was an axillary gland, and there were no other abnormal findings. The chest x-ray picture was clear; white blood cells, 5,400 (normal differential count); blood sedimentation rate, 13 mm. in the first hour; Mantoux test (1:1,000) negative. The household included two cats with which the patient frequently played, sustaining several scratches and bites. This suggested cat-scratch disease as a possible diagnosis. He was referred to the bacteriology department at the London Hospital, and Professor Barwell reported: "Frei antigen and control, negative; cat-scratch antigen, red papule 9 mm. in diameter, positive. Complement-fixation test for psittacosis-L.G.V. antibody, negative."

The glands subsided without further treatment. The lad's mother has noticed that his skin "puffs up" when and where the cat scratches him, but this in no way disturbs his general health.

Case 5

A woman aged 58 was seen in the surgical out-patient department on November 9, 1956, because of a lump in the left axilla. It had been present for two weeks, and was not painful or tender; there was no history of injury or discharge from the nipples. She had suffered from an abscess in the other (right) breast three years previously. On examination she was seen to be a very obese woman, with big pendulous breasts; there was a mass the size of a golf-ball in the axillary tail of the left breast, not fixed to the skin but attached deeply. There were no other abnormal physical signs. It was thought probable that the mass was a carcinoma, and admission was arranged for surgical exploration. This was carried out on November 28, when the lump was found to consist of suppurating lymph nodes. The histological report stated: "Chronic purulent inflammation of and granulomatous tuberculosis in axillary glands and adjacent tissue." However, in view of the absence of any other sign of tuberculosis this diagnosis was unacceptable, and cat-scratch disease was considered. The specific antigen was obtained from the Virus Laboratory (Public Health Central Laboratory), Colindale, and on intradermal injection it produced an erythema 12 mm. across, with a papule 5 mm. in diameter—a positive result.

Summary

Five examples of cat-scratch disease are described, four of them in children.

Two of the children are brothers, but they were separately infected with a year's interval in between, by different cats.

The axilla twice was the site of the disease, and the groin twice; one patient presented with conjunctivitis and pre-auricular adenitis.

The histological picture is not clear-cut, and the diagnosis depends upon consideration of all the data, clinical and pathological.

I should like to thank Dr. W. W. Walther, pathologist at the hospital, for his reports; Mr. S. G. Nardell, surgeon, who carried out the biopsies on the first three patients and showed me the fifth; Dr. M. L. Hutchinson, general practitioner at Leyton, for the follow-up note on Case 4; and Dr. G. Boden and Professor C. F. Barwell, of the London Hospital, for their help in establishing the diagnosis of some of the patients.

Discussing the relation between smoking and lung cancer, Dr. I. HIEGER writes in last week's *Nature* (August 17, p. 308): "The report [of the Tobacco Manufacturers' Standing Committee] brings its heavy guns to bear on the statistical aspect of the problem. It emphasizes that a contingent statistical relation does not guarantee causation. Let us take an example of what could be called contingent. Seaside-sunburn in London schoolchildren, before the motor-car, was always preceded by a railway journey. The railway journey is contingent to the sunburn but is not the cause of the sunburn. To take a strictly practical point of view, the seaside-sunburn could have been avoided by shutting down the railways, and in the same way lung cancer could be largely avoided by closing the cigarette factories, quite independently of whether lung cancer and smoking have a causal or a contingent relationship."

CAT-SCRATCH DISEASE WITH PNEUMONIA

HUGH SMELLIE, M.B., M.R.C.P.

Medical Registrar, King's College Hospital, London

Since Lee Foshay, in America, recognized cat-scratch disease as an entity (Daniels and MacMurray, 1951) excellent reviews of the condition have appeared in France (Debré *et al.*, 1950), in America (Daniels and MacMurray, 1954), and in Great Britain (Brand and Finkel, 1956). In addition numerous case reports have appeared in the literature. These writers have described the main features of the disorder and its complications. The clinical diagnosis is based on history of contact with a cat, and the appearance of a small local lesion followed by regional adenitis which may suppurate and produce sterile pus and mild general symptoms with fever. Histological examination of an affected node shows reticulo-endothelial hyperplasia with focal granulomata which may undergo central necrosis. An intradermal test (Mollaret *et al.*, 1951a) provides confirmation of the diagnosis. Complications are usually mild, encephalitis (Daniels and MacMurray, 1954) being the most serious so far described. Others include mesenteric adenitis, Parinaud's oculo-glandular syndrome (Daniels and MacMurray, 1954), erythema nodosum, and transient generalized rash.

The disease has been produced in apes, and is thought to be due to a virus of the psittacosis-lymphogranuloma venereum group (Mollaret *et al.*, 1950, 1951b).

We have recently observed a patient who has suffered from typical cat-scratch disease complicated by a severe pneumonia which could not be attributed to any other cause and which responded slowly if at all to antibiotic therapy. The case history is presented in detail, as we can find no previous record of pulmonary complications in this disorder.

Case Report

A housewife and domestic help aged 46 had previously enjoyed good health. She worked as part-time housekeeper for a family who owned an ageing cat. This animal habitually deposited its excreta about the house, and it was the duty of our patient to clean up after it. She was never bitten or scratched by the cat.

In July, 1956, she noticed a small "cyst" on the palm of her left hand. This remained, but she was otherwise quite well until September 1, when she had a severe continuous headache lasting for a week. On September 6 a slightly tender swelling appeared at her left elbow. This was found by Dr. K. R. Hughes, her practitioner, to be an enlarged epitrochlear lymph node. He also noted an enlarged left axillary node, an infected papule on her left palm, and a lymphangitis. The latter proved to be transient, as it was not subsequently observed. He administered 1 mega unit of crystalline penicillin intramuscularly and prescribed "distaquine" V, 2 tablets (120 mg.) four-hourly by mouth.

Two days later Dr. L. DuLake saw her in the absence of Dr. Hughes. She appeared to be more ill, her temperature was 100.4° F. (38° C.), and the epitrochlear node was now the size of a large hen's egg and that in the axilla the size of a tangerine. There was a palmar papule surmounted

AUG. 24, 1957

CAT-SCRATCH DISEASE WITH PNEUMONIA

BRITISH
MEDICAL JOURNAL 447

by a crust, which was removed to liberate a small bead of pus. Next day penicillin therapy was replaced by tetracycline (250 mg. six-hourly by mouth), and after this her temperature fell to 99° F. (37.2° C.), the nodes became slightly smaller, and she felt better. On September 15, however, she complained of pleuritic pain on the right side and of feeling ill again.

She was admitted to East Surrey Hospital two days later under one of us (G. C. S.). By then she had become very ill. Her temperature was 102.8° F. (39.3° C.), pulse 120, and respirations 26. In addition to the lesions of her left arm already described she had signs of consolidation of the right lower lobe. A chest radiograph confirmed this, showing homogeneous shadowing in the right middle and lower zones and some pleural reaction at the left base, and also showed some pleural reaction at the left base. A blood culture was sterile. Intramuscular penicillin and streptomycin were given. Her general condition improved slightly and during the next day she produced a small amount of "red jelly" sputum. On September 19 she was transferred to King's College Hospital. The palmar lesion was now healing, but the regional lymph nodes were still moderately enlarged. All antibiotic treatment was stopped and the illness was thoroughly investigated during the next three days.

Her haemoglobin was 90% (13.3 g.); white-cell count, 5,950 per c.mm., with 77% neutrophils. Her E.S.R. was 38 mm./hour. A catheter specimen of urine showed a trace of protein, many leucocytes, and *E. coli* on culture. Sputum was purulent on three occasions, but no pathogenic organisms were grown from it and *M. tuberculosis* could not be found in smears. A blood culture was sterile. Her Wassermann and Kahn reactions were negative, and complement-fixation

tests for influenza A and B viruses, A.P.C. group viruses, and Q fever were also negative. Serial tests for psittacosis-lymphogranuloma group viruses showed no rise from the original titre of 1/32. The streptococcus M.G. agglutination titre was low. An intradermal injection of 0.1 ml. of cat-scratch antigen produced an area of erythema and induration just over 1 cm. in diameter after 48 hours, which we regarded as a positive result.

Four days after her admission to King's College Hospital the patient was still very ill, and treatment was then resumed, using crystalline penicillin, 1 mega unit six-hourly for eight days. Although there was slight improvement she relapsed on October 2 with a rise in temperature to 101.6° F. (38.7° C.) and increase in dyspnoea. Penicillin was stopped and tetracycline, 250 mg. six-hourly, was given by mouth. She failed to improve in the next two days, so intramuscular

penicillin was again added to the treatment. On October 7 she had another slight relapse with return of the right-sided pleuritic pain for 12 hours. No haemoptysis was present, and no evidence of peripheral thrombosis or change in the appearances on the chest radiograph. After this she gradually improved and the signs of pneumonia receded both clinically and radiographically. All this time the enlarged lymph nodes in her left arm were steadily regressing. Treatment was stopped on October 23 and she was discharged on November 6 much improved. A radiograph taken on December 17, three months after the onset, showed complete clearing of the right-sided pneumonia, the small pleural shadow at the left base remaining unchanged. The previously enlarged epitrochlear node had vanished and the axillary node was very much smaller. Suppuration had not occurred.

The main features of the illness are summarized in the accompanying diagram.

Discussion

There can be little doubt that this patient was suffering from cat-scratch disease, as she had a typical local lesion followed by subacute regional adenitis and a positive intradermal test. The complicating pneumonia had not previously been described in this disease; much effort therefore went into excluding other possible causes for it, such as the pneumococcus, psittacosis, influenza, Q fever, or "virus." All bacteriological and serological tests for these organisms were negative. The clinical picture of protracted illness yet with eventual recovery and sluggishness to respond to antibiotics is reminiscent of psittacosis. However, serial complement-fixation tests for this virus failed to demonstrate a rise in titre, and it seems reasonable to attribute the pneumonia to the cat-scratch organism.

The site of inoculation in this patient is unusual. A lesion on the palm would be unlikely to result from a scratch or bite; probably the infection entered an existing abrasion at that site either from stroking the cat or from contamination by excreta. A patient described by Daniels and MacMurray (1954) was thought to have contracted cat-scratch disease involving the throat and cervical lymph nodes by sniffing cushions soiled by a cat, and it is tempting to suppose that the pneumonia in our patient also followed inhalation of the infecting agent. In fact, we do not believe this to be so, because more obvious enlargement of the hilar lymph nodes should have followed a primary inoculation of the lung. We presume the pneumonia was the result of a viraemia.

The cat was destroyed within a month of the onset of our patient's illness, and a post-mortem examination, conducted by Dr. P. S. Gardner, of the Virus Reference Laboratories, Colindale, revealed no signs of disease. No virus has been isolated despite a most exhaustive search.

Summary

The case of a patient suffering from cat-scratch disease with pneumonia has been described. The pneumonia was thought to be an integral part of the disease, and represents an uncommon but severe complication of this relatively minor complaint.

We are grateful to Dr. L. DuLake for the early clinical findings; to Dr. J. Talbot for bacteriological advice; and especially to Dr. Clifford Hoyle for encouragement and permission to publish this case report.

PRIMARY TORSION OF THE GREATER OMENTUM IN CHILDHOOD

BY

P. FARRUGIA-BONNICI, M.D.

AND

H. B. MARSDEN, M.B., D.C.H., D.Path.

The Royal Manchester Children's Hospital

Since the first report of primary torsion of the greater omentum by Eitel in 1899, fewer than 100 cases have been recorded in the literature. The greatest incidence of this condition has been mainly in young adults and persons of early middle age, whilst its occurrence in childhood has been regarded as particularly rare, as evidenced by its omission from the majority of standard paediatric textbooks.

During a period of three months three cases of primary torsion of the greater omentum have been seen at the Royal Manchester Children's Hospital, the age of the patients being 6, 8, and 11 years.

Our experience suggests that this condition is not as rare in childhood as is generally believed, and we are therefore presenting this report so that omental torsion may receive greater consideration in cases of suspected appendicitis in childhood when the vermiform appendix is found to be apparently normal at operation.

Case 1

A 6-year-old girl with no previous relevant history was admitted to hospital on March 1, 1956, with a one-day history of generalized abdominal pain of sudden onset commencing immediately after eating a slice of bread-and-butter. The pain was accompanied by repeated vomiting and retching. It was colicky at first, becoming continuous later. The bowels were regular and were opened on the day of admission.

The patient was of normal development and not obese. She had a loose unproductive cough. The tongue was furred and moist. Her temperature was 98° F. (36.7° C.), pulse 120, and respiratory rate 24. Auscultation of the chest showed the presence of a few scattered inspiratory rhonchi and moist rales in the left lung, and the x-ray picture suggested the presence of simple bronchitis.

Examination of the abdomen revealed rigidity all along the right flank, with maximal and rebound tenderness in the right iliac fossa. There was also vague tenderness over the remainder of the abdomen, and Rovsing's sign was positive. The bowel sounds were normal, and examination of the hernial orifices and rectum yielded no additional information.

Other findings included a total white-cell count of 12,000 per c.mm., and urine examination was entirely negative. A diagnosis of acute appendicitis was made and the patient underwent operation on the day of admission.

Through a gridiron incision the appendix was inspected, and, although apparently normal, it was removed. There was no free fluid or blood in the abdominal cavity, but some of the mesenteric glands were rather large although otherwise normal. Digital exploration of the abdominal cavity revealed a small firm mass in the right hypochondrium, which, on enlargement of the original incision, was found to be a torsion of a segment of the greater omentum with the pedicle attached to the anterior superior border of the transverse colon just distal to the hepatic flexure. It had a mottled purple colour, a smooth convex anterior surface, and a nodular concave posterior surface, with sharp firm edges. The mass measured 9 cm. in greatest diameter and

was 7 cm. in length, tapering to a point at the tip. The pedicle had three clockwise twists and was about 3.5 cm. long. The rest of the omentum appeared healthy and not unduly loaded with fat. The twisted portion of omentum together with a piece of healthy omentum was excised above the pedicle. Histological examination showed distension of veins with numerous red corpuscles between the fat-cells.

A rather extensive subserosal haemorrhage in the transverse colon, medial to the attachment of the twisted pedicle, was noted.

The child made an uneventful post-operative recovery and was discharged home on March 11. When seen on April 5 she was reported to be quite well.

Case 2

A boy aged 11 years with no recent relevant history was admitted to hospital on March 12, 1956. For three days before admission he had complained of intermittent pain in the right lower abdominal quadrant. The pain was occasionally so severe as to make him cry out, and was associated with nausea but no vomiting. The bowels had previously been regular, but were not opened on the day of admission.

On examination the child was obese and complained of mild continuous pain in the right lower abdomen. His temperature was 98° F. (36.7° C.), pulse 80, and respirations 24. The tongue was clean and the breath not offensive. The abdomen was difficult to palpate owing to the obesity, and no definite mass could be felt. The hernial orifices were clear and the testes were present in the scrotum. There was marked generalized guarding, with tenderness and rebound in the right and left iliac fossae. Bowel sounds were normal. Rectal examination revealed nothing of note.

A straight abdominal x-ray film yielded no additional information. A white-cell count showed a total of 14,400 cells per c.mm., with 76% polymorphs. Examination of the urine disclosed nothing abnormal.

A diagnosis of acute appendicitis was made and the child underwent operation on the day of admission.

Through a gridiron approach the peritoneum was opened. No free fluid or blood was present. The appendix contained a solitary soft small faecalith but no signs of inflammation, and was removed. Digital exploration of the abdominal cavity revealed a small mass lying in the right hypochondrium. The wound was enlarged, and the mass was seen to be a torsion of a segment of the greater omentum. No enlarged mesenteric glands were seen and all the viscera were apparently normal.

The omental torsion arose from a pedicle attached to the anterior superior surface of the transverse colon just distal to the hepatic flexure. It had a mottled purple appearance, a smooth convex surface anteriorly, and a nodular concave surface posteriorly, the edges being sharp and firm. The greatest diameter was 5.5 cm. and the length 9 cm., tapering to a point at the tip. The pedicle contained four twists in a clockwise direction and was about 1.5 cm. long. The mass was excised together with a piece of normal omentum. There appeared to be a slight excess of fat in the neighbouring unaffected omentum.

Post-operative recovery was rapid and uneventful. The patient was discharged home on March 24 and was reviewed on April 14, when his condition was entirely satisfactory.

Case 3

An 8-year-old girl was admitted to hospital on June 8, 1956, with abdominal pain of two days' duration. The pain, appearing two hours after a normal meal, was gradual in onset and was first felt in the right lower quadrant. It was aggravated by walking and by rising up from a supine to a sitting position, and the severity was such as to disturb her sleep. There was nausea, but no vomiting. The bowels were regular and had been opened on the day of admission. There was no previous relevant history.

AUG. 24, 1957

On examination she was found to be a well-nourished child, intelligent and co-operative, and did not appear to be in obvious pain. The face was flushed. Her temperature was 100° F. (37.8° C.), pulse 120, and respirations 24. The tongue was clean and moist and the breath not offensive. Examination of the abdomen revealed marked tenderness and guarding in the right iliac fossa with some rebound tenderness in this area. No masses were detected and the hernial orifices were clear. The white blood cell count was 15,400 cells per c.mm., with 71% polymorphs. Examination of the urine was negative. A diagnosis of subacute appendicitis was made.

At operation the following day, through a gridiron incision, the appendix was found to be normal and was removed. No free fluid or blood was seen in the abdominal cavity. There was some enlargement of the mesenteric glands.

Digital exploration of the abdominal cavity revealed a small mass just above the umbilicus. Enlargement of the wound revealed a haemorrhagic segment of omentum which had undergone torsion and become adherent to neighbouring healthy omentum. It arose by a pedicle from the anterior superior border of the transverse colon just distal to the hepatic flexure. It had a polygonal shape and measured about 4 cm. in length by 3.5 cm. in width. The margins were sharp and firm. The pedicle was about 1.5 cm. long and had three twists round a large central vein. The twisted omentum was excised together with a piece of healthy tissue, including the adherent portion.

The child made an uneventful recovery and was discharged home on June 26. When seen one month later she was symptom-free.

Discussion

The aetiology of primary torsion of the great omentum is not clear. Donhauser and Locke (1954) have listed the most generally accepted theories, which include predisposing and exciting factors. Predisposing factors are the presence of a large omentum, a long pedicle with narrow attachments, and excessive deposition of fat in the distal portion of the omentum. In our patients there was torsion of a part of the omentum which was distinct from the main mass. The pedicle in each instance was very narrow—possibly rather long in two cases—and a relatively large distal adipose mass was present.

The exciting agents include the application of external force in addition to violent exercise, tossing of the omentum due to peristaltic waves, and the haemodynamic theory. The latter suggests, briefly, that with venous obstruction the arteries become tense and the longer and more tortuous veins rotate round these more rigid structures.

We could not obtain any history of trauma or violent exercise in our cases, and the only noteworthy feature concerning the blood supply was the presence of a large central vein in the pedicle of Case 3. However, we felt that in this case the vein behaved as an axial band around which torsion was more likely to occur.

Peristalsis was thought to be the most important single exciting factor in the production of the torsion in our cases. In Case 1 the pain began immediately after the consumption of food. The situation of the torsion—namely, in the right hypochondrium—and the direction of rotation were similar in each of our cases and involved the right free border of the omentum. In this connexion it is noteworthy that the great majority of reported cases have been in the right upper quadrant. This suggests that antagonistic peristaltic forces may have played a part in our cases owing to the attachment of the omentum to the stomach and transverse colon.

As regards the clinical features of this condition the patients are generally described as being robust or obese (Altemeier and Holzer, 1946). Two of our patients were of average build and development, and only Case 2 showed definite evidence of obesity. The marked preponderance of male cases as found by Smythe (1906) in the adult patients

was not a feature of our material, although this is of little significance in so small a series.

In practically all the reported cases and in each of our own patients a pre-operative diagnosis of appendicitis was made. The differential diagnostic features for distinguishing these conditions have been listed by Smythe. A relatively mild systemic disturbance with low-grade pyrexia and little leucocytosis is regarded as the usual finding in torsion of the omentum, and in only Case 3 of our series was there slight elevation of temperature. In the six cases reported by Altemeier and Holzer there was nausea but no vomiting, although in our first case repeated vomiting was associated with retching. Only in this instance did we find a furred tongue, and in none of the cases was the breath offensive.

Primary right-sided localization of the pain in omental torsion is also suggested by Smythe as one of the distinguishing features, but, again, in Case 1 there was generalized distribution of the pain at the onset. Finally, the greater degree of abdominal rigidity and the severity of the pain are thought to be points in favour of appendicitis. In our patients, however, there was considerable rigidity, and in Case 2 the pain was exceptionally severe.

In conclusion we feel that it is not always possible to make a correct pre-operative diagnosis in cases of omental torsion. In addition, it is important not to mistake the sharp, firm edge of the twisted segment for the liver edge on digital exploration at operation. In two of the cases the mesenteric glands were thought to be appreciably enlarged, and in the presence of an apparently normal appendix the clinical picture might have been attributed to mesenteric adenitis. Our findings support the opinion of Cavanagh and Campanale (1955) that careful examination of the omentum should be part of the abdominal exploration whenever the suspected pathological lesion is not confirmed at laparotomy. This is particularly true when a gridiron incision is made following a diagnosis of appendicitis which is not supported at operation.

Summary

Three cases of primary torsion of the great omentum in childhood are described, and it is felt that this condition is not as rare as would appear from a study of the literature.

The aetiology is discussed and the differential diagnosis from acute appendicitis considered.

Examination of the omentum should be carried out in all cases of suspected appendicitis in children when the appendix is found to be normal at operation, especially when making use of a gridiron incision.

We thank Mr H. A. Haxton and Mr. A. Jolleys for permission to use the clinical records.

The British Standards Institution has issued a memorandum on therapeutic x-ray equipment. Recommendations are made to ensure safety and efficiency in the use of the machinery; the amounts of permissible extraneous radiation are stated. The memorandum suggests that the essential dimensions of x-ray equipment should be uniform to allow for interchangeability between parts produced by various manufacturers. Recommendations on the electrical parts of the equipment are also included. Radiologists and manufacturers have collaborated with the Ministry of Health in the preparation of the memorandum (B.S.2849). It is obtainable from the British Standards Institution, Sales Branch, 2, Park Street, London, W.1 (price 4s. net).

PERFORATION OF GALL-BLADDER DURING PREDNISONE TREATMENT

BY

G. L. MOUZAS, Dip.M.(Athens)

AND

J. H. BRIGGS, M.B., B.S.

From the Departments of Surgery and Medicine, Hammer-smith Hospital and Postgraduate Medical School of London

During the past few years cases have been reported of gastro-intestinal ulceration, sometimes accompanied by massive haemorrhage or perforation, in patients receiving steroid therapy. A marked rise in the incidence of such cases, due to the increasing use of these drugs, is apparent. The recognition of the complications arising in these cases therefore merits careful consideration. The following case is of interest, as no similar occurrence of perforation of the gall-bladder during steroid therapy has been reported previously.

Case History

A man aged 45 had suffered from rheumatoid arthritis for 11 years, and during the last three years had developed psoriasis with severe polyarthritis. Salicylates, rest, and physiotherapy failed to give any relief, and in 1953 he was treated with corticotrophin, 40 units daily, and in the next years with cortisone, 100 mg. daily, which produced a satisfactory remission of both the arthritis and the psoriasis for a period. After four months, however, he developed severe fluid retention, which was not controlled by sodium restriction; so in September, 1955, he was given prednisone acetate 30 mg. daily, which is five times more potent than normal cortisone; there was symptomatic improvement, although the anaemia was not corrected and the E.S.R. remained raised. The dose was gradually reduced to 15 mg. daily, and in March, 1956, he discontinued treatment on his own initiative, which resulted in his urgent admission to hospital on July 10 with a severe exacerbation of both arthritis and psoriasis. In August he first complained of nausea and vomiting, which occurred before and after meals, and also of abdominal pain. There was no diarrhoea, colic, or jaundice, but he had lost 14 lb. (6.4 kg.) in weight in the previous eight months.

The arthritis and psoriasis responded to 20 mg. of prednisone daily, but the dyspeptic symptoms persisted. There was no abdominal tenderness. Traces of occult blood were present intermittently in the stools, and a barium-meal examination on August 9 showed an inconstant deformity in the prepyloric region but no ulcer crater. A diagnosis of acute prepyloric ulceration with pylorospasm was made and a full medical regime instituted. Therapeutic response was not good and there was an exacerbation of the arthritis and psoriasis, probably due to vomiting, which prevented adequate absorption of prednisone.

In the early hours of September 28 he developed acute epigastric pain radiating to the right iliac fossa, and there was marked abdominal tenderness, slight rigidity, with normal bowel sounds and liver dullness intact. The temperature was 100.2° F. (37.9° C.) and the pulse 95, and a straight x-ray film of the abdomen showed no subdiaphragmatic gas or fluid collection. These symptoms slowly improved, but in view of the severity of his arthritis and the inadequate oral absorption of prednisone it was decided to change to intramuscular cortisone, 100 mg. daily, and corticotrophin, 20 units, in addition.

Thirty-six hours after the first attack he had a recurrence of acute abdominal pain radiating down to the right iliac fossa, persistent and progressive in severity. Rigidity developed and bowel sounds were absent. A diagnosis of gastro-intestinal perforation with peritonitis was made and an emergency laparotomy was performed.

Operation.—On September 29 a right paramedian incision was made. The liver was found to be enlarged to three and a half fingerbreadths below the costal margin. The stomach and first part of the duodenum were normal. On raising the duodenum thick dark fluid was found in the Rutherford Morison pouch, and there was a perforation, about 2 by 2.5 mm., in the postero-lateral wall of the gall-bladder. The gall-bladder was enlarged and had a thickened wall; on palpation no stones could be felt. Cholecystectomy was performed and the abdominal cavity was drained by a stab drainage. Fifteen minutes after the beginning of the operation the patient's blood pressure fell to 90/50; hydrocortisone administration was begun immediately, and after 10 minutes the blood pressure rose to 120/80 and was maintained at this level. During the operation he received 1 pint (570 ml.) of blood and 15 mg. of hydrocortisone in 5% dextrose.

Post-operative Progress

The immediate post-operative period was covered by intravenous hydrocortisone, which was gradually reduced and withdrawn after 36 hours, when a total of 240 mg. had been given. Corticotrophin was then given. The patient was icteric in the immediate post-operative period, and in the absence of evidence of blood destruction or incompatibility, as shown by a negative modified indirect Coombs test, this was thought to be obstructive in origin: it cleared within five days.

For the first 24 hours after operation the patient was oliguric, but after this there was polyuria and proteinuria with granular casts. No proteinuria was detected after the tenth day. The blood urea was raised (95 mg. per 100 ml.), and it was thought that amyloid involvement of the kidney was a possible underlying cause, in spite of proteinuria before operation; this was subsequently proved. Bowel sounds returned on the sixth day. The wound healed by first intention and the sutures were removed on the fourteenth day. The patient was then transferred to the medical ward, where treatment was continued to stabilize his rheumatoid arthritis, and 12 weeks later he was discharged in a fit condition.

Pathological Report

The gall-bladder measured 2 cm. × 5 cm. Its outer surface was red and covered by a film of fibrin up to 2 mm. in thickness. The inner surface showed a red but largely intact mucosa, though there were localized deposits of fibrin, including one at the site of the perforation. The wall varied

Low-power view of a section of the thickest part of the wall, showing abscesses and Rokitsky-Aschoff sinuses.

from 1 to 10 mm. in thickness, and in the thicker parts pockets of pus could be seen in the substance of the wall. Microscopically the lining epithelium was mostly intact. The lamina propria was oedematous and infiltrated by inflammatory cells comprising polymorphonuclears, macrophages, plasma cells, lymphocytes, and eosinophils. There were also collections of red cells. The muscularis was intact. The perimuscular connective-tissue layer was greatly thickened and was the seat of a severe purulent inflammation. This layer contained numerous large Rokitsky-Aschoff sinuses distended with pus, and in addition there were abscesses free in the wall (see Fig.). This layer was much more severely

inflamed than the mucosa, and the cell reaction was largely polymorphonuclear. The outer surface showed peritonitis of apparently some days' duration. An occasional Gram-positive coccus was seen. Special staining revealed amyloid deposits in small vessels and in the basement membrane.

Discussion

The diagnosis of peritonitis was based on the sudden onset of upper abdominal pain radiating to the right iliac fossa and acute abdominal tenderness, followed later by rigidity and absence of bowel sounds. In retrospect, the episode three days previously was one of perforation with local peritonitis, and this was supported by histological examination. Before operation the gall-bladder was not suspected as the seat of disease, and it is probable that a reflex pylorospasm was responsible for the symptom-complex.

The significance of the relationship of onset of dyspepsia to the starting of treatment with prednisone is difficult to assess. It is known that peptic ulceration occurs more frequently with prednisone than with cortisone, but cholecystitis has not yet been described as a complication of either of these drugs. Because of deterioration in the general condition associated with persistent vomiting, prednisone was replaced by intramuscular cortisone. The stress associated with surgical trauma was covered by intravenous hydrocortisone.

Corticotrophin has been found to bring the temperature and pulse rate to normal levels within 12–36 hours after its administration (Beck *et al.*, 1950). It also causes a decrease of the leucocytes during the first few hours, with lymphopenia and eosinopenia. In the reported cases of patients undergoing treatment with corticotrophin and cortisone we found that the physical signs of all underlying diseases were obscured and there was a delay in diagnosis due to the reduction of inflammatory response caused by these drugs.

When an operation is contemplated on a patient undergoing treatment with corticotrophin and cortisone, care must be taken to ensure that large doses of cortisone are given immediately before and after the operation, because there is a possibility that, without taking this precaution, the patient may develop post-operative adrenal cortical insufficiency due to stress (Salassa *et al.*, 1953). As cortisone was withdrawn, adrenal stimulation with intramuscular corticotrophin was maintained. Adequate dosage of corticosteroids must be ensured, otherwise clinical features of adrenal cortical insufficiency develop quickly, the most important being restlessness, nausea, vomiting, weakness, hypotension, and coma. In treating the adrenal cortical deficiency state, intravenous hydrocortisone—the quickest therapeutic agent—gives an almost immediate response; oral cortisone acts in four to six hours, and intramuscular cortisone more slowly.

Because the severity of the post-operative renal failure was more marked than could be accounted for by the transient oliguria, the possibility of amyloidosis was considered and a special staining technique confirmed this in the specimen removed. Two months later the congo-red retention test (Unger *et al.*, 1948) was shown to be positive, 90% of the dye being retained after one hour.

In life the overall incidence of amyloid in rheumatoid arthritis is 4% (Fearnley and Lackner, 1955) and should be suspected in any patient with persistent and prolonged activity of the arthritis who has proteinuria, hepatomegaly, or splenomegaly.

Summary

A case of perforation of the gall-bladder in a patient with rheumatoid arthritis treated with prednisone is described. Histological examination of the gall-bladder revealed amyloidosis. The clinical features of the illness and its management are discussed.

We are grateful to Professor C. V. Harrison for the pathological report; to Mr. R. Shackman and Dr. E. G. L. Bywaters for their permission to publish this case; and to Dr. B. M. Ansell for her assistance.

Medical Memoranda

Treatment of Acute Primidone Poisoning with Bemegride and Amiphenazole

Since its introduction as an anticonvulsant in 1950 primidone ("mysoline") has shown itself to be a valuable drug, particularly in grand mal. For this reason it has come to be used extensively; but, in spite of this, only one fatal case of acute poisoning with the drug has been reported—no doubt, among other things, owing to its relatively low toxicity. Up to the present it appears that only four cases of serious acute poisoning with the drug have been reported. Three of these cases were suicide attempts by adults, and one was a 4½-year-old child, in whom the poisoning was due to lack of supervision. Among the three cases of attempted suicide the amount of primidone taken by the first reported case (Arnold and Ceranke-Höfermayer, 1953) was 30 g. (120 tablets). This produced unconsciousness for 12 hours, followed by sleepiness for another two days. In another case, reported by Sciarra *et al.* (1954), a dose of 6.5 g. (25 tablets) only produced a deep sleep lasting four to five hours. In the third case, which was quoted by Morley and Wynne (1957), a dose of about 20–30 g. (80–120 tablets) led to death in the course of 12 to 24 hours. In the fourth case, reported by Morley and Wynne (1957), a 4½-year-old boy had taken about 12.5 g. (50 tablets), which caused loss of consciousness lasting about 36 hours.

In the case described below, a 57-year-old man had taken about 25 g. (100 tablets) of primidone in an attempt at suicide; this put him into a state of drowsiness, which passed into unconsciousness after about 36 hours. This lasted about 12 hours, after which unconsciousness was terminated by means of treatment with bemegride ("megimide," "malysol") and amiphenazole ("daptazole," "fenamizol"), which was obviously effective. About 40 minutes after the beginning of treatment the patient was quite lucid.

We have been unable to find in the literature a single case of primidone poisoning treated with these drugs. But, since they have a good antidotal effect against barbiturates, these drugs should obviously be tried. This is because primidone and phenobarbitone are closely related in chemical constitution, although they differ substantially in toxicity. Primidone can be regarded as a reduction product of phenobarbitone, one oxygen atom in the pyrimidine ring of the molecule being replaced by two hydrogen atoms linked to the same carbon atom.

CASE REPORT

A 57-year-old man with symptomatic epilepsy of some years' standing had for the past six months been put on primidone in a dosage of 2–3 tablets a day. His attacks had been controlled by that treatment. Earlier he had been suffering from mental depression, and had attempted suicide in August, 1956. For some time before admission he had again been depressed and had uttered threats of suicide. According to his own statement, in the evening of November 19 he took 100 0.25-g. primidone tablets with intent to kill himself. He was admitted to hospital on the following day, and brought with him an empty jar which had contained 100 primidone tablets dated November 19, 1956. He was admitted in a dazed condition, with slurred speech. He confirmed that he had attempted suicide with primidone.

On the morning of November 21 he was unconscious, but not very deeply, since pharyngeal reflexes were still present.

Blood values on November 21 were: Hb, 77%; R.B.C. 4,000,000; W.B.C., 6,900; residual nitrogen, 39 mg. per 100 ml. Unconsciousness continued throughout the day. As the patient soon became more deeply unconscious bemegride and amiphenazole were given in the evening on the same principle as for barbiturate poisoning. Isotonic glucose was given by intravenous drip. At 19.53 hours 50 mg. of bemegride and 15 mg. of amiphenazole were introduced into the intravenous drip. This was repeated at 19.56, 19.59, 20.04, and 20.09 hours. Altogether, therefore, 250 mg. of bemegride and 75 mg. of amiphenazole were given. After the second injection the patient made swallowing movements and sighed deeply. After the third injection he became more alert and turned his head. After the fourth injection his eyelids began to twitch. After the fifth injection, at 20.09 hours, he awoke and could talk a little, but his speech was slurred. Recovery progressed, and at 20.30 hours he was fully awake and aware of having been poisoned by tablets. In the night preceding November 22 he showed motor agitation, sprang out of bed, and had pronounced visual hallucinations. He calmed down after an injection of 50 mg. of chlorpromazine.

In the morning of November 22 he was drowsy, but answered adequately when spoken to. He was, however, a good deal more drowsy than after the bemegride and amiphenazole injections on the previous evening. He required no more stimulants but brightened up later. During the further course pleuropneumonia supervened, which was treated with antibiotics; there were no other complications. The patient was transferred to a mental hospital after staying in this hospital for ten days.

Examination on November 28 showed: W.B.C., 5,600 (polymorphonuclear 54%, "stab" cells 2%, eosinophils 1%, basophils 0%, lymphocytes 37%, monocytes 6%); thrombocytes, 173,000 per c.mm.; prothrombin according to Quick-Lehmann, 96; residual nitrogen, 30 mg. per 100 ml.; Meulengracht, 1:3; Takata-Ara, negative.

Acute Epidemic Myalgia of the Hip

During the five months August to December, 1955, a series of cases were seen in the neighbourhood of Heatherwood Orthopaedic Hospital all showing a similar clinical picture—that is, severe pain in the hip, with limitation of movement. Most of the cases were pyrexial. Children and adolescents were mainly involved. A characteristic of the illness was early recovery following rest, and it left no after-effects. Eight of the cases were seen by me personally, and the histories and follow-up of six other cases were kindly supplied by Dr. E. V. Lambert.

All these cases were seen during the poliomyelitis epidemic of 1955 (see Chart), and in seven cases poliomyelitis was first diagnosed. Other diagnoses made initially were osteomyelitis in two cases, suppurative arthritis in one case, and some form of trauma in four cases.

The age range of the patients was 3½ to 35 years (average 12.8 years), only one being over 20. The sex distribution was eight males and six females. The right hip was affected in eleven cases and the left in three.

The commonest initial diagnosis was poliomyelitis, and this was suggested by the history of being off-colour for one to seven days, pain in the leg, and in the majority of cases a temperature up to 105° F. (40.6° C.), in some of them associated with coma, vomiting, and frontal headaches. The diagnosis of an infective lesion made in three cases was suggested by a raised sedimentation rate, a raised white-

cell count in two, and severe pain. Those cases thought to be due to injury had given some history of injury prior to admission which it was thought might have accounted for the symptoms. In all cases where x-ray pictures were taken, these were normal. In all cases except

Seasonal occurrence of poliomyelitis and acute myalgia in 1955.

one the symptoms were severe enough to justify admission to hospital. One patient was seen at home, and the symptoms were settling with rest in bed. The average stay in hospital of the other cases was just under 14 days. All patients had made a full recovery in a month, and a follow-up at nine months showed no recurrence of any symptoms.

The outstanding symptoms in these cases were: pain in 14 cases, spasm in 14, pyrexia in 10, and raised E.S.R. in 5. In the majority there was marked spasm in the hip when it was moved. In all cases a few degrees of passive movement could be obtained which was painless.

COMMENT

The clinical picture in these cases suggests that some infection was occurring during the months of August to December, 1955, causing an acute myalgia which seemed to single out the muscles in the region of the hip-joint and mainly affected children and adolescents. It ran a course lasting about two weeks and then subsided completely. In the majority of cases a raised temperature and other general reactions were noted.

From this description one would have to consider a virus infection as being the cause, and the fact that it coincided with a fairly severe epidemic of poliomyelitis during the same season of the year suggests that the virus may have been related—such as a Coxsackie infection (see Chart).

Coxsackie infection was first described by Daldorf and Sickles in 1948. Since then further work has shown that it is the cause of Bornholm disease (epidemic pleurodynia, epidemic myalgia), and herpangina.

It is an acute febrile, self-limiting, infectious disease affecting children and young adults, and in the above conditions the virus has been isolated from the stools or throat.

No specific treatment is available. The disease appears to be widespread and has been reported from most of the countries of the world. It occurs most frequently during the poliomyelitis season and is sometimes found coincidentally in patients suffering from poliomyelitis. It has been shown to be spread by sewage and flies, and is highly infectious—often involving several members of one family. Many may carry the virus without showing any clinical signs of the disease.

I have been unable to find any description in the literature of acute myalgia affecting the hip region, but the present cases were all similar in that they occurred during the poliomyelitis season; the main feature was acute pain; while the condition cleared up completely, leaving no after-effects.

I am grateful to Dr. E. V. Lambert for providing clinical notes of his cases. From the six cases that he had seen he had independently come to the conclusion that these cases were probably due to a Coxsackie-like virus infection.

Reviews

OBSTETRICS TEXTBOOK

Munro Kerr's Operative Obstetrics. Sixth edition by J. Chassar Moir, Hon.L.L.D., M.A., M.D., F.R.C.S.Ed., F.R.C.O.G. (Pp. 1,008+x; illustrated. £5 5s.) London: Baillière, Tindall and Cox. 1956.

This new edition marks a turning-point in the history of this classic, because Professor Munro Kerr, having fathered the work for 40 years, has retired from active responsibility. Nevertheless, his name remains in the title, his portrait by Simon Elwes becomes the frontispiece, and his spirit pervades the pages. Professor Chassar Moir is to be congratulated on the manner in which he has managed to introduce his own personality without destroying the original, so preserving and even accentuating this book's unique personal flavour. For its charm lies in the absence of systematic and didactic teaching, in its atmosphere of reminiscence, medical history, and clinical experience, and in its digressions from the strict range of its title. The very features which make it so attractive sometimes create the impression that it is old-fashioned. It may be that certain out-of-date methods, external pelvimetry for example, should be more critically discussed or no longer advised, but, generally, the mention of older and traditional techniques is wise and desirable. It should do much to instil a proper perspective in the minds of those younger obstetricians of to-day who are prone to streamline obstetrics into nothing more than spontaneous delivery, forceps extraction, and caesarean section. Moreover, no reader can fail to sense the sound basis of knowledge and experience on which the work is built.

The main features of the book are well known to the obstetric world; they remain unchanged, although there is much new material with new illustrations (including colour plates). I enjoyed particularly rereading the stimulating and almost provocative chapter on tumours associated with pregnancy. One specially valuable feature is some 1,500 references to which the reader is directed for further reading; these have clearly been carefully chosen after critical appraisal of their worth. Unfortunately all the references and the vital statistics are more than four years old. This perhaps reflects the interval which must elapse between completion of an author's manuscript and its appearance in print; it may, however, be to some extent deliberate, because the passage of time is often necessary to determine the real merit of any contribution to the literature.

Professor Chassar Moir's book is a "must" for any library which caters for obstetricians in training.

ALCOHOLISM

Alcoholism. Edited by George N. Thompson, A.B., M.D., F.A.C.P. (Pp. 548+xiii; illustrated. 72s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

Alcoholism: A Manual for Students and Practitioners. By Lincoln Williams, M.R.C.S., L.R.C.P. (Pp. 62+x. 8s. 6d.) Edinburgh and London: E. and S. Livingstone Ltd. 1956.

At the present time, when an increasing use is being made of so many of the new chemical tranquillizers, it is a good thing that the older and better-remembered ones, such as alcohol, are not being entirely forgotten. But these two books serve to re-emphasize the many dangers of alcohol as a brain tranquillizer, especially when the dosage becomes uncontrolled.

The larger American volume, edited by George Thompson, is beautifully produced. It contains a mass of information on all aspects of alcoholism, and there are some excellent articles in it. Harold Himwich, for instance, writes exhaustively and interestingly on alcohol and brain physiology. Joseph Hirsh discusses the social aspects of alcoholism, and provides a mass of quite frightening statistics. Albert Marinacci shows how the E.E.G. of some patients is affected by alcohol, and cites patients in whom alcohol produces

epileptic seizures. This finding becomes a very important one indeed when one realizes that alcohol has also induced psychomotor seizures in predisposed persons, resulting in the fatal shooting of passers-by and other crimes of violence. This book may be too detailed for the general practitioner, but is a most useful reference book in any library.

Dr. Lincoln Williams's book is, on the contrary, short and very much to the point. It can be highly recommended for all who want a short account of the alcohol problem at the present time, especially of the more effectual treatments now given. Williams has lived for his subject—the skilled and specialized treatment of such patients—for many years, and his sincerity of approach shows up well in this book. The work of a select band of pioneers in this country on the use of new aversion treatments and the advent of Alcoholics Anonymous have made the outlook for many alcoholics much more hopeful. This book states quite simply what can and what cannot be done for patients who sincerely desire to give up drinking altogether. But the author points out that as yet there is no treatment for the person who desires to remain a moderate drinker and not a teetotaler. Relapse for him is certain, as it is in almost all other forms of established addiction where the dosage of a drug is only cut down rather than stopped altogether. Williams makes out a good case for the establishment of special clinics for alcoholics, to help to eliminate "the apathy, the scepticism, and the atmosphere of pessimism so long associated with this problem." And he is almost certainly right.

WILLIAM SARGANT.

TREATMENT WITH RADIOISOTOPES

Therapeutic Use of Artificial Radioisotopes. Edited by Paul F. Hahn, Ph.D. (Pp. 213+x; illustrated. 80s.) New York: John Wiley and Sons, Inc. London: Chapman and Hall Ltd. 1956.

Artificially induced radioactive materials from the cyclotron have been available for 20 years for therapeutic use, and for the last 11 years similar products have come from the chain-reacting pile. The field of application is still changing, and this book presents a cross-section of efforts being made in exploiting radioisotopes in therapy. It is written by internationally recognized authorities from both sides of the Atlantic, and can be strongly recommended as a balanced compilation of first-rate essays. Every type of use of radioisotopes has been covered: internal administration for metabolism (for example, ³²P and ¹³¹I); the various forms of radiocolloids; isotopes as intravascular sources, for interstitial implantation, as surface beta- and gamma-ray sources, and also in teletherapy. Introductory chapters deal lucidly with the necessary radiological physics, with problems of dosage, handling, and protection, and the emphasis throughout is on practical aspects. Each clinical problem is clearly defined, the principles underlying the application of radioisotopes are discussed, and the practical procedures are presented with all necessary detail. In a remarkable way each chapter has been made valuable as an introduction to the subject, as a reliable guide to practice, and also as a stimulus to further research. It is instructive to compare, for instance, the effects of treatment with radioisotopes in chronic leukaemia, as presented in two chapters in juxtaposition—the one by titrated, regularly spaced ³²P therapy, and the other by intravenous colloidal radio-gold. The treatment of polycythaemia rubra vera with ³²P appears to have resulted in a nearly normal life expectancy. However, the statement that "some cases of polycythaemia secondary to arterial anoxia are worth treating by titrated ³²P" seems remarkable (even if the red cell count is maintained above normal), as this blood picture represents a compensatory mechanism. Potential hazards and complications are given due consideration throughout; possible genetic and carcinogenic effects are discussed under the treatment of thyrotoxicosis. Each chapter is a model of presentation, and the editor and authors are to be congratulated on this comprehensive, up-to-date volume. This book must surely be essential for everyone concerned with the therapeutic use of radioisotopes.

It is often said that radioisotopes applied to medicine have provided more spectacular results in diagnosis than in treatment. While this is probably true, this book records real achievements in therapy, and the results already given recall Osler's remark in a different context: "The lock has been turned. The door stands partly open, and we are permitted a glimpse of the future possibilities to be attained."

ARTHUR JONES.

NEUROLOGICAL EXAMINATION

Clinical Examinations in Neurology. By Members of the Sections of Neurology and Sections of Physiology, Mayo Clinic and Mayo Foundation for Medical Education and Research Graduate School, University of Minnesota, Rochester, Minnesota. (Pp. 370+xviii; illustrated, 52s. 6d.) Philadelphia and London: W. B. Saunders Company. 1956.

Several books on the methods used in clinical examination of the nervous system have been published in the past few years, and this is another. The art of history-taking and clinical examination can really be learned only in the wards and out-patient departments under the guidance of experienced clinicians, but doubtless books of this type are useful in describing methods of eliciting physical signs and indicating their interpretation. This one is written by members of the sections of neurology and physiology of the Mayo Clinic as an expression of gratitude to their teachers Dr. Woltman and Dr. Moersch. The book follows orthodox lines in giving an admirably clear and thorough account of neurological examination, and there is one observation which is frequently overlooked in Great Britain, the slow muscle relaxation after eliciting a tendon jerk which occurs in myxoedema. This sign was described by Dr. Woltman, and is stated to be invaluable in confirming the diagnosis in a case of suspected myxoedema. A short but succinct account of the help given in clinical neurology by electroencephalography is included, and there is also a helpful description of the uses of electromyography and the recording of strength-duration curves in clinical diagnosis.

J. W. ALDREN TURNER.

TUBERCULOSIS IN CHILDHOOD

Le Traitement de la Tuberculose de L'Enfant. Séminaire in Paris December 7-10, 1955, by the Centre International de l'Enfance under the presidency of Professor R. Cruickshank. (Pp. 354; illustrated, 2,500 fr.) Paris: Masson et Cie. 1956.

In December, 1955, a four-day seminar on the treatment of tuberculosis in childhood was held in Paris under the auspices of the International Children's Centre. Nineteen papers were read, and considerable discussion followed from many of the hundred or so participants. The field was widely covered, the subjects ranging from experimental, bacteriological, and pathological work to prophylaxis and treatment, including surgery. Much that was discussed was controversial, and much more was too recent to allow of general confirmation of the results obtained. The papers presented, and the subsequent discussions, have now been published in a 353-page volume, edited by the secretary, Dr. Gautier. The work is entirely in French, and there are no summaries.

It is difficult, in a short review, to do justice to the various authors and impossible to avoid the invidiousness of selecting a few of them for special comment, for all of them have some particular information to impart. With such authorities as Professor Cruickshank (who, as chairman, introduced the subject and also summed up), and Professors Wallgren, Debré, Gernez-Rieux, and Tucker, to name but four of the speakers, it might be expected that the standard of the papers would be high, and such indeed is the case. Gernez-Rieux discusses his experimental studies in chemotherapy and concludes that there are still many unsolved problems, particularly with regard to iatrogeny and to the systematic treatment of primary infection and to the duration of therapy. Wallgren discusses the effect of specific treatment on the pathogenesis of the tuberculous process in

childhood and concludes that the long-term effects are as yet little understood. Dubois describes at length the various treatments for miliary and meningeal tuberculosis. The questions about the necessity for intrathecal treatment and the possibility of domiciliary treatment were both debated subsequently and no firm conclusions reached. Tucker discusses the results with different chemotherapeutic regimes, including viomycin and cycloserine (which latter causes convulsions if the level in the blood exceeds 50 µg./ml.). He concludes that, in general, combinations of isoniazid and P.A.S. are preferable, but isoniazid alone is as good in mild cases; much more research is necessary before firm conclusions can be drawn. In the final chapter Holm discusses the place of chemoprophylaxis *vis-à-vis* B.C.G., Debré makes a general appraisal of future objectives, and various participants describe the work at present being done in their respective countries.

WILFRID GAISFORD.

CYTOLOGY OF MALIGNANT TUMOURS

Leitfaden der Nativcytomorphologie maligner Tumoren. By Hans Siering and Karl Aderhold. (Pp. 139; illustrated, D.M. 15.20.) Jena: Gustav Fischer Verlag. 1956.

This book has been published as a guide to the cytological examination of malignant tumours. Four methods of examination are considered: the use of stained specimens, vital cytological examination by phase-contrast microscopy, fluorescent microscopy, and the use of the electron microscope. The authors are, however, almost entirely concerned with the examination of fresh unstained specimens by phase-contrast microscopy, with which they claim to have been very successful. The great majority of the illustrations are prepared from photographs obtained by this method. For routine cytological diagnosis most workers would prefer the use of stained specimens prepared by the fixation of "wet" films, and this would appear to be the most practicable procedure. There are, however, certain advantages to be gained in the use of fresh unstained specimens, especially for the purposes of research. The more intimate details of the cell are better shown, and this applies particularly to the mitochondria and microsomes in the cytoplasm. After some introductory chapters on the physiology of normal and malignant cells and the changes associated with malignancy, the authors deal with the cytological appearances found in normal cells, in hyperplasia, in benign tumours and metaplasia, and finally in various malignant conditions. The book is well illustrated and should be of considerable assistance to those interested in phase-contrast microscopy.

J. BAMFORTH.

ARTICULAR RHEUMATISM

Les Rhumatismes Articulaires Inflammatoires. (Arthrites rhumatismales). By S. de Seze and A. Ryckewaert. (Pp. 246; illustrated, 1,600 fr.) Paris: J.-B. Baillière et Fils. 1957.

This is a very well produced little book on "the inflammatory articular forms of rheumatism," by which the authors, whose names are well known in this field of medicine, mean acute and subacute rheumatic fever, rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, "palindromic" rheumatism, and intermittent hydrarthrosis. It is not obvious why they omit any description of, or reference to, the other disease processes which are generally grouped under the heading of the rheumatic diseases, such as osteoarthritis, non-articular rheumatism, or even the various collagen diseases which are now classified by the World Health Organization as "para-rheumatic diseases." However, the entities they mention they describe in every aspect in great detail, and their views, including those on therapy, would seem to be generally acceptable in Great Britain. The illustrations are particularly well reproduced and the price is reasonable.

W. S. C. COPEMAN.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY AUGUST 24 1957

PALLIATIVE RADIOOTHERAPY

Most general practitioners have had the experience of looking after patients dying from cancer of the breast or lung. Radiotherapy is the most frequently used method for palliation of symptoms (as distinct from attempts at cure, which is a different matter) in these two forms of cancer, and the question has been asked whether patients later suffer more while dying if they have had such treatment than if they have not. This is often difficult to answer. The degree of suffering is not easily estimated, and a comparison with what might have occurred if circumstances had only been different is almost impossible. In those people who have one outstanding and distressing symptom, which is relieved, and who die shortly afterwards, the benefit is clear to see; but if death is long delayed it may often be difficult to set the quality of life lived in the interval since treatment against the manner of dying and strike a satisfactory estimate of loss or gain.

To take cancer of the lung first. Members of the joint cancer consultation clinic of the Brompton Hospital and the Royal Marsden Hospital have been investigating the effects of radiotherapy for some years. The first five years' work was reported¹ in 1951, and the following statement was made on palliation: "The palliative value of x-ray therapy has been most marked. In fact, it holds out the only regular means of symptomatic relief in the majority of patients with this disease who come to hospital." The next account of radiotherapy of lung cancer from this clinic, given by D. W. Smithers² in 1955, discussed the value of this method of palliation. Death from obstruction of the superior vena cava is most distressing, and Professor Smithers wrote: "Probably the outstanding service the radiotherapist gives to these patients is the relief of superior-vena-caval obstruction." Though the obstruction may return after treatment it does not usually do so if a dose of 3,000 r or more is given. Radiotherapy can also arrest haemoptysis, usually a distressing rather than dangerous symptom, and relieve dyspnoea and cough, though it may be unwise to submit feeble patients to the

strenuous course of treatment required. With cancer of the lung radiotherapy is far less successful in relieving pain than in many other forms of cancer, though pain due to blood-borne metastases can generally be alleviated. Professor Smithers concluded that "there are many patients whose symptoms are not severe who are best left untreated, and there are a few for whom some treatment must be given for the sake of their morale alone."

The proportion of cases showing relief of each of the major symptoms has been well set out by I. Churchill-Davidson.³ J. R. Bignall,⁴ in the next report from the joint clinic, reviewed 317 patients and studied the manner of dying in 128 of these. The difficulties of assessment are clear, but the suggestion emanating from this investigation was that those who had had the primary cancer removed tended to die more easily than those who had not, and that the mode of death in the untreated and in those who had had radiotherapy was little different, with the exception of a lower incidence of obstruction of the superior vena cava in the treated group. The clinic then appointed a full-time research almoner to examine the way these patients die at home and to find out what their chief needs are. A report of this work is to be published later, but the great value of skilful management by some general practitioners is already obvious. Bignall⁵ has also studied the natural duration of bronchial carcinoma with a view to assessing the influence of treatment; and the effect of surgery⁶ and of radiotherapy⁷ on the duration of the disease has been estimated. The effect of combined radiotherapy and resection for bronchial carcinoma was reported on not very favourably by L. L. Bromley and L. Szur,⁸ and of radiotherapy for operable cases surprisingly favourably by J. Smart and G. Hilton.⁹

There is no doubt that careful radiotherapy applied to selected patients with bronchial carcinoma is of great palliative value and that unwisely given it can add to the patient's distress. For obstruction of the superior vena cava its contribution is outstanding. The additional span of comfortable life is difficult to assess; it is not long on the average, but well worth while for a few. When radiotherapy is a cause of greater suffering requiring special treatment in the last stages of the disease, then this suggests a failure of judgment by the radiotherapist.

Cancer of the breast is a very different story. Here radiotherapy is part of the first planned treatment in all but the earliest cases and has done much to improve results. A vast literature exists on the subject. While it is true to say that the outcome of the disease depends more on the nature of the tumour than on any other single factor, the influence of treatment on its course is clearly to be seen. The five-year survival rates in the larger treatment centres have steadily improved from just over 20% in the 1920's

⁹ Smart, J., and Hilton, G., *ibid.*, 1956, 1, 880.

to over 40% in the 1950's. In the later stages, when only palliation is possible, alterations in hormone balance have done much to make things easier for those with hormone-dependent tumours. Radiotherapy remains, however, of outstanding palliative value, especially for relief of pain from bony metastases. Though it has added to patients' discomfort at times, with fibrosis of muscle or lung and necrosis of bone, the incidence of these complications is diminishing, and the risks are better understood and sometimes quite deliberately taken for the sake of known gain.

Increase in suffering due to the radiotherapy of cancer is seldom to be seen in patients treated in good departments to-day, and is no longer a real problem, though there may have been some increase in fibrosis of lung since supervoltage radiotherapy became more generally available.

PROOF OF HARMLESSNESS

Our continued existence in a well-developed and largely urbanized community owes much to chemical technology. Life is made easier by new and more efficient consumer goods of all kinds, and food remains fresh and varied in adequate amounts at reasonable cost at all seasons because new chemical processes have been developed. When considering any possible threats to the nation's health by the increasing chemical treatment of consumer goods it is as well to bear in mind that most of these processes are introduced in the honest belief that they do represent an improvement. Only a few, practised on a small scale, are designed to deceive. A recent W.H.O. publication¹ echoes the thoughts of the consumer when it points out that "safety for use is an all-important consideration."

There are two main problems in assessing the toxic hazard from chemicals in consumer goods. The first concerns the possibility of showing satisfactorily that a substance not obviously toxic is in fact harmless and may therefore be deliberately added to food, for instance, in order to perform its appointed role. The second problem is related to the possibility of determining the safe or permissible quantity of an undoubtedly poisonous substance which persists in traces in the finished article.² Naturally such problems have been to the fore for many years in the U.S.A., whence so many technical advances in agriculture and food processing have come in recent years. The Food and Drug Administration (F.D.A.), which last year celebrated its jubilee, is responsible for

advising manufacturers on the safety or otherwise of new processes; for setting up permitted limits of chemicals such as pesticides in food; and for checking, by seizure and chemical analysis, that food sold in interstate commerce does comply with these recommendations and regulations. Moreover, the F.D.A. may be consulted by potential sellers before a new material is released. To try to answer the oft-repeated question of what experimental tests should be carried out to check for toxicity, the F.D.A. has suggested an experimental programme which it believes will provide satisfactory evidence on which to make a decision about the safety of the proposed chemical process. The first draft was published in 1949,³ and though it met some criticism⁴ there is no doubt that the suggestions made by the Food and Drug Administration have been widely quoted the world over. A slightly modified version of their recommendations was published in 1955.⁵

There is a danger in making detailed recommendations for the conduct of toxicity tests. The suggestions may be interpreted too rigidly, especially by administrators, and the conduct of an experimental investigation may be hampered by a need to conform to some set of recommended procedures. In the same way the body responsible for making the suggestions will feel obliged to provide an answer when the results of tests conforming to their suggestions are eventually presented for their consideration. It would be unfortunate if the recommendation of any particular group of toxicologists were to become accepted as a *sine qua non* for the proper conduct of a toxicity test. The Toxicology Committee of the Medical Research Council has clearly been considering the same problem, and a short paper containing its views has recently been published.⁶ In its recommendations for the assessment of toxicity the Committee underlines a number of important principles, but is much less precise in its recommendations for experimental studies. However, neither the committee nor the Medical Research Council has any statutory responsibilities in the matter. Toxicologists in Britain engaged on similar tasks to those of their counterparts in the F.D.A. may well regret the absence of any specific details of suitable tests for toxicity. Yet this M.R.C. committee, with a distinguished membership clearly considered it important to state in the opening of the second paragraph, "There is no prescribed pattern of toxicity tests to be applied routinely to every compound studied from the point of view of its toxic properties." Routine tests are not the way to tackle this difficult scientific problem. But some kind of pattern of tests might have a place in establishing the harmlessness of a compound, so that before its widespread use it could be said to have fulfilled a number of specified requirements—in that

for example, certain species of animal show prolonged tolerance to large doses of it. Usually it is easy to detect toxic properties when they cause acute or sub-acute symptoms. The significance of much that is called chronic toxicity has probably been exaggerated by loose thinking on the nature of the problem. One fear, however, that inevitably dominates the whole field is the possibility that a substance might have carcinogenic properties.⁷ Recently P. Shubik and J. Sicé⁸ have drawn attention to some of the difficulties encountered in the proper design of valid experiments. One point they emphasize is that there is probably no "safe dose" for a carcinogenic substance. If this idea is generally acceptable, then an urgent problem of interpreting the existing experimental data in terms of their applicability to man demands attention.

Meanwhile, if suitable tests for assessing toxicity were to be outlined for the guidance of manufacturers by the administrators who control the use of such chemicals in Britain, there would still exist a problem of where the work is to be conducted. Pharmaceutical firms have long conducted toxicity tests, but with one or two notable exceptions no industrial firms in Britain have toxicology laboratories. Nor is there any authority which has both the powers of the F.D.A. to make recommendations and the scientific resources to carry out experimental work such as the F.D.A. does in Washington. In America not only do private firms have their own laboratories but there are large commercial laboratories devoted almost entirely to toxicity testing. In addition sponsored work in university departments is widespread. By contrast, a few small private laboratories exist in Britain, and a little sponsored work is carried out in a few university departments. If the Ministries of Health and of Agriculture, Fisheries, and Food are considering advising manufacturers on suitable toxicity tests for new chemicals they must have laboratories of their own where they can check results obtained in private laboratories run for industry. As both parties lack facilities for toxicity testing, it is perhaps possible that the national genius for compromise might enable some jointly run enterprise to serve the best interest of the public and the parties directly concerned.

THE RHESUS PUZZLE

K. Landsteiner and A. S. Wiener¹ were the first to discover that human blood groups could be divided into two main categories, Rh+ and Rh- (or Rh and rh). Since then the subject has grown greatly in complexity and two main systems of notation have been developed in association with two genetical theories. These form the subject of a review article in the *Journal* this week (page 461) by Dr. A. E. Mourant, one of the leading workers on blood groups.

It was soon found that there were three different Rh+ antigens, and in due course a wide variety of Rh+ and Rh- antigens all different were discovered. Antibodies which agglutinated Rh+ cells were called anti-Rh, and those which agglutinated Rh- cells were called collectively anti-Hr. This nomenclature was associated with the idea that genes at a single locus are responsible for the Rh antigens. In 1943 R. A. Fisher studied the distribution and inheritance of the four Rhesus antigens known at that time: Rh₀, Rh', Rh'', and Hr'. He showed that Rh' and Hr' were antithetical and inherited as if the genes responsible for their presence were alleles²—that is, alternative to each other. They were called C and c respectively. One locus on a chromosome was held to be the C locus and could be occupied either by the C gene or by the c gene but not by both; C and c were allelomorphs. The other two antigens (Rh₀ and Rh'') were not antithetical and their inheritance bore no simple relation to the inheritance of the C-type antigens; they were called D and E. This nomenclature was developed to imply that there was not a single locus for the Rhesus genes but that on one chromosome there were three neighbouring loci. Each locus is occupied by one gene, the C locus by C or c, the D locus by D or by a hypothetical d, and the E locus by E or by a hypothetical (as it then was) e. Whereas Wiener postulates a single locus for the Rhesus genes with multiple alleles at it, Fisher and Race suggest that there is a chain of three distinct loci. The actual arrangement of the loci is believed to be better symbolized by the order DCE than CDE.³

Soon after Fisher and Race had postulated the existence of an antigen e, Mourant⁴ discovered anti-e, and the rare blood groups R_z and R_y were found to fit into the Fisher-Race pattern, giving the reactions expected for CDE and Cde respectively. At one time it was thought that anti-d had also been found, but this was not confirmed subsequently. Another serum (anti-f) seems to indicate the existence of a fourth locus F. Wiener has laid much emphasis on the fact that anti-d has never been shown to exist. However, no one doubts the existence of a blood group O gene, though no antibody specific for the product of this gene has yet been discovered. There are antigens whose presence is related to blood group O, and though anti-H and "anti-O" do not act specifically on the O blood group they will preferentially agglutinate O cells. Perhaps in a broad sense anti-f may be regarded as being similarly related to d.

The most important difference between the theory of Fisher and Race and that of Wiener is that the first allows of "crossing over." When the germ cells mature and the chromosomes unfurl and are divided into two halves, the chromosomes concerned with the Rhesus groups would cross and separate between the Rhesus loci. On their recombination new combinations of genes would arise. Such a cross-over would explain how certain rare Rhesus blood groups could have been formed. These unusual combinations would be rare, because the CDE loci (arranged DCE) are close neighbours and would usually be inherited all together.

To account for the existence of these rare types (which is not in dispute) Wiener's theory postulates a change of the single gene by mutation. No evidence of crossing over between D and C or between C and E is yet known, and if it is found it will still be possible to argue that only one gene is at work. A bridge between the theories may be seen in the ideas of some geneticists who have in recent years postulated an arrangement of "pseudo-alleles" which, situated at one locus, allow a cross-over. In summary, Wiener's criticisms of the Fisher-Race theory concern merely "the highly academic and interesting point whether the three allelomorphic sites of Fisher are to be placed within or without the boundary of one gene."

But, whatever the origin and meaning of the two theories, the CDE nomenclature is usually more easily understood than Wiener's Rh notation. Thus for blood groups of cattle and chickens^{6,7} a nomenclature of the Fisher-Race type was adopted, though the workers assumed they were dealing with multiple alleles of the kind Wiener postulated for the Rhesus system. Moreover, Mourant's modification of the Fisher-Race notation, which he mentions in his article, brings a further simplification which makes the CDE symbols more attractive to use. Many people would agree with the view recently expressed by the distinguished American serologist, W. C. Boyd:⁸ "For practical purposes there is no difference between Wiener's series of alleles and the closely or completely linked loci postulated by the British. The same findings may be predicted from both theories, and both are based on facts. The swing to the British notation is rather to be traced to the advantages that it has as a notation, and for teaching and medicolegal purposes."

LUNG CANCER IN WOMEN

Despite the twelve-fold increase of lung cancer in Great Britain since the first world war, it is still an uncommon disease in women. In 1955 it accounted for just under 1 in 100 of all female deaths and for 1 in 18 of all the female deaths due to cancer. In contrast, the mortality

among men has increased forty-fold and now accounts for 1 in 18 of all male deaths and for nearly 1 in 3 of cancer deaths. As a result of this more rapid increase in men, the sex ratio has increased steadily, and in 1955 the ratio of the crude death rates in men and women was nearly 6½ to 1. In clinical series the ratio has been even greater—for example, 9 to 1,¹ 10 to 1,² or 13 to 1.³

The high sex ratio and the fact that the disparity between the two sexes continues to increase has sometimes been thought to militate against the view that smoking was an important cause of the disease. W. C. Hueper,⁴ for example, has stated that the recent increase in cigarette smoking has been relatively greater in women, and that if smoking were an important cause the sex ratio should be decreasing rather than increasing. The facts, however, are somewhat more complex. For instance, the sex ratio is not the same at all ages. For the quinquennium 1951-5 the ratio was about 2½ to 1 at ages 20-29, nearly 10 to 1 at ages 55-59, and 3½ to 1 at ages 80 and above. Moreover, the trend in the ratio has been different at different ages. A consistent increase has been observed only at ages 50-54 and above; at younger ages the ratio has been decreasing—in fact, since as far back as 1926-30 for the age group 20-29 years. Moreover, the maximum effect of smoking on the induction of cancer may not be observed for 20, 30, or even more years after the habit is established. Comparison of the sex ratio with gross figures for cigarette consumption may therefore be misleading unless a detailed picture has been obtained of the distribution of smoking habits at different ages, including the ages at which smoking was first started.

A detailed study of this type was first attempted in the U.S.A. by W. Haenszel and M. B. Shimkin.⁵ They made estimates of the relative risks of smoking different amounts of tobacco by different methods; they derived them from the results of the principal retrospective and prospective studies carried out in the U.S.A. and multiplied the estimated risks by the numbers of people of each sex and age group in the population who smoked corresponding quantities of tobacco. These latter numbers could be estimated with considerable confidence as a result of a nation-wide survey into the smoking habits of the population, sponsored by the National Cancer Institute of the U.S. Public Health Service and carried out by the trained staff of the Bureau of the Census.⁶ These calculations showed that the sex ratio attributable to differences in smoking habits would be expected to be about 3.6 to 1 in persons aged 35 years and above, whereas the observed ratio was approximately 5 to 1. In order to make this estimate it had to be assumed that the risk of lung cancer increased in direct proportion to

the duration of smoking. If the actual risk rises at a rate greater than in direct proportion to the duration of smoking (as is not unlikely), the correspondence between the calculated and the observed sex ratio would be still closer, so that it would appear that differences in smoking habits might well account for a large part (if not for all) of the difference in incidence between the two sexes. This conclusion is in accord with R. Doll's finding that the British data were not inconsistent with the hypothesis that in the absence of smoking there was no appreciable sex difference in the incidence of the disease.⁷

A more complete study of the role of all the environmental factors thought to be important in the production of lung cancer in women has been reported by E. L. Wynder and colleagues.⁸ They collected data by personal interview, or by questionnaire sent to the relatives, for 105 women known to have had lung cancer proved histologically at one of eleven hospitals in New York or Boston during 1953-5. They compared these results with those obtained by personal interview from 1,304 women treated for cancer or benign growth in other parts of the body at the Memorial Centre, New York. This comparison (which at first sight might seem risky) was justified because the results obtained by questionnaire were practically identical with those obtained by direct interview. No appreciable differences were found in the occupational histories given by the control patients and those given by the lung-cancer patients, irrespective of the histological variety of the growth; nor was there any history of longer residence in large towns among any of the groups of lung-cancer patients. In contrast, nearly half the patients with epidermoid lung cancer gave a history of chronic cough against 29% among the patients with adenocarcinoma of lung and 20% of the controls; most of those with chronic cough were, however, also cigarette smokers. Analysis of the smoking habits showed that patients with epidermoid lung cancer were more often smokers and very much more often heavy smokers than were controls of the corresponding ages. Patients with anaplastic lung cancers gave similar results, but patients with adenocarcinoma of the lung gave smoking histories which were practically identical with those given by the control group. The results therefore confirm the previous studies which have shown that in women also there is a direct relationship between cancer of the lung and cigarette smoking,^{9,10} and they also confirm L. Kreyberg's finding that there is a sharp distinction in smoking habits between patients with the different histological varieties of growth.¹¹ The smoking habits of the control patients accord well with those found in the national survey conducted by the Bureau of the Census, and they underline the fact that in the U.S.A., as in Britain, the proportion of women who smoke is still small at the ages at which cancer is common, and the proportion who are heavy smokers and have smoked for a long time is minute. Among women over 60 years, for example, 86% were non-smokers and less than 1% smoked more than 20 cigarettes a day. Even at younger ages there are still considerable differences in the amount smoked by the two sexes, and Wynder and his collaborators do not expect to see any dramatic increase in the female death rate for at least 25 years.

ANTIBIOTICS IN CHRONIC BRONCHIAL INFECTION

Chemotherapy is much more successful in acute than in chronic infections. There are probably several reasons for this, among others that some structural change or other predisposing cause underlies many chronic infections, and that the bacteria responsible are multiplying less rapidly: not only sulphonamides but most antibiotics have comparatively little action on resting bacteria. Catarrh in its various forms has always been one of the most intractable of chronic infections, and with the advent of antibiotics highly active against the common causes of bronchial catarrh this became an obvious field for their exploitation. It is generally agreed that the organism most frequently found in the sputum in both chronic bronchitis and bronchiectasis is *Haemophilus influenzae*, and the antibiotic to which this species is most sensitive is chloramphenicol. A. W. Franklin and L. P. Garrod¹ treated 32 cases of bronchiectasis in children, all but one infected with *H. influenzae*, and reported that chloramphenicol in adequate doses eliminated the infection and relieved the symptoms, the sputum being much reduced in volume and merely mucoid, but this relief continued, at least in severe cases, only as long as the drug was given. Treatment consequently maintained for many weeks led in one child to the development of a fatal marrow aplasia. This forbidding example and other evidence that chloramphenicol cannot safely be given for long periods has made it necessary to find some alternative.

H. influenzae is more or less sensitive to most antibiotics, and several others have been tried. J. Mulder and his colleagues² obtained their best results from a course of intramuscular penicillin and streptomycin. Most other workers have preferred an antibiotic which can be given orally, if necessary for long periods, and the best alternative to chloramphenicol in this category is one of the tetracyclines. W. H. Helm, J. R. May, and J. L. Livingstone³ explored the possibility of long-continued treatment with oxytetracycline ("terramycin") and found it feasible, no serious toxic effects being produced, and in many cases effective. All their patients, with one doubtful exception, were infected with *H. influenzae*. Of 17 bronchitics, 15 gave a good early response and 9 had remained in an improved condition during treatment continued for 7-20 months. The corresponding figures for 7 patients with bronchiectasis were 6 and 4. These patients were given a maintenance dose of 1-1.5 g. daily. J. R. May and N. C. Oswald⁴ report good results in 22 out of 37 cases given similar treatment with either oxytetracycline or tetracycline throughout the winter months. The administration of 2 g. of oxytetracycline on only two days in each week, continued for one year, was the system of dosage employed in a study recently reported in this Journal.⁵

¹¹ Kreyberg, L., *Brit. J. Cancer*, 1955, 9, 495.

This was a blind controlled trial organized by a Medical Research Council team. It was conducted at seven centres, dealt only with severe bronchiectasis, and compared the effect of oxytetracycline with that of penicillin and a placebo (lactose). There was some improvement in all three groups, that in the third being presumably due to the regular postural drainage which is mentioned as having been another feature of the treatment. As judged particularly by diminished volume and purulence of the sputum and by freedom from exacerbations leading to days off work, the group on oxytetracycline did distinctly better than either of the others. Nevertheless the authors of this report conclude that the widespread use of such treatment is unjustified in view of its limited effects and of its cost of £60 a year.

In the same issue a similar trial of oxytetracycline in the treatment of chronic bronchitis was described by G. Edwards and his colleagues,⁶ of Leeds. Most of their patients were infected with *H. influenzae*; unlike some other observers they found that it persisted in the sputum despite clinical improvement. Oxytetracycline was given daily for six months (at a cost of £45 per patient), the initial dose being 1.5 g. daily, later reduced to 1 g. Other groups were given the same dose of a triple sulphonamide mixture and an autogenous vaccine. The latter had no effect, and the sulphonamide mixture little, but most of the patients taking oxytetracycline were improved as judged by various objective and subjective criteria. Some patients had combined treatment, and there is a suggestion that oxytetracycline with sulphonamide gave better results than oxytetracycline alone. Another recent report, by A. C. Douglas and his colleagues,⁷ of Edinburgh, represents a rather different approach. It concerns immediate results in exacerbations of chronic bronchitis (89 cases) and bronchiectasis (42) requiring admission to hospital, and the method was treatment for one week with penicillin, followed when this was unsuccessful by one week of either oxytetracycline or chloramphenicol. The latter was the more successful of these two, and both for this reason and because it is cheaper the authors advocate giving it when penicillin has failed. Cultivation of the sputum revealed a supposedly pathogenic organism in less than half the cases examined in both categories, and was found unhelpful in predicting the response to treatment. This is contrary to most experience. Whatever else may be concluded about the handling of patients with chronic bronchial infection, it can confidently be asserted that the nature of the infection should be determined before embarking on a prolonged and expensive course of treatment. Many of them are infected with *H. influenzae*, with or without pneumococci, and the probabilities of response to various antibiotic treatments in such cases are now reasonably well ascertained. On the other hand in some cases of fetid bronchiectasis the sputum swarms with anaerobic streptococci and *Bacteroides*, and to expect the same treatment to have the same effect on them would be futile. Whether and when a long course of antibiotic treatment is justifiable must be very difficult to decide. To have to consider the taxpayer as well as the patient—to balance a little benefit to one against a heavy charge on the other—makes it much more difficult still.

KING EDWARD'S HOSPITAL FUND

No one reading the sixtieth annual report¹ of the King Edward's Hospital Fund for London could fail to see the continuing need of hospitals in the Health Service for voluntary help. The report itself points out that hospital finances are uneasily balanced between urgent demands for economy in the spending of public money and the natural and proper desire to treat patients in the best conditions. The predicament is all the more serious because the steady rise in salaries, wages, and prices has absorbed such increased funds as the hospitals have been granted since 1948 and because so many hospital buildings are old and "suffer from a grime and dreariness in their general appearance which is out of place to-day." But the report optimistically affirms that, given enough money, "many of the wards in these old buildings could be brought to rival (as some do already) the best examples of modern construction." The King's Fund, of course, cannot renovate all the old hospital buildings in London, but it can sometimes set in train improvements which add immensely to the value of the work a hospital is doing. The Fund, for instance, recently allocated £250,000 to mental and mental deficiency hospitals, and much of this money has already been spent. The need for the modernization of mental hospitals has been much emphasized lately, but the report quite rightly notes that there is no general agreement yet on the ideal form of accommodation for the mentally ill. In the meantime the King's Fund is supporting promising schemes for the improvement of treatment at a number of mental hospitals.

The Emergency Bed Service is one of the best-known departments of the King's Fund, but it has many other activities. It is investigating the problem of noise in hospitals; its gardening advisers have done some splendid work, particularly at St. Clement's Hospital, Bow, and Paddington Hospital; it has been primarily responsible for establishing twelve homes for the aged sick; and it has provided money for a cancer registration scheme in the metropolitan region. The Division of Hospital Facilities has been continuing its investigation of hospital supplies, departmental costing, and electronic accounting for hospitals. The Division of Nursing, among other tasks, maintains a staff college for matrons and another for ward sisters, and, apart from the work of the School of Hospital Catering, it has arranged refresher courses for those responsible for the domestic management of hospitals. The King's Fund is a firm believer in investing in "people" as well as in "materials," and the Hospital Administrative Staff College is mainly concerned with selection and training for management. One extension of this work was the holding of a course² for physician-superintendents of mental hospitals—the first essay of the King's Fund in the field of postgraduate medical education. The hospitals of London are indeed fortunate that the King's Fund has done so much to increase—to quote the words of the report—"interest and enthusiasm for the never-ending task of improving hospital provision for the sick in all practicable ways."

Rh NOTATION

BY

A. E. MOURANT, D.M., M.R.C.P.

Director, Blood Group Reference Laboratory (Medical Research Council), Lister Institute, London

The observed serological and genetical facts relating to the Rh system of blood groups are highly complex even when seen in the light of all the simplifying hypotheses proposed by a number of outstanding scientists. It is therefore not to be expected that it will be easy, or even possible, to devise a notation which will cover them completely and at the same time simply.

Two main bodies of theory exist, each associated with a special notation. One theory and system of notation is due to Dr. A. S. Wiener and the other to Sir Ronald Fisher and Dr. R. R. Race. The principal Rh blood-group antigen was discovered by the late Dr. K. Landsteiner and Dr. Wiener (1940) in collaboration. It was subsequently found that a complex system of antigens was involved, and the earliest notation embodying that complexity is due to Dr. Wiener (1943), who by the end of 1943 had set up the main framework of his present system. Soon after this Sir Ronald Fisher, as described below, proposed a second and complementary system of notation. The main object of this paper is, however, to describe the present state of knowledge and its codification, and not to discuss priorities. For comprehensive statements of the facts and theories, including the history of the subject, the reader should consult recent books by Race and Sanger (1954) and by Wiener (1954a, 1954b).

Rh-positive and Rh-negative

In an article in a journal emphasizing clinical medicine it must first be said that it is not necessary for clinicians managing cases of Rh immunization to be able to manipulate a complex notation. The most recondite of the facts and theories are occasionally vitally relevant to the treatment of a case, and here a specialist must in any case be consulted, but it is still as true as it was fifteen years ago that the essential piece of knowledge is whether a mother or a transfusion recipient is Rh-positive or Rh-negative, terms which in clinical use, and in terms of Fisher's notation, should always be regarded as synonymous with "D-positive" and "D-negative" respectively. In terms of Wiener's notation these will be "Rh_o-positive" and "Rh_o-negative" respectively; at this low level of complexity there is obviously little to choose, theoretically or practically, between the two notations. The great majority of immunized persons are D-negative, and, when this is so, any transfusion of the immunized person or of the baby of an immunized woman must be performed by using D-negative blood.

In the treatment of the rare cases where a D-positive mother or recipient becomes immunized it may help to know the theoretical background; but it is much more important to be able to apply a thoroughly reliable direct matching test when selecting blood for transfusing the immunized person or baby with haemolytic disease.

The Rh Antigens

Antigenically, however, the Rh system is much more complex than is implied by the above simple scheme, and comprises in fact about six common entities (C, c, D, E, e, f, in Fisher's notation), and several rare ones, each of which is generally regarded in Great Britain as a separate antigen or haemagglutinin; Wiener, however, calls them "factors" or "partial antigens." Each of them reacts specifi-

cally with a single well-defined antibody or haemagglutinin. While antigenically these entities are distinct, genetically they are invariably transmitted in groups of at least two and usually of three or more. Wiener regards each genetically combined group of antigens as a single antigen and considers that it is transmitted by a single gene, whereas Fisher and Race regard each elementary antigen (or "factor") as the product, probably, of a separate gene.

The Rh Genes and their Arrangement

In order to describe the Rh system any further it is necessary to use some notation, and in this article Fisher's notation is used primarily. The theory and notation were first put forward as a communication from Fisher in a paper by Race (1944), and were subsequently further developed by Fisher and by Race. The primary purpose of Fisher's notation was to provide a distinct designation for each elementary antigen and therefore also for the antibody by which each may be detected, and there was no intention of superseding Wiener's names for the larger genetic units, which were at this stage looked upon as genes. It was only as a result of later investigations that each of the elementary antigens came to be regarded as the product of a separate gene. Taking into consideration all well-established Rh antigens the theory of Fisher and Race, in its genetic aspect, now postulates the existence, on each of the two members of one particular pair of human chromosomes, of a series of four or possibly five loci; to each locus there corresponds a set of two or more alternative or allelomorphous genes. The distances between the loci must be very small compared with the total length of the chromosome. The linear order of the loci is thought to be DCEF; each D locus may be occupied by any one of the allelomorphous genes D, D^u, or d; the C locus by C, C^u, C^w, C^x, c^v, or c; the E locus by E, E^u, E^w, e^x, or e; and the F locus by F or f. A further gene, provisionally called V, certainly belongs to the Rh complex, but it is not yet known whether it is an allele of F and f or whether it corresponds to a fifth locus, the latter hypothesis being the more probable. Thus each individual will have a pair of genes, like or unlike, selected from the D group, a pair from the C group, and so on, giving a genotype represented by two sets of four letters such as, for example, DCEf/Dcef. With the few exceptions mentioned below, each of the genes in the above sense gives rise to a distinct antigen recognized by red-cell agglutination in the presence of a corresponding and distinct antibody. The d and F genes have not been convincingly shown to give rise to antigens. The genes D^u, C^u, c^v, E^u, and apparently e^x give rise to antigens, but none of these is clearly defined in terms of reaction with a single antibody; a given D^u antigen, for instance, will react with certain anti-D sera but not with others, but it is not possible to separate anti-D and anti-D^u components from such sera by absorption; here the term "partial antigen" in the original sense may be justified though the analogy is not complete.

Besides chromosomal sets each consisting of four genes, one at each hypothetical locus, there exists, as shown by Race *et al.* (1954), a very rare type of set or genetical unit consisting solely of D, in which it is assumed that a chromosome segment, comprising the C, E, and possibly F loci, has been deleted. Wiener, Gordon, and Cohen (1952) have described a set which is apparently equivalent to c and D without a detectable gene at the E locus; no investigation with anti-f appears to have been done; a deletion of the E locus would be compatible with the order DCE.

According to Wiener's hypothesis only one locus on each chromosome is responsible for the Rh blood groups. This locus can be occupied by any one of a large number of allelomorphous genes. These genes are, as we have seen, the equivalents of groups of four of Fisher's genes. Each of Wiener's genes is given a symbol containing the letters R, r, or R followed by an index. The synonymy between the systems is shown in Table I. The second column of this table is explained in a later paragraph. It will be observed that R corresponds to the presence of D, r to that of d, and

* Partly based on Wiener (1954, Table 9). The Rh notation is that used by Wiener, which differs in certain respects from that in common use in Britain.

as CDE and CdE in the British population can be explained if they have resulted from rare cross-overs—the first in individuals of the common genotype CDe/cDE and the second only in these with certain rare genotypes. On the whole the distribution of Rh chromosomes throughout the world is compatible with such rare crossing over. The combinations in which the f gene is found are strongly in favour of crossing over having occurred, and the same appears to be true of V.

When Fisher first proposed the genetical theory associated with his name relatively few cases had been discovered of combinations of a number of closely linked genes having closely related effects, and these cases were not widely known, but examples of similar sets of genes have now been found in a great many kinds of organism—especially in micro-organisms but also in *Drosophila*. In these various lowly creatures very numerous matings can be made and crossing-over frequencies of the order of 1 in 1,000 can be and have repeatedly been observed and measured. Such low frequencies, if they occurred in the Rh system in man, would demand inordinate numbers of tests for their detection. Several species of animals, especially cattle and domestic poultry, have systems of blood-group genes somewhat resembling the Rh system in man. In these, however, not only have no cross-overs been found until recently, but there is little or no clear-cut allelomorphism of the CC^wc type. For such systems the evidence in favour of a genetic mechanism of the type supported by Wiener is much stronger than it is in the case of the human Rh system. Recently, however, Amos, Gorer, and Mikulska (1955) have not only demonstrated the existence of a system of blood-group antigens in the mouse genetically similar to the Rh system in man, but by virtue of examining the offspring of very numerous matings have actually detected crossing over within the system.

There remain a few facts which, at first sight at least, might be regarded as weighing against Fisher's theory. One of these is the "position effect" demonstrated by Race *et al.* (1951) whereby, for instance, by the use of empirically selected antisera, quantitatively different expressions of the genes C and E can be demonstrated according to whether they are present in the genotype CDE/cDE or in CDe/cDE, though the total complement of genes is the same in each case. Such a "position effect" was, however, already known in a number of systems of proved closely linked genes in other organisms; and it was indeed the knowledge of the existence of this effect elsewhere that led Race and his colleagues to search for and to find it in the Rh system.

The existence of the isolated D gene of enhanced activity, though explicable on Fisher's theory by a deletion of the C and E loci, is not entirely favourable to that theory, since deletions, especially in the homozygous form in which -D- was first found, are usually lethal, whereas no suggestions of abnormality of the germ plasma have been found in any of the -D/-D- persons examined. Wiener's theory, on the other hand, allows considerable freedom in the combinations of "factors" which may be determined by a single "gene." However, even on this theory there must be some rather big difference between this "gene" which he calls R^{ox} and the other genes of the Rh system, and something like a deletion or loss of active chemical groups must be involved. Moreover, on Fisher's theory, it is the C and E loci which are deleted without the D, in conformity with other facts which point to the linear order being CDE.

Most of the facts which help to discriminate between the two theories arise from highly specialized genetical investigations: they are, on the whole, more readily and completely explained by Fisher's theory than by Wiener's. Either theory accounts about equally well for the greater part of the observed facts, including nearly all those encountered in clinical investigation. To the minds of most people, however, Fisher's notation appears much more convenient than that of Wiener, and is to be recommended for this reason even if the validity of the genetical theory associated with it be disputed. It may be mentioned that the current gene

and genotype notation for certain complex blood group systems in cattle includes a separate symbol for each antigen present, as does Fisher's Rh notation, despite the fact that some workers, whilst using this notation, adopt a genetical hypothesis similar to that supported by Wiener for the Rh system.

Other systems of Rh notation are outside the scope of this article. It should, however, be mentioned that Strandkov (1949) proposed a notation which was a compromise between those of Fisher and Wiener; while Ford (1956) on the basis of Fisher's theory, has suggested a modification which brings the genetical notation into line with modern genetical practice. If it and the corresponding notations for other blood-group systems are generally adopted by geneticists it will be necessary for blood-group workers to be familiar with it and perhaps ultimately to use it for routine clinical purposes.

Preparations and Appliances

VARIABLE-SPEED MOTOR-DRIVEN SYRINGE FOR CONTINUOUS INJECTION

Dr. RONALD A. BOWEN, of St. Bartholomew's Hospital, London, writes: Drugs such as trimetaphan ("arfonad"), noradrenaline, and suxamethonium are commonly given by continuous intravenous drip, a method having certain disadvantages. Firstly, the volume of diluent is large. Again, intravenous infusions are notoriously liable to fluctuation in rate. A third objection is the necessity for frequent counting of drip rates and the difficulty of altering the rate without a great deal of adjustment. If a syringe containing a concentrated solution of the drug is driven by an electric motor and variable gear these objections are overcome.

A prototype of the apparatus described was home-made from ex-W.D. parts. It was used by myself and colleagues in the department of anaesthesia for two years without trouble, after which it was decided to produce a commercial model. The present apparatus consists of a synchronous electric motor driving a stepless variable gear. This in turn rotates a threaded rod. Mounted on the rod and located by a guide is a metal platform. Within this is a split nut whose halves are held in contact with the thread of the rod by spring pressure. As the rod rotates, the platform is moved forwards. A small button mounted on it contacts the piston of a syringe. The halves of the split nut may be separated by a catch, allowing the platform to be moved to any position on the rod. The stepless variable gear transmits the drive by friction and permits the platform to be stopped or to be driven at any speed up to 2 mm. a minute. Slip does not occur, as the power required is small. The speed is indicated by the position of a pointer on an engraved dial. A 20-ml. syringe is held in a spring carrier, which holds it rigidly and permits rapid replacement. An adaptor and a length of fine nylon tubing connect the syringe to a needle.

This may be inserted into a vein, through the diaphragm of a Gordh needle, or through the tubing of an intravenous drip close to the vein.

A warning device is fitted. When the syringe is almost empty an adjustable stop on the platform trips a mercury switch, stopping the motor and switching on a neon lamp.

A separate mercury on-off switch is also provided. The apparatus is safe to use in the presence of explosive anaesthetics. The machine is mounted in a "perspex" case with carrying handle and lid. The overall length is 12½ in. (31.8 cm.), width 4½ in. (11 cm.), and height 6½ in. (16 cm.). The weight, including 23 ft. (7 metres) of flex, is 7½ lb. (3.4 kg.).

Advantages of the apparatus are: (1) the volume of diluent is small; (2) the injection rate is constant within narrow limits; (3) counting of drip rates is obviated, and instantaneous changes of speed may be made; and (4) the machine is silent and of small compass.

Calibration is necessary for each drug. If syringes of different manufacture are used, further correction is needed. By a happy chance, if a Froude 20-ml. syringe is used, calibration for arfonad is easy.

Length from 20 ml. mark to 0 mark = 62.5 mm.
 ∴ if 20 ml. contains 250 mg. of arfonad,

$$1 \text{ mm. length contains } \frac{250}{62.5} = 4 \text{ mg. of arfonad,}$$

 and rate of injection = figure on dial (mm. per minute) × 4.

The machine is made by Talley Anaesthetic Equipment Ltd., 37a, New Cavendish Street, London, W.1. The idea of driving a syringe through this type of stepless variable gear occurred independently to Dr. Ronald Woolmer, Director of the Research Department of Anaesthetics, Royal College of Surgeons. He has designed a more elaborate machine which is being produced by the same manufacturers. My thanks are due to Mr. N. K. Harrison, of the Photographic Department, St. Bartholomew's Hospital, for the illustrations.

Motoring News

Under this heading we shall from time to time publish articles giving information and advice about motoring of special interest to members of the medical profession.

ECONOMICAL CARS

In recent years the demand for small cars has increased considerably, and production of these models has been stepped up. Manufacturers have even suspended production of their larger models in some cases to meet the demand for their inexpensive economy cars. Many doctors have gone over to low-horsepower new cars which they can change easily when signs of wear and tear appear and at the same time enjoy low running costs. The heyday of the big coupés and the impressive saloons is probably over for doctors, who are mostly big-mileage motorists, and the use of a small car over a long period of time means that very considerable economies can be effected.

Perhaps the most popular of the smaller cars which comes nearest to the familiar coupé of pre-war days is the Morris Minor. For those who spend a large amount of time at the wheel of a car the convertible does enjoy a considerable vogue, especially as sliding roofs are no longer fitted on the mass-produced saloons. For this reason the Minor appeals to all sections of the community, as it can be supplied with varying types of body to suit all tastes. Mechanically it is well able to compete on equal terms with Continental rivals, having good handling qualities coupled with a powerful engine which endows it with a very satisfactory performance. Precise steering, sensible centrally mounted gear-lever, and a wide track all help to make the Minor a comfortable and pleasant car to drive. A 12-volt electrical system provides more than adequate power for starting the small engine and at the same time caters for powerful headlights and for other accessories such as heaters or radio. A large lockable luggage boot is a further asset.

The Minor's sister car, the Austin A35, is fitted with the same power unit and gearbox but has a narrower track, making the inside rather too narrow, though the front seats are well padded for extra comfort. The four-door model also has very small doors, which, from a doctor's point of view, might be inconvenient. It would appear that the two-door car is more suited to a general practitioner, because the doors are large and can be quickly locked.

The Volkswagen is another small car which has appealed to some doctors because it is designed to cover large mileages without attention or overhaul and can be left out in winter without freezing up. All models have only two doors and are fitted with rubber flooring for easy cleaning. They are light to drive, having an easy synchromesh gearbox and finger-light steering. In spite of the air-cooled engine a very efficient heater is fitted as standard equipment. Volkswagens are well known as easy starters in all weathers, and servicing facilities are good both in Britain and abroad.

Another firm favourite is Ford. Giving value for money, Fords take a lot of beating. With the exception of the Popular, which is definitely an austerity model, the prices of the Anglia and Prefect compare very favourably with those of their rivals. Anglias are supplied only with the two doors, but the Prefect has four and they are of generous proportions. Although the design of Ford engines is slightly behind the times, they are quiet, powerful, and reliable, and spares are available anywhere. In addition the famous Ford exchange-parts service is unrivalled. Criticisms of these two models are that the seats are uncomfortable, the gear-change mechanism is not as smooth as it might be, and they are not as economical as, say, the Minor 1,000 or the A35. Nevertheless, they are roomy and have first-class acceleration coupled with the ability to take heavy loads for touring without complaint. The luggage boot is enormous for only a 10 h.p. car and the rubber flooring material is helpful both for hard wear and for the annual spring clean.

Standards offer orthodox small saloons with varying interior layouts and on most models an opening luggage boot. Mechanically both the eight and the ten are well up to the mark; the engines are smooth and silent, giving over 45 m.p.g. in some cases. The quality of the coachwork does not quite meet that of the engines, however, though all models have four doors.

Finally the Hillmans. For over 20 years the Hillman Minx has been a familiar sight on British roads, and the 1957 example is no discredit to its predecessors. Rootes Ltd. have gone out of their way to achieve comfort in all their models, and the new Minx carries on this tradition. Both the side-valve and overhead-valve engines fitted to the Husky and the Minx saloon respectively are extremely quiet and smooth and can be driven near their maximum speeds for long periods without distress. Soft suspension tends to allow too much roll on corners, but otherwise these models are very light and untiring to drive and can usually be expected to better 40 m.p.g. in general use. The quality of the seats supplied even on the Husky would warrant their fitting to a £2,000 car, a pleasant feature for the everyday driver.

We can therefore sum up by saying that the 10 h.p. two-door cars will satisfy the requirements of many doctors. Starting is no longer a problem, as all modern cars which are sold in quantity have sufficiently large batteries for winter starting. Comfortable seating is another point which requires careful thought, and, of course, economy. But it is not always a wise policy to put too much emphasis on this if a loss of a few m.p.g. is going to mean the difference between comfort and discomfort.

IAIN GELLATLY.

Lung Changes During Methonium Therapy

SIR,—We were interested to read your annotation on lung changes during methonium therapy (*Journal*, August 10, p. 345). Last year we¹ published the case report of a patient who died with marked respiratory distress shortly after delivery at the 36th week of pregnancy following 17 weeks' methonium therapy for severe hypertension. The lungs showed the characteristic patchy fibrinous oedema and fibrosis described by Doniach and his co-workers.² We noted that these authors were cautious in attributing the pulmonary changes to a direct effect of the drug on the pulmonary capillaries, and, in our own case, although it seemed possible that there might be such a connexion, we also felt that other factors might be involved. Since then the further cases reported by Perry and colleagues,³ to which you refer, would seem to give some support to the idea of direct drug toxicity.

Our paper refers to two further articles,^{4,5} not mentioned in your annotation, whose authors also encountered pulmonary lesions in patients under methonium therapy. You raise a question regarding the true incidence of the complication. We ourselves were unable to assess this from our own data, but of 258 patients treated by Morrow and his colleagues⁴ with combined hydrallazine hydrochloride and hexamethonium over periods of from 6 to 25 months 37 died, and the lungs of 5 of these showed "interstitial pneumonia," a lesion almost certainly the same as that under discussion. To the other question you raise, whether the appearance of lung changes is an indication for discontinuing methonium therapy, the answer would seem to be a firm "Yes." Indeed, data available so far suggest that by the time a patient develops respiratory symptoms the pulmonary lesion may already be irreversible, the patient often deteriorating steadily thereafter, with increasing respiratory embarrassment, to

death. The clinical course of a few of the reported cases offers the hope that, with earlier recognition of the grave significance of respiratory symptoms, immediate cessation of methonium therapy may halt the pulmonary changes before they become irreversible and allow some measure of recovery.

We agree that the syndrome, in its fully developed form at any rate, is a rare complication of treatment with these drugs, but it is one that carries a serious prognosis; and in view of the widespread and long-term use of methonium compounds we feel that the occurrence of fatalities of this kind should be widely known.—We are, etc.,

Dundee.

Compulsory Powers over Mental Patients

SIR,—I am sure that all of us will concur with the ideal of reducing compulsory powers over mental patients to an absolute minimum, but we must not gloss over the inescapable fact that many a person suffering from mental illness is completely blind to his disordered state and refuses to enter a mental hospital when this appears a staring necessity to relatives and friends. Further, when admitted, some patients refuse to accept the treatment advised, or wish to have some other form of treatment. I have come across patients requiring a lengthy psychotherapy who demanded E.C.T., and vice versa; or a request for leucotomy where there is not the slightest indication for such an operation. Sometimes patients insist on leaving before a planned course of treatment—e.g., insulin-shock therapy—is completed, and return after a short interval in a relapsed state. Only the other day a voluntary patient suffering from paranoid schizophrenia insisted on leaving against medical advice. I argued for half an hour with him, finally warning him that he would soon be brought back certified. This, of course, duly happened, and when I reminded him of my warning, his only comment was, "But why on earth was I brought back?" These difficulties, due to lack of insight and co-operation, will not dissolve as a result of any new legal code, and they are very naive indeed who believe that an alteration of the law will miraculously solve such problems.

Dr. Donald McI. Johnson suggests (*Journal*, August 10, p. 351) that no judicial formalities should be used at the beginning of an acute mental illness, but only after two to four weeks. However, the reasons he gives are not convincing. The majority of serious complaints concerning improper detention refer to an admission under certificate of an acute case; it is alleged that the medical certificate was insufficient or inaccurate; and at present doctors are protected because the order for admission rests with a judicial authority. Such an arrangement should not be altered, except that two medical certificates should be necessary as a routine. Compulsory detention is primarily required for social, not medical, reasons—because the mentally sick patient is a danger to himself or others, or is a dreadful trial to society, and a judicial authority should be invoked. The responsibility should not rest with a doctor, not even the most experienced psychiatrist.

Dr. Johnson's reference to the establishment of a diagnosis also seems beside the point so far as the problem of compulsory detention is concerned, though it is important in deciding the programme of treatment. A patient suffering from mental illness is compulsorily detained because he is a serious behaviour problem, not because he happens to be suffering from hysteria, schizophrenia, paranoia, mania, or senile dementia. The impression Dr. Johnson gives is that

the presentation of a diagnostic label to a judicial authority will help to settle the question of compulsory detention. I doubt whether any psychiatrist would subscribe to such a proposition.—I am, etc.,

Basinstoke.

I. ATKIN.

SIR,—Dr. C. R. Birnie, in his letter on this subject (*Journal*, July 27, p. 234), has raised some old bogeys which were fully dealt with and, one had hoped, effectively laid in the evidence given to the Royal Commission by the B.M.A. and the Royal Medico-Psychological Association (*Supplement*, May 7, 1955, p. 211), as well as in the report itself. As the report points out, the admission and detention of patients depends on a consensus of medical and non-medical opinion—doctors, relatives, mental welfare officers, and, later, hospital management committees and the board of control. To this, under the present law, there is added, at one point, the justice's order. The medical organizations and the Commission itself were satisfied that this addition was of no value, and contributed to the "stigma" by introducing an authority whose main function is the punishment of crime. Neither were so foolish as to imagine that by eliminating this one factor the "stigma" could be eradicated; all recognized that it lies in the minds of men and is manifold, and they have done their best to attack it at many points.

Every certified patient knows that, from the moment of his admission, the justice's order is not the factor which is keeping him in hospital, since he is well aware that the doctors can recommend his discharge at any time. Unless he has built up a paranoid fantasy about imaginary persecutors, he regards himself as being in the doctors' hands. And this is what he wishes, as was well brought out in the evidence given by one of the few patients who appeared before the Royal Commission:

"Dr. Rees: Supposing a doctor thought the [voluntary] patient was not well enough to go home and the patient did not agree. What would happen then?—I think it rests with the doctor.
"You would give power to the doctor?—Yes, I would.
"You have great confidence in the doctor?—In the right sort of doctor, yes. You have got to be careful if you take up mental health."

Even now, mental hospital doctors very often take part in the certification of patients whom they are to receive; for, as consultants to observation units (which may actually be within their own hospitals) or in the course of domiciliary visiting, it falls to them to recommend compulsory admission, even if the statutory certificate is written by another hand. Our patients are not deceived and know where the responsibility lies. But there is no "odium," no "poisoning of the doctor-patient relationship"; on the contrary, the patient is pleased to know that the initiative was taken by the doctor in whom his subsequent treatment has led him to have confidence.

The notion that doctors are in any way "protected" by what Dr. Birnie quaintly calls the magistrate's "certificate" has no substance at all. The courts long ago decided that the certifying doctor could not claim the status of a privileged witness, but was fully responsible for the consequences, and successful actions for wrongful certifications were common enough before 1930. The protection we now enjoy was conferred on us in that year by Section 16 of the Mental Treatment Act, and the Royal Commission expressly recommends that this protection should be re-enacted in the new legislation. Dr. Birnie draws a grotesque picture of his colleagues dodging and shirking unpleasant cases. Surely we are not as irresponsible as all that. We could pick and choose now among our voluntary patients, and among our certified ones too, since we can recommend their discharge immediately after admission. The new recommendations merely put the voluntary and compulsory on the same footing and give us an opportunity of assessing needs and priorities as a whole.

If the review tribunals are constituted as the Commission intends (including experienced hospital psychiatrists as well as lay members) and follow the practice outlined in the

report (which should be informal rather than litigious), we in the mental hospitals should be able to remain undismayed and need not fall into the unseemly panic which Dr. Birnie fears.—I am, etc.,

ALEXANDER WALK.

Coulsdon, Surrey.

Improving Medical Practice

SIR,—It was pleasant news to learn from the *Journal* of June 22 (p. 1468) about the formation of an International Federation of Surgical Colleges to improve and maintain the standards of surgical practice. I believe there is great need for such an institution of physicians in order to raise and maintain the standard and prestige of medical practice. It is most unfortunate that, while various surgical colleges co-operate in the maintenance of a certain minimum standard, there is practically no common platform for the medical colleges and corporations. It is high time that the physicians took a lesson from their surgical colleagues, who are sparing no effort to make their profession scientific and safe for their patients. There can be little doubt that mutual discussions among the representatives of various medical colleges and corporations would go a long way towards improving the standards of specialist medical practice. It might also provide a platform to discuss the present-day controversy about medical education. Will some medical college or corporation in Great Britain take a lead in this matter?—I am, etc.,

Hyderabad, W. Pakistan.

ALI MUHAMMAD.

Malaria

SIR,—Referring to your leading article "Malaria Control" (*Journal*, May 11, p. 1108), it is interesting to recall that Richard Burton, in *First Footsteps in East Africa*, wrote in 1856, a year before Sir Ronald Ross was born, that the people of Zayla (now Zeilah in British Somaliland) believed that the mosquito bites bring on deadly fevers: he goes on to say the superstition probably arises from the fact that mosquitoes and fevers become formidable about the same time. The belief of the people would appear to have been more correct than Richard Burton's supposition.—I am, etc.,

H. M. FISHER.

Karen, Kenya.

Teeth of London Children

SIR,—Lady Mellanby and her co-workers (*Journal*, August 10, p. 318) state: "Comparison of the surface structure of the teeth examined over the years reveals that up to 1947 there was a great improvement, but that from this period onwards more M-hypoplasia was seen, although the increase did not appear to be as pronounced as was the increase in caries during the same period" (my italics). They omit to state the incidence of M-hypoplasia in any year except 1955, but reference to the earlier articles in the series suggests that the above statement may be a little misleading. From 1949 to 1955, for example, there was a marked fall in the incidence of M-hypoplasia together with a marked rise in caries incidence. It also appears that in 1945 and 1955 the incidence of each grade of M-hypoplasia was very nearly the same, but caries incidence was more than 15% higher in 1955.

In referring to variations, over the years, in the caries incidence of teeth in each grade of structure (Fig. 4) the authors say that "it will be noticed that there is little difference in the case of the teeth of good structure (Hy₀), whereas there is much in those with the more severe grades of M-hypoplasia (M-Hy₂, M-Hy₃) and with G-hypoplasia," as if this in some way supported the theory that poor structure predisposes to caries. On the contrary, the marked fall in 1947 in caries incidence in hypoplastic teeth must account for much of the total fall in that year, but was itself clearly caused by some

other factor than the fall in hypoplasia incidence. Furthermore, there was in fact a marked rise in the caries incidence of teeth in the two best grades of structure, although the scale of the graph obscures this; from 1945 to 1951 there was a steady increase amounting to nearly 100%, but it would be absurd to express this fact in a way that implied that good structure predisposed to caries.

The admirably detailed and extensive data presented in these articles would seem to justify a more thorough statistical analysis than they have received. The authors seem to have been tempted to select parts which support the vague theory that "in general, the better the structure of a tooth—that is, the less M-hypoplasia—the greater its resistance to caries," and to gloss over the evidence they have found that some systematically variable factors other than structure must account for much, if not all, of the large variations in caries incidence observed. The theory as expressed here does not, of course, mean that such relationship as there may be between structure and caries is a causal one, but they omit to point this out or to discuss the other explanation of such a relationship that has been suggested. The orthodox explanation of most of the facts discovered can hardly be compressed into the space of a letter, but it is far more satisfactory than any theory that the authors offer.—I am, etc.,

London, S.W.10.

R. B. D. STOCKER.

Drug Addiction

SIR,—It would be interesting to know on what evidence the author of your annotation on drug addiction (*Journal*, July 27, p. 210) considers the official estimates of its prevalence to be reliable. Six cocaine addicts are listed; a patient of mine (presumably one of these six) was able to name seven.

Cocaine is difficult to obtain illegally, but the same can certainly not be said for either heroin or morphine. In this area, on the fringe of the West End, there can be no doubt whatever that the amount of addiction is increasing *pari passu* with the increase in prostitution. The problem posed by these people to the conscientious general practitioner is very great, and he receives very little support from the hospital service. No unit exists for the specialized care of drug addiction, other than alcohol, and mental hospitals and general hospitals are reluctant to admit cases and unable to follow them up adequately.

Another aspect of this problem not mentioned in the annotation is the practice of certain doctors in allowing it to become known that they will supply any addict with whatever he or she wants. It is difficult to see how such a practitioner could even be prosecuted under the Dangerous Drugs Act, and in fact the police are really powerless in these cases, which unquestionably exist, in London at least. One can only hope that this handful of irresponsible practitioners will be watched carefully by their local colleagues, and any known breach of the ethical code followed up energetically.—I am, etc.,

London, W.11.

J. TUDOR-HART.

Traction on the Cord

SIR,—It is probably true to say that old phobias never die, but simply fade away. The inordinate fear of puerperal sepsis, justifiably contracted in the pre-wonder-drug days, still persists to such an extent that many who practise obstetrics are yet loath to introduce the gloved finger into the vagina to discover in doubtful cases whether, during the third stage of labour, the placenta has descended into the vagina. I do not suggest that this is often necessary, but in cases of doubt it does supply that absolute conviction which is desirable before traction on the umbilical cord can be used with an easy conscience to assist extraction of the placenta. As a routine procedure traction on the cord is not necessary to deliver the placenta, but there is no doubt that, when expulsive efforts of the patient fail, this is a much less uncomfortable procedure for her than forcible pressure on the

uterine fundus. There are, however, a few instances which we meet now and again in the course of flying-squad obstetric practice where the placenta is retained without any post-partum bleeding or shock, where all efforts of midwife and doctor have failed to extract it, and yet it is found to be completely separated and lying in the vagina. In these instances the patient usually resents any further pressure on the fundus and responds by tightening both her abdominal muscles and levatores ani, so that general anaesthesia would be necessary to deliver the placenta by this method. It is in these cases that I find, after catheterization and vaginal examination to confirm the situation of the placenta, that traction on the cord can be used with speedy and rewarding results.

I do not wish to minimize the dangers of inverting the uterus by traction on the cord when the placenta is still attached to the uterus, and, though it may be a safe method in skilled hands, there is no doubt that it would be a dangerous procedure in domiciliary obstetric practice. Once the placenta has been proved to be lying in the vagina, however, ergometrine may be safely given and cord traction applied. The appearance of the placenta will be ample reward for the purchase of a pair of surgical gloves.—I am, etc.,

Birmingham, 15.

A. L. DEACON.

Scorpion Stings

SIR,—The treatment advocated by Dr. Syed Abdullah (*Journal*, June 8, p. 1366) and Dr. M. McA. Holmes (*Journal*, August 10, p. 353) is non-specific. Actually antivenene for scorpion venom is obtainable commercially, and I have often used it with success. As both writers emphasize, young children may suffer severely or be killed by the venom of a scorpion, which, however, does not "bite." The creature "stings" with an apparatus at the end of its tail. The last caudal segment—the telson—bears a strong, curved, very sharp hollow spine, with exits near the point through which the venom is injected into the victim. On one occasion I was the victim. I was awakened out of a deep sleep and accused my wife of leaving a needle in the bed. The scorpion was then found crouching between the sheets at the foot of the bed. Very soon the stung areas began to swell. The earliest was the size of half a pullet's egg, the next rather smaller, and the third and last merely a macule some 20 millimetres in diameter. The stings were rather painful, but I did nothing about them (like Dr. H. A. Reid, *Journal*, July 6, p. 26) and soon went to sleep. Next day the stings were still rather painful, but I forgot about them while at work. Two days later I awoke with rather violent vertigo and sickness and had to stay in bed for a day. I felt rather "washed out" for a day or two, and then felt nothing more of the infliction. Scorpion stings are the subject of two previous notes.^{1,2}—I am, etc.,

Snake-bite

SIR,—There are many who will endorse the general sense of Mr. Robin Burkitt's letter (*Journal*, July 20, p. 159) as it applies to the treatment of snake-bite in this country. The public, goaded on very frequently by the popular press, labours under a false impression of the dangers from the common adder, or viper, bite (*Vipera berus*). Some statement about this is badly needed. Are the dangers really as great as they are popularly supposed to be? Certainly not; all the known evidence is against it. The venom of the common viper, or adder, in this country is of low toxicity. It rarely, if ever, kills adult humans, and is dangerous only to small children. This is shown by vital statistics in the United Kingdom, which register only some seven fatalities from viper bite during the last 50 years. In England and Wales only two deaths from snake-bite were registered in the years 1940–8. The danger to life arises

much more from the heroic methods of treatment so often applied than from the viper venom.

The adder does not wish to kill humans; it only strikes in self-defence when rudely disturbed or trodden on. The real object of viper venom is to paralyse small animals upon which it feeds. The venom, when injected through the fangs into the subcutaneous tissues to a depth of less than $\frac{1}{2}$ in. (1.25 cm.), is rapidly absorbed. Toxic symptoms are noted 2 to 3 hours afterwards. Usually all that has to be done is to put the patient to bed and give copious draughts of glucose. Heroic methods such as incising the wound, sucking, or even the tourniquet (when applied too late) are useless and should be abandoned. This is the verdict of those who are responsible for the treatment of real snake-bite on a large scale at Kasauli in India and at the Instituto Butantan, São Paulo, in Brazil. As to the necessity for injection of viper antivenin, opinions are divided. Popular clamour demands it, mainly because in the more dangerous snake-bites, such as that of Russell's viper in India, it is absolutely essential. But when given for our viper-bites it should be injected deep subcutaneously, certainly not intravenously, on account of the danger from anaphylaxis, as Mr. Burkitt points out.

Attention should be drawn to the use of carbolic soaps, which have been found to neutralize and to delay, to some extent, the absorption of viper venom. It is an old-fashioned remedy which has been revived in the last few years. It should be rubbed into the wound, or, better still, injected in 5% solution¹ into the loose subcutaneous tissues at the site of the fang marks. This simple method is in the reach of everyone. It is harmless and practical and has received the sanction of so great authorities as M. L. Ahuja and A. G. Brooks,² who have written extensively on this subject from Kasauli.—I am, etc.,

London, W.1.

Premedication in Children

SIR,—In his comment (*Journal*, May 11, p. 1121) on our paper on the sedation of children for dental operations (*Journal*, April 13, p. 855), Dr. C. H. Neville-Smith asks whether "the hand that held the medicine glass was more therapeutic than the drug that glass contained." Since our investigation was not designed to test this very reasonable hypothesis we cannot draw any valid conclusions about it from our results. To compare our unpremedicated group of the preliminary trial with a group treated with a placebo at a later date would be to perpetrate the fallacy of the retrospective control, the limitations of which were referred to in the report of the M.R.C. Collagen Diseases and Hypersensitivity Panel on treatment of polyarteritis nodosa with cortisone (*Journal*, March 16, p. 608). We have nevertheless assembled the figures for behaviour distribution in these two groups—published in chart form in our original paper—and present them in the following table.

Treatment	On Entry to Theatre			On Presentation of Anaesthetic		
	Calm	Dis-turbed	Tur-bulent	Calm	Dis-turbed	Tur-bulent
Untreated Placebo (Sum of pilot and main trials)	65 82	34 33	15 9	50 70	34 32	30 22

Applying the χ^2 test we find: on entry to the theatre, $\chi^2 = 3.06$ and $0.2 < p < 0.3$; on presentation of the anaesthetic, $\chi^2 = 4.21$ and $0.1 < p < 0.2$. It is now clear that the differences, suggestive at first sight, can be attributed to chance with a fairly high probability. We have also recorded the distribution of classes of behaviour in the theatre of two other groups of 105 and 98 children who were

untreated in the waiting-room. On comparing these two unpublished sets of results with the combined placebo-treated group results the differences are of less significance than those examined above.

While our results do not offer any convincing support to Dr. Neville-Smith's hypothesis we would emphasize that they do not deny it, and we would certainly agree that the hypothesis is worthy of being submitted to a properly designed test.—We are, etc.,

ROY GOULDING.

Insufficiency of Internal Cervical Os

SIR,—I have read with great interest the article by Mr. V. B. Green-Armytage and Professor J. C. McClure Browne (*Journal*, July 20, p. 128). Evidence that there is a sphincter-like mechanism at the level of the internal os is now overwhelming, based on the anatomical studies of Hughesdon¹ and the physiological studies of Palmer,² Nixon,³ Borell and Fernström,⁴ and others. Failure of this mechanism may well be a cause of habitual abortion, and in these cases operations as devised by Palmer and Lacomme,⁵ Lash and Lash,⁶ and Shirodkar⁷ are frequently followed by satisfactory results.

It is, however, essential that stringent diagnostic criteria should be fulfilled before any operative treatment. These are threefold. (1) There is usually a history of previous over-enthusiastic dilatation of the cervix, or difficult labour, followed by several abortions, which characteristically occur

in the second trimester and are preceded by bulging or painless rupture of the membranes. (2) While on examination the external cervical os frequently appears normal, the internal os will admit easily a dilator of at least 8 mm. diameter (Hegar size 8), often without anaesthetic. The passage of a Hegar size 4 dilator is of no diagnostic value in view of the careful findings of Asplund⁸ and Dorangeon⁹ that the cervical canal is widest in the proliferative menstrual phase, when it averages 6 mm. (3) Radiologically, in a typical case (see figure), an internal os of over 10 mm. is usually demonstrable, a criterion incidentally first established by Palmer and Lacomme.⁵

Judged on these criteria, Cases 1, 2, and 7 in Mr. Green-Armytage's and Professor McClure Browne's series have no relevant aetiological factors, while past history is not discussed in Cases 4, 5, and 6. Case 4 is not a true case of habitual abortion. The hystero-grams of Cases 1 and 2 are not convincing and Cases 5, 6, and 7 have not yet become pregnant, so that their true significance cannot be assessed. Finally the success in Case 1 might equally well be attributed to the progesterone implant.

Javert,¹⁰ who stresses the importance of the psychotherapeutic approach to habitual abortion, has recently again referred to the "great power of the placebo" in this condition. Operations on the cervix undoubtedly have a place in therapy; but to employ them in cases insufficiently investigated and unproved is dangerous and may discredit an ingenious procedure, reducing it to the level of yet another placebo.—I am, etc.,

London, W.C.1.

Scapulo-thoracic Crackling

SIR,—I recently saw a housewife aged 45, attending the department of orthopaedic surgery, Manchester Royal Infirmary, for a minor knee injury, who also complained of an intermittent diffuse pain in the right shoulder for about ten years. This was associated with pain at the back of the neck and at the medial border of the right scapula, severe during the past month. She further drew attention to a grating noise on movement of this shoulder, which she had noticed for many years. A coarse crepitus could be heard and felt over the area of the right scapula on active forward elevation or circumduction of the arm. Both shoulder and neck showed a full range of movement, and there was no postural deformity such as Dr. Guy Beauchamp describes (*Journal*, June 8, p. 1362); nor did the scapula appear to be excessively mobile. X-rays of shoulder and cervical spine were normal.

The patient's pain was much relieved by physiotherapy, but the crepitus remains. As in Dr. F. Parkes Weber's case (*Journal*, May 18, p. 1181) the crackling seems to arise from movements between the scapula and the chest wall, and this view is supported by its occurrence in movements involving serratus anterior, which keeps the medial border and inferior angle of the scapula firmly applied to the chest wall as it rotates forward. It is curious, however, that the crepitus should be present on one side and not on the other. I thank Mr. D. Ll. Griffiths for permission to mention this case.—I am, etc.,

Manchester, 13.

P. F. EARLY.

Churches' Council of Healing

SIR,—The letters of Dr. Jane H. Thompson (*Journal*, July 27, p. 238) and Mr. Griffith Evans (*Journal*, August 10, p. 356) appearing under the above heading in recent issues of the *Journal* will have aroused interest in the minds of many readers. But is not Dr. Thompson's term "spirito-psycho-somatic medicine" a linguistic hybrid of the most illegitimate breed? Mr. Evans's "pneumato-psycho-somatic," while semantically more accurate and etymologically less unfortunate, tends to mislead owing to the association, habitual though entirely unwarranted, of the first three syllables with conditions pertaining to the lung. The term "triatriatic medicine" would serve to designate medicine as applied to the three essential elements of the human trinity, while avoiding both the ponderosity of the doubly hyphenated word and the linguistic crime of the mixed derivation.

Be words what they may, many will concur in Dr. Thompson's view that the increased interest of the profession in the spiritual aspect of medicine is a wholesome revolt against the materialism of the times, in every way to be encouraged and fostered, while, to the metaphysically minded, Mr. Evans's suggestion that the equation of the 2-D plane with the spiritual plane is a study well worth the attention of those who "find themselves extruded from the practice of medicine at 65" might open a fresh and fascinating sphere of research. Perhaps, too, a guild for the pro-

motion of etymological purity in medicine might render good service by eliminating some of the more cacophonous linguistic teratomata which at present deface the medical vocabulary.—I am, etc.,

London, N.W.11.

SYLVIA G. CHAPMAN.

Stove-in Chest Injury

SIR,—Mr. L. Henry (*Journal*, August 10, p. 339) is to be congratulated on the recovery of his patient with a stove-in chest injury treated by plating the sternum. Before he tempts providence again he should read Hulman's description¹ of the treatment of these cases by tracheotomy.

Mr. Henry's patient illustrates the marked change when the "wet lung" syndrome supervenes, producing increase in the paradoxical movement and dramatic deterioration in the general condition. Tracheotomy with repeated suction will prevent this complication and is the only treatment required by a patient who is reasonably comfortable with a dry lung. These injuries are uncommon and my experience is limited, but the improvement with tracheotomy is so striking that I am prepared to accept the suggestion that operations of the screw, wire, or plate variety are obsolete.—I am, etc.,

Pontefract.

Foreign Body in Stensen's Duct

SIR,—Some 20 years ago I had a similar experience to that of my friend Dr. Hardy Kinmont (*Journal*, August 10, p. 356) and successfully removed a feather from Stensen's duct in an infant of about 10 months. I was left marvelling that a feather could find its way in. Perhaps a colleague of original mind, with a knowledge of anatomy and physics and an interest in solving paediatric puzzles, can explain.—I am, etc.,

London, W.1.

ALFRED WHITE FRANKLIN.

The Liver

SIR,—Your timely annotation on liver function (*Journal*, August 10, p. 345) will help to focus attention on important effects of increasing the oxygen supply of the liver, where the bulk of the chemical regulation of the body takes place. The most recent demonstration of the benefit of giving oxygen by the mouth, so that it reaches the liver directly via the portal vein, is the 200% increase in the glycogen content in the liver in one hour, effected by introducing 10 ml. of oxygen gas into the intestinal cavity of rats.¹ How to give oxygen in sufficient quantity by the mouth to human patients is a problem which has defied solution, despite assistance to various investigators (including myself) from the British Oxygen Company. Dr. R. A. Holman,² however, following my suggestion that a peroxide should be given to cancer patients,³ has given a 0.45% solution of hydrogen peroxide to tumour-bearing rats, in place of ordinary drinking water. Over 50% of the rats, all of which had been implanted with the Walker 256 adenocarcinoma, responded to the peroxide treatment by completely destroying their tumours.

Since it is unlikely that orally administered hydrogen peroxide could escape decomposition in the intestinal cavity and wall, portal blood stream, and liver, by catalase, peroxidase, and bicarbonates, this cure of tumour-bearing animals may be attributed provisionally to decomposition of hydrogen peroxide with release of activated oxygen, which is conveyed to the liver and enables that organ to bring about the biochemical destruction of the tumour. Pre-oxidation of intestinal contents by the hydrogen peroxide may also play a part. Professor R. A. Willis, in the first edition of his book, *The Spread of Tumours in the Human Body*,⁴ expressed his view that poor oxygenation of the liver is a factor favouring the survival and proliferation of cancer cells. Dr. Holman's findings indicate the correctness of this view, and suggest that the liver can produce far more potent anti-cancer compounds than any so far synthesized in research laboratories.

AUG. 24, 1957

In accordance with this point of view, I am investigating the oral administration of catalase, together with 0.45% hydrogen peroxide in water, milk, tea, and other drinking fluids, in order to facilitate release of oxygen in the gut, and thereby the regulatory activities of the liver. In so far as the liver is largely responsible for antibody formation as well as detoxication, deamination, and breakdown of fat, the matter is of general medical interest, and points the way to greater control over a wide variety of pathological processes.—I am, etc.,

Sevenoaks, Kent.

Dangers of Cigarette-smoking

SIR,—Smoking is spread by smokers, by their example and persuasion of various kinds, including the proffered cigarette—i.e., by "psychological infection"—and Sir Ronald Fisher's suggestion (*Journal*, August 3, p. 297), unsupported by any evidence, that whether or not an individual smokes may be influenced by his genotype is so fantastic as not to merit serious consideration. It is merely, in fact, the latest of a large number of red herrings drawn across the associated paths of smoking and lung cancer.—I am, etc.,

Wallasey, Ches.

LENNOX JOHNSTON.

Circumscribed Myxoedema

SIR,—In your annotation on this subject (*Journal*, August 3, p. 285) you mention the failure of thyroid, cortisone, and hyaluronidase to cure localized myxoedema. You make no reference to the use of L-iodothyronine. As this may be the thyroid hormone functioning at tissue level, I suppose it must have been tried in this condition. I have used it by mouth recently on two cases of pretibial myxoedema in male subjects suffering from hyperthyroidism controlled by anti-thyroid drugs. In neither case was there any demonstrable effect.—I am, etc.,

Dewsbury, Yorks.

GODFREY B. TAIT.

Hydrocortisone in Orthopaedics

SIR,—Last year in his review (*Journal*, March 31, 1956, p. 730) of my little book *Hydrocortisone in Orthopaedic Medicine*,¹ Professor J. H. Kellgren stated that the hormone was "most effective in relieving pain for periods up to several weeks" (my italics). It had seemed that in my hands relief could last much longer, but at that time I had only clinical impressions to base that opinion on. Owing to the work of our research assistant, Mrs. Granger-Taylor, figures are now to hand on patients followed up for at least one, and up to four, years—i.e., since 1953, when the M.R.C. first granted me hydrocortisone suspension for experimental purposes. The statistics show as follows.

Tennis-elbow (Teno-periosteal Variety).—207 cases. After one or two injections 60.4% have stayed well ever since—i.e., for one to four years. Only a further 4% were put right by one or two more injections; hence it seems scarcely worth while giving the injection more than twice. *Tendinitis at Shoulder.*—94 cases. Supraspinatus 52%; infraspinatus 31%; subscapularis 17%. Of these cases 47 (50%) remained well after one infiltration of the affected part of the tendon; 22 (24%) after two or three injections, and only 2 after four or five. Failed or recurred: 23 (26%). It follows that if the patient is not well in three injections, it is not worth while going on. *Arthritis at Shoulder.*—103 cases. Of these, 56 were judged to be monarticular rheumatoid cases and 50 recovered, 27 of them after one to three intra-articular injections. Failed or recurred: 6.

In traumatic arthritis, 17 out of 23 patients were put right, 10 of them with one to three injections into the joint. In freezing arthritis and arthritis of uncertain type, only 11 out of 24 patients were any better for the injections, and of

these only 7 got well with one to three injections. It is true that permanent cure cannot be claimed even after, say, a tennis-elbow has remained well for four years. Nevertheless, these statistics should serve to correct any impression that hydrocortisone does not give satisfactory—and at least semi-permanent—results in a number of common and disabling conditions.—I am, etc.,

London, W.1.

JAMES CYRIAX.

Visceral Cardiac Reflex Mechanism

SIR,—The case cited by Dr. Raymond Daley as an example of the visceral cardiac reflex mechanism, in which infarction of a gall-stone coincided with myocardial infarction (*Journal*, July 27, p. 173), prompts me to report a recent case in which renal colic and myocardial infarction occurred simultaneously.

A man aged 53 developed severe colicky pain in the right loin, radiating across the back, which continued intermittently during the following week. Two weeks later the pain in the right loin returned, and at the same time he developed a severe gripping pain across the front of the chest. Both pains lasted for several hours, and were accompanied by vomiting. The results of the investigations were as follows: chest x-ray, moderate cardiac enlargement; I.V.P., large stag-horn calculus in right kidney; urine, numerous pus cells and *Bact. coli*; E.C.G., deep inversion of T wave in leads 2 and 3. He received a three weeks' course of treatment with phenindione, and subsequently the right kidney was removed.

The simultaneous onset of the symptoms of renal colic and myocardial infarction is unlikely to have been coincidental. It seems more probable that the renal colic produced a reflex diminution in blood flow through coronary arteries already narrowed by atheroma.—I am, etc.,

Liverpool, 18.

J. W. B. FORSHAW.

Tendo Achillis Rupture after Hydrocortisone Injection

SIR,—I read with interest Mr. H. B. Lee's description (*Journal*, August 17, p. 395) of a ruptured tendo achillis after injection of hydrocortisone. I have just had a similar case in a female sprinter. I would like to know if there are other similar cases, because if this is a common occurrence it means that the old treatment of deep transverse friction for strains to tendo achillis seems to be the best treatment. In the past, I have found that it is a most successful treatment, although it means more frequent attendances.—I am, etc.,

London, W.1.

R. BARBOR.

Clinic for Homosexuals

SIR,—Ever since the celebrated case in 1954 the subject of homosexuality has been simmering in the public mind. The report of the Wolfenden Committee is expected shortly and its publication will bring the matter to the boil again. Much research has been done, and must continue to be done, into the causes and possible cure of homosexuality, but the fact remains that there are a great number of established homosexuals, perhaps not far short of a million, in this country to-day. This number will not change if the law is changed. Homosexuality will still be a problem, both to society and to the individual. A change in the law, should it be recommended and carried through, must never be interpreted by the public as meaning that the problem is no longer of any significance beyond its relation to young people and to public decency. Certain it is that homosexuals will go on having their trials and tribulations (perhaps more, perhaps less, for who can tell?).

Existing opportunities for a homosexual to obtain help are limited. The medical profession as a whole has unfortunately been unable over the years to dissociate itself

from the distaste with which the general public views the matter. Consequently there has been confusion of thought and practice, confusion too easily conveyed to the homosexual seeking help. He is often reluctant to consult his own doctor, who, he believes, is unlikely, because of prejudice or ignorance, to be able to understand him. This is a sorry state of affairs, and, while there are indeed some outstanding experts on the subject, the paths to their consulting-rooms are not well signposted.

A few months ago a feeler was put out to assess the reaction of some fifty men and women, in all spheres and walks of life, to the idea of setting up a clinic to be devoted exclusively to homosexuality and its related problems. The reaction was overwhelmingly favourable, and at a meeting in June, attended by twenty people (nine of whom were doctors), a proposal that the project was valid, was worth undertaking, and deserved support was carried unanimously. Although there is still much preliminary work to be done before the clinic can come into operation it is felt that a great many doctors will be interested to know of the project at this stage. The primary aim is clear: it is to decrease the magnitude of the homosexual problem. The clinic will be run on an out-patient basis in a convenient part of London. It will offer no new therapeutic technique except in so far as a clinic concerned solely with homosexuals is new, and this may well prove to be a big step forward.

The objectives of therapy are only touched upon briefly here. For the young who have encountered difficulties on the road to maturity, and for the adults who have a bivalent sexual instinct, the objective will be adjustment to heterosexuality. For the people in whom any heterosexual urge has always been absent and will never, humanly speaking, be present, the objective will be better adjustment to homosexuality, thereby releasing, for the benefit of the community at large, the great potential for good work which so often lies dormant in homosexuals. There are certainly well-adjusted homosexuals whose contribution to society must be rated very highly. The clinic will also act as a centre for the spread of knowledge. Research will be carried out concurrently with therapy, which will include group therapy conducted under proper medical supervision; the scope in this direction is considerable. To start with, at all events, the project will have to be financed by funds raised by private subscription, but it is hoped that the clinic will become self-supporting. The general interest and support of the medical profession is sought for this project, which represents a sincere attempt to tackle a serious problem. The Church and all responsible bodies are anxious and willing to play their part, but, on the admission of everyone seeking to enlighten the shadows of homosexuality, medicine's contribution is the most vitally important.—I am, etc.,

Hurst Green, Surrey.

RODNEY H. N. LONG.

POINTS FROM LETTERS

Fainting on Parade

Dr. R. S. WALSH (Henley-on-Thames) writes: I think I can help shed some light on the points raised in Dr. A. H. Skinner's letter (*Journal*, August 10, p. 356), having spent two years as a regimental medical officer in B.A.O.R., most of it with an infantry battalion. The temperature in the summer in Germany equals anything usually encountered in Britain, but fainting on parade was relatively uncommon. I saw all those who fell out within a very few minutes of the event, and, though I have no detailed records, I recall that all cases could be grouped into four classes. First, those who had over-indulged in alcohol the night before; secondly, those who had missed breakfast, usually by leaving too much of the preparation for the parade until the last moment; thirdly, those sickening for acute illness such as influenza; and, fourthly, recruits fresh from the regimental depot, whose physical development was below average. Clearly the state of morale and discipline of the unit has much to do with the problem, as has clothing suitable to the weather. Shirt-sleeve order was the regulation summer dress in Germany. The mechanism of fainting appeared in all cases to be a vasovagal attack, and the freedom from fainting once recruits had been brought to a high degree of physical fitness was most striking.

Obituary

R. A. KERR, M.C., M.B., F.R.C.S.

Mr. R. A. Kerr, consulting surgeon to the National Temperance Hospital, London, died on July 12 at St. Leonards-on-Sea, Sussex, where he had been living in retirement. He was 67 years of age.

Robert Andrew Kerr was born on March 22, 1888, and was educated at the former Queen's Colleges at Galway and Belfast, gaining the first- and second-year medical scholarships while at Galway and the fourth- and fifth-year medical scholarships at Belfast. He was also awarded the Malcolm and Coulter exhibition at the Royal Victoria Hospital, Belfast. Graduating M.B., B.Ch., with first-class honours, in 1910 from the recently founded Queen's University of Belfast, he then held the appointment of house-surgeon at the Down County Infirmary, Downpatrick. Up to the outbreak of the first world war in 1914 he held a number of other appointments, including those of junior and senior demonstrator in anatomy at the Queen's University and several resident posts at the Bristol Royal Infirmary. He served throughout the first world war with the R.A.M.C., and in 1917, while attached to the Royal Warwickshire Regiment, was awarded the Military Cross for conspicuous gallantry and devotion to duty: "He succeeded in rescuing his three bearers who were entombed when the aid post was blown in. He constantly visited the most dangerous parts of the line in order to tend the wounded."

After the war Kerr settled in London, and held the posts of clinical assistant in the genito-urinary department of the London Hospital, resident medical officer at the London (now National) Temperance Hospital, and house-surgeon at St. Mark's Hospital for Diseases of the Rectum. He was admitted F.R.C.S. in 1920. Later he became surgical registrar at the London Temperance Hospital, and in 1922 was elected honorary assistant surgeon, becoming senior surgeon in 1951. When he retired three years ago he was appointed consulting surgeon to the hospital. He was also consulting surgeon to the Sittingbourne Memorial Hospital. He is survived by a widow and one son.

D.D.P. writes: For one who was his colleague and friend since 1921, and more recently his grateful patient, it is easy to write of "Bob" Kerr, as he was known to his many friends. Following the first world war, in which he served in the R.A.M.C. with distinction, being awarded the Military Cross, he was appointed resident medical officer at the London Temperance Hospital (as it was then named) in 1921. A vacancy occurring towards the end of that year, he was appointed surgical registrar, and in this post began to attract attention by his keenness and ability. There was an unexpected retirement from the honorary staff in 1922, and he was elected as honorary assistant surgeon. His wide theoretical knowledge now had the opportunity of being put to practical use, and he rapidly established himself as a surgeon well known for his most thorough examination of the patient and whose opinion and operative skill began to be in great demand. He was insatiable in his reading of surgical and medical literature; in fact, surgery was not only his profession but his hobby. He was very modest, and, although a regular attendant at the various surgical society meetings, it was very rarely that he would speak, and only infrequently that he reported a case or wrote an article. During the second world war, his immediate senior having joined the R.A.M.C., he took charge of the National Temperance Hospital for the Emergency Medical Service and worked indefatigably. He became senior surgeon at the hospital in 1951, and held this position with distinction until his retirement in 1954; this was the occasion of great regret to his colleagues and to the nursing staff. The North-West Metropolitan Regional Hospital Board honoured him by appointing him consulting surgeon. Bob Kerr was a man of quiet demeanour, but with a great sense of humour

AUG. 24, 1957

and of most upright principles, and his death is a great loss not only to his wife and son but to his hospital and his friends.

J. I. LESH, M.D., D.P.H., D.T.M.&H., D.I.H.

By the untimely death of Dr. J. I. Lesh in Portsmouth on July 30 from acute poliomyelitis with respiratory paralysis, the Medical Service of Northern Nigeria has lost one of its most active and experienced medical officers of health. He was 46 years of age.

James Ian Lesh was the son of a journalist, and was born in Manchester on July 4, 1911. He received his early education at Queen Elizabeth's Grammar School, Kingston-upon-Thames, from where he gained a Surrey major scholarship and entrance scholarship to St. Thomas's Hospital Medical School. There he studied from 1929 to 1935, graduating M.B., B.S. from London University in 1935. After graduation he held the post of house-surgeon at the Royal West Sussex Hospital, Chichester, and he joined the old Colonial Medical Service in 1937.

During his twenty years' service in Nigeria, Dr. Lesh became a widely known and respected personality, experienced and knowledgeable in many different fields of medicine in the tropics—clinical, administrative, and in public health work. His earlier years in the service were occupied as a medical officer in clinical practice in various stations in Nigeria. In those days, before and during the second world war, no doctor in Nigeria was purely a clinician, but was constrained to occupy himself with all matters indirectly and even remotely connected with the running of a medical service—hospital administration, finance, storekeeping, discipline, teaching, local government, and all aspects of the public health. It was during this period that Dr. Lesh acquired his taste for public health work and for what may be termed, for lack of a more suitable phraseology, administrative medicine.

In 1947 he took the Diploma in Tropical Medicine and Hygiene of the English Royal Colleges and proceeded to the M.D. in tropical medicine. In 1949 he became acting senior medical officer in charge of the tin-mining area of the Plateau Province, which post he held for two years until he went home to study for the Diploma in Public Health of London. This he obtained, with distinction, at the London School of Hygiene and Tropical Medicine in 1952, taking, with characteristic enthusiasm and thoroughness, the Diploma in Industrial Health immediately afterwards. From then until his death he was medical officer of health in Jos, Plateau Province, the centre of the minefields.

His social and private life was centred on his home, his main interests being his family, his house, and his garden, and his collection of records of classical music, with which he delighted friends who called to see him when passing through Jos. His keen, inquiring intellect was not devoted solely to professional matters, but embraced such diverse subjects as the mechanical reproduction of music, the petrol engine, and the intricacies of income tax. To spend an evening with James Ian, to listen to a near-perfect reproduction of a Beethoven sonata, to dine at his well-appointed table, and to discuss with him such subjects as double-taxation relief and the problems of the motor-car in Nigeria, was one of the more pleasant and stimulating experiences of life in Jos. The enthusiastic and constructive work which he did in Nigeria will be remembered. He is survived by a widow and two children, to whom the deepest sympathy of all his colleagues in Nigeria is extended.—I. K. H.

E. R. BENNION, M.D., D.P.H.

Dr. E. R. Bennion, consultant chest physician to the Stoke-on-Trent Group of Hospitals under the Birmingham Regional Hospital Board, died on August 5 after a long illness. He was 56 years of age.

Edgar Rhodes Bennion was born at Market Drayton, Salop, on June 15, 1901. He received his clinical training

at the Westminster Hospital, qualifying M.R.C.S., L.R.C.P. in 1924. After holding the post of house-surgeon at the Westminster Hospital he went into general practice at Bradford. Later he moved to Hertfordshire, becoming assistant medical officer at Ware Park Sanatorium. In 1932 he took the D.P.H. of the English Royal Colleges, and having decided to specialize in tuberculosis he became a clinical assistant at the Chelsea Tuberculosis Dispensary. In 1935, the year in which he took the M.B., B.S. degrees of London University, he was appointed tuberculosis officer for Staffordshire. Ten years later he proceeded to the M.D. At the beginning of the second world war he was tuberculosis officer and deputy medical officer of health for Greenwich, taking a prominent part in civil defence work during the bombing. He returned to North Staffordshire in 1941 to become tuberculosis officer under the Staffordshire, Wolverhampton, and Dudley Joint Board. With the coming of the National Health Service in 1948 his appointment became that of chest physician under the Birmingham Regional Hospital Board. A popular and well-liked physician, Dr. Bennion never let his keen sense of humour desert him. His long illness was a matter of real concern to his patients. He is survived by his widow and one daughter.

W. S. BURR, F.R.C.S.Ed., D.O.M.S.

Mr. W. S. Burr, honorary consultant ophthalmic surgeon to the Royal Eye Infirmary, Plymouth, died suddenly at his home in Plymouth on August 5 from a recurrence of coronary thrombosis. He was 58 years of age.

A native of Bo'ness, West Lothian, William Simpson Burr graduated M.B., Ch.B. from Edinburgh University in 1921. He obtained the D.O.M.S. of the English Royal Colleges in 1925, and was elected F.R.C.S.Ed. two years later. After graduation he held appointments as ophthalmic house-surgeon at Bury Infirmary and Derbyshire Royal Infirmary, and then became senior house-surgeon at the Royal London Ophthalmic Hospital, Moorfields. On settling at Plymouth in 1927 he was appointed honorary ophthalmic surgeon to the Royal Eye Infirmary. He retired from this post about three years ago, but continued as honorary consultant surgeon and carried on his private practice. He was a member of the Ophthalmological Society of the United Kingdom, the South-western Ophthalmological Society, and the Plymouth Medical Society. In his particular branch of medicine he held a high reputation, his advice and services being always in great demand. Although of a quiet and retiring disposition, he never hesitated to express forthright views at local meetings of the British Medical Association. Outside his profession his chief interests were in motor-cars and boating; indeed, at the moment of his death he was preparing for an afternoon's cruise. The large attendance of colleagues and citizens at his funeral service at Trinity Presbyterian Church was a testimony of the high esteem in which he was held. Our sympathy goes out to his widow and son, and to his brother, Mr. George Burr, also an ophthalmic surgeon at Plymouth.—G. D.

BARBARA M. BRADSHAW, M.B., Ch.B.

Dr. Barbara M. Bradshaw, part-time anaesthetist to the Salford Royal Hospital, died suddenly on August 7 at the age of 31.

Barbara Morris Couldwell was born on March 12, 1926, and was a medical student at Manchester University, where she graduated M.B., Ch.B. in 1950. She married Mr. William C. L. Bradshaw, and he survives her, together with the two sons of the marriage.

A. N. G. writes: No member of the staff of Salford Royal Hospital over the past five years but has learned of the tragic and untimely end of Dr. Barbara Bradshaw with the deepest regret and dismay. She was from the first a most reliable resident, and she later became a competent and accomplished anaesthetist. In each successive post she held, the delightful gaiety of her manner won all hearts—but

Medical News

Polio Vaccine.—Dr. G. A. CLARK, of the Ministry of Health, and Dr. W. L. M. PERRY, of the Medical Research Council, are visiting Canada and the U.S.A. to explore the possibility of manufacturing additional supplies of the British-type vaccine overseas. They also hope to discuss the safety and potency of the Salk vaccine.

Charing Cross Hospital.—The Ministry of Health has issued a proposal to build a new Charing Cross Hospital and Medical School on the site at present occupied by the Fulham Hospital. The Ministry now awaits comment from the various authorities concerned. Even if the scheme is approved, the Charing Cross Hospital is not likely to move from its present site for some years.

Clean Food in Scotland.—Mr. A. W. RITCHIE, who was appointed food hygiene officer in 1950, retires at the end of this month. Owing to increased public interest in the need for the clean handling of food, his functions will be taken over by the chief milk inspector, Mr. C. H. CHALMERS, and the department's six milk inspectors. They are to be renamed food and dairy officers, and the title of Mr. Chalmers's post will be chief food and dairy officer.

Ophthalmological Prize.—The council of the Ophthalmological Society has instituted a prize of £100 entitled the Treacher Collins prize essay, to be awarded triennially. Medical practitioners of any nationality may compete; the essay must be written in English. The subject for the next award is "The Eye in Relation to the Collagen Diseases," and the closing date is December 31, 1959. Full details from the honorary secretary, Ophthalmological Society of the United Kingdom, 45, Lincoln's Inn Fields, London, W.C.2.

Animal Welfare.—An appeal for funds is to be broadcast by the B.B.C. on Sunday, August 25, at 8.25 p.m. (Home Services) by Freddy Grisewood on behalf of the Universities Federation for Animal Welfare. The work of this organization includes the discovery of techniques to reduce the numbers of animals used in experiments, the search for painless substitutes for cruel poisons, and the elimination of foot rot in sheep. Its president is Professor E. Hindle, F.R.S. Information may be obtained from the Secretary, The Universities Federation for Animal Welfare, 7A, Lamb's Conduit Passage, London, W.C.1.

West Indies.—Dr. D. C. TURK has been appointed lecturer in bacteriology from January 1, 1958, in the department of pathology of the University College of the West Indies. He is at present a senior registrar in the department of clinical pathology at Guy's Hospital.

Dr. W. K. Vernon Bernfeld received the award for flute solo at the National Eisteddfod held recently in Anglesey.

B.M.J. Index.—The half-yearly indexes to Volume I of the *Journal* and the *Supplement* for 1957 are now being sent to members who receive them regularly and to subscribers. Members who have not previously asked for the indexes to be sent regularly to them can obtain copies, post free, on application to the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1: those wishing to receive the indexes regularly should mention this.

COMING EVENTS

Wireless Programme.—"Beginnings and Endings," a typical day's activity in a large hospital, B.B.C. North Home Service, August 27, 7.30-8.30 p.m.

Sheffield Dinner.—Annual dinner of Sheffield Medical School Old Students Association in Firth Hall of the University, Western Bank, Sheffield, 10, on Saturday, October 12, 6.30 for 7 p.m. Further details from the secretary, c/o Pathology Department, University of Sheffield.

NEW ISSUES

Journal of Neurology, Neurosurgery, and Psychiatry.—The new issue (Vol. 20, No. 3) is now available. The contents include:

EXPERIENCES IN THE TREATMENT OF RUPTURED INTRACRANIAL ANEURYSMS. The late Cecil A. Calvert.
ON THE ADVANTAGES OF OPENING CERTAIN INTRACRANIAL ANEURYSMS. J. R. Gibbs.
FAMILIAL CALCIFICATION OF THE BASAL GANGLIA WITH RESPONSE TO PARATHORMONE. W. B. Matthews.
SOME EXPERIENCES WITH WALTON'S FREQUENCY ANALYSIS OF THE ELECTROMYOGRAM. J. Fox and C. E. T. Krakau.
THE EFFECT OF CHLORPROMAZINE ON THE ELECTROENCEPHALOGRAPH OF EPILEPTIC PATIENTS. Walter Fabisch.
CHOLINESTERASE IN NORMAL AND ABNORMAL HUMAN SKELETAL MUSCLE. Evelyn B. Beckitt and G. H. Bourne.
TUBERCULOUS MENINGITIS. G. Donald W. McKendrick and R. J. Grose.
A NOTE ON TRANSNEURONAL ATROPHY IN THE HUMAN LATERAL GENICULATE BODY. F. Goldby.
A STUDY OF DYSLLEXIA. Elizabeth Warrington and O. L. Zangwill.
THE SIGNIFICANCE OF HYPERKINESIS IN LESIONS OF THE ANTERIOR STRIATUM IN RHESUS MACACUS. Eric A. Turner.
ISCHAEMIC AND POSTISCHAEMIC PARAESTHESIAE IN MOTOR NEURONE DISEASE. E. W. Foote.
METASTATIC PARAPLEGIA OF PROSTATIC ORIGIN WITH NOTES OF A CASE OCCURRING 28 YEARS AFTER SUPRAPUBIC PROSTATECTOMY. Lambert Rogers.
PROCEEDINGS OF THE SOCIETY OF BRITISH NEUROLOGICAL SURGEONS: 55th MEETING.
BOOK REVIEWS.

Issued quarterly; annual subscription, £2 2s.; single copy, 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Friday, August 30

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. H. Nicholson: clinical demonstration.

APPOINTMENTS

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—R. D. Eastham, M.D., D.C.P., D.Path., Consultant in charge of Department of Pathology at Frenchay Hospital, Bristol; K. Lloyd Owen, F.F.A.R.C.S., M.R.C.S., L.R.C.P., Consultant Anaesthetist to North Gloucestershire Clinical Area; J. G. Kendall, M.B., Ch.B., F.R.C.S., Consultant Orthopaedic Surgeon to West Cornwall Clinical Area; James Browne, M.D., D.P.M., Consultant Psychiatrist at St. Lawrence's Hospital, Bodmin; Lewis Couper, M.B., Ch.B., D.P.M., Consultant Psychiatrist and Medical Superintendent of Dieby-Wonford Hospital, Exeter; Leon Brotmacher, M.D., Ph.D., M.R.C.P., Senior Medical Registrar at Royal United Hospital, Bath; Nerida M. Dilworth, M.B., B.S., Anaesthetic Registrar at Southmead Hospital, Bristol; N. S. Thomas, M.B., B.S., Anaesthetic Registrar at Frenchay Hospital, Bristol.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Jillitt.—On August 12, 1957, at Poole General Hospital, Dorset, to Dr. and Mrs. R. L. Jillitt, St. Ann's, Canford Cliffs, Dorset, a daughter—Sally Anne.
Lichter.—On June 29, 1957, in Johannesburg, to Heather (formerly Lloyd) and Ivan, a daughter, Shelley, sister to David, Jonathan and Barry.
Warner.—On August 5, 1957, at Bristol Maternity Hospital, to Amy (formerly Mair), wife of Dr. James Warner, a brother for Jennifer—Nicholas James.

MARRIAGES

Reynolds—Aldridge.—On July 6, 1957, at St. Matthias' Church, Worcester Park, Surrey, Patrick Reynolds, M.B., B.S., of Bognor Regis, Sussex, to Patricia Aldridge, M.C.S.P., of Cheam, Surrey.

DEATHS

Atkey.—On August 8, 1957, at Woking, Surrey, Percy James Atkey, M.R.C.S., L.R.C.P., D.P.H., aged 90.
Bennion.—On August 5, 1957, Edgar Rhodes Bennion, M.D., D.P.H., of The Oakes, Barlaston Old Road, Trentham, Staffs.
Bradshaw.—On August 7, 1957, Barbara Morris Bradshaw, M.B., Ch.B. (formerly Couldwell), aged 31.
Burr.—On August 5, 1957, William Simpson Burr, M.B., Ch.B., F.R.C.S.E.D., D.O.M.S., of 3, Windsor Villas, Plymouth, aged 58.
Chambre.—On August 4, 1957, John Chambre, M.B.E., M.D., of Oakfield, Ealing, London, W., aged 78.
Gonin.—On August 1, 1957, Bertram Winter Gonin, M.R.C.S., L.R.C.P., of The Gables, Shortlands, Kent, aged 82.
Kerr.—On July 12, 1957, at St. Leonards-on-Sea, Sussex, Robert Andrew Kerr, M.C., M.B., B.Ch., F.R.C.S.
Lennox.—On July 25, 1957, at St. Richard's Hospital, Chichester, Sussex, David Lennox, M.D., D.P.H., D.T.M.&H.
Lesh.—On July 30, 1957, James Ian Lesh, M.D., D.P.H., D.T.M.&H., D.I.H., of Picket Croft, Ringwood, Hants, formerly of Nigeria.
Mills.—On August 5, 1957, Surgeon Lieutenant-Commander Oswald Mills, M.R.C.S., L.R.C.P., R.N., late of Ireth, Broadstone, Dorset.
Russell.—On July 31, 1957, at Fleet, Hants, William Russell, M.C., M.B., Ch.B., Colonel, late R.A.M.C., retired, of Ballynahinch, Co. Down.
Sanderson.—On July 20, 1957, at St. Mungo's, West Linton, Peeblesshire, Robert Hall Sanderson, M.B., Ch.B.
Thirtle.—On July 30, 1957, at Stoke Mandeville Hospital, Bucks, Jessi Ann Thirtle, M.R.C.S., L.R.C.P.
Trouton.—On August 5, 1957, at 196, Ruskin Park House, Champion Hill, London, S.E., Derrick Starling Trouton, M.Sc., M.B., B.Chir., aged 32.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Survival in Untreated Cancer

Q.—What is the natural history of untreated carcinoma of the common sites such as stomach, rectum, breast, and uterus? How, for instance, does the survival of treated cases of cancer of the breast compare with that of untreated cases?

A.—It is difficult to obtain reliable data about untreated cancer nowadays, because most patients receive some form of treatment, and those who receive none would not be a representative sample. Probably the best data available on the survival of untreated cancer cases are those reported by Greenwood in 1926.¹ This report gives the mean duration of the disease from onset of symptoms to time of death in the sites mentioned by the questioner as follows: Breast (651 cases), 38.3 months; uterus (1,749 cases), 20.9 months; rectum (887 cases), 26.7 months; and stomach (154 cases), 16.8 months. Greenwood's figure for the mean natural duration of breast cancer is thus about three and a quarter years; but, since this is measured from onset of symptoms to time of death, it is not strictly comparable with, and should in any case be longer than, the "survival time subsequent to treatment" which is the figure usually

Breast cancer: x—x—x = Duration of survival from onset of symptoms in 651 untreated patients. +—+—+ = Symptom-free period following treatment of Stage I patients, some of whom were still symptom-free ten years after treatment. — = Symptom-free period following treatment of 1,286 patients in all stages, some of whom were still symptom-free ten years after treatment. Based on data in Table L in the review by Smithers *et al.*²

average duration of 38 months for untreated cases, but this merely indicates that a simple comparison of mean survival times for all cases is not a sensitive test of the efficacy of treatment: for there are, in fact, very significant differences

	No. of Cases	Percentage Alive at 3 Years After Treatment	No. of Cases	Percentage Alive and Free from Recurrence 10 Years After Treatment
Stage I ..	256	71%	79	54%
" II ..	374	54%	113	25%
" III ..	345	32%	85	4%
" IV ..	238	17%	52	4%
Untreated ..	73	52%	23	17%
Total ..	1,286	45%	352	23%

Post-operative Anal Stricture

Q.—What treatment is advised for a partial stricture of the anus following operation for fissure in ano three years ago? Digital removal of faeces has to be performed quite often. There is a band of scar tissue at the site of operation, the sphincter feels hypertrophied, and the rectum is ballooned. How often is this complication of operation encountered, and what accounts for it?

A.—The treatment for this condition is surgical and consists in what is well described as "superficial external proctotomy." The tight constricting band of scar tissue should be incised (usually in the midline dorsally), and then the fibrous constricting lower border of the internal sphincter will be both seen and felt. After passing a bivalve proctoscope this muscle should then be divided either with a scalpel or with a fine pair of scissors (internal sphincterotomy), and when this has been properly done the anus will now feel quite smooth and relaxed. Some external drainage must be provided, and a triangular-shaped wound is usually very effective. The after-treatment is exactly the same as that for the primary operation for cure of a fissure, and the passage of a St. Mark's pattern dilator should be started on the fourth or fifth post-operative day. The dilator should be passed morning and evening until the final stage of healing has been reached. By then the anus should admit a finger smoothly and the patient should be able to pass a normal formed stool. It is a good plan to continue passing the dilator at gradually increasing intervals for another two or three months to make sure that contraction of the scar does not take place again.

This complication following operation for fissure is not encountered very often, and may be due to either inadequate or too short after-treatment, or to extreme nervousness on the part of the patient which may have prevented the normal after-treatment being carried out properly.

Anaesthesia for the Single-handed Practitioner

Q.—What anaesthetic techniques are recommended for the single-handed practitioner in the tropics liable to be faced with major surgical and obstetrical emergencies? Reasonable hospital facilities and moderately competent nursing staff may be assumed.

A.—Without question spinal analgesia, provided the surgeon is prepared to familiarize himself with the hazards and how to avoid them.¹ If the lower intercostal muscles are paralysed, as they will be in abdominal surgery, oxygen is highly desirable. If in addition the movement of the diaphragm is restricted, as by a large ovarian cyst or during caesarean section, the inhalation of oxygen throughout the operation is imperative. If the blood pressure falls the head must be kept below the heart level. Needles and ampoules must not be placed in disinfectants. Another approach, adequate though inelegant, is to use the Russian method of local analgesia. Here the surgeon injects a large volume of a weak solution (1-4%) of procaine, without adrenaline, as he goes along. Up to three litres is not uncommon.

Outside the abdomen the results are very satisfactory. For abdominal surgery a splanchnic block must be given as well or patience and skill must be exercised in injecting the mesentery.² The third possibility is general anaesthesia, preferably ether or even chloroform, but not for intestinal obstruction unless a stomach tube is passed on a conscious subject. If your inquirer learns how to pass an endotracheal tube he will prevent many of the alarms encountered in the circumstances he mentions.

Motion Sickness and Its Palliation

Q.—In the prevention and treatment of motion sickness are there drugs of particular benefit for the different varieties of this malady—that is, for seasickness and car sickness—or is the response likely to be the same whatever the cause of the motion sickness? If the former is the case, what drug is recommended for each type of motion sickness?

A.—It is inherently improbable that motion sickness produced by different forms of travel would respond specifically to different drugs, and no such specificity has ever been demonstrated. A large-scale controlled clinical trial in which 26 compounds were tested on about 17,000 subjects during Atlantic crossings showed that three antihistamines, cyclizine, meclizine, and promethazine were highly effective.¹ Hyoscine, which is widely used, gave relief in a smaller proportion of cases.

Refreshments

Q.—What are the principal constituents of drinks such as coca-cola and pepsi-cola? Do they contain any stimulants and if so in what dosage?

A.—The exact composition of drinks of this type is a trade secret, but among other ingredients they contain sugar, which is partially caramelized, phosphoric acid, carbon dioxide, and caffeine. A 6-oz. (170-ml.) bottle usually contains about $\frac{1}{2}$ gr. (32 mg.) of caffeine, which is only about half the amount of this stimulant to be expected in a cup of tea.

Acute Pulmonary Oedema

Q.—What should be the immediate treatment of acute pulmonary oedema developing in a chronic bronchitic in general practice? The patient is too ill to move to hospital, oxygen is not immediately available, and morphine is contraindicated.

A.—If the case is one of acute left ventricular cardiac failure occurring in a patient with chronic bronchitis, the questioner is correct in saying that morphine is contraindicated. Emergency treatment consists in the intravenous injection of 0.25–0.5 g. of theophylline ethylenediamine (aminophylline), diluted in 10–20 ml. of sterile normal saline. The injection should be given slowly, as some degree of respiratory stimulation follows. In addition, a bloodless phlebotomy should be performed by bandaging the thighs to impede venous return. Preferably the sphygmomanometer cuff should be used, the pressure being kept at about 70 mm. Hg.

If the cause of the pulmonary oedema is hypertensive left ventricular failure, rapid relief may follow reduction of blood pressure to normal levels. 5–15 mg. of hexamethonium bromide can be given slowly by the intravenous route, checking the blood pressure the while. If the practitioner is single-handed, it would be easier to give the injection intramuscularly, starting with 5 mg. and giving a further 5 mg. if no improvement has resulted in 15 minutes.

The blood pressure must be carefully checked to avoid undue hypotension, since patients may be very sensitive to hexamethonium when in acute heart failure.

If uncontrolled auricular fibrillation is present, rapid digitalization will be indicated. Provided the patient has not been previously receiving digitalis, 1–1.5 mg. of digoxin should be given by mouth. The intravenous route should be avoided if possible in acute left ventricular failure.

Finally, if there is any question of an acute chest infection in this chronic bronchitic patient, soluble penicillin, 0.5 mega-unit, should be given by intramuscular injection also.

Treatment of Early Acne

Q.—A girl of 6 $\frac{1}{2}$ is already beginning to show a few blackheads. Her father had very severe acne in adolescence. Can anything be done to prevent a similar occurrence in the case of his daughter?

A.—There seems little doubt that the type of skin which is prone to the formation of comedones may be inherited, and the acne which results in adolescence may be somewhat intractable. There is occasionally a history of acne appearing soon after birth or at the age of 1 to 2 years, clearing within a few months but appearing once more in adolescence.¹ In the questioner's case treatment of acne along the usual lines is indicated. The affected skin should frequently be washed well with soap and water and rinsed daily or every other day with a solution of cetrimide (1%) to remove the excess of sebum. At night a sulphur lotion should be applied (for example, precipitated sulphur 6% in lot. calaminae N.F.). The diet is of some importance: chocolate, cheese, and nuts should be avoided, and fried food, pastry, and suet puddings taken sparingly. Daily treatment with ultra-violet radiation in an erythema dose is worth a trial, and in late adolescence x-radiation in fractional doses is often helpful, as it seems to reduce the activity of the sebaceous glands. The use of cosmetics should at that age be encouraged in order to improve morale, but they should be non-greasy. Treatment with oestrogen in moderate dosage is also worth consideration in late adolescence (for example, stilboestrol 0.5 mg. daily for three weeks after each menstrual period).

"FLUOTHANE": A REPORT TO THE MEDICAL RESEARCH COUNCIL BY THE COMMITTEE ON NON-EXPLOSIVE ANAESTHETIC AGENTS*

The Committee on Non-explosive Anaesthetics was formed by the Medical Research Council to consider what steps can be taken to find anaesthetics the use of which is unattended by the risk of explosion. The best-known substances which can give rise to explosion are ether and cyclopropane. While it is true that the explosions they cause are rare, much time and money is spent in taking precautions to minimize the risk, in particular to prevent the accumulation of electrostatic charge on operating-theatre equipment.

The interest of the Committee has therefore been to encourage the synthesis of new compounds which will not explode and which are suited for use as anaesthetics, and to examine substances synthesized by commercial firms for this purpose. Recently "fluothane"† (halothane) has been prepared by Imperial Chemical Industries Ltd. (Pharmaceuticals Division), and reports on its properties and clinical use have been published (Raventós, 1956; Johnstone, 1956; Bryce-Smith and O'Brien, 1956). Chemically it is a derivative of ethane, in which three of the hydrogen atoms have been substituted by fluorine, a fourth has been substituted by bromine, and a fifth by chlorine. Fluothane probably owes its non-explosive character to the presence of the three fluorine atoms and to the reduction of the number of hydrogen atoms to one.

The following report describes investigations into the properties of fluothane, both pharmacological and clinical, in order to clarify some points in its pharmacology and to further its clinical assessment.

SOME PHARMACOLOGICAL ACTIONS OF FLUOTHANE

by PROFESSOR J. H. BURN, DR. H. G. EPSTEIN, DR. G. A. FEIGAN,‡ and PROFESSOR W. D. M. PATON

In the first pharmacological studies of fluothane, by Raventós (1956), it was established that this vapour could produce a rapid, effective, and flexible anaesthesia. It appears to possess, however, some unusual features when compared with other anaesthetics. First, it has a distinct hypotensive action. Raventós made the suggestion that this was due to ganglion block by fluothane, although it was necessary to postulate that such block was particularly effective on the mesenteric ganglia, since it was found that the superior cervical ganglion was not very readily paralysed. He did not think that fluothane appreciably depressed the cardiac output by weakening the cardiac muscle. Secondly, the effects of the anaesthetic appeared to pass off rapidly, and this recovery depended little on the duration of exposure. This is a particularly interesting point, in view of the high oil/water partition coefficient of fluothane. It is greater than that of chloroform, from which it might be expected that after prolonged administration a good deal of fluothane

would be absorbed by fatty tissues and would take a considerable time to be eliminated.

In the following experiments (1) the effect of fluothane on the cardiac output has been studied; (2) the extent to which the fall in blood pressure could be attributed to ganglion block has been analysed further; (3) since fluothane undoubtedly possesses some ability to paralyse ganglia, a test of its actions on another cholinergic synapse, the neuromuscular junction, has also been made; (4) finally, evidence about the time course of its actions has been obtained.

Methods

For experiments on cardiac output, the dog heart-lung preparation was set up, ventilated by a Starling respiration pump. The experiments were made with constant venous pressures, usually 6 cm. of water, in some experiments at 11 and 15 cm. of water also. The pressure in the artificial resistance was adjusted to about 130 mm. of mercury and the venous inflow regulated to permit a systemic output of 800–1,200 ml. a minute at a venous pressure of 6 cm. of water. The outflow was measured directly by diverting the blood on its way to the venous reservoir and recording the outflow for a period of 15 seconds. When a series of observations showed that heart rate and output were constant, a change was made from the pump inflating the lungs with air to a pump giving a known concentration of anaesthetic. The output was measured at intervals of one minute for 10 to 25 minutes. Ventilation with air was then resumed and continued until the output had recovered its original value or until it had become steady at a lower figure. The procedure was then repeated with a different concentration of fluothane or of some other anaesthetic.

*Members of the Committee: Professor J. H. Burn (chairman), Dr. H. G. Epstein, Dr. G. S. W. Organe, Professor W. D. M. Paton, Dr. J. D. Robertson, Professor J. M. Robson, Professor M. Stacey, Professor G. Stead, Dr. T. H. S. Burns (secretary). The pharmacological report was written by Professor W. D. M. Paton and the clinical report by Dr. J. D. Robertson.

†The name "fluothane" is the trade mark of Imperial Chemical Industries Ltd. (Pharmaceuticals Division) and is used throughout the report to describe their brand of trifluorochlorobromomethane (halothane). The Committee wishes to express its thanks to the company for the generous assistance they have given and for providing the fluothane used for this trial.

‡Travelling Scholar of the American Heart Association.

For the experiments on autonomic ganglia, the blood pressure, the neuromuscular junction, and the knee-jerk, cats anaesthetized with chloralose after induction with ethyl chloride and ether were used. Records were made of the contraction of the nictitating membrane (after enucleation of the eyeball) in response to maximal stimulation at 10 per second of the cervical sympathetic, separated from the vagus nerve and cut centrally. In some experiments the peripheral stump of the vagus, cut in the neck, was stimulated and the effect on the heart rate recorded. The blood pressure was recorded through a cannula in a carotid artery. In the study of neuromuscular actions, the response of the soleus and tibialis muscles, recorded by means of flat spring myographs, in response to maximal shocks applied to the sciatic nerve was used. The knee-jerk was elicited by a solenoid tapping the quadriceps tendon and recorded by means of a thread attached to the ankle moving a lever writing on the smoked drum.

To obtain known concentrations of fluothane, modified E.M.O. inhalers calibrated for fluothane were used. The same inhalers were also calibrated for trichlorethylene ("trilene") and chloroform, and for experiments with ether an Oxford vaporizer was used. In the experiments on the dog heart-lung, a stroke volume of 150 ml. and a rate of 26 a minute were usually employed; in the experiments on the cat a stroke volume of 50 ml. and a rate of 19-20 a minute were used. The inhalers were immersed in a water-bath at about 27° C. to stabilize their temperatures.

Effect of Fluothane on Cardiac Output

Table I shows the effect of fluothane at various concentrations on four preparations. Fig. 1 A shows the mean results plotted, giving the reduction in cardiac output against

TABLE I.—Effect of Fluothane on Systemic Output

Exp.	Concentration of Fluothane	Control Before	Control After	During Fluothane	Time of Admin. (min.)	Venous Pressure (mm. Water)	% Fall
1	1%	243	221	191	24	60-69	17.6
	2%	217	192	110	7.5	60-69	46.0
2	1.5%	220	203	173	10	60-65	18.2

the duration of exposure for five different concentrations of fluothane. From these lines can be estimated the time required for each concentration to reduce the output by 30% of the initial value. If the logarithm of the reciprocal of this time is plotted against the concentration of fluothane an approximately linear relationship is obtained (Fig. 2).

Experiments on Chloroform, Ether, and Trichlorethylene

Similar observations with chloroform were made (Table II) and the results in Experiment 5 are shown in Fig. 1B. In Experiment 4 a direct comparison with fluothane was made (Table III). This comparison indicated that 1.7% fluothane produced the same fall in output as 1.2% chloroform; thus fluothane had about 70% of the action of chloroform in diminishing cardiac output.

With ether in concentrations up to 10% only small changes in output were obtained (Table IV). Similarly with trichlorethylene in concentrations up to 2% only small changes were seen (Table V).

TABLE II.—Effect of Chloroform on Systemic Output

FIG. 2.—The reduction in cardiac output is proportional to the concentration of fluothane. The ordinate is the logarithm of the reciprocal of the time taken to reduce the output by 30%.

Effects on Heart Rate

The heart-lung preparation does not receive impulses from the central nervous system, so that the heart rate depends only on the pacemaker. Fluothane, 1-2%, had little effect on the rate; thus a concentration of 1% caused the rate to rise from 150 to 160 a minute, and at 2% the rate fell again to 148, where it remained when ventilation with air was resumed.

Chloroform 1% had little effect, but 2% raised the rate from 150 to 179. The rate returned to 150 on air.

Ether accelerated the heart distinctly. Thus a concentration of 5% raised the rate from 114 to 133, and 10% produced a further rise to 145 a minute.

Trichlorethylene had the greatest effect on the rate; with a concentration of 1% the rate increased from 148 to 174 in one experiment and from 133 to 142 in another. In two experiments a concentration of 2% raised the rate from normal values of 148 and 133 to 213 and 160 a minute respectively.

In the cat under chloralose, fluothane has little effect on the heart rate; there may be a slight slowing of the heart—for example, from 172 to 160 beats a minute. Atropine (0.1 mg./kg.) does not cause any significant cardio-acceleration, if given during the fluothane administration; nor does it antagonize the fall in blood pressure produced by fluothane (discussed below).

Hypotensive Action of Fluothane in Relation to Ganglion Block

Fig. 3 shows a comparison of the effect of 2.65% fluothane on the systemic blood pressure and on the response

FIG. 3.—Records of the knee-jerk (upper tracing), contraction of the nictitating membrane (middle tracing), and blood pressure (lower tracing) in a cat under chloralose. A, Effect of fluothane 2.65%, showing large effect on knee-jerk and blood-pressure and small effect on ganglion transmission. B, Effect of hexamethonium, injected intravenously: first 0.5 mg., then 5 mg., showing greater effect on ganglion transmission than on blood pressure. C, Effect of fluothane inhalation when recovery from hexamethonium not quite complete; ganglion block by fluothane is intensified.

of the nictitating membrane to sustained preganglionic excitation. It will be seen that, despite the fall in blood pressure from 118 to 52 mm., the action on ganglionic transmission is rather small. In the same figure (Fig. 3 B) is shown a later test of the effect of hexamethonium, when it can be seen that even a large dose of hexamethonium fails to lower the blood pressure so far, whereas a dose of hexamethonium producing a distinct depression of transmission in the ganglion has a rather slight effect on the blood pressure. The discrepancy between the intensity of ganglion block and the hypotensive action produced by fluothane is a large one, sufficient to make it doubtful whether ganglion block could account for the fall. The suggestion has been made that the vasomotor ganglia in the visceral area are particularly sensitive to ganglion block by fluothane. It was found, however, that if the animal was eviscerated a

vigorous fall in blood pressure could be produced (Fig. 4), despite the absence of the circulation in the alimentary tract and liver.

A test was also made on the effects of fluothane on the response of the heart to vagal stimulation, which is mediated through the parasympathetic cardiac ganglia. It was found that, even after a profound fall in blood pressure, vagal action could still be obtained (Fig. 5). Indeed, the experiment was difficult, since the vagal action was sufficiently intense, despite the greatly lowered blood pressure, to threaten the survival of the animal. The contrast with hexamethonium is again striking, since with a dose of the latter of comparable or lesser hypotensive action the vagus effect is almost abolished and sometimes consists chiefly of a cardiac acceleration.

It is clear, on the other hand, that fluothane can weaken ganglionic transmission (Fig. 3 A), even if this can hardly account for all its hypotensive actions. The aspect of this which may be of most practical importance is that of synergism with the action of a ganglionic blocking agent. Thus a dose of hexamethonium exerts a bigger effect in the presence of fluothane. This phenomenon is also seen with D-tubocurarine (Fig. 6). Conversely, if there is some

FIG. 4.—Record of the action of fluothane 1.35% on the blood pressure of a cat under chloralose and eviscerated.

FIG. 5.—Record of the effect of vagal stimulation on the blood pressure of a cat under chloralose: A, normally; B, during inhalation of fluothane 1.35%; C, D, and E, during recovery from fluothane. The fluctuations of blood pressure before and after vagal stimulation are respiratory, the pulse rate being too fast (about 140 a minute) to show; but during vagal stimulation with the accompanying bradycardia individual heart beats are seen.

FIG. 6.—Record of blood pressure (lower tracing) and of contraction of nictitating membrane to continuous stimulation of the cervical sympathetic at 10 shocks a second (upper tracing) in a cat under chloralose. A, Start of sympathetic stimulation. B, D-tubocurarine 1 mg. intravenously: no effect on ganglion transmission. C, Hexamethonium, 0.3 mg., producing moderate ganglion block. D, Fluothane inhalation produces a substantial fall of blood pressure, but no blocking action on the cervical sympathetic. E-tubocurarine now, however, produces a deep paralysis of ganglion transmission. E, Return to breathing air. Reduction of blood pressure, and ganglion block, persist until fluothane inhalation ceases.

hexamethonium still remaining in the body, despite a nearly completed recovery of ganglionic transmission, administration of fluothane now has a much stronger ganglion-blocking action (Fig. 3 C).

It was concluded, therefore, that the ganglion-blocking action of fluothane could not account for its hypotensive effect, and that some other explanation should be sought for it.

FIG. 7.—Effect of fluothane inhalation in various concentrations on the knee-jerk of one leg (A-F) and on the contraction of the soleus and tibialis muscles of the opposite leg excited by single maximal shocks to the sciatic nerve every 10 seconds, in the cat under chloralose. A-E, Increasing speed of paralysis of the knee-jerk with increasing concentrations of fluothane. E (lower part). The highest concentration of fluothane tested (4.4%) failed to reduce the indirectly excited tibialis or soleus twitch. D-F, Comparison of the rates of recovery from fluothane 2.65% inhaled for different periods (shown by the black dots below the tracings). Recovery is longer the further the reduction of the knee-jerk is carried.

Action of Fluothane on Knee-jerk

The cat deeply anaesthetized with fluothane presents a blood-pressure record strikingly like that of a spinal animal; this suggested that the fall in blood pressure might be due to an action on the central nervous system. To obtain evidence in this direction, records of the knee-jerk (which is vigorous in the animal under chloralose) were obtained. It was found that all concentrations of fluothane tested (from 0.5% upwards) depressed the knee-jerk considerably, and a concentration of 1% abolished it (Fig. 7). The intensity of this action corresponded much more closely to the effects on the blood pressure than did the ganglionic action (Fig. 3).

These experiments also threw light on the duration of action of the drug. It was found that recovery was not in fact always of the same duration, and that the longer the exposure or the deeper the anaesthesia, the longer it took for the knee-jerk to return. On the other hand, if equal depressions of the knee-jerk were produced in different ways, the recovery times were comparable. It is difficult to make

FIG. 8.—Record of blood pressure under chloralose. A, Effect of beginning fluothane inhalation. B, 40 minutes later, return to breathing air, showing initial partial rapid recovery followed by slower recovery phase.

a corresponding assessment of recovery time on blood pressure, since this is apt to change during the course of an experiment in the absence of any treatment. But if the records in Fig. 3 and Fig. 8 are examined, it is clear that, despite an initially rapid component in return of blood pressure, there is a much more prolonged slower component whose duration corresponds tolerably well with that of the return of the knee-jerk.

The evidence is therefore compatible with the idea that fluothane exercises a centrally depressant action, and that the central autonomic paralysis resulting is a principal cause of the hypotension which fluothane induces. Fluothane, on this view, contrasts with other anaesthetics which lead to excitation of autonomic centres.

Action of Fluothane on Neuromuscular Junction

The highest concentration of fluothane tested (4.4%) failed to reduce the twitch of either the tibialis or soleus muscle; indeed, a slight increment in twitch tension was sometimes seen, perhaps related to change in blood flow. If, however, a comparison was made of the actions of muscle relaxants in the presence or absence of fluothane, a neuromuscular effect could be demonstrated. D-Tubocurarine was distinctly potentiated, and suxamethonium (succinylcholine) was distinctly antagonized by fluothane 1.35% (Figs. 9 and 10). These effects correspond satisfactorily with the idea that fluothane has a feeble antagonism to

FIG. 9.—Record of the contractions of the soleus and tibialis to single maximal shocks to the sciatic nerve every 10 seconds, in a cat under chloralose. Thirteen minutes before the second panel, fluothane inhalation began. D-Tubocurarine, 1.1 mg. intravenously, has a deeper and more prolonged effect during fluothane inhalation. Return to breathing air accelerates recovery from the neuromuscular block.

FIG. 10.—A similar experiment in another animal to that shown in Fig. 9, showing a reduction in the neuromuscular block produced by suxamethonium (succinylcholine), 200 µg. intravenously, if fluothane is inhaled.

acetylcholine (or other end-plate depolarizing drugs, such as suxamethonium) at the neuromuscular synapse, corresponding to its feeble antagonism at a ganglionic synapse. It may be, however, that some of the augmentation of D-tubocurarine's action may be related to the circulatory effect of the drug; for if the blood pressure is lowered enough the elimination of D-tubocurarine might be interfered with, leading to a more prolonged effect. The potentiation of D-tubocurarine by fluothane suggests that, in the event of a prolonged action by the relaxant, care should be taken to ensure the elimination of fluothane. Fig. 9 illustrates this point; the effect of D-tubocurarine persisted until fluothane anaesthesia was stopped and only then began to regress.

Discussion

These experiments show that the hypotensive action of fluothane is more complex than had been suggested. On the one hand, it is clear that fluothane in concentrations between 1 and 2% has a distinct depressant effect on the myocardium. Even though it is difficult to say precisely how great this action will be in the human, it is necessary, in the light of this evidence, to assume that in some degree it will also be present in clinical practice. On the other hand, it has been found that the ganglionic action of fluothane is hardly sufficient to account for the reduction of blood pressure it causes in the cat. It can produce a marked fall in the presence of a trivial action on the superior cervical ganglion; this fall is just as great in the eviscerated animal in which the mesenteric ganglia and splanchnic vascular bed can no longer influence the blood pressure. During the hypotension, vagal stimulation is still effective, although ganglionic block by hexamethonium, producing a smaller fall in blood pressure, may block the vagus much more intensely.

The experiments on the cat suggested, further, that another mechanism might be involved, that of a central depression of vasomotor mechanisms. Such an effect would be compatible with the reduction of the response to carotid occlusion described by Raventos. Evidence was obtained that fluothane in concentrations comparable to those exerting a hypotensive effect could depress a central nervous reflex, the knee-jerk; and that the magnitude and time course of this action correspond tolerably well with that on the blood pressure. It seems best, therefore, to suppose for the present that the hypotensive action of fluothane is made up of a central depressant action, together with some weakening of the heart, and possibly a small contribution of peripheral ganglion block.

There is, however, a distinct action by fluothane on autonomic ganglia. The most important practical aspect of this may be potentiation of ganglion-blocking agents if these are also administered. The ganglionic action of D-tubocurarine, as well as that of hexamethonium, is augmented. Corresponding to this depressant action at the ganglionic synapse is a similar action on the neuromuscular junction. Fluothane in a concentration up to 4.5% did not itself block transmission in either the tibialis or soleus muscles; but at 1.5% it was able to antagonize suxamethonium slightly and to potentiate D-tubocurarine markedly.

The preservation of vagal action in the presence of fluothane is an important feature of the anaesthetic, particularly in man, in whom a distinct bradycardia commonly occurs. Although it seems clear that the bradycardia in man is mediated, on the efferent side, by the vagus, its origin is still obscure and deserves further study. The preservation and (in man) activation of the vagal pathway means that effective atropinization may be particularly important with fluothane, especially if a drug such as neostigmine is to be given to accelerate recovery from a muscle relaxant. Among muscle relaxants, gallamine may prove to have a special place in fluothane anaesthesia, for Riker and Wescoe (1951) showed that it had a rather specific action in paralyzing the ability of the vagus to slow the heart. This action is produced by ordinary dosage. Gallamine is virtually devoid

of ganglion-blocking action, and one would anticipate such ganglion block by gallamine to be negligible even after potentiation by fluothane.

Finally, observations were made on the rate of recovery from fluothane. With the blood pressure there is, typically, a fairly rapid partial recovery sometimes followed by a subsequent depression, and then a second much slower phase of recovery. The knee-jerk, however, does not show this biphasic response but recovers more or less steadily, in parallel with the slower phase of return of blood pressure. The duration of recovery depends both on duration of exposure and on the depth of anaesthesia. Thus, after a prolonged or deep exposure it might require up to an hour before blood pressure and knee-jerk could be regarded as normal.

Summary

Fluothane reduces cardiac output in the dog heart-lung preparation. It is about 70% as active as chloroform in this respect.

Fluothane lowers the blood pressure, in the cat under chloralose, more than can be readily accounted for by ganglion block. It is equally active in the animal in which the splanchnic vascular bed is removed by evisceration.

Fluothane depresses the knee-jerk of the cat under chloralose in concentrations from 0.5% upwards. The intensity of this depression, together with its time course, corresponds sufficiently with that of the hypotensive action to suggest that the latter is produced by depression of central vasomotor mechanisms.

Fluothane, though not itself strongly ganglion-blocking, potentiates ganglion block by hexamethonium and D-tubocurarine.

Fluothane up to 4.5% does not paralyse the neuromuscular junction; but it antagonizes suxamethonium and potentiates D-tubocurarine.

CLINICAL INVESTIGATIONS OF FLUOTHANE

by DR. T. H. S. BURNS, PROFESSOR W. W. MUSHIN, DR. G. S. W. ORGANE, and DR. J. D. ROBERTSON

The results of clinical trials with fluothane have been reported by Johnstone (1956) and by Bryce-Smith and O'Brien (1956). The Committee has carried out a trial with fluothane in 245 patients undergoing surgical operations in four teaching hospitals.

Methods

The operations are classified in Table VI. There were 118 males and 127 females. The age distribution is shown in Table VII.

Premedication consisted of morphine and atropine or scopolamine in various combinations according to the requirements of the individual patient and to the practice of the anaesthetist concerned. In a few cases atropine only was given, while in two hydrocephalic infants undergoing neurosurgical procedures a small dose of a barbiturate with atropine was used.

Induction with fluothane and air or fluothane and oxygen was employed in 65 patients, the others receiving a sleep dose of thiopentone sodium before the mask was applied to the face. When adequate reflex depression had been achieved orotracheal intubation by direct-vision laryngoscopy was carried out in most of the cases. Thereafter surgical anaesthesia was maintained with fluothane vapour in air, oxygen, or nitrous oxide and oxygen mixture throughout the surgical operation. In 110 cases no muscle relaxant was used. In 123 other cases a small dose of relaxant was

given before intubation or during the opening or closing of the peritoneal cavity. Usually suxamethonium was employed for this purpose, the average dose being about 50 mg. In 41 cases in the series a competitive blocking type of muscle relaxant was given to see if the cardiovascular effects observed by Johnstone (1956) could be confirmed. Neostigmine sulphate (0.25 mg.), atropine sulphate (0.5 to 1 mg.), and pethidine hydrochloride (up to 50 mg.) were also given in a few cases to observe their effects on the circulation and respiration during fluothane anaesthesia.

In 118 cases fluothane was administered in air or oxygen or nitrous oxide and oxygen from a specially calibrated E.M.O. inhaler (see Appendix B) either for induction and maintenance or during the maintenance of anaesthesia only. Here the concentration of fluothane vapour received by the patient could be accurately determined. On the other hand, in the 137 cases where fluothane was administered from the trichlorethylene bottle of a Boyle apparatus no attempt has been made to assess the fluothane concentration, as it has been shown by Mapleson (see Appendix A) that this varied considerably with small changes in tap setting and temperature. A closed-circuit method was not used in any of the cases referred to in this report in view of the possibility of a rapidly mounting fluothane vapour concentration. A case of fatal cardiac arrest has been reported (Foster, 1957) in which fluothane was used in a closed circuit. The possibility of this being caused by an excessively high fluothane vapour concentration has not been excluded.

In all cases where the peritoneal cavity was opened during the surgical procedure the patient's respiration was assisted or controlled by hand or by a respiratory pump. Otherwise spontaneous respiration was permitted so long as the pulmonary ventilation appeared to be adequate for full oxygenation and carbon dioxide elimination. This allowed observations on tidal exchange and respiratory rate to be made.

The systolic and diastolic blood pressures as measured by a mercury sphygmomanometer, the rate and rhythm of the pulse, the respiratory rate and excursion, and the state of the skin were observed before and at five-minute intervals throughout operation. In addition, in 31 cases the cardiac rhythm was monitored during the period of administration of fluothane and for varying periods after its withdrawal by a continuously recording electrocardiogram. An estimate of blood loss was made by weighing the swabs in 44 cases, and in four patients anaesthetized with fluothane hypotension was induced with a short-acting ganglion-blocking drug "trophenium" (Robertson, Gillies, and Spencer, 1957).

In 10 cases in which major surgical operations were performed under fluothane anaesthesia liver and kidney function has been investigated by a battery of tests on the day before operation, the day after operation, and on one to four subsequent occasions, depending on the findings. In all these cases fluothane vapour in oxygen has been used in known concentrations for induction and maintenance of anaesthesia, and, apart from a small dose of "omnupon" and atropine as premedication, no other sedative, anaes-

thetic, or relaxant drug has been used. The respiration was assisted as required to ensure adequate pulmonary ventilation throughout. A similar investigation has been carried out in a control series of 10 cases, comparable in respect to pre-operative state, type of operation, surgeon, and premedication. In this group standard anaesthetic techniques have been employed, the anaesthetic agents being sodium thiopentone, nitrous oxide, trichlorethylene, cyclopropane, and ether in various combinations. In addition, in some of these control cases muscle relaxants were used—suxamethonium, gallamine, and D-tubocurarine. Pethidine was used in three cases and trimetaphan in two. The average age of the patients was 57.3 years in the control series and 58.7 years in the fluothane series.

Induction

In approximately 85% of our cases the induction with fluothane was pleasant and rapid, sufficient jaw relaxation and depression of the laryngeal reflexes being present to allow orotracheal intubation in six to seven minutes after commencing the administration. However, on several occasions these conditions were not achieved for up to 13 minutes. In some instances the prolonged induction time occurred in robust subjects, but in many it was associated with marked respiratory depression, so that cyanosis frequently occurred when the fluothane vapour was carried in air. Adding oxygen to the mixture or assisting the breathing by the hand-operated bellows of the E.M.O. inhaler speedily restored the patient's colour to normal in all instances, as the respiratory inadequacy was due to under-ventilation and not to laryngeal spasm. In most cases where the concentration of fluothane used for induction could be assessed it was between 2 and 3%, the average maximum concentration during induction of anaesthesia being 2.5%.

We were unable to relate the respiratory depression to the type or dose of premedication used, but where the sequence thiopentone sodium—fluothane by E.M.O. inhaler was employed induction tended to be slower than in cases induced with fluothane and oxygen from the Boyle machine. In the former group some depression of breathing was no doubt due to the action of the barbiturate, while in the latter group the concentration of fluothane was uncertain and was probably considerably higher than 2.5%.

Although struggling and coughing were rarely seen, occasionally mild restraint was necessary, especially following the too early insertion of an oral airway.

Circulation During Fluothane Anaesthesia

Blood Pressure

During induction of anaesthesia with fluothane in air or oxygen or nitrous oxide and oxygen the systolic blood pressure often fell considerably, usually to between 80 and 100 mm. Hg. Following the stimulus of endotracheal intubation there was some recovery of pressure, but this rarely lasted for more than a few minutes and by the start of the operation it had frequently fallen again to under 100 mm. Hg. Immediately after the skin incision a slight transitory rise occurred in most cases before it settled down to a steady level, which, in the presence of efficient pulmonary ventilation, was usually maintained throughout the operation. In about 60% of cases this maintenance level of systolic blood pressure was under 100 mm. Hg and in approximately 25% under 80 mm. Hg. In 17 cases the systolic pressure fell to less than 60 mm. Hg. A reduction in the fluothane concentration was usually associated with a rapid recovery of blood pressure. Despite these low pressures the skin remained pink, warm, and dry. We were sometimes struck by the "brick-red colour" of some patients, but spectroscopic analysis of blood samples obtained from a few cases revealed no abnormal blood pigment.

When the ganglion-blocking agent trophenium was administered to four patients anaesthetized with fluothane, a further fall in systolic blood pressure occurred. In each

case a steady level of systolic blood pressure between 60 and 70 mm. Hg was maintained throughout the operation by adjusting the intravenous drip rate.

A prompt recovery of the blood pressure occurred in every case after the withdrawal of fluothane, so that by the time the patient was ready to leave the theatre the systolic pressure was usually over 100 mm. Hg.

Heart Rate

There was usually some slowing of the pulse rate within a few minutes of starting the administration of fluothane. In most cases this amounted to 15 to 20 beats a minute, but in a few instances the rate decreased by 50 to 60 beats a minute, pulse rates as low as 40 beats a minute being recorded in a few cases. Following intubation or skin incision there was usually a small rise in pulse rate of 10 to 20 beats a minute, which quickly settled again to a maintenance level of between 80 and 100 beats a minute for the duration of the operation. In approximately 45% of cases the rate remained below 80 beats a minute throughout the administration of fluothane. In a few cases when the pulse rate had fallen to 60 beats a minute or below, the intravenous injection of 0.5 to 1 mg. of atropine sulphate raised the rate by 20 to 30 beats. There was little change in the blood pressure following atropine.

In 45 cases the cardiac rhythm was under electrocardiographic scrutiny during fluothane anaesthesia, and in six of these changes of rhythm were observed. In one hypertensive subject exhibiting inversion to the T wave in the pre-operative subject this became upright during fluothane anaesthesia. Short bursts of ventricular extrasystoles were observed in three patients and two developed auriculo-ventricular nodal rhythm. Towards the end of the operation, in one of these cases in which a shift of the pacemaker had occurred, transient periods of alternating bundle-branch block were observed. Irregularities of the pulse were detected in three other cases during the course of anaesthesia with fluothane in which an electrocardiogram was not taken. Two of these showed bigeminy. In some instances the few arrhythmias disappeared spontaneously within a few minutes, but where they persisted a reduction in the concentration of fluothane vapour or the intravenous injection of atropine sulphate, 0.5 to 1 mg., quickly restored the rhythm to normal. On a few occasions where this was done the arrhythmia recurred later in the anaesthesia. There was no clinical evidence of suboxygenation or carbon dioxide retention in any of the cases where alterations in cardiac rhythm were detected.

In most cases bleeding during the operation was reduced, a feature which was favourably commented on by the surgeons. This impression was confirmed by weighing the swabs in 44 cases. The loss was no more than might be expected where hypotension was induced with one of the standard techniques—spinal analgesia or ganglion block.

Respiration During Fluothane Anaesthesia

In the early stages of induction with fluothane in air or oxygen the respirations were deep and regular with little irritation to the airway by the vapour. On the other hand, once consciousness was lost, as has already been mentioned, the breathing became shallow. Where the E.M.O. inhaler was being used with air as the vehicle for the fluothane vapour, cyanosis tended to occur. This reduction in tidal exchange usually persisted during the period of maintenance of anaesthesia with fluothane, some idea of the degree of depression being obtained from the low flow of gases necessary to keep the bellows of the inhaler from collapsing. This reduction in the depth of breathing was usually associated with an increase in rate, 36% of cases showing values of over 30 a minute. In one instance the respiratory rate rose to 60 a minute. Following the intravenous injection of 25 mg. of pethidine a dramatic slowing occurred, respirations dropping within five minutes to 28 a minute. In most cases the breathing tended to be rapid during the first

half-hour or so of fluothane anaesthesia and then gradually slowed to between 20 and 30 a minute during the rest of the administration.

Post-operative Period

The laryngeal and swallowing reflexes returned in most cases within a few minutes of stopping the administration of fluothane, so that the patients could safely be returned to bed at the end of the operation. Recovery of consciousness was, however, more variable (see Table VIII).

TABLE VIII

Duration of Fluothane Administration	Recovery Time (Minutes)	
	Range	Average
Less than 29 minutes	15-60	29.5
30-59 "	15-65	34.5
60-119 "	25-120	70

In one small infant of 7 months, undergoing a neurosurgical investigation of two hours' duration, consciousness returned five minutes after stopping the fluothane and a feed was offered, taken, and retained (!) within half an hour of return to bed.

Vomiting, although never persistent or distressing, was nevertheless not as rare as preliminary reports have suggested (28%). In fact, the ward sisters were inclined to the view that it was no less than with the usual anaesthetic procedures now employed.

Post-operative chest complications requiring active treatment by the physiotherapist occurred in 4% of the cases. These were all in patients who had had an abdominal operation. Three cases had post-operative wound haematoma and one patient in whom mitral valvotomy was carried out was jaundiced for a few days after operation. This, no doubt, was the result of hepatic congestion associated with a degree of right heart failure. There were seven deaths in the series.

Case 1.—One patient, aged 55, who had had a pneumonectomy, died of pulmonary oedema 36 hours later, after a good initial recovery from the operation.

Case 2.—A man aged 44, who had porto-caval anastomosis under fluothane anaesthesia, died from haemorrhage at a second operation at which fluothane was not used.

Case 3.—A patient with a mediastinal neoplasm died from general cardiovascular failure 14 days after an "orlon" graft had been applied to an innominate vein.

Case 4.—A man of 65 with inoperable carcinoma of the bladder went into congestive heart failure and died 48 hours after bilateral ureteric transplantation. A post-mortem examination revealed a large pulmonary embolism.

Case 5.—A workman fell 40 ft. (12 metres) from a scaffolding and sustained a fracture of the cervical spine and base of the skull as well as a compound fracture of the shaft of one femur. He was unconscious on admission and required intubation to maintain a clear airway. As the level of unconsciousness was less profound on the following morning it was decided to apply skull traction and pin fixation of the fractured femur. A tracheotomy was also carried out to allow aspiration of secretions from the air passages. Light anaesthesia with fluothane and oxygen from a Boyle machine lasting 75 minutes was required to keep the patient immobile during these procedures. Twelve hours later he died, as had been expected.

Case 6.—A man of 46 was admitted with perforation of a gastric ulcer and localized peritonitis. The perforation was closed under fluothane anaesthesia. He developed paralytic ileus in the post-operative period and died on the eleventh day following his operation. At post-mortem examination there was generalized peritonitis, a large right anterior subphrenic abscess, and patchy bronchopneumonic consolidation through the right lung.

Case 7.—A man of 56, with malignant ulcer on the left side of the tongue, received fluothane, nitrous oxide, and oxygen from a Boyle apparatus for a period of 30 minutes for total clearance of remaining teeth and biopsy of tongue ulcer. The immediate post-operative state was satisfactory apart from a rise in temperature to 100.4° F. (38° C.) on the evening of operation. Two days later radium needles were inserted into the tongue under

Raventós (1956) carried out two tests of renal and two of hepatic function in several rats and dogs following repeated periods of anaesthesia with fluothane. No significant difference was found between the results of the control tests and those carried out after anaesthesia. None of these cases was subjected to any operative procedure. On the other hand, sections of specimens from these animals revealed dilatation of the proximal convoluted tubules of the kidneys associated with slight cytological changes in the cells of these tubules. He also reports "minor" but

unspecified histopathological changes in the livers. Comparison with the changes produced in liver and kidneys of mice by chloroform is hardly relevant, as chloroform is now rarely used alone as an anaesthetic agent in major surgery in humans.

The striking feature about the results of our studies of liver and kidney function in both the fluothane and the control series is the considerable proportion of cases in which evidence of deterioration of function in one or both organs occurred after operation. Although the anaesthetic agent cannot be excluded as a factor leading to this impairment of function in the post-operative period, there are many other factors connected with a surgical operation which are known to affect the activity of the liver and kidneys. Thus protein catabolism, starvation, dehydration, blood transfusion, absorption of extravasated blood, and alterations in organ blood flow are common to most operations and particularly to those within the abdomen. In addition, minor variations in the technique of collection of specimens or in the biochemical estimations and variable factors connected with the anaesthetic management, such as anoxia, falls in systemic blood pressure, etc., may to some extent account for alterations in the results over the period of study. So far as possible such confusing factors have been avoided in this investigation, but in every case in which deterioration of liver or kidney function was observed several of these were known to be involved.

Further, wherever clinical evidence of impaired function was seen following operation this had either been present in some degree before operation or some obvious cause, such as urinary retention, was present to account for it. It should also be emphasized that many of the patients in this investigation could be classed as "poor surgical risks" who were undergoing extensive procedures involving a considerable degree of tissue damage, metabolic upset, blood and fluid loss, and restriction of fluid intake. Thus, despite the high incidence of deterioration in liver and kidney function observed in this investigation, it is doubtful whether in any single case the anaesthetic agent can be held responsible. The fact that impairment occurred with approximately equal frequency in the control and in the fluothane series suggests that, even if the anaesthetic is a factor, it is unlikely that fluothane is significantly worse in this respect than the other anaesthetics used. Before any definite conclusions could be reached, either a very much larger series would require to be studied or variations in liver and kidney function would have to be observed in a number of subjects anaesthetized with fluothane and with other anaesthetic agents, but not subjected to operation.

GENERAL DISCUSSION

Pharmacological and clinical experience with fluothane agrees remarkably well in several respects. First, both in animals and in man hypotension is produced. The hypotension in man is marked by the retention of a warm pink skin, and by a modest reduction in bleeding during surgical operation; the analogies with hypotension by ganglion block or spinal analgesia are clear. Likewise in the cat, the fall in blood pressure is not accompanied by any signs of sympatho-adrenal discharge, and yields a steady blood-pressure tracing resembling that of the spinal pithed animal more than any other. But neither in man nor in the cat can a general ganglion block by fluothane be plausibly postulated; and the evidence suggests that the hypotension is due to a depression of central vasomotor centres combined with diminished cardiac output.

Secondly, transmission through the vagal ganglia is remarkably unimpaired by the anaesthetic. Although in the cat anaesthetized with chloralose no marked bradycardia occurs, it can be striking in man, and is abolished by suitable dosage with atropine.

Thirdly, in the cat, fluothane can potentiate the ganglion-blocking action of drugs such as hexamethonium or D-tubocurarine. With the latter, ganglion-block is probably not usually of major clinical importance; but under fluothane

it would be expected to become significant. It may be that this accounts for Johnstone's experience clinically, in which he found serious hypotension to follow the use of D-tubocurarine during fluothane anaesthesia. If the possibility of ganglion block is not appreciated, it would be easily possible, by overventilation or by slight postural change, to produce an unexpected hypotension.

Fourthly, the animal and clinical experience described in this report agree in finding that recovery from the anaesthesia is not always as rapid as predicted from earlier reports, although in the blood pressure at least there is regularly a rather prompt *partial* recovery. Further information about the distribution and elimination of fluothane is needed.

Despite our advance in knowledge about fluothane, a final opinion cannot be passed on it at the present stage. Only when several thousand patients have been anaesthetized with it will it become possible to estimate its advantages and disadvantages with accuracy.

Provisionally, it may be said that the properties of fluothane indicate that there is a good hope of finding a safe and pleasant inhalation anaesthetic which is not explosive. Fluothane is an important step in that direction and can provide a flexible and effective anaesthesia. It appears, however, not to be as pleasant as cyclopropane and not to be as safe as ether. It is clear that fluothane should not be administered by an untrained person, because it depresses respiration and may even arrest it during the early stages of administration, and because it depresses the blood pressure. The possible dangers of assisted respiration with a potent drug in the closed circuit have been mentioned. Even in the hands of a skilled anaesthetist wishing to use an anaesthetic given by inhalation, there are certain patients for whom ether or cyclopropane is preferable. For the time being, therefore, the advent of fluothane does not remove the necessity for taking precautions against electrostatic charge and other electrical hazards of operating-theatre equipment.

APPENDIX A

REPORT ON CALIBRATION, FOR FLUOTHANE, OF TRILENE VAPORIZING UNIT OF THE BRITISH OXYGEN GASES LTD., BOYLE-TYPE ANAESTHETIC APPARATUS

BY

WILLIAM W. MAPLESON, Ph.D.

Physicist to the Department of Anaesthetics, Welsh National School of Medicine, Cardiff

The fluothane concentration emerging from the Boyle apparatus was determined by passing oxygen through it and drawing a sample, at the outlet, through a katharometer. The katharometer was calibrated by a mixture of fluothane in oxygen, saturated at a known temperature.

The main factors which affect the emergent concentration of fluothane are: (1) gas flow; (2) distance from plunger to fluothane surface; (3) temperature of fluothane; and (4) tap setting. The factor of varying eccentricity of plunger and U-tube was eliminated in all units calibrated by adopting the Hillard (1957) modification.

1. In these calibrations the gas flow was kept constant at 7 litres a minute.

2. It was found that, although the concentration generally decreased as the plunger-to-surface distance increased, there was a tendency to a "flat" in the characteristic. Thus a suitable setting of the plunger, different for different units, could be selected, so that a fall in liquid level from the 24- to the 16-drachm mark had very little effect on the concentration. (This represents about one hour's use at 1½% fluothane.) Outside this range the concentration may fall by as much as one-third for an evaporation of 8 dr. (28 ml.). By requiring that the liquid level be maintained between 24 and 16 dr. (84 and 56 ml.), and by fixing the plunger in the appropriate position, a calibration could be prepared in terms of tap setting and fluothane temperature.

3. The effect of fluothane temperature on concentration is considerable: a fall from 25 to 15° C. (which is not uncommon in clinical usage) reduces the concentration by one-third (see calibration graph, Fig. 10).

4. Small changes in tap setting gave large changes in concentration: a movement of 1 or 2 mm. was sufficient to change the concentration by ½ to 1% fluothane.

In the old style tap, manufactured before January 1, 1947, the effect was so marked that units incorporating these taps were rejected. Variation between individual taps necessitated the individual calibration of each vaporizing unit.

Since making these calibrations Falkner Hill (1957) has published some measurements made on a modified trilene unit. The concentrations he obtained were somewhat lower than those shown in Fig. 10, but the discrepancies could well be due to the different conditions.

Fig. 11.—Typical calibration of one vaporizing unit for four temperatures of the liquid fluothane. The tap-setting numbers refer to the four horizontal lines, alongside the lever, which separate the words "off" and "on." The lines are spaced at approximately 1-cm. intervals.

APPENDIX B

INHALERS USED IN TRIALS FOR ADMINISTERING MIXTURES OF FLUOTHANE VAPOUR WITH AIR OR WITH MEDICAL GASES

BY

DR. H. G. EPSTEIN

Nuffield Department of Anaesthetics, Radcliffe Infirmary, Oxford

The inhalers used both for clinical and for pharmacological trials were based on the apparatus (E.M.O.) developed in recent years for ether anaesthesia (Epstein and Macintosh, 1956). These possess a concentration scale calibrated up to 20% ether vapour, and a temperature compensator which ensures that within a range of from 60 to 85° F. (15.5 to 29.4° C.) the concentrations remain fairly constant. The ether concentrations delivered vary only slightly for respiratory minute volumes from 7 to 12 litres.

The original plan of using these standard inhalers with only slightly modified concentration control and thermocompensator had to be abandoned when the particular chemical properties of fluothane became better known. A prototype inhaler used with fluothane since October, 1955, showed progressive corrosion of certain parts. Some months later it had become obvious (a) that fluothane vapour in the presence of atmospheric air strongly corrodes light metal alloys as well as tin; and (b) that most of the common, resilient gasket materials made from artificial rubber and other elastomers are attacked to varying degrees.

Various protective methods were tried in the inhalers used for the trials. In the latest models corrosive attack has been excluded by covering all exposed metal parts with a nylon layer and by using gaskets made from similar materials.

Fluothane which had been kept in one of these inhalers which was in regular use for two months in the trials was

examined by Professor Stacey's department. Gas chromatography, infra-red spectroscopy, and chemical analysis showed it to be indistinguishable from the contents of a fresh bottle of fluothane supplied by the manufacturers.

Inhalers for Clinical Trials

Concentration Range.—The concentration control was modified to permit administration of vapour up to 3 or 4% (v./v.) in some of the inhalers. Preliminary investigations on animals had shown that the maximum concentrations required in clinical work was unlikely to exceed these values.

Temperature Control.—In order to avoid further delays, no attempt was made to adapt the temperature compensator for a wide range of ambient temperatures. It was considered adequate to limit accurate regulation of concentrations to a range of from 65 to 75° F. (18.5 to 24° C.). Actually the regulation was quite satisfactory for clinical work even outside this range. Thus, for a fixed minute volume the variation in concentration with the control set to the 2% mark was less than 0.1% (v./v.) when the temperature rose from 63 to 85° F. (17 to 29.4° C.).

Calibration.—The concentrations delivered at varying temperatures and flow rates were measured by means of a gas refractometer. Intermittent flows of air between 5 and 10 litres a minute, simulating the patient's respiration, were passed through the inhaler and samples of the output were analysed continuously. The absolute concentration values were based on calibration of the analyser with known fluothane/air mixtures and also on published values for the refractive index (I.C.I., 1956).

Effect of Respiration.—The vapour density of fluothane is approximately two and a half times that of ether, and without special modifications of the ducts in the inhaler an increased variation of concentration with respiratory minute volume was to be expected. Nevertheless, for minute volumes down to 6 litres the concentrations decrease only slightly. An inhaler delivering 2.8% (v./v.) at 9 litres a minute (22 respirations a minute), gave an output of 2.6% at 6 litres a minute. The concentration decreased to 2.1% at 5 litres a minute and to 1.9% at 4 litres a minute. For a lower setting of the concentration control the variations in vapour strength are less pronounced.

Use of Inhaler.—In view of the very low respiratory exchange which may occur during fluothane anaesthesia, certain rules should be observed to ensure that the strength of mixture delivered to the patient is known with reasonable accuracy. (a) When the apparatus is used as a draw-over inhaler for fluothane/air mixtures, the bellows unit containing the non-return valves is inserted between inhaler and patient.* As mentioned above, the vapour strength would decrease appreciably if the respiration fell to 5 litres a minute or below. Repeated manual depressions of the bellows followed by their unimpeded expansion will flush the system with the correct mixture so that the inhaled concentration is again near that indicated by the concentration control. (b) If medical gases are to be given with fluothane vapour, the inhaler should be inserted between the bellows unit and the patient. The medical gases are best admitted to the main inlet of the bellows unit, whereby inadvertent dilution with air is avoided. This arrangement permits also an approximate estimation of the respiratory minute volume, by adjusting the metered gas flow until the bellows oscillate about their normal position. There is another advantage in adjusting the gas flow to the patient's requirements: if the flow should greatly exceed the respiratory requirements, the vapour strength delivered would deviate from the indications on the concentration scale; the present procedure considerably reduces such variations.

Inhalers for Pharmacological Investigations

Most of the apparatus for the pharmacological investigations with fluothane, trichlorethylene, and chloroform were based on the standard E.M.O. inhaler. In order to ensure

*See brochure supplied by Pentland Instrument Co. Ltd.

Case 4.—A multipara was referred for consultation because of a slight red "show" at the 38th week of pregnancy. Abdominal palpation showed that the head was mobile and free in the abdomen and prominent anteriorly, and pressure backwards on

the foetal head on to the sacral promontory caused slowing of the foetal heart. Posterior placenta praevia was diagnosed clinically, and placentography was reported as showing a posterior placenta praevia of first degree. The patient was admitted to hospital for observation and a recurrent unstable foetal lie was noted until term. Examination under anaesthesia revealed a posterior placenta praevia of third degree, and this was confirmed at caesarean section.

In the whole series there were 12 cases in which a major degree of placenta praevia was reported on placentography, and 11 were proved correct at caesarean section. In one patient (Case 5) the x-ray report was erroneous.

Case 5.—A multipara had a high and free foetal head at term, and placentography purported to show an anterior wall placenta of probably second or third degree praevia. The patient was admitted to hospital, and the foetal head gradually became more and more deeply engaged without any ante-partum haemorrhage. Vaginal delivery was accomplished easily with a blood loss of 12 oz. (340 ml.). Inspection of the placenta and membranes was inconclusive.

Placenta Praevia

In the complete series of 80 patients there were 25 cases of placenta praevia. Placenta praevia of first degree occurred in 11 patients, of whom 10 were delivered vaginally with a blood loss in each case of 8 oz. (2,207 ml.) or less, and one patient was delivered by caesarean section for foetal distress.

Major degrees of placenta praevia were found in 14 patients, all of whom were delivered by lower segment caesarean section. Elective operations were performed on six of these patients in whom no ante-partum haemorrhage had occurred at all, and on 11 patients without any examination under anaesthesia. Only three patients with major placenta praevia were submitted to examination under anaesthesia; once because an upper segment placenta had been predicted but ante-partum haemorrhage had later occurred (Case 2); once because placenta praevia of first degree had been predicted by x-ray examination (Case 4); and once to confirm a prediction of posterior placenta praevia of third degree. Examination in this last case provoked an instantaneous torrential haemorrhage, and this could have been avoided had we followed our present custom and acted on the radiological findings.

The results at delivery in the 25 cases of placenta praevia were satisfactory, for there were no maternal or foetal deaths. Indeed, in the whole series of 80 patients, which included a large number of obstetric abnormalities, there were no maternal, foetal, or neonatal deaths. The success of conservative measures in avoiding the hazards of prematurity can be illustrated by the birth weights in the 25 cases of placenta praevia; they averaged 7 lb. 2 oz. (3.2 kg.) and only two babies weighed 5 lb. 8 oz. (2.5 kg.) or less. The average birth weight of the other 55 cases with upper segment placentae was 7 lb. 9 oz. (3.4 kg.).

Discussion

Radiography for the location of the placenta is a technique only recently evaluated and adopted in Great Britain. The results obtained in those centres which have developed it have been remarkable for their consistency and accuracy. Despite these successes the technique has not been used universally, because many obstetricians distrust it. In a recent discussion of the problem Donald (1955) stated: "This is a method which has been employed with varying success during the last twenty years, although there are few who regard it as sufficiently reliable." From the practical point of view, most obstetricians are of the opinion that, however interesting this method of location may be, the results cannot be trusted, and it is felt that no stay in hospital is likely to be curtailed or dispensed with as a result of radiological investigation. This may indeed be the opinion of most obstetricians, but we disagree with it completely. From the practical point of view, it is our experience that the results of this essentially practical technique are sufficiently reliable and can be trusted.

The accuracy and reliability of placentography without the use of contrast media are remarkably high. Even when all borderline and doubtful cases are labelled as misdiagnoses the number of mistakes is small. Considering that the x-ray films are usually taken several weeks before term, when the lower uterine segment is incompletely developed, and when the relationship between the junction of the upper and lower uterine segments to the level of the bony pelvis is uncertain, the results are closely correlated to those found at term or at birth. Hartley (1954) reported an accuracy rate of radiological diagnosis of the placental site of 98% out of 365 cases in one year, and over 99% out of 351 cases in the following year. Percival and Murray (1955) recorded an accuracy rate of over 96% in a series of 275 cases, which included 50 instances of placenta praevia. We have obtained an accuracy rate of 94% in our series of 80 cases containing 25 placenta praeviae. Other larger series were mostly routine examination of antenatal patients, and slightly better results can be expected with a higher proportion of upper segment placentae, which are easier to visualize. We have here shown that placentography on definite clinical indications can yield useful results.

Placentography is not fool-proof and does not give "penny-in-the-slot" machine answers. The radiographic technique must be careful and exact, but it is not time-consuming, needs no expensive or complex equipment, requires no special preparation of the patient, and its routine performance can be left to a radiographer schooled in this method. The technique is not more difficult to master than the technique of x-ray pelvimetry, and any department which can produce reliable pelvimetric results should be capable of reliable placentographic results. Patients may have placentography and pelvimetry examination combined when indicated.

Interpretation of the film requires practice and judgment, and close co-operation between the radiologist and the obstetrician. The films are examined when completely dry both before an ordinary viewing-box and before a screened illuminator with spotlight, to look for calcification. Placental calcification lends precision and certainty to the radiological location and should therefore be sought in every case.

The accuracy of the radiological location of the placenta is greatest when it is sited in the upper segment, and it is not possible to achieve the same degree of accuracy in placenta praevia. Difficulties in interpretation rarely arise with placentae which are wholly upper-segment, fundal, or cornual in their siting, whether they are implanted on the anterior, lateral, or posterior uterine walls. Most difficulties occur in assessing the exact lower edge of the placenta and the precise degree of praevia. In some cases greater accuracy is obtained by repeating the lateral films at a later stage of pregnancy.

Whitehead (1953) examined 525 cases where placenta praevia was suspected clinically. He predicted 455 upper segment placentae, all of which predictions proved to be correct; and 70 cases of placenta praevia, 9 of which were not confirmed. In this series 23 cases were confirmed as placenta praevia and in 20 the degree of encroachment on to the lower segment was correctly estimated.

The obstetrician who selects cases for placentography must eliminate so far as possible any factors prejudicial to accurate radiological assessment. Patients with marked hydramnios are unsuitable for placentography. Donald (1955) has asserted that the multipara with a lax abdominal wall is also unsuitable; we do not think this is true, as over half of our series were multiparae. An undiagnosed soft-tissue pelvic tumour is a possible source of error in interpretation of the films, and the obstetrician may have to exclude this clinically. But a positive x-ray diagnosis of soft-tissue tumour is possible when the mass is large enough to displace the presenting part from its normal relationship to the pelvic brim and at the same time a clearly separate placental shadow is visible (Reid, 1952).

Clinically, placentography is required in all cases of ante-partum haemorrhage where the patient's condition permits

the examination. Even if the haemorrhage occurs in a patient known to have pre-eclamptic toxemia, placenta praevia cannot be discounted. Ante-partum haemorrhage from the placental site in a case of placenta praevia may be due to partial separation consequent upon the taking up of the lower segment, or due to toxemic accidental haemorrhage or to non-toxaemic causes of accidental haemorrhage (Bender, 1953). The timing of the initial haemorrhage in placenta praevia is very variable. Even if the bleeding occurs before the 28th week of pregnancy, it must be regarded as suggestive of placenta praevia, and placentography should be performed after the 32nd week, when location is more certain than earlier in the gestation. Also, although cases of ante-partum haemorrhage may be divided into those associated with and those without clinical displacement of the presenting foetal part (Table II), placentography should be performed in all cases. Significant degrees of placenta praevia may be found without clinically obvious displacement of the presenting part. On the other hand, cases of ante-partum haemorrhage with gross foetal displacement of the presenting part will contain a significant number of normally sited placentae. All these factors emphasize how inaccurate is the clinical diagnosis of placenta praevia contrasted with the higher degree of accuracy of placentography.

Great as is the value of placentography in all patients with ante-partum haemorrhage, its value is greater still in the diagnosis of placenta praevia before ante-partum haemorrhage has occurred. Here it is that clinical methods of diagnosis are most defective, and the correct use of placentography constitutes a major advance in the management of these cases. Clinically, the suspicion of placenta praevia is commonly aroused by cases of unexplained instability of lie, or unexpected lack of engagement of the presenting part in the pelvic brim, in the absence of disproportion. Especially important are cases of transverse or oblique foetal lie in the last six weeks of pregnancy. We found 8 placenta praeviae in 17 cases of transverse lie (47%). Stevenson (1951) studied by placentography 52 cases of transverse or oblique lie, and found the major causes to be placental implantation either wholly at the fundus (46%) or wholly in the lower segment (44%). Our experience closely tallies with that of Stevenson. The relationship thus shown of the effect of placental implantation on foetal lie is remarkable and certainly deserves careful consideration in each case. Interpretation of the films in cases of transverse lie is sometimes difficult, but in most cases a correct answer can be obtained. Occasionally it can be facilitated by the obstetrician very gently performing external version, with the patient lying on the x-ray table, in an endeavour to ensure a longitudinal lie at the time of the exposure.

The modern management of placenta praevia has been developed to achieve the greatest safety for both mother and child. Stallworthy (1951) has declared that an ideal standard should be aimed at would be no maternal mortality and less than 10% foetal wastage. The greatest maternal hazard is haemorrhage, and the greatest foetal hazard is prematurity. The initial haemorrhage in placenta praevia may occur at any period of gestation until the first stage of labour, and may vary in amount from a slight red "show" to a sudden loss of pints of blood.

Placentography affords a safe and accurate diagnosis of the absence of placenta praevia, and a safer and more accurate diagnosis of the presence of and the degree of placenta praevia than has hitherto been available. The x-ray diagnosis is becoming reliable after the 32nd week of pregnancy, and consideration of the x-ray diagnosis and the clinical features will enable the optimal time, place, and mode of delivery to be decided.

The advent of placentography has modified the management of ante-partum haemorrhage and placenta praevia. Before term, all patients in whom placenta praevia is suspected are x-rayed whether or not bleeding has occurred. This and other series show that accurate diagnosis of upper segment implantation can be made by placentography, and this reduces the number of patients retained in hospital, and

indeed some may be judged safe and suitable for domiciliary delivery. If placentography confirms the presence of placenta praevia, then the patient is retained in hospital and compatible blood is cross-matched in readiness. If the films indicate a major degree (types 3 and 4) of praevia, then all vaginal examinations are eschewed and vaginal examination under anaesthesia is not performed. A planned elective lower segment caesarean section is carried out in the 38th week, or before if bleeding necessitates it. In anterior placenta praevia, the uterine incision is placed so as to minimize trauma to the placenta and reduce haemorrhage from mother and baby (Russell and Warrick, 1955).

If the x-ray report discloses a posterior placenta praevia of first or second degree, the patient is admitted to hospital and observed closely, for this siting is dangerous, and may occasion compression of the cord (Stallworthy, 1951). The final assessment of these cases depends on clinical findings, and vaginal examination under anaesthesia plays no part. If disproportion at the pelvic brim is present, elective caesarean section is performed. If foetal distress develops during engagement of the foetal head in the pelvis, the administration of nasal oxygen and emergency caesarean section are required. If the foetal head engages fully without any irregularity of the foetal heart, vaginal delivery at term will be awaited, but throughout labour a constant watch for foetal distress must be maintained.

If the radiologist reports an anterior placenta praevia of first or second degree, careful daily assessments will be made in hospital of the engagement of the foetal head in the pelvic inlet. In many cases full engagement will occur spontaneously and a successful vaginal delivery will result. But, if the foetal head does not engage in the pelvis, vaginal examination under anaesthesia is made to ascertain the exact lower edge of the placenta and whether or not the head can be made to engage; the alternative treatments of immediate caesarean section or rupture of the membranes will depend on the result.

The revaluation of vaginal examination under anaesthesia has been one of the benefits of the use of placentography. The traumatic haemorrhage which vaginal examination may provoke in major degrees of placenta praevia may be torrential and deadly to both mother and foetus. Experience has shown that there is no place for this manoeuvre where the clinical suspicion of major placenta praevia has been confirmed by placentography. There is equally no place for examination under anaesthesia where radiology shows posterior placenta praevia. This leaves only two indications for vaginal examination under anaesthesia; firstly, the appraisal of minor degrees of anterior placenta praevia where the radiograph fails to define clearly the lower edge of the placenta, and the foetal head does not engage in the pelvis; and, secondly, the elucidation of cases of ante-partum haemorrhage admitted at term or in labour where the diagnosis is in doubt and placentography is inexpedient. Even in the latter cases vaginal examination is best avoided if abdominal palpation reveals a transverse lie or obvious displacement of the presenting foetal part.

Summary

Radiography provides a safe, convenient, and efficient method of locating the site of placental implantation.

A series of 80 cases is presented in which placentography was performed for clinical reasons, with an accuracy rate of placental location of 94%. There were 25 cases of placenta praevia, of which 14 were delivered by caesarean section. There was no maternal, foetal, or neonatal mortality in the whole series.

The clinical indications for the performance of placentography are discussed. Among others, a significant relationship between transverse lie and placenta praevia is mentioned. The value of placentography in the conservative management of the varieties of placenta

praevia is discussed. Stress is laid on the avoidance of vaginal examination under anaesthesia in cases of major degrees of placenta praevia.

Placentography is of the greatest importance in the diagnosis of placenta praevia before the occurrence of ante-partum haemorrhage and will permit definitive treatment.

The exclusion of placenta praevia by placentography in cases of ante-partum haemorrhage makes it possible to send some of these patients home to await delivery, thereby saving hospital beds.

We wish to acknowledge the help given by the radiographers, midwives, and resident medical officers of Solihull Hospital, who have all greatly assisted in the care of these cases.

CYSTICERCOSIS OF THE BRAIN

BY

C. ARSENI, M.D.

Associate Professor of Neurosurgery, Postgraduate Institute of Medicine, Bucharest, Rumania

AND

D. C. SAMITCA, M.D.

Cerebral cysticercosis has been known for many years. Ramler is said to have described a case in 1558, and in 1650 Paracelsus came to the conclusion that the epileptic fits of one of his patients were due to this condition. Nowadays it is rare, the highest incidence being in India and South America.

Here is reviewed a personal series of 65 cases seen at the Postgraduate Institute of Medicine, Bucharest, during the years 1935 to 1955. The patients came from all over Rumania.

Aetiological Factors and Associated Cerebral Disease

Cerebral cysticercosis is commoner after the age of 20 (see Table). Of our 65 patients (37 males and 28 females), 23 were under 30. Changes in the mucous membrane of

Age Distribution of 65 Cases of Cerebral Cysticercosis

Age Group (Years)	No. of Cases	Age Group (Years)	No. of Cases
0-10	2	30-40	16
10-20	4	40-50	15
	17	50-	11

the alimentary tract and a diminished gastric acidity are recognized as being two of the most important factors that determine infestation with cysticerci. In the patient's personal history there may sometimes be a record of taeniasis. This was so in six of our cases. Neurological symptoms appeared shortly after the intestinal disturbance, and in such cases auto-infestation is almost certain.

Cysticerci are usually found limited to a single organ, and only exceptionally in several. In 90% of our cases the cysticerci were limited to the brain; a second tissue besides the brain was affected in only 10%—muscles (4%), subcutaneous tissues (4%), retina (2%). Cysticercosis may co-

exist with a primary or metastatic brain tumour, with syphilis, or with cerebral injuries. One of our cases had a primary glioma of the brain stem, and in two cases there were multiple cerebral metastases of pulmonary origin; in one case there was associated syphilis (four patients had a positive blood Wassermann reaction); in one patient who died from a cerebral injury cysticercosis was discovered at necropsy.

Clinical Manifestations

The duration of symptoms prior to admission to hospital varied from a few weeks to several years. Twenty-three of our cases were admitted less than six months after the onset of symptoms, 19 between six and twelve months after onset, and 23 more than a year after. In one-third of our cases the onset was sudden, while in the remainder it was gradual. In about two-thirds of our cases the course of the disease was intermittent.

Clinical symptoms arise solely from the presence of cysticerci within the nervous system. They depend both on the number of parasites and on their precise loca-

FIG. 1.—Microscopic view of an intracerebral cysticercus, showing hooklets. (Reproduced by courtesy of D. Bagdasar, F. Bagdasar, and I. Bazgan from *Bull. Soc. med. Hôp. Bucarest*, 1935, 17, 6.)

tion within the brain. Such other factors, as whether the cysticercus is alive or dead and the tissue reactions within the brain (cerebral oedema, arachnoiditis, ependymitis), are also of importance.

Onset

Symptoms of the initial stage of cysticercosis comprise: (1) early and very intense signs of intracranial hypertension; (2) epilepsy; and (3) a pseudomeningeal reaction. Fifty-two of our patients had signs of intracranial hypertension at the onset, usually headache and less often vomiting. In 26 cases epileptic seizures were the first symptom, occurring either alone or associated with headache. Very often epilepsy remains the only symptom of the disease for quite a long time, the case then perhaps being regarded as one of idiopathic epilepsy. In five of our patients the onset consisted in only mild and transient meningeal symptoms, which sometimes recurred.

When fully developed, cerebral cysticercosis may give rise to a syndrome of marked intracranial hypertension, as occurred in 56 of our cases. Headache, vomiting, vertigo, and changes in the optic disks are the chief manifestations. Headache was found in all 56, either alone or, as in 29 cases, associated with vomiting. Depending on the number and location of the cysticerci, headache may be slight (when there are few parasites), severe (when there are many), intermittent (when there are parasites within the ventricles), or continuous. Vomiting was always associated with headache. Fundal changes were found in 39 cases, 35 showing papilloedema and 4 secondary optic atrophy.

Mental disturbances, due to involvement of the brain as a whole and mostly confusional in type, may accompany intracranial hypertension. They occurred in eight of our cases, being met with equally in cortical and basal

Epilepsy and Meningeal Symptoms

Epilepsy is common in cysticercosis of the brain. It occurred in 31 of our cases during the fully developed stage of the disease. The incidence of epilepsy and its clinical variants depended on the situation of the parasite within the cerebral cortex; on the proximity to the so-called epileptogenic area; on the number of parasites and hence of potential epileptogenic foci; and, lastly, on whether the cysticercus was living or dead. At the time of infestation and during the stage of calcification of the cysticercus, a larger amount of toxin is elaborated, giving rise to more severe symptoms and also to epileptic seizures. At these times Jacksonian or generalized convulsions may occur frequently, and sometimes even a "status epilepticus." This last condition may persist for several days, being followed by a symptomless period of a few months or even years; it may, however, recur in the same way as before. In 10 of the 31 cases in which epilepsy occurred the fits were grand mal in type; in 20 there were Jacksonian fits, starting sometimes in one segment, sometimes in another; and in one there were akinetic seizures.

Epilepsy may occur without any regular periodicity; the fits may be intermittent, or they may occur in outbreaks of several fits at short intervals. In 10 cases the fits occurred without any periodicity, in 16 they were intermittent, and in 5 there were outbreaks of several fits at a time.

Meningeal symptoms included fever and stiffness of the neck. Attacks of meningitis occurred, lasting some hours or days, then subsiding for a while and reappearing after a symptomless period. Such meningeal symptoms are provoked by toxins liberated by the cysticerci. The toxins circulate in the cerebrospinal fluid and cause a meningo-ependymitis.

Various Neurological Syndromes

The neurological syndromes in cerebral cysticercosis are related to the anatomical location of the parasites and to their actual number. A single parasite, or only a few

FIG. 2.—Vertico-frontal section through brain. Cysticerci are localized in cortex. A somewhat bigger subpial cysticercus is visible.

cysticerci situated within a silent area, may not give rise to symptoms, and may be found incidentally at necropsy. Cysticerci in the motor or sensory areas will always give rise to epileptic seizures, but symptoms of intracranial hypertension are uncommon and usually mild, the Jacksonian or generalized epileptic seizures being the only clinical manifestation. The fits occur in groups of repeated convulsions over the course of a few days, followed by a long symptomless period; Jacksonian epilepsy may be unilateral or bilateral (alternating Jacksonian seizures). If there are many cysticerci in the brain, in addition to intracranial hypertension and epilepsy, there may be various

focal manifestations depending on the areas affected. In our series 18 cases had a cortical cysticercosis (Figs. 2 and 3).

One or more cysticerci may be found within each lateral ventricle, or in the third or fourth ventricle. They float freely in the ventricular fluid, and produce symptoms of intraventricular tumours. In our series 10 cases had ventricular cysticercosis.

At the base of the brain cysticerci are usually numerous and large in size. Here they may block the basal cisterns and cause severe internal hydrocephalus. Cysts in the posterior fossa give rise to severe symptoms of intracranial hypertension and mild cerebellar symptoms, which may be unilateral or bilateral. Cysticerci may lodge near the brain stem or within the ponto-cerebellar angle, on one side or both, giving rise to symptoms characteristic of these sites. Cysticerci may occur in the middle or anterior fossa at the base of the brain, the symptoms varying according to the site. Frequently, basal cysticercosis involves the whole base of the brain and thus gives rise to a complex supra- and sub-tentorial group of symptoms, to which are added symptoms of a severe leptomeningitis. Generalized epileptic fits, and infratentorial tonic seizures due to brain-stem disturbances, may also occur. In our series there were 19 cases of basal cysticercosis.

Generalized and Suppurative Cysticercosis

In diffuse generalized cysticercosis there are hundreds of parasites. The course of the disease is rapid, with a marked oedema due to the toxins of the parasite, intracranial hypertension, mental disturbances, epileptic seizures, meningeal symptoms, fever, drowsiness, and diffuse neurological symptoms. Eighteen of our cases had diffuse generalized cysticercosis.

Suppurative cerebral cysticercosis is very rare. It is due either to the transportation of bacteria with the oncospheres or to delayed secondary infection. In either case a cerebral reaction may occur after the death of the parasite and thus an aseptic suppuration may take place. We had a single example of aseptic suppuration, in a case of long-standing calcified cysticercosis. The patient was an adult with a hydrocephalic skull.

Clinical Course

The progress of the disease depends on the number of parasites, their location, and the reaction of the nervous system to the infestation. If the infestation is massive there will be severe symptoms of intracranial hypertension, and

FIG. 3.—Cysticerci situated at junction of grey and white matter of brain.

FIG. 4.—Cysticerci situated in thalamus near the ventricular wall.

the patient soon seeks medical aid. If there are few cysticerci they may lead only to epilepsy, without any other symptom developing for years.

The course is intermittent, with acute phases followed by long intervals of improvement during which both subjective and objective symptoms are entirely in abeyance. In patients in whom the onset of symptoms is abrupt the prognosis is bad, whereas in those with a gradual onset the general outlook is much better.

Ancillary Investigations

There are certain biological reactions due to the effects of the toxin elaborated by the parasite. We found that the blood eosinophil count was above 3% in 19 cases, and above 6% in 13 cases (in one it was as high as 20%, in another 16%). In the cerebrospinal fluid eosinophilia may occur, with lymphocytosis, a high albumin content, and a colloidal-gold curve similar to that in syphilis.

Serological tests, which may be positive, include Vosnia's specific precipitation test, using an antigen prepared from mealy pork, and a complement-fixation test with an antigen prepared from cysticerci from pigs. These reactions are positive while the brain is being invaded by cysticerci or when they die—that is, when toxin is being elaborated—but negative in the silent periods of the disease.

Ophthalmoscopy and general physical examination (skin, muscles) may also help by revealing the presence of cysticerci at various other sites.

Radiographical Appearances

Plain radiography of the skull may yield a normal picture, or there may be evidence of intracranial hypertension and

a number of round, discrete areas of calcification may be seen, each the size of a millet grain, distributed either haphazardly (Fig. 5) or in lines. Radiography of the skeletal muscles may reveal calcified cysticerci which are elongated bodies resembling a grain of rice. Plain radio-

FIG. 7.—Filipov's sign (see text).

FIG. 8.—Mechanism of Filipov's sign in cysticercosis.

graphy of the skull showed no abnormality in 40 of our cases, intracranial calcifications in 7, and signs of intracranial hypertension in 18.

If there is no papilloedema, pneumo-encephalography may be performed; if papilloedema is present, ventriculography is indicated. Pneumo-encephalography usually shows no abnormality, but there may be severe hydrocephalus from basal leptomeningitis or signs of cortical atrophy. In early cases without marked leptomeningitis it may be possible to demonstrate Filipov's sign of the "clear vesicle" (Figs. 7 and 8). On the skiagram translucent spherical or ovoid areas, the size of a lentil or a bean, may be seen, with a very clear centre, darker towards the edges and with a sharply defined outline.

Ventriculography may prove normal, as when there are few parasites with a cortical distribution; or it may show small ventricles (multiple cortical parasitic cysts). There may be a hydrocephalus with dilatation of the third ventricle, as when cysts lie in the posterior fossa; or hydrocephalus with an upward displacement of the third ventricle (Fig. 9) if parasites have invaded the base of the brain. The ventricles may show irregular margins (ventriculitis), and occasionally a cysticercus may be seen attached to the ventricular wall (Fig. 10). Ventriculography was carried out in 35 of our patients. In 32 a symmetrical internal hydrocephalus was found; in one the appearance was normal; in one there were very small ventricles; and one gave a picture suggesting a brain tumour.

Differential Diagnosis

A positive diagnosis can be based upon such pathognomonic signs as intracranial calcifications, the pneumo-encephalographic signs of Filipov, and the serological test of Vosnia. The diagnosis is suggested by an intermittent development of clinical symptoms with remission, evidence of raised intracranial pressure, and few and diffuse neurological symptoms. To these suggestive clinical pictures may be added evidence, such as may be found in the above-

FIG. 5.—Lateral skiagram of skull showing signs of increased intracranial pressure, as well as many small round intracranial calcifications.

FIG. 6.—Pneumo-encephalography; antero-posterior view. Calcified suppurative cerebral cysticercosis. Both frontal horns are compressed by the suppurative process. Multiple intracranial calcifications are shown.

mentioned ventriculographic findings, a history of infestation with *Taenia solium*, and the presence of cysticerci in other parts of the body (retina, muscles).

The differential diagnosis must exclude any intracranial space-occupying process, such as cerebral tumours, including tuberculoma and metastases, abscesses, subdural haematoma, and pseudo-tumour cerebri.

The course of the disease, the previous history, the present condition, and the auxiliary tests may establish the diagnosis by itself.

Prognosis and Treatment

The prognosis is poor in generalized, basal, or ventricular cysticercosis. Patients die as a result of raised intracranial pressure or ventricular block. Cortical cysticercosis runs a more chronic course. In cortical cases with only a few cysts there may be spontaneous remissions followed by relapse.

The only non-operative treatment is the administration of anticonvulsant drugs if there are fits. In cortical or ventricular forms, however, the parasites may be excised surgically. In generalized or basal cysticercosis extensive bilateral decompression should be performed to relieve the severe intracranial hypertension.

We operated on 48 of our 65 patients; in 20 cases large decompressive craniotomies were performed, in 7 a decompression according to Cushing's technique, and in 21 the posterior fossa was explored. Wherever possible the cysticerci were excised during the operation. The operations

were well tolerated and complications rare. Cerebral oedema was treated by massive dehydration and daily lumbar puncture. In the ventricular form, if collapse occurs after tapping the ventricles the patients must be rehydrated.

In the successful cases the signs of raised intracranial pressure disappeared, as did most of the neurological signs. Convulsions, however, continued. Of the 48 patients submitted to operation 11 died at or within a short time of operation, and two more 1 and 2½ years post-operatively respectively. There was no operative mortality with the 12 cases of cortical cysticercosis; but 2 of the 6 ventricular cases, 4 of the 17 basal cases, and 5 of the 13 generalized cases died after operation.

Summary

A personal series of 65 cases of cerebral cysticercosis seen in Bucharest is presented.

Their clinical features and the results of laboratory and radiological examination are described. Operation was performed in 48.

Differential diagnosis and prognosis are discussed.

PROTEUS INFECTION OF URINARY TRACT, WITH SPECIAL REFERENCE TO TREATMENT WITH NITROFURANTOIN

BY

J. E. MIDDLETON, B.M., M.R.C.P.

Assistant Lecturer in Clinical Pathology,
Louis Jenner Laboratory, St. Thomas's Hospital and
Medical School, London

Infection produced by potentially pathogenic commensal organisms resistant to the chemotherapeutic agents in general use is becoming prevalent as their more virulent competitors are eliminated by these agents. Among such resistant organisms discussed by Bryer (1955) are members of the *Proteus* group. In the last few years there have been several reports in the American literature on the use of nitrofurantoin ("furadantin") in infections of the urinary tract due to proteus, notably by Richards *et al.* (1955). This relatively non-toxic drug, active *in vitro* against many Gram-positive and Gram-negative bacteria, including the *Proteus* group, is excreted in high concentration in the urine following oral administration, although effective blood and tissue levels are not produced.

The *British Medical Journal* (1955) and the *Lancet* (1955) suggested that it might prove a helpful addition to the established urinary antiseptics, especially in the treatment of proteus infections, but there have been few reports of its use in the British literature. Heffernan *et al.* (1955) and McGeown (1956) recorded only moderately satisfactory results in a small number of cases.

The sensitivity tests performed *in vitro* in this laboratory against *Proteus* strains showed that many were resistant to the commonly used antibiotics but sensitive to nitrofurantoin. A series of patients with a known proteus urinary infection was therefore studied so as to determine whether the response to treatment reflected these observations.

Material and Methods

The series consisted of a group of 58 patients (23 males, 35 females) with a proteus urinary infection. There was no complicating disease of the urinary tract in 12 (21%),

FIG. 9.—Ventriculograph of a case of basal cysticercosis; antero-posterior view. Both lateral ventricles are dilated. The third ventricle is dilated and displaced upward.

FIG. 10.—Ventriculograph showing a cysticercus attached to the wall of the lateral ventricle.

though 4 of these had recurrent or chronic urinary sepsis. The remaining 46 (79%) had complicating factors. Of these, 27 (47%) had chronic local disease, which included urethral stricture, prostatic hypertrophy, urolithiasis, hydro-nephrosis, and automatic bladder; some of these infections were post-operative. Sixteen cases occurred in women during the post-partum period or after operations for genital prolapse, and in the remaining three patients with a normal urinary tract the infection resulted from urethral catheterization. Most of the patients had signs and symptoms of a urinary infection.

Bacteriology

A catheter or mid-stream specimen of urine was examined in all cases before treatment was started, and in many instances both during and after treatment. In each case this confirmed the presence of an infection by revealing protein, pus cells, and organisms. The urine was cultured on blood agar and litmus lactose agar.

The identification of the *Proteus* group was based on the usual cultural, morphological, and biochemical criteria described by Cook (1948), Kauffmann (1954), and Wilson and Miles (1955). The strains isolated were typed biochemically as detailed by Cook (1948), and the *Proteus* group was thus divided into the four species: *P. mirabilis*, *P. vulgaris*, *P. morganii*, and *P. rettgeri*. Organisms of the Providence group, defined by Kauffmann (1954), were also included, since they have close affinities with *Proteus* as discussed by Singer and Bar-Chay (1954).

The dried-disk technique described by Fairbrother and Jennings (1955) was used for testing the sensitivity of the strains to penicillin, erythromycin, bacitracin, streptomycin, neomycin, chloramphenicol, tetracycline, chlortetracycline, oxytetracycline, polymyxin, and nitrofurantoin. A few strains were also tested against novobiocin and spiramycin as they became available. Sulphonamide sensitivity tests were not performed. The concentration of antibiotic per disk is recorded in Table I. For comparison a zone of inhibition of growth 10 mm. or more in diameter was considered to indicate sensitivity to the antibiotics, the disks being 5 mm. in diameter. Tablets of nitrofurantoin containing 10,000 µg. were used routinely, and in some instances paper disks containing 100 µg. of the drug were also employed.

Treatment

The series was not a controlled trial, so there was no selection or random sampling of cases for treatment, which was directed by the clinician in charge of the patient. In many instances a lack of response to the initial treatment necessitated a change of drug. Some infections following urinary tract or gynaecological operations were not prevented by prophylactic chemotherapy.

Nitrofurantoin dosage was based on body weight—5–8 mg. per kg. in divided doses in 24 hours. Most patients received 100 mg. six-hourly, and two children were given 25 and 50 mg. six-hourly respectively. With other drugs the dosage was at least that recorded in Table II.

Bacteriological Results

The *Proteus* species isolated initially was identified as *P. mirabilis* in 49 patients (84%), *P. vulgaris* in 3, *P. morganii* in 2, and *P. rettgeri* in 3. One infected with *P. mor-*

ganii initially became reinfected with *P. mirabilis* at a later date. A Providence strain was found in one case, and in another one occurred with *P. rettgeri*. In 30 cases (52%) there was a pure proteus infection, but in 28 (48%) other organisms were also present. There was an enterococcus in 27 (47%), *E. coli* in 4, and *Staph. pyogenes* in 3.

The results of the sensitivity tests are detailed in Table I. Although with some species the number of strains tested were few the results suggested that each *Proteus* species has a different antibiotic spectrum. Thus, only *P. mirabilis* was sensitive to penicillin, and the other three *Proteus* species were more sensitive to the tetracycline antibiotics than *P. mirabilis*. *P. rettgeri* was resistant to both streptomycin and chloramphenicol. Providence strains were particularly resistant to the antibiotics. All the *Proteus* and Providence strains were sensitive to nitrofurantoin and neomycin. The latter two drugs and chloramphenicol were the most effective against the two commonly occurring organisms, *P. mirabilis* and the enterococcus.

The zones of inhibition of growth produced by the 10,000-µg. nitrofurantoin tablet varied from 10 to 20 mm. in diameter (tablet diameter being 7 mm.). Two strains were only partially inhibited, a few less sensitive colonies being present in a larger zone of general inhibition of growth. Thirteen *Proteus* strains were tested against the 100-µg. disk (also 7 mm. in diameter), and the zones of inhibition were

TABLE II.—*Results of Treatment (Four or More Days' Course)*

Drug and Dosage	Average Course of Treatment (Days)	Total Nos. Treated	Cured			Nos. Failed Treatment
			Laboratory and Clinical Cure	Clinical Cure	Total Cured	
Nitrofurantoin (dose see text)	8	23 (12)	12 (6)	6 (2)	18 (78%) (8)	5 (4)

			1 with nitrofurantoin			
Penicillin, 1 mega unit per day in divided doses	6	7 (2)	2 both with streptomycin	1 with streptomycin	3 (0)	4 (2)
						2 with streptomycin, 1 with sulphonamide
Novobiocin, 500 mg. 12-hourly	7	1 (1)	0	0	0	1 (1)
Mist. pot. cit. B.P.C. alone	11	7 (4)	1 (1)	1	2 (1)	5 (3)
Mandelic acid derivative	13	4 (3)	1 (1)	1	2 (1)	2 (2)

Numbers in parentheses refer to cases with chronic complicating urinary tract disease.

from 9 to 14 mm. in diameter, but five strains showed only partial inhibition of growth as described above. These results demonstrated that the 10,000-µg. tablet produced zones of inhibition comparable with the 100-µg. disk, which contained a concentration of the drug nearer the therapeutic level in urine. Sensitivity tests on serial isolations of the organisms from 10 patients who received nitrofurantoin showed no significant change of sensitivity. These included six patients in whom treatment failed after three or more days' administration.

Clinical Results

Table II shows the results of four or more days' treatment with a variety of drugs. This minimal period was not necessarily considered to be optimal, especially in complicated cases, but was adopted for comparative purposes, since a cure had occurred in a number of instances by this time with the most effective drugs. The average course of treatment was seven days or more with most of them. The term "laboratory and clinical cure" in Table II indicates known sterilization of the urine, with cure of signs and symptoms of infection, and without evidence of relapse within seven days of the cessation of treatment. A clinical cure denotes a similar cure of signs and symptoms when the urine was not examined after treatment.

The largest groups of patients were those treated with nitrofurantoin, streptomycin, or a sulphonamide. The numbers in these groups were similar, as were the proportions of patients with a chronic urinary tract complication, the number of mixed infections, and the average duration of treatment. In addition, some patients served as their own control, having failed to respond to one or other drugs. The cures were respectively 78%, 43%, and 23%, and if only patients with chronic complicating urinary tract disease were compared the results were even more divergent: 8 of 12, 3 of 13, and 0 of 13 were cured respectively. Thus, nitrofurantoin was more effective than the other two drugs, especially in complicated cases.

A proportion of the patients who received other drugs were cured, but the numbers treated with each were too small for direct comparison.

The correlation between bacterial sensitivity *in vitro* and successful therapy was not absolute. All the strains eliminated by nitrofurantoin were sensitive, though one was only partially so. In the failures, however, the initially isolated organisms were also sensitive. Eight of the 10 infections which responded to streptomycin were due to a sensitive *Proteus* strain, but so were 5 of the 13 failures. Similar discrepancies were observed in the patients who received other antibiotics.

Twenty-three patients received nitrofurantoin, and 18, including 8 with chronic complicating urinary tract disease, were cured, with bacteriological proof in 12. In 11 of those who responded to treatment, other drugs had failed to eradicate the infection. A course of streptomycin had been given to six of these patients and penicillin with streptomycin to another; oxytetracycline therapy had preceded streptomycin in one of them. One patient had received a combination of sulphadimidine with penicillin, and another chloramphenicol. In two the urine had been rendered alkaline. A known relapse of infection occurred in four complicated cases. The average course of treatment lasted eight days (limits 4–12 days).

The drug failed to remove the infecting *Proteus* strain in five patients. One of them, however, received only four days' interrupted therapy and another complicated case five days' dosage. There were only three failures with more prolonged administration, and all were complicated cases. A nitrofurantoin-resistant *Ps. pyocyanea* replaced the accompanying enterococcus during nine days' treatment in the first patient, who had an automatic bladder. Sulphadimidine had also previously failed. Successive courses of sulphamethizole, streptomycin, 16 days' nitrofurantoin, and chloramphenicol all failed in the second

patient, who had renal calculi and abscesses and died of the infection which followed prostatectomy and removal of bladder stones. In the last case a combination of first streptomycin and later oxytetracycline with nitrofurantoin was required to cure the infection which followed a ureteral transplant for carcinoma of the ureter. This patient received a total of 19 g. of the drug in two courses of 31 and 16 days over a period of two months.

The only toxic effect encountered with the drug was vomiting in two patients, but it was severe enough for abandoning of treatment in both. In one the dosage was reduced from 150 to 100 mg. six-hourly without relief. The other had vomited intermittently before treatment as a result of cholecystitis. Two children, aged 3 and 9 years, were treated without ill-effect.

Discussion

The present series of proteus infections of the urinary tract confirmed the findings of Coleman and Taylor (1949) and Erlanson and Jönsson (1953) that *Proteus* strains were uncommon pathogens in acute uncomplicated cases, but occurred frequently in chronic infections, especially after previous antibacterial therapy, following catheterization and instrumentation, and in cases with a chronic urinary tract abnormality or disease. Blahey (1952) also demonstrated that prophylactic chemotherapy during urethral catheterization following gynaecological operations increased the number of proteus infections. Shackman and Messent (1954) similarly found proteus organisms in the bladder urine more frequently after than before prostatectomy. In all such complicated cases the incidence of mixed infections also increased.

The relative frequency of the four *Proteus* species found in this study was similar to that noted by Cook (1948) in isolations from human faeces. The results of the sensitivity tests confirmed the findings of Poole (1954) and Potee *et al.* (1954) that the four *Proteus* species each have an individual and different antibiotic spectrum. Lutz and Hofferer (1955) showed that this also applied to Providence strains. The enterococcus was sensitive to a range of antibiotics similar to that reported by Fairbrother and Jennings (1955).

Garrod *et al.* (1954) found that treatment with drugs in urinary infections was not always successful against organisms sensitive to them, especially when complications were present, and, in contrast, that even resistant bacteria were sometimes removed. Inconsistencies in the correlation between individual sensitivity tests and the results of treatment were also noted in this series.

The poor results with sulphonamides confirmed the opinion of Kass (1955) that such therapy often failed in infections with proteus and the enterococcus, despite a sensitivity *in vitro* of 80% and 30% for the two organisms. He also observed that rendering the urine alkaline or treatment with a mandelic acid derivative were frequently ineffective. With streptomycin acquired resistance was observed in a number of cases in this series and accounted for lack of response, but the low sensitivity of the enterococcus perhaps contributed to other failures. Too few cases were treated with a tetracycline analogue to determine whether the *Proteus* species most sensitive *in vitro* respond clinically. The combination of penicillin with a sulphonamide or streptomycin appeared to add no advantage; perhaps a higher dosage would have been more effective. Only one patient in the series received novobiocin, and without benefit, but some of the *Proteus* strains were sensitive to the antibiotic, as reported by a number of authors in the April issue of *Antibiotic Medicine* (1956).

Chloramphenicol has been found to give inconsistent results in the treatment of urinary infections, and Welch (1954) stated that excretion of the active unconjugated drug is variable and unpredictable. Its routine use is also undesirable because of the occasional complication of fatal aplastic anaemia. The toxicity of neomycin similarly restricts its employment in urinary infections to short

courses. No patient in this series received the antibiotic. The good results with nitrofurantoin confirmed the original bacteriological findings, and in view of its relative lack of toxicity suggest that it is the drug of choice. In one case the infection was cured only when nitrofurantoin was given with an antibiotic. Apart from the value of combined therapy in removing resistant organisms or delaying the emergence of resistance, such combinations would perhaps also be useful in severe pyelonephritis, since effective blood and tissue levels of nitrofurantoin cannot be attained.

The patients were not all observed for a long period following treatment, and the incidence of relapse and reinfection was not determined. In view of this and the consequent criteria accepted for cure it is recognized that perhaps little can be concluded regarding the ultimate effects of therapy. Complicated infections especially are prone to relapse, in addition to their relatively poor response to treatment. However, the object of the investigation was to correlate and compare the relative ability of various drugs in removing infecting *Proteus* strains from the urinary tract with their activity *in vitro*. The results showed that this was in the main achieved. In any case, a final cure in many instances may depend more upon the relief of complicating factors than upon antibacterial therapy alone, and, as McGeown (1956) remarked, a relapse does not detract from the therapeutic value of a drug, but merely indicates the proneness of a damaged renal tract to become infected. Richards *et al.* (1955) observed a relapse of proteus infections which had been treated with nitrofurantoin. However, the relative freedom of the drug from toxic effects and the slow emergence of resistant bacterial strains to it would fit it well for repeated administration or long-term therapy.

Summary

A series of 58 patients with a proteus infection of the urinary tract, of whom 46 (79%) had local complicating factors, were observed in order to compare the results of treatment with sensitivity tests *in vitro*.

The *Proteus* strains isolated were typed biochemically. *P. mirabilis* was the pathogenic species in 49 cases (84%), and in 27 cases (47%) there was a mixed infection with an enterococcus.

Sensitivity tests were performed *in vitro* with nitrofurantoin and 12 antibiotics. All the strains tested were sensitive to nitrofurantoin.

Nitrofurantoin, streptomycin, or a sulphonamide was given to the majority of patients, and these treatment groups were comparable. Nitrofurantoin proved superior to the other two in curing the infection.

There were occasional discrepancies in the correlation between individual sensitivity tests and therapeutic outcome.

Twenty-three patients received nitrofurantoin, and only three failures were recorded with prolonged therapy. The only toxic effect noted was vomiting in two cases.

The results indicated that nitrofurantoin was the most effective drug used, even in complicated cases and mixed infections, and that it is worthy of further trial in a larger series of cases.

I thank Dr. J. L. Pinniger for help and encouragement in the preparation of this paper. I am indebted to Mr. R. H. O. B. Robinson, Mr. T. W. Mimpriess, Mr. A. J. Wrigley, and the other members of the staff of St. Thomas's Hospital for access to their patients, and to Duncan, Flockhart and Co., of Edinburgh, for the furadantin diagnostic tablets and disks.

STABILITY OF *H. PERTUSSIS* VACCINE ESTIMATED BY MOUSE-PROTECTION TEST

BY

J. UNGAR, M.D.

AND

B. BASIL

Glaxo Laboratories Limited, Greenford, Middlesex

The Whooping-cough Committee of the Medical Research Council (1956) has reported an average deterioration rate of 0.2 log unit per annum for the vaccines used in its trial. This deterioration rate was determined from the results of mouse-protection tests and was not in conflict with the clinical results. In the treatment of the results the Committee regarded the deterioration as a sample value and did not quote the significance of its difference from zero. Moreover, the Committee states that its conclusions are unaltered if the deterioration rate is ignored.

TABLE I.—Results of Mouse-protection Tests on *H. pertussis* Vaccine BIV. (Survivors/Total in Group)

Date of Test	Dose of BIV		
	40 × 10 ⁶ Cells	200 × 10 ⁶ Cells	1,000 × 10 ⁶ Cells

17	870	41	

Graph showing dose and age of vaccine, and proportion of mice surviving.

We have observed no deterioration of certain vaccines, and our finding agrees with that reported by Kendrick, Eldering, Hornbeck, and Baker (1955). In particular we have records relating to one vaccine, BIV, stored at 4° C. over a period of three years. In this paper we assess the highest rate of deterioration for this vaccine to be legitimately inferred from mouse-protection tests. The supply of BIV being now exhausted, no further tests are possible with it.

Statistical Note

In Table I are shown all the available results from 22 sets of three doses as the number of survivors out of the total in each group of mice obtained over a period of 41 months; Table II gives the ImD₅₀ values. A plane was fitted to log dose, time, and probit of percentage survivors with a single cycle of weighting (Finney, 1947). The regression equation for log dose and time on probits was calculated. The ratio of the two regression coefficients was used as a measure of the rate of deterioration. Heterogeneity was found, as was expected (Ungar and Basil, 1957), and provided for. The lower fiducial limits of this ratio (Fieller, 1944) were calculated for P=0.05 and P=0.01 (single tail) and expressed as log units per annum and half-life in years. The procedure is illustrated in the graph. This is a projected graph in which the dose of vaccine, the age of the vaccine, and the proportion of mice surviving are plotted at right angles. The 66 observed values are marked as solid circles, and for each the deviation from the fitted plane is marked by a line. The plane between dose of vaccine and age of vaccine is also shown at the 50% level. The two planes, the fitted one and the one between dose and age of vaccine, intersect in a line that is the regression of the ImD₅₀ dose of vaccine on the age of the vaccine. The slope of this line measures the rate of deterioration.

Results

The deterioration as determined above is not different from zero. Indeed, the sample value indicates a slight increase in activity. Its lower fiducial limit (P=0.05) is 0.05 log unit, or a half-life of 5.76 years. At P=0.01, the lower limit is 0.09 log unit, or a half-life of 3.23 years. Although, as can be seen, an appreciable deterioration may have

occurred, the limiting value found is much smaller than the one given in the Whooping-cough Committee's report.

Discussion

The reasons for the deterioration of the vaccine, as given in that report, are a matter of speculation. One could lie in the method of preparing the vaccine—namely, incomplete killing of the organisms and destruction of enzymes. It is known that certain chemicals will act as bacteriostatic or slow bactericidal agents—for example, organic mercurial compounds—without at the same time inactivating proteases. The enzymes can in the course of months affect the antigenicity of the prophylactic, particularly if it happens to have been kept at room temperature.

Another explanation of the alleged deterioration may be found in the assay method. The mice used might vary with time in their response to the antigen, unless precautions are taken to use a specially uniform strain of mice and a stable standard is available for comparison. Further, the challenge strain of *Haemophilus pertussis* used in the method may vary in virulence.

Finally, the possible effect of changes in the diet of the animals must be kept in mind.

Summary

The mouse-protection test has been used to show that *H. pertussis* vaccine stored at 4° C. does not deteriorate appreciably and that there could be a half-life of 5.76 years (P=0.05) or, at worst (P=0.01), of 3.23 years.

BRITISH STANDARD FOR PERTUSSIS VACCINE: ITS USE IN ROUTINE CONTROL OF COMMERCIAL VACCINES

BY

P. ARMITAGE, Ph.D.

Member of Medical Research Council's Statistical Research
Unit at the London School of Hygiene and Tropical
Medicine

AND

W. L. M. PERRY, M.D.

Director of the Department of Biological Standards,
National Institute for Medical Research

Pertussis vaccine has been used in this country for a number of years on a fairly wide scale. Control of the vaccine for safety and potency has been carried out in the usual way through the Regulations made under the Therapeutic Substances Act and through the monograph on the vaccine in the *British Pharmacopoeia*. Up to the present time the control measures have not included any direct test for potency, and indirect methods depending upon opacity, etc., have been the only ones applied. In recent years several large-scale field trials of the protective power of pertussis vaccine have been organized by the Medical Research Council. All vaccines used in

these trials have been tested for potency by the mouse-protection method (W.H.O., 1953) and some have also been tested by an agglutinin test (Evans and Perkins, 1953, 1954).

It was generally believed that the former was a valid method of assessing the protective power of vaccine in children, and, in fact, vaccine used in other countries, notably the United States, has for some time been officially controlled by use of this method. There was, however, little direct evidence that the results obtained in the mouse-protection test were correlated with the protective power of the vaccine in children until the publication of a further report on the British field trials (Medical Research Council, 1956, referred to below as the M.R.C. report). In giving this evidence the authors of the report recommended that only vaccines so tested should be used in this country. It is the purpose of this paper to examine the practicability of this general recommendation.

Like all bioassay methods the mouse-protection test is essentially comparative, and depends upon the determination of the ratio between some dose of the batch under test and that dose of a standard preparation giving an equal protection. The need for a standard was recognized at an early stage of the M.R.C. trials, and a particular batch of vaccine was set aside for this purpose. Unfortunately, at a much later stage, when the analysis of the assays was completed, it became apparent that this standard batch, and many of the other vaccines, might, on storage in the fluid state for several years, have lost a good deal of their antigenic potency (M.R.C., 1956, p. 459). For any one vaccine the dose required to produce a given protective effect in mice appeared to increase at a fairly constant rate over a period of four years. If this trend was assumed to be due to a steady rate of deterioration of the vaccine, it was possible to allow for this and to estimate the actual potency of all vaccines used in the trial (M.R.C., 1956, p. 461). Nevertheless the apparent instability of fluid vaccine made it wholly unsuitable for use as a standard preparation, and in May, 1953, it was decided to investigate the possibility of using freeze-dried vaccine as a standard.

The M.R.C. Whooping-cough Committee, acting in conjunction with the Department of Biological Standards of the National Institute for Medical Research, set up a subcommittee* to organize these studies. Preliminary experiments showed that there was little practical difficulty in freeze-drying the vaccine, that there might be a loss of antigenic potency during drying, and that 6% dextran added to the suspending fluid of the vaccine might help to protect the antigen during the drying process.

Preparation of the British Standard

It was decided to make the British Standard, if possible, from a batch of vaccine which, in the fluid state, had been used in the field trial and found to have good protective power in children. Accordingly, in 1954, a vaccine (V 12) was selected and a supply of 4.3 litres was made available by the generosity of the Glaxo Laboratories. This vaccine had been manufactured in 1951, used in the field study during 1952, and was consequently nearly three years old at the time of drying. The vaccine was of the usual strength for field use—namely, with an estimated 20,000 million organisms per ml.—but, with the help of Dr. J. Ungar, it was concentrated 2½-fold—that is, to a concentration of

50,000 million organisms per ml.; this final concentrate also contained 6% dextran and 1 in 7,500 parts of thiomersal.

The concentrated solution was dispensed by accurate volumetric methods in 1-ml. amounts in ampoules. The ampoules were placed in a freeze-drying apparatus and the solution lyophilized. The ampoules were then filled with pure dry nitrogen and sealed. A sample of the original V 12 vaccine was retained for further study and was held as a fluid at 4° C.

Ampoules of the dried material were then selected at random for the tests to be described, and the remainder have been stored ever since at -10° C.

Effect of Drying on Potency of Standard

Ampoules of the standard were reconstituted with distilled water to make a solution containing 10,000 million organisms per ml. The reconstituted standard was then compared by the mouse-protection test with the starting material. The results in Table I were obtained in three

TABLE I.—Estimates of Potency-ratio of Dried Vaccine Against Original V 12 Vaccine

Laboratory	No. of Assays	Pooled Value of Log Potency Ratio (With 95% Fiducial Limits)
1	6	-0.041 (-0.223 to 0.141)
2	8	-0.508* (-0.808, -0.207)
3	4	-0.396 (-0.780, -0.011)
Pooled value for laboratories 1 and 3		-0.173 (-0.318, -0.038)
Antilog=estimated potency		0.67 (0.48, 0.94)

* Results from individual assays differ significantly at 1% level.

different laboratories—the Glaxo Laboratories, the Wellcome Research Laboratories, and the National Institutes of Health, Bethesda, U.S.A. The results from the eight assays performed in Laboratory 2 were discrepant from each other, and the pooled result from this laboratory differed significantly from the other two. The best procedure seemed to be to omit these particular results. The pooled results from the other two laboratories gave an estimated log potency after drying of -0.173, with a standard error of 0.074. Thus (taking limits of twice the standard error) the antigenicity appears to have dropped during drying by between 6 and 52%. Loss of potency during drying, provided its degree is known with fair accuracy, is not a serious problem, since due allowance can be made for it in deciding what potency, in terms of the standard, should be required for fresh batches.

Stability of Standard

Of much greater importance than the loss of potency during drying is the stability of the standard. Steps were accordingly taken to check as far as possible that no further loss of potency need be expected, once the standard had been dried.

Methods of checking the stability of standard preparations are necessarily all indirect, and the various possibilities have been discussed by Jerne and Perry (1956). The method chosen for this study was the accelerated degradation test. Randomly selected ampoules of the standard were divided into three groups which were stored at -10°, 22°, and 37° C. respectively. At the end of two months' storage, one-half of the ampoules in each group was removed from the storage boxes; the rest of the ampoules were left in storage at these temperatures for 24 months in all.

Each of these sets of ampoules was tested in the same way—namely, by comparing, in mouse-protection tests, the potency of those stored at 22° and 37° C. with those stored at -10° C. The assays were done in three separate laboratories on the two-month samples and in two laboratories on the 24-month samples. The laboratories taking part were the Glaxo Laboratories, the Wellcome Research Laboratories, and the Lister Institute. The results of all the assays were calculated by standard probit analysis, sometimes modified to allow for survivors in the control groups of unvaccinated mice.

AUG. 31, 1957

BRITISH STANDARD FOR PERTUSSIS VACCINE

The results of the two-month assays are given in Table II, and those of the 24-month assays in Table III.

TABLE II.—Estimates of Potency-ratio of Standard Vaccine Stored for 2 Months at 22° and 37° C., in Terms of That Stored at -10° C.

Laboratory	No. of Assays	Pooled Value of Log Potency-ratio (With 95% Fiducial Limits)	
		22° v. -10°	37° v. -10°
1	4	0.132 (-0.091 to 0.354)	0.162 (-0.063 to 0.387)
2	4	0.003* (-0.862, 0.868)	-0.065* (-1.116, 0.986)
4	7	-0.019 (-0.308, 0.271)	-0.092† (-0.611, 0.426)
Pooled value for three laboratories		0.069 (-0.098, 0.236)	0.090 (-0.099, 0.279)
Antilog=estimated potency		1.17 (0.80, 1.72)	1.23 (0.80, 1.90)

* Results for individual assays differ significantly at 0.1% level.
† Results for individual assays differ significantly at 5% level.

TABLE III.—Estimates of Potency-ratio of Standard Vaccine Stored for 24 Months at 22° and 37° C. in Terms of That Stored at -10° C.

Laboratory	No. of Assays	Pooled Value of Log Potency-ratio (With 95% Fiducial Limits)	
		22° v. -10°	37° v. -10°
1	6	0.138 (-0.047 to 0.323)	-0.201* (-0.824 to 0.421)
4	8	0.012 (-0.163, 0.188)	-0.017 (-0.190, 0.156)
Pooled value for both laboratories		0.072 (-0.056, 0.199)	-0.049 (-0.206, 0.109)
Antilog=estimated potency		1.18 (0.88, 1.58)	0.89 (0.62, 1.29)

* Results for individual assays differ significantly at 5% level.

There seems to be some inconsistency between repeated tests in the same laboratory (Labs. 2 and 4, Table II; and Lab. 1, Table III). This heterogeneity is allowed for when results from different laboratories are combined. The results from all laboratories then agree satisfactorily when tested by the χ^2 method, and the pooled estimates in all cases are not significantly different from unity, the fiducial range in all cases including unity. For the two-month assays both estimates are greater than unity.

The tests provide, therefore, no evidence that storage at 22° or 37° C. for up to 24 months caused a greater loss of potency than storage at -10° C. for the same length of time. The limits of error are wide enough to permit the data to be consistent with a loss of up to 20% of the potency in two months. That this rate of loss did not continue for 24 months is quite clear, but there might have been a loss of up to 40% in the longer period. But if there had been any appreciable loss at -10° C., the loss at 37° C. over 24 months would have been enormous. It therefore seems reasonable to suppose that when stored at -10° C. the standard is stable enough to allow its legitimate use without correction for loss of potency.

Use of Standard

Instructions to Users.—The ampoule of dried standard should be carefully opened and exactly 5 ml. of distilled water added. Great care should be taken to ensure that the dried powder suspends completely before use. The suspension thus made is estimated to contain 10,000 million organisms per ml.

Routine Use of Standard in Control of Commercial Vaccines.—Final decisions on the methods used for the control of commercially prepared pertussis vaccines lie in the hands of the authorities responsible for drafting Regulations under the Therapeutic Substances Act and for monographs of the *British Pharmacopoeia*. Our present purpose is merely to outline the purpose and practicability of such control. The control measures, whatever they may be, must take account of two things: (1) the need to ensure that material is, on the average, at least as potent as vaccine known to have been effective in the field trials; and (2) the need to ensure

that as few batches as possible of material as low in potency as vaccine known to have been ineffective in the field trial ever pass the test.

Relation of Potency of Standard to Field Results

The question of the relationship between the results of field trials and those of mouse-protection tests raises the problem of estimating the deterioration (if any) of fluid vaccines, and we shall first make the same assumption as in the M.R.C. report—that all fluid vaccines considered there lost potency at a rate of 0.2 log units a year over the period 1947–51, during which the laboratory tests reported there were performed.

In Table XII of the M.R.C. report, all vaccines were calibrated by the mouse-protection test in terms of vaccine G 61 as tested in the early months of 1947. If all the vaccines used in the field trials are divided into two groups—those with a log potency (in terms of G 61 in 1947) above and below -0.25 (which we call R)—we find that those with a potency greater than R had home-exposure attack rates varying from 4% to 30%; those with a potency less than R had attack rates varying from 29% to 87%. This means that the value R is a fairly good index of discrimination between apparently acceptable and apparently unacceptable vaccine.

We must next try to determine the value of R in terms of the potency of the standard, which means trying to evaluate the log potency of the standard relative to vaccine G 61 in 1947.0.* If we call this m, then $m = x - y + z$, where x = log potency of standard in terms of V 12 in 1954.75 (when tested together—see above);

y = amount of deterioration (in logs) of V 12 between 1952.4 and 1954.75;

z = log potency of V 12 in 1952.4 (when tested in the field) in terms of G 61 in 1947.0.

The estimated value of z is obtained from the data included in the M.R.C. report (Table XII), and is -0.150 ± 0.147 . The estimated value of x is that quoted in a previous section of this paper—namely, the result of the test done to determine whether there was any loss of potency of the material during drying (Table I); the figure is -0.173 ± 0.074 . To estimate y we have examined the trend in the dose required to protect 50% of mice (ImD_{50}) in a number of experiments with V 12. The estimated change in log potency over the relevant period of 2.35 years is 0.045 ± 0.148 . Since an increase in potency is unlikely to have occurred it will be safest to take a figure of 0 ± 0.148 .

Hence $m = -0.173 - 0 - 0.150 = -0.323$;
Standard error of $m = \sqrt{(0.074)^2 + (0.148)^2 + (0.147)^2} = 0.221$;
95% fiducial limits for m are $-0.323 \pm (1.96)(0.221) = -0.756$ and 0.110 .

We can, on this basis, express the desirable level, R, as a multiple of the standard (Table IV). The lower limit for m , of course, determines the upper limit for the "desirable" level.

TABLE IV.—Desirable Level for Potency in Terms of Standard, With 95% Fiducial Limits, on Assumption that Vaccine Referred to in M.R.C. Report Deteriorated at Rate of 0.2 log a Year

Assumed Value of m (Logs, in Terms of G 61 in 1947.0)	Desirable Level, R = -0.25, as a Multiple of Standard, i.e. (-0.25 - m)	
	Log Scale	Antilog
Upper limit, 0.110	Lower limit, -0.36	0.44
Estimate, -0.323	Estimate, 0.07	1.2
Lower limit, -0.756	Upper limit, 0.50	3.2

The weakest link in the above argument seems to be the assumption that during the period 1947–51 the potency of the vaccines declined at the same rate, 0.2 log a year. This seemed to the authors of the M.R.C. report to be

*The decimal indicates a proportion of the way through a whole year—e.g., 1952.4 means 0.4 of the way through 1952.

*The members of the subcommittee were: Dr. P. Armitage, Dr. W. C. Cockburn, Dr. D. G. Evans, Dr. J. O. Irwin, Dr. J. Knowelden, Dr. W. L. M. Perry (chairman), and Mr. A. F. B. Standfast.

a reasonable assumption to make, since the ImD_{50} s of a number of vaccines increased fairly consistently at this rate. However, an examination which we have carried out of more recent results of mouse-protection tests performed in laboratories on these and other vaccines suggests little or no loss of potency over a period of several years, a conclusion confirmed by Kendrick *et al.* (1955). It therefore seems quite possible that the previously observed trends in ImD_{50} s were due to temporary fluctuations in the behaviour of the mice rather than to deterioration of the vaccines. We shall now consider an alternative (and presumably extreme) assumption that fluid vaccines do not deteriorate at all. This assumption could not invalidate the general conclusion of the M.R.C. report that field and mouse results are related (as may be seen by plotting the home-exposure attack rates from Table XII of the M.R.C. report against the uncorrected log potency-ratios in terms of G 61 given in Table IX of that report). But it does affect the relative potencies of different vaccines.

In Table IX of the M.R.C. report, uncorrected potencies are expressed in terms of G 61. A reasonable value for R' , the desirable level in terms of G 61, appears to be 0.25. Vaccines with a potency greater than R' had home-exposure attack rates varying from 4% to 29%; those with a potency less than R' had attack rates varying from 30% to 87%. It will be seen that R' provides almost exactly the same discrimination between vaccines as did the level R on the previous assumption. If we denote by m' the value of R' in terms of the standard, then $m' = x + y'$, where

$x = \log$ potency of standard in terms of V 12 (as before);

$y' = \log$ potency of V 12 in terms of G 61.

As before, $x = -0.173 \pm 0.074$. The estimated value of y' (cf. Table IX of the M.R.C. report) is 0.928 ± 0.147 .

Hence $m = -0.173 + 0.928 = 0.755$;

Standard error of $m = \sqrt{(0.074)^2 + (0.147)^2} = 0.165$;

95% fiducial limits for m are $0.755 \pm (0.96)(0.165) = 0.432$ and 1.078 .

We can now express the desirable level, R' , as a multiple of the standard (Table V).

TABLE V.—Desirable Level for Potency in Terms of Standards, With 95% Fiducial Limits, on Assumption that Vaccines Referred to in M.R.C. Report did not Deteriorate

Assumed Value of m' (Logs in Terms of G 61)	Desirable Level, $R' = 0.25$, as a Multiple of Standard, i.e. $(0.25 - m')$	
	Log Scale	Antilog
Upper limit, 1.078	Lower limit, -0.83	0.15
Estimate, 0.755	Estimate, -0.50	0.32
Lower limit, 0.432	Upper limit, -0.18	0.66

A comparison of Tables IV and V shows that the two different assumptions about the possible deterioration of the vaccines referred to in the M.R.C. report considerably affect the estimate of the "desirable" potency in terms of the standard. The two estimates are 0.3 and 1.2, and the upper and lower limits given in these tables show that either estimate might well be inaccurate by a factor of two in either direction. Nevertheless, it is upon these figures that any control requirements must be based. There is no way of determining which of the two estimates is correct, since they depend upon alternative interpretations of past experiments which cannot be repeated. The choice must therefore be arbitrary, and we do not wish to embarrass the legal authorities who will make it. Consequently, we propose to discuss the implications of both choices.

Precision of Assay Methods

Having decided upon the level of potency which it is desirable to ensure, we must then discover whether the available assay methods are precise enough to enable us to attain such a level with any degree of certainty and regularity. The precision of the mouse-protection test is not great, and depends to a very large extent upon the slope of the dosage-response line.

The stability tests of the standard, described above, provided an opportunity of determining again the value of this slope, under conditions of reasonable accuracy. The mean values for the three laboratories were 1.1, 1.3, and 1.4 (probits/log dose). Irwin and Standfast (1957) report a slope of 0.8 in assays performed some years ago; the more recent values indicate an improved precision since then, and go far toward making it possible to introduce laboratory control of the potency of the vaccine.

Previous assays have usually been carried out at three-dose levels of vaccine, using 15 mice per dose (a total of 90 plus uninoculated controls). In Table VI we show the limits of error of an assay of this design when the slope has the values 0.8, 1.1, and 1.4 respectively. When the slope is 0.8, a total of eight complete tests (720 mice) are required to obtain limits of error of roughly 50% to 200%. When the slope is 1.4 comparable limits of error are obtained with only two tests (180 mice).

TABLE VI.—Limits of Accuracy Achieved in Tests with Three Fivefold Doses on Each of Two Vaccines, with 15 Animals per Dose. The 95% Fiducial Limits are Expressed as Percentages of the Estimated Potency

	Slope 0.8	Slope 1.1	Slope 1.4
% Survivals:			
(a) ..	(29, 50, 71)	(22, 50, 78)	(16, 50, 84)
(b) ..	(20, 39, 61)	(12, 35, 65)	(7, 31, 69)
1 test:			
(a) ..	15-689	37-369	36-281
(b) ..	21-2,423	31-643	38-387
2 tests:			
(a) ..	30-334	42-238	50-201
(b) ..	33-368	43-313	50-238
4 tests:			
(a) ..	45-225	55-182	62-162
(b) ..	45-295	55-211	61-178
8 tests:			
(a) ..	57-175	66-152	71-140
(b) ..	56-204	65-166	67-148

The survival rates have been chosen so that their probits are exactly linearly related to the log dose. Those marked (a) are the same for each vaccine, and are symmetrically placed about 50%. These give the narrowest possible fiducial range for a given probit slope. Those marked (b) correspond to a fivefold difference in potency between the two vaccines.

It seems possible that some slight saving of animals might be effected by using a (2 plus 2) dose design with groups of 20 mice per dose (80 plus uninoculated controls per test). Table VII gives the limits of error for this design with the same values as before for the slope; these are very similar to the limits obtained using the three-dose design.

TABLE VII.—Limits of Accuracy Achieved in Tests With Two Fivefold Doses on Each of Two Vaccines, With 20 Animals per Dose. The 95% Fiducial Limits are Expressed as Percentages of the Estimated Potency

	Slope 0.8	Slope 1.1	Slope 1.4
% Survivals:			
(a) ..	(39, 61)	(35, 65)	(31, 69)
(b) ..	(29, 50)	(22, 50)	(16, 50)
1 test:			
(a) ..	0-109	18-565	31-320
(b) ..	0-∞	30-1,535	37-1,393
2 tests:			
(a) ..	20-492	38-265	48-208
(b) ..	31-7,614	41-774	48-391
4 tests:			
(a) ..	40-252	53-188	61-164
(b) ..	42-677	51-315	58-228
8 tests:			
(a) ..	55-183	65-154	71-141
(b) ..	52-299	61-205	67-170

See note to Table VI.

From the practical point of view, therefore, it is reasonable to expect a lower fiducial limit of error of 50% of the estimated potency in an assay which is not too cumbersome for routine use.

Recommendations for Routine Control

A lower fiducial limit (L.F.L.) with $P = 0.95$ implies that, unless a 1 in 20 chance has come off, the real potency

is greater than the value of the L.F.L. Thus, if we require that the L.F.L. should exceed the minimum potency we wish to secure, the "desirable" potency, we shall be fairly safe in assuming that accepted batches are of satisfactory quality.

However, we do not know the "desirable" potency exactly, and we shall err on the safe side if we use the upper fiducial limits (U.F.L.) given in Tables IV and V: (a) assuming no deterioration (Table V), the "desirable" potency has a U.F.L. of 0.66 times the standard; and (b) assuming deterioration to have occurred (Table IV), the "desirable" potency has a U.F.L. of 3.2 times the standard.

If we now require that the L.F.L. of the estimated potency in a routine assay shall exceed one of these levels—namely, 0.66 or 3.2 times the standard—we shall have a high probability that the true potency of the vaccine exceeds the true value of the "desirable" level.

Furthermore, if we require that the L.F.L. in a routine assay shall be greater than 50% of the estimated potency, then we must set the requirement for estimated potency at about 1.3 and 6.4 times the standard. These are the two extremes. The choice might fall on either, or on some figure intermediate between them. As we have seen, whatever the choice may be, it must be arbitrary, and it must lie with the legal authorities.

We can, however, conclude that a measure of control is now practicable, and we would accordingly endorse the recommendation to this effect in the M.R.C. report.

The experimental work upon which this paper is based was carried out by Dr. A. E. Francis, of the Wellcome Research Laboratories, Beckenham, Kent, U.K.; Dr. M. Pittman, of the National Institutes of Health, Bethesda 14, Maryland, U.S.A.; Dr. A. F. B. Standfast, of the Lister Institute, Elstree, U.K.; and Dr. J. Ungar, of the Glaxo Laboratories, Greenford, Middlesex, U.K. We are greatly indebted to them for undertaking the work and for allowing us to quote from it.

SENSITIZATION TO P.A.S., STREPTOMYCIN, AND ISONIAZID

BY

PETER MACPHERSON, L.R.C.P.&S.Ed.
L.R.F.P.S.

Tuberculosis Physician, County of Argyll

During the latter part of 1952 several articles relating to the simultaneous development of sensitivity to P.A.S. and streptomycin were published in the *British Medical Journal* (Cuthbert, 1952; Julian, 1952; Jeffery *et al.*, 1952; Macpherson, 1952). The cases described were the first of this nature to be reported.

I have seen no previous record of a patient who proved more or less simultaneously hypersensitive to P.A.S. and isoniazid and possibly also to streptomycin.

Case Report

A man aged 62 was admitted to hospital on April 22, 1955, and found to have bilateral pulmonary tuberculosis. On May 17 a course of isoniazid, 300 mg., plus P.A.S., 15 g., daily was begun. On June 16 he developed a rash which was ascribed to P.A.S. sensitivity, and the administration of this drug was discontinued. The isoniazid was continued. By June 19 the rash had greatly diminished in intensity, and streptomycin, 1 g. daily, was substituted for the P.A.S.

The patient was transferred to the County Sanatorium, Oban, on June 22. As the rash was again increasing in extent and intensity drug treatment was discontinued. By June 27 there occurred oedema of the eyelids, exfoliative rash on the face and upper part of the trunk, swelling of the forearms associated with papular rash, and punctate erythema over the lower part of the trunk.

Desquamation of the whole face, head, upper trunk, and upper limbs occurred during the ensuing three weeks.

On July 28 a test dose of one 50-mg. tablet of isoniazid was given at 10 a.m., as it was assumed that this was the least likely of the three drugs to have caused the sensitization. No reaction followed, and another tablet was given at 6 p.m. At 9.30 p.m. he complained of headache. His temperature was 100.2°F . (37.9°C .) and he had a generalized erythematous rash. During the next few days he developed oedema of the right eyelid and a papular rash on the right forearm.

On August 4 desensitization to isoniazid was begun: 12.5 mg. was given orally, the dose being increased by 12.5 mg. daily until he was receiving 200 mg.

As recrudescence and considerable worsening of the initial rash had occurred coincidentally with the beginning of streptomycin therapy, it was thought wiser to proceed with desensitization to this drug rather than risk a further recurrence of the sensitivity reaction. While the course of isoniazid was continued, 20 mg. of streptomycin in 0.06 ml. was injected intradermally on August 20 without upset. However, the dose of 40 mg. on the second day resulted in an indurated and erythematous reaction which persisted for 36 hours round the site of injection. The same dose was repeated the following day. Thereafter the daily dose was increased slowly to 1 g.

By November 27 he had completed a 90-g. course of streptomycin. Isoniazid was continued and desensitization to P.A.S. was begun, using sodium P.A.S. in the strength of 6 g. per fl. oz. (21 g. per 100 ml.). A test dose of $\frac{1}{2}$ dr. (1.75 ml.) at 9 a.m. produced no reaction. Further $\frac{1}{2}$ dr. (1.75 ml.) doses were given at intervals of 2½ hours, until 9.30 p.m. During the next few days the single dose was increased to $\frac{3}{4}$, 1, 1½, and 2 dr. (2.6, 3.5, 5.2, and 7 ml.), and on December 3 to 3 dr. (10.5 ml.) six times daily.

On December 4 his temperature rose to 99°F . (37.2°C .) the respiratory rate increased, the face became flushed, and a punctate erythema appeared on the trunk, upper arms, and legs, and a papulo-erythematous rash on the forearms. P.A.S. was discontinued. On December 6 he was still moderately breathless. In view of the case reported by Cuthbert (1954) an x-ray film of the chest was taken, but there was no evidence of Löffler's syndrome. However, there was an eosinophilia of 11%.

Because the pulmonary condition merited long-term drug treatment a further attempt at desensitization was begun on January 20, 1956, and proved successful. On this occasion the daily dose was increased more slowly.

Discussion

Allied Chemical Compounds.—Mayer (1928) noted that sensitization to substances containing an aminophenol group may be caused by that group and not by the whole molecule. He showed that the skin transforms these substances into their derivatives and that it is to these that the reaction occurs. This is more common when the amine radical is in the para position. Jeffery *et al.* (1952) reported a case of P.A.S. sensitization which developed an acute generalized skin rash when 0.5 g. of "sulphatriad" was given, and another in which patch tests were markedly positive to 1% dilutions of P.A.S., para-aminobenzoic acid, sulphanilamide, procaine, para-phenylenediamine, meta-aminophenol, and para-aminophenol.

Antibiotics.—There appears to be some slight antigenic similarity among the members of the antibiotic group. Bedford (1951) reported that a patient known to be sensitive to penicillin developed a violent reaction to chlortetracycline.

Acquired hypersensitivity to streptomycin and penicillin, also to P.A.S., has been recorded by McKendrick (1951) and by Jeffery *et al.* (1952).

Heterogeneous Drugs.—Julian (1952) regarded the occurrence of simultaneous sensitization to streptomycin and P.A.S. to be most probably coincidental. Since then there has been a growing weight of evidence to suggest that a patient sensitive to one of these drugs is particularly apt to show sensitivity to others. I have noticed that, although various types of drug rash may result from sensitivity to either streptomycin or P.A.S., in a case where dual sensitization has developed the form of rash, and indeed the whole reaction, tends to be similar when each drug is tested separately. In the case described above isoniazid was likewise incriminated. It seems a reasonable assumption that a state of drug sensitization, once induced, in some way renders the individual at least temporarily more susceptible to other drugs with potential sensitizing properties. P.A.S. has been blamed as the most frequent precipitating agent in this type of multiple sensitivity state (Jeffery *et al.*, 1952). In the case reported above, the sensitization to P.A.S. was definitely the first to develop, though a further severe reaction to P.A.S. was not associated with the development of re-sensitization to isoniazid.

Conclusions

Sensitivity reactions to P.A.S., isoniazid, streptomycin, and probably other antibiotics may be identical, and if a combination of these drugs is given, any or all of them may be involved in a state of sensitization. Accordingly, in a sensitivity state associated with combined therapy one is no longer justified in assuming that a single drug is responsible. All drug therapy should be discontinued and a test dose of each drug given, if one would avoid risking further discomfort for the patient. In the case reported fairly severe subsequent reactions occurred to both isoniazid and P.A.S. before full dosage had been reached, despite the fact that the test dose with these drugs had proved negative. After a sensitivity reaction it is now our practice to carry out a modified desensitization programme where the initial test dose of a drug produces no reaction, as well as full desensitization to a drug which gives a positive reaction.

The occurrence of a sensitivity reaction also indicates that care will be necessary in the future and that an initial test dose will be desirable before administering allied preparations or another antibiotic.

I am grateful to Dr. A. S. Hutcheson, consultant tuberculosis physician, Argyll Area, for criticism of this article and for permission to publish the case.

ADDENDUM.—Since this article was submitted for publication I have had a case similar to the one reported above. A man aged 37 was admitted from another hospital and stated that he had developed a streptomycin rash after having been for 80 days on a combined course of streptomycin, 1 g., and isoniazid, 300 mg., daily. Four months after his eruption we gave him a test dose of isoniazid and later of streptomycin. With both drugs he developed features which he reported were identical with his initial sensitivity reaction (fiery erythematous rash on the anterior aspects of the elbows and in the axillae, and oedema of the eyelids; mild eosinophilia was also present).

CLEANSING OF HOSPITAL BLANKETS

BY

B. R. FRISBY, M.D.

Senior Bacteriologist, Public Health Laboratory Service (M.R.C.), Oxford, and Department of Bacteriology, Radcliffe Infirmary, Oxford

As part of the investigation into staphylococcal diarrhoea (Cook, Elliott, Elliot-Smith, Frisby, and Gardner, 1957) the bacterial flora of the blankets at the hospital concerned was examined.

In October, 1955, the criteria used for selecting blankets for washing were as follows: (1) a patient using them had died; (2) an obviously infectious patient had used them; and (3) they looked dirty. The latter contingency arose usually after the blankets had been in use some 12 weeks or more. These criteria are obviously unsatisfactory. The blankets from the bed of a patient who had died may be comparatively clean. Patients who are carriers of pathogenic organisms may contaminate blankets as heavily as an overt case. Finally, blankets may be heavily contaminated and still appear quite clean.

The blankets were washed in a Manlove and Allott open pocket machine with intermittent rotation gear with the water at 37° C. and using a commercial detergent. They were sampled by the technique used by Blowers and Wallace (1955). The medium used for culture was horse-blood-agar, and an area of about 18 in. (45 cm.) square of each blanket to be tested was swept in ten forward-backward strokes of the plate.

In most tests the counts obtained from both the dirty and the clean blankets at this time were very high. Of 115 dirty blankets sampled, 44 (38%) yielded uncountable plates—that is, at least 500 colonies per plate. Scanty growths of *Staph. aureus* were obtained from 18 (15.7%) of the blankets. The corresponding washed blankets, of which 59 were tested, also gave high counts, the majority being over 100 colonies per plate, and 1 (1.7%) giving a scanty growth of *Staph. aureus* (see Table I). Most strains of *Staph. aureus* belonged to group III and were resistant to penicillin.

The number of bacteria obtained by this sweep-plate method was compared with that obtained by homogenizing a given area of blanket and performing total counts. Portions of ordinary dirty blanket 1 sq. in. (6.4 sq. cm.) in size were placed in 15 ml. of digest broth in an "M.S.E." homogenizer and run at 18,000 r.p.m. for 15 minutes with crushed ice in the cup-holder to prevent overheating. Dilutions of the homogenate were then made in broth and the organisms present counted by the pour-plate method, using nutrient agar at 22° C. and 37° C. These experiments showed that the sweep-plate picked up 1 in 10,000 to 1 in 20,000 of the organisms actually present. A blanket having a sweep-plate count of 200 would therefore have an actual count of 2 to 4 million organisms for each section 18 in. (45 cm.) square, giving a calculated count for the whole blanket of some 40–80 million organisms.

Experimental Tests

From these findings it was obvious that the blankets were a rich source of bacteria and that they harboured *Staph. aureus*. The "lissapol-cirrasol" method of cleansing blankets as described by Blowers and Wallace (1955) was then instituted experimentally. To facilitate sampling, distinctive peach-coloured blankets were issued to B ward

TABLE I.—Dirty and Clean, Ordinary and Peach Blankets, Plate Counts on P.B.A. Medium

U.C. = Uncountable—that is, over 500 colonies per plate. Such blankets were not included in calculating the mean counts.

and laundered separately. Furthermore, each patient was given a freshly laundered set of blankets on entering the ward.

Before use, 12 peach blankets were sampled, using blood-agar sweep-plates, and a mean count of 22 was obtained (see Table I). These organisms all belonged to the aerobic spore-bearing group.

The blankets became bacteriologically very dirty after the first period of use. In one illustrative batch of 12 (Table I), 10 gave a mean count of 242 and two were uncountable. The organisms consisted of neisseriae, micrococci, and aerobic spore-bearing bacilli with 2% of the plates showing *Staph. aureus*.

After the first wash three media were tested for the neutralization of the cirrasol: (1) plain blood-agar; (2) nutrient agar with 0.75% of "permal COL" as used by Blowers and Wallace (1955) (P.A.); (3) blood-agar with 0.75% of "permal COL" (P.B.A.). These three media were tested on adjacent portions of each blanket. The plain blood-agar gave hardly any growth at all. The results on the P.A. and P.B.A. are given in Table II, where it is seen that for 12 clean blankets the mean count on P.A. was 6 and on the P.B.A. 11.

Similarly with dirty blankets, the mean count for 12 blankets on P.A. was 128 and on P.B.A. 223.

Because of the appreciably stronger neutralizing properties of P.B.A., this medium was used for the remainder of the tests.

After the first wash the average mean count of the same 12 blankets was 40. After the second period of use the mean count was 241 (with one blanket uncountable), but fell to 21 after the second wash. After the third period of use the count again rose, but only to a mean count of 98. After the third wash it fell again to 7. After the fourth period of

use it was 69, and after the fourth wash 11. After the fifth period of use it was 52, and after the fifth wash 3, with two blankets giving counts of 0 (Table I). No *Staph. aureus* was isolated from any blanket. Over 400 further samples were taken during a period of six months, all confirming this improvement.

The state of the rest of B ward in respect of *Staph. aureus* did not improve during the six months that the blankets were being washed after every patient. The blankets were introduced into an already dirty ward abounding in *Staph. aureus*, and it is a measure of the success of the lissapol-cirrasol method of washing that the blankets improved so much in such a contaminated environment.

The method of washing using cirrasol thus brought about a very substantial reduction not only in the counts obtained from clean blankets but also in those from the dirty ones, indicating an accumulation of bactericidal agent in the blankets over the period. The method was then extended to the whole of the hospital, but it was found impossible to wash sufficient blankets to give every patient a clean set on entering a ward. A rule was laid down, therefore, that blankets should be washed regularly every 12 weeks.

The ordinary clean hospital blankets did improve with the new method even when washed at intervals of 12 weeks. The corresponding dirty blankets, however, did not improve a great deal compared with the situation which existed before the lissapol-cirrasol method was introduced (Table I), although *Staph. aureus* was not isolated from any of them.

The ward using the peach blankets was reserved for a further experiment. All patients entering and leaving this ward had nose and rectal swabs taken, which were examined for *Staph. aureus*. Of 850 patients tested, 366 (43%) gave *Staph. aureus*, 272 (32%) of these being nasal carriers, 193 (23%) rectal carriers, and 99 (12%) both nasal and rectal carriers (Table III). The blankets used by the patients harbouring this organism were washed immediately the patients were discharged from hospital. The other blankets were washed every 12 weeks. The peach blankets unfortunately showed an immediate deterioration when washed at this longer interval, the mean count for some 200 dirty blankets rising to 228 and uncountable plates again occurring.

TABLE III.—Nasal and Rectal Carriers Admitted as Patients to B Ward from October, 1955, to January, 1957

Nose and Rectal Swabs from 850 Patients			
366 (43%) Carriers of <i>Staph. aureus</i>			
Resistance to Penicillin	Nasal	Rectal	Nasal and Rectal
Resistant	179	138	68
Sensitive	93	55	21
Nasal sensitive/rectal resistant ..	—	—	4
Nasal resistant/rectal sensitive ..	—	—	6
Totals	272 (32%)	193 (23%)	99 (12%)

Recently both peach-coloured and ordinary blankets were tested before and after washing. The ordinary blankets before washing were quite dirty, having a mean count for the 20 tested of approximately 200. Two of them gave growths of *Staph. aureus*, both strains being resistant to penicillin and belonging to group III.

The 27 peach blankets tested were cleaner but varied in count from 15 to 200. The mean count was 70, but three gave growths of penicillin-resistant *Staph. aureus*, all belonging to group III. After washing the mean counts were respectively 31 and 14.

Since the practice of washing the peach blankets after each patient was discontinued the situation had deteriorated, indicating that a bactericidal concentration of cirrasol had not been built up or maintained in the blankets.

B ward was again tested recently (Frisby, 1957), and *Staph. aureus* was isolated with ease from the following 40 out of 48 situations:

Sister's desk	Power point
Case note trolley	Armchairs (4)
X-ray viewing-box	Bed tables (4)
Notice board	Ward wash-basins (staff) (2)
Cupboard top	Nail brushes (staff) (2)
Anglepoise lamp	Fluids trolley
Floor (5 different areas)	Kitchen sink
Table	Kitchen tap
Bed locker	Kitchen floor
Bed rails (6 different ones)	Sluice-room table
Curtain rails (2)	Sluice-room floor

All these strains were resistant to penicillin and all but one belonged to group III. This was similar to the findings on three previous occasions over the past year when the ward was swabbed.

The air of B ward was also sampled by means of a slit-sampler. This was done on four occasions, once while dressings were being done. On each occasion all samples yielded *Staph. aureus*, whatever the time of day and condition of ventilation. For the dressings samples, the machine was placed next to the dressings trolley and 4 ft. (1.2 m.) from the wounds. All the strains isolated were resistant to penicillin and belonged to group III.

As a comparison four other wards were also swabbed. Out of 48 swabs from M ward, 38 were positive for *Staph. aureus*; all strains were resistant to penicillin and most of them belonged to group III. L ward, A ward, and LM ward gave a similar picture; the strains isolated were from situations similar to those in B ward. Thus group III strains are seen to be generalized throughout the hospital.

Discussion

Bourdillon and Colebrook (1946) said that, whilst a freshly laundered gown or sheet is almost sterile, "all woollen or flannel objects must be regarded as infected." Barnard (1952), in a review of the literature, noted that the majority of freshly laundered blankets contained *Staph. aureus*.

The investigation described above confirmed the findings of these workers. The woollen blanket is a bad piece of hospital equipment. To make it suitable for use it needs to be specially laundered, and this more often than may be physically possible in probably most hospital laundries.

For this reason blankets made of terylene are being tried here. These are boiled like sheets, and the resulting counts of the clean blankets are under 20 with no *Staph. aureus*. They have the added advantage that they produce very little fluff, and they have stood up to an average of 14 boilings very well. They are light and warm, two only being required for each patient. Of course, boiling does not leave a protective deposit on the blankets, and it might be advisable to rinse them in cirrasol after boiling to ensure maintenance of a low bacterial count.

However, if a blanket which can be boiled is obtained, there must still be adequate facilities for washing each set after every patient. This is not only aesthetically desirable but bacteriologically necessary.

The evidence supporting the latter statement is overwhelming. The hospital staphylococcus must be attacked before it reaches the patient (Howie, 1956), and one of the points of attack must be the blanket.

Summary

Hospital blankets, unless specially laundered, are bacteriologically contaminated and potentially dangerous.

Provided they can be washed frequently—for example, after every patient—the lissapol-cirrasol technique is adequate to keep ordinary woollen blankets clean.

Some laundries may not be equipped to deal with the increased washing required for the technique to give satisfactory results.

Blankets of materials other than wool—for example, terylene—may help in the solution of this problem, although there must still be adequate facilities for providing each patient with a clean set of blankets.

I thank Miss M. Cossey (assistant matron), Miss M. McFall (laundry superintendent), and Sister R. M. Cole, of the Radcliffe Infirmary, Oxford, for their kind assistance with this investigation.

ADDENDUM.—Since this article went to press, Matthias *et al.* (1957) reported an analysis of nasal and faecal carriers of *Staph. aureus* among hospital patients. The figures shown above are similar to the corresponding ones given by these authors, and of the 37 combined nasal and rectal carriers shown in Table III 26 were of the same phage type in both situations, 9 were different, and 2 were untypable.

EUPHORIANT EFFECTS OF "PRELUDIN"

BY

JOHN B. RANDELL, M.B., M.R.C.P., D.P.M.
 Physician for Psychological Medicine, Charing Cross
 Hospital, London

Amphetamine, methylamphetamine hydrochloride, and other euphoriant drugs are commonly used for their anorexic properties in the treatment of obesity. It is therefore not surprising that a drug introduced for its anorexic properties should be found to have euphoriant and stimulant effects. "Preludin" (2-phenyl-3-methyl-tetrahydro-1,4-oxazine hydrochloride) is available without prescription in this country, and is claimed to assist weight reduction. Bethell (1957) reported a case of addiction to this drug in an unstable psychopathic personality. The cases reported here do not include a single case of addiction, although a patient presented at the casualty department of Charing Cross Hospital apparently suffering from addiction to preludin.

In a careful study of the effects of amphetamine, Harris, Ivy, and Searle (1947) concluded that the anorexic action of this drug occurred at two levels: (1) a central and cortical centre, and (2) a "hunger centre" in the hypothalamus. There appeared to be reduced intake of food and loss of weight by alteration of appetite and of the attitude to food, and by diminution of the subjective sensations of hunger.

Wendt and Caspar (1954), in a controlled trial of preludin in 18 subjects, concluded that it was superior to caffeine in promoting the impetus of trends of thought, relaxation, and ease. The pharmacological effect lasted five hours.

Reporting on the anorexic effects of preludin, Berneike (1954) and Kujat and Mühl (1955) found increased mental activity and alertness. The stimulant effect of the drug has also been examined by Spiegelberg (1954) in 28 normal and 135 neuropsychiatric cases. He found a strong stimulant effect with removal or delayed onset of the signs of fatigue and liberation from psychic tension. Favourable effects were noted in cases of depression, convalescence after insulin therapy, certain psychopathic reactions, "psychasthenic failure," conditions with vegetative dystonia, and organic illnesses caused by brain conditions with stimulus decreases.

Lennartz and Maass (1955) claim improvement in cases of Parkinson's disease and brain contusion, where the effect of preludin was said to be "vitalizing rather than euphoriant." These reports indicate a euphoriant similar to amphetamine and its derivatives.

Amphetamine has been used since 1938 as a stimulant drug in psychiatry and has found widespread application. Sargent and Slater (1954), in a survey of stimulant drugs in current psychiatric use, have commented on the now well-known euphoriant effect of amphetamine, dexamphetamine sulphate, and methylamphetamine hydrochloride, and discussed the indications and dosage to be used.

Method

The effect of preludin as a euphoriant was investigated in 10 student volunteers at Charing Cross Hospital. Palpitations, anorexia, relative insomnia, perspiration, restlessness, irritability, and difficulty in concentration were reported. One student noticed a sense of compulsion to activity. On withdrawal, increased hunger, depression, and fatigue occurred. The dosage was 25 mg. and later 50 mg., taken as a morning dose. The subjects were not aware of the nature of the drug, although the technique of morning administration may have suggested that it was similar to amphetamine.

Following this trial in normal subjects, a clinical trial was conducted in the psychiatric out-patient departments of four general hospitals. 147 patients given preludin have been followed up. The initial dosage was 25 mg. at 8 a.m. and noon, as the trial with student volunteers indicated that insomnia was likely to occur. This was not a controlled trial, and the "blank" and "double blank" technique involving the use of placebo tablets was not used. The drug was given as a variant of dexamphetamine, methylamphetamine, and combinations of these drugs with amylobarbitone. The case material consisted of mild depressive and psychoneurotic conditions. Some of the patients were considered candidates for E.C.T., and were to that extent a selected group. No instruction to reduce food intake was given.

Results

In addition to anorexia, some patients complained of excitement, palpitations, insomnia, trembling, dryness of the mouth, abdominal pain, and subjective sensations of increased energy. Mild depersonalization also occurred. Elevation of mood, increased mental activity, and concentration were reported by some subjects. In some a mild aggressive reaction was experienced. In two cases appetite was increased. Two further patients reported symptoms of hunger, and in one case there was a definite increase in weight. It did not appear that weight reduction was a significant finding, as there was little voluntary reduction of food intake. The patient in whom weight increase occurred also improved in mental condition, but Shorvon

and Richardson (1949) recorded several cases in which weight gain was associated with depression. Their depressive cases increased their food intake (and so gained weight) in a search for more pleasant sensations and as a substitute for normal sensations of enjoyment.

No patient suffering from severe psychosis was given preludin. E.C.T. had been given to some patients in this series. Many had been given other stimulants, including dexamphetamine. Some had been given sedation by barbiturates and the phenothiazine derivatives before receiving preludin. Two cases of Parkinson's disease with concomitant depression appeared to be made worse; this is contrary to the findings of Lennartz and Maass (1955).

Of the 147 patients, 87 (59.2%) appeared to be improved, 17 (11.5%) were unchanged, and 43 (29.3%) complained of symptoms which indicated that the drug had an adverse effect. The breakdown of these figures into symptom groups shows that cases of depression were significantly improved (see Table); this applied to patients who were given the drug

Results of Treatment

	Depressive State			Anxiety State	Hysteria	Obsessional State	Personality Disorders
	Preludin Only	Preludin Post-E.C.T.	Total				
Improved	29	25	54	3	17	9	4
Unchanged	7	2	9	—	7	—	1
Worse	10	11	21	8	9	4	1

after treatment by E.C.T. had failed to secure total remission as well as to those who did not require E.C.T. The figures obtained in the two groups show a close similarity. Of 33 patients suffering from hysteria, 17 were improved. The stimulant effect of preludin produced an increase of tension in the patients diagnosed as suffering from anxiety state, as was to be expected. Surprisingly, obsessional patients were improved in 9 of the 13 cases treated; but this total is small, and many of the cases had depressive features. Of the personality disorders, four cases in a small series of six were improved. A similar response is seen in the treatment of such cases with amphetamine.

Summary and Conclusions

A report of a clinical trial of preludin is given. The effects of the drug in normal volunteers and in psychoneurotic patients are reported. The drug appears to be pharmacologically active and similar to the amphetamines in its anorexic and euphoriant effects.

This trial seems to show that the effects of preludin are similar to those of amphetamine. The impression was gained that the euphoriant and stimulant effects were more powerful than those produced by 5 mg. of amphetamine twice daily. This finding differs from that of Bethell (1957), who reported that many more preludin tablets were needed to obtain the same stimulant effect as a few of dexamphetamine. The percentage of cases improved was higher than that to be expected from a placebo effect, and there seems to be no doubt that the drug is pharmacologically active. It would appear appropriate that this preparation should be classified under the same pharmaceutical schedule as the amphetamines.

Medical Memorandum

Trichobezoar Presenting as Nutritional Oedema

Bezoars, or masses of foreign material in the stomach and intestines, are known to occur in both man and animals. Their presence in the stomach of goats has been known for centuries, and magical healing properties were accorded to the concretions found there.

Trichobezoars, or hair-balls, are masses of hair, wool, or similar substance, matted together and forming varying amounts of indigestible matter. As would be expected, trichobezoars affect the gastro-intestinal tract and give rise to dyspepsia, peptic ulceration, haematemesis, perforation, intestinal obstruction, exhaustion, and inanition. The following case is of interest in that the presenting symptoms were oedema of the extremities and paraesthesiae.

CASE REPORT

A girl aged 15½ was referred to the out-patient department complaining of swellings of her feet, ankles, and legs for three months, and of her fingers for one week. There was no history of sore throat, injury, or pain, but her ankles were stiff in the mornings. Occasionally her toes had become blue and numb, and there had been paraesthesiae in her feet, and nocturnal cramp in her legs. She did, however, have infrequent "bilious attacks" and dizzy spells, but these antedated the swellings by many months. Anorexia had been present for one week. Increased frequency of micturition was present, ten times daily and four times nightly. Her periods and bowels were regular. She had been confined to bed intermittently for three months without effect.

There was nothing significant in her previous medical history. She and her elder sister were orphans, having been brought up by an aunt, who was very attached to them, as they were to her.

Examination revealed a bright, co-operative slim-built girl of average intelligence. During the early part of the physical examination a comment was made about her hair style. "I used to pull it out," she said. A provisional diagnosis of trichobezoar was made on examination of the abdomen, where a

FIG. 1.—Radiograph showing trichobezoar.

hard, painless, smooth, mobile mass was palpated, extending from under the costal margins, down as far as the umbilicus. The diagnosis was confirmed by the patient, who then, when asked, admitted having swallowed her hair intermittently for

over three months. Pitting oedema was present on her feet and legs half-way up to her knees, and was also present on her fingers.

Investigations.—Hb, 81%; W.B.C., normal; plasma proteins, 6.9 g./100 ml. (albumin + fibrinogen 2.6 g., globulin 4.3 g.). A:G ratio 1:1.6; blood urea 26 mg. per 100 ml. Urine was normal. The trichobezoar was visualized on x-ray examination following two mouthfuls of barium sulphate solution (Fig. 1).

The patient was admitted that day, and the trichobezoar was removed the following day through an upper midline

incision in the abdominal wall and a transverse incision across the lower anterior wall of the stomach. The hair-ball came away as a complete cast of the stomach and first two parts of the duodenum, where it showed signs of digestion and decomposition. Its fresh weight was 1½ lb. (794 g.) (Fig. 2).

FIG. 2.—Photograph of trichobezoar.

The girl made a speedy recovery and soon regained her appetite on a high-protein diet, supplemented with vitamin-B complex. The oedema rapidly disappeared, and there were no further symptoms of cramps or paraesthesiae. Ten days after the operation, although the total plasma protein level had not yet risen, the A:G ratio was 1.4:1. When seen one month later she had put on weight and her hair was growing thick and long.

COMMENT

Trichobezoars most commonly occur in females (90%), and, of these, 80% arise under the age of 30 years. De Bakey and Ochsner (1938), in a comprehensive review of the world's literature, collected 171 cases and added one case of their own. They showed that the effects of bezoars were intestinal obstruction, gastro-duodenal ulceration leading to haematemesis, perforation and peritonitis, inanition, and exhaustion. A case presenting with intestinal obstruction is reported by Trafford (1954), with perforation (Osmond and Price, 1951), vomiting, and colitis with nutritional upset from disordered liver function (Nussey and Leask, 1949). Cases occurring in children are recorded (Fox and Stiles, 1951; Hurwitz and McAlenney, 1951). Davis (1921) reported a case with severe abdominal pains, indigestion, vomiting, and oedema of the limbs. In his case the hair-ball weighed 6½ lb. (2,950 g.) fresh, but the average weight is 1½ lb. (680 g.).

In the case reported above, the possible effect of the trichobezoar was to cause a protein deficiency, as was shown by the inverted A:G ratio. That the oedema was not of renal origin, such as might have been produced by pressure effects upon the renal veins, was shown by an absence of albumin in the urine, while the blood urea level was 26 mg. per 100 ml. Liver-function tests were not performed. Furthermore, when the hair-ball was removed the A:G ratio returned to normal within 10 days, and the oedema rapidly subsided. The period of hair-swallowing, so far as could be judged from the girl and her foster-mother, started only two or three weeks before her ankles first began to swell, so the effect of the trichobezoar was relatively rapid.

I thank Dr. J. G. Dathan and Mr. G. G. Crowe for permission to publish this report and for help and advice, and Mr. J. E. Turner and Mr. B. Goodfellow for the x-ray film and the photograph.

Reviews

A LITERARY SURGEON

Surgeon's Journey. The Autobiography of J. Johnston Abraham. (Pp. 441+viii; illustrated. 25s.) Melbourne, London, Toronto: William Heinemann Ltd. 1957.

It takes an unusual combination of abilities and qualities for the same man to be a distinguished surgeon, a capable administrator, a famous writer, and an enterprising publisher. Yet that is what the writer of this excellent autobiography has succeeded in being at different periods of his life. Johnston Abraham was born at Coleraine in Northern Ireland and was brought up according to the strict principles of his nonconformist parents. At Trinity College, Dublin, he studied medicine, but showed such a taste and aptitude for literature that he asked Professor Dowden if he ought to abandon the one career for the other. Dowden advised him to continue with medicine, and quoted Charles Lamb, "Literature is a very bad crutch but a very good walking stick"; he added that another man had some years previously asked him the same question and he had given the same answer—to Altmouth Wright. A breakdown in health proved in fact a piece of good fortune, for it induced Abraham to take a voyage to the East as ship's doctor. This resulted in his writing *The Surgeon's Log*, one of the most readable and popular travel books ever published, now in its 30th edition. (Strange that *The Other Side of the Lantern*, that other popular travel book, should have been written by a surgeon, Sir Frederick Treves.) When the first world war broke out Abraham had already started his surgical career in London, but this did not prevent his volunteering for service with the Red Cross in Serbia and later serving with the Army in Egypt and Palestine. There his outstanding administrative abilities were promptly recognized in 1917 by his being appointed A.D.M.S. Palestine Lines of Communication.

The reader must himself read this book to learn of Abraham's success in practice and of his fame as a writer and a publisher. In spite of the great success of the books published under the name of James Harpole, very few people know that they were written by the author of *The Surgeon's Log*. Throughout the book we get glimpses of many famous men and women whom the author knew as friends or acquaintances, and there are many good stories told. This is indeed a very readable autobiography of a distinguished and lovable person who has recently become an octogenarian.

ZACHARY COPE.

ADOLESCENTS IN INDUSTRY

Youth at Work. A Five-year Study by an Appointed Factory Doctor. M. E. M. Herford, D.S.O., M.B.E., M.C., M.D., D.P.H. (Pp. 154+xvi. 18s. 6d.) London: Max Parrish 1957.

Most social workers and G.P.s are vague to the point of ignorance concerning the scope and significance of the work of the appointed factory doctor, and this account by Dr. Herford of his experiences while engaged as an A.F.D. in Slough will go a long way to remedy the deficiency. The A.F.D. is appointed by the Chief Inspector of Factories and is responsible for the physical health and welfare of adolescents employed by industrial concerns from the time of their intake until their eighteenth birthday. There has been some discussion on whether such work does not more properly fall within the sphere of the local authority school medical service, but Dr. Herford suggests that the most useful form of collaboration between the National Health Service, industry, and such statutory departments as Youth Employment would result if the A.F.D., presumably himself in general practice, were also to be made an assistant school medical officer, primarily responsible to the Medical Inspectorate of Factories. In the process of discussing such administrative matters Dr. Herford has given us a very

convincing and comprehensive account of his own work in industry, and he has shown himself to have a sympathetic approach to the young people with whom he has had to deal. Naturally he is as much concerned with their psychological adjustment as with their physiological disabilities, and he deplores the fact that sometimes "employers, driven by need for labour, often compete for juvenile labour in a manner detrimental . . . to the training and proper discipline of youth." The whole business of apprenticeships is something that the trade unions and the employers need to get straight before present anomalies are eliminated. As the author says, a boy's first year in industry, a year supremely vital for the development of future attitudes towards work and the dignity of labour, is often wasted doing odd jobs and making tea, with the result that he often gets "into bad habits and becomes resentful."

Dr. Herford has some pungent comments on the work of the Youth Employment Service which its sponsors and officials would do well to study. In his own experience he finds little evidence that any truly vocational guidance is ever given to the school-leavers, and that the bureau tends to operate merely as a juvenile labour exchange. Youth employment officers, moreover, do not see enough of the young people while they are at work or maintain contact with the A.F.D. All this is to be deplored, and reflects, no doubt, the general apathy of the adult community to the problems of youth at work. At the moment we spend a great deal of time and money on education, but after the age of 15, until military service looms on the horizon, the only link that the young worker has with preventive and advisory medicine is supplied by routine examination by the A.F.D. Since this service covers only those in industry and ignores young people working in offices and other types of employment it is obvious that there are gaps which we ought to be attempting to cover and so implement the proposals of the Gowers Report of 1949.

The author of this book is not concerned to invent imaginary problems or to exaggerate the needs of the young people he meets during the course of his work. On the whole he finds them a sensible and well-adjusted group. The proposals he puts forward, the criticisms offered of existing services, are solely designed to assist young workers through a difficult developmental phase and when attitudes may be created inimical to both personal and communal well-being and which may entail both personal illness and productive inefficiency. This is a matter we all ought to be concerned with; and the strength of Dr. Herford's suggested alterations lies in their financial economy and the ease with which they could be carried out for the benefit of all concerned.

JOHN BARRON MAYS.

CYTOLOGY OF THE DIGESTIVE TRACT

Atlas der Gastroenterologischen Cytopathologie. German and English text. By N. Henning and S. Witte. English translation by R. O. K. Schade. (Pp. 103+vii; illustrated. D.M. 38.) Stuttgart: Georg Thieme Verlag. 1957.

This atlas is devoted to the practical uses of modern cytological methods in the study of diseases of the gastro-intestinal tract and of the liver. The authors have been using cytological methods since 1948, when they developed a simple instrument, the *Zelltupfsonde* ("cell-swabbing tube"), which permitted them to obtain cellular material from both oesophagus and stomach. During the succeeding years they extended their studies to include examination of the duodenal contents, from which useful information can be gleaned about the state of the liver and of the biliary system. The mouth and rectum have been studied chiefly by the technique of direct swabbing. The short text is both in German and in English. The main part is devoted to describing the abnormal cells which may occur in various parts of the gastro-intestinal tract and discussing their diagnostic significance. There are short sections on how to collect material and on the methods of cytological examination. The German text has been put into fluent English by Dr. R. O. K. Schade, senior lecturer in pathology in the University of

Durham. There are 114 plates showing examples of the various cytological abnormalities that may occur. These all take the form of black-and-white photomicrographs. The authors state that they chose photographs rather than drawings "for the purpose of achieving the objective truth." High costs made the reproduction of coloured photomicrographs prohibitive. However, the black-and-white reproductions give a good idea of the characteristics to be observed in the normal cells, particularly when looked at in conjunction with reading the text. Many of the illustrations are of phase-contrast preparations, where the question of colour does not arise.

The authors are to be congratulated on their clear and concise account of a new aspect of clinical medicine. They give a useful list of 64 references, confining themselves to recent monographs and articles. The paucity of British references in their list is notable. However, this should not be interpreted as being due to prejudice but as no more than a reflection of the fact that in our country we have been somewhat tardy in applying modern methods of cytology to the problems of disease. To those physicians, surgeons, and clinical pathologists who are interested in the gastrointestinal system but have no knowledge of modern cytological methods this atlas will prove an invaluable introduction.

S. C. TRUELOVE.

VECTORCARDIOGRAPHY

Atlas d'Electrocardiographie avec des notions de Vectocardiographie. By V. Fattorusso and O. Ritter. 4th edition. (Pp. 295; illustrated. 3,200 frs.) Paris: Masson et Cie. 1956.

This atlas is very well done indeed. The illustrations are particularly numerous and of praiseworthy clarity. The descriptions are always adjacent, so they are easily studied together. There are very good explanations based on the cardiac vector which make understanding of the abnormalities in the T waves easier. The actual section on vectorcardiography is well set out. At first glance many of the diagrams may seem rather elaborate, but they are well worth study, and if only a fraction of the time devoted to this compilation is given to their comprehension much will be learned. For the authors the theory of circus movement is still the most acceptable to-day.

There are numerous useful tables and a fair number of references. The index is adequate. The print and expression are clear and concise. A very attractive book.

TERENCE EAST.

SOVIET PSYCHOLOGY

Psychology in the Soviet Union. Edited with an introduction by Brian Simon. (Pp. 305 + viii. 32s.) London: Routledge and Kegan Paul Ltd. 1957.

This book arose out of a visit the editor made to the Soviet Union, during which he asked Professor Smirnov, director of the Institute of Psychology in Moscow, for his co-operation in selecting some 30 articles and lectures which he felt were representative of contemporary Soviet psychology. The book consists of a selection of these, and it is claimed that "the articles cover the main field of psychological research and thinking in the Soviet Union." Clearly such a venture has much to recommend itself. So little is known about post-Pavlovian work in the U.S.S.R. that a well-chosen selection of papers, well translated, would have been most welcome. Unfortunately, the present selection is rather like the curate's egg, with the bad parts predominating. What one would have liked to have would be important experimental contributions giving all the necessary details about conditions, number of subjects, selection of subjects, statistical treatment of data, and so forth, which would enable one to assess the value of the work. Instead of that the book contains a great deal of material which is either irrelevant or impossible to appreciate. There is a lot of theoretical discussion, at a very elementary level, which argues philosophical points which might have been of

interest 50 years ago. Political incursions and obeisances to Pavlov are frequent and intensely irritating. Repeated summaries are given of large areas of work which are so cut down that they are almost entirely meaningless. When occasionally original researches are reported they attract by an air of novelty, but the reports never give sufficient detail to make it possible to evaluate the results. One has the impression that very few subjects are used, that there is no statistical treatment of the data at all, and that the results are somehow forced into agreement with Pavlovian theory by hook or crook. American experience has indicated that it is often impossible to duplicate results confidently claimed as definitely established by Russian authors, and some of the claims, such as those relating to the improvement of dark vision through conditioning, appear quite incredible to anyone who has worked in this field. (Incidentally, the author of this report gives all his results in terms of percentage improvement from a base line which itself is not reported. This is almost meaningless and brings Soviet psychologists in line with their economists, whose use of a similar technique has reduced Western economists and statisticians to a state of fury.)

Altogether, then, this book is very disappointing, although to the professional psychologist it still contains enough material of interest to warrant its perusal. It is not impossible that the deficiencies of the book mirror the deficiencies of Soviet psychology; if this is so, the editor and Professor Smirnov are to be congratulated on giving us so faithful a mirror of Soviet psychology. My own contacts with Russian psychologists lead me to believe, however, that this is a caricature rather than an accurate picture, and that the venture will have to be repeated by someone better equipped to sort the wheat from the chaff.

H. J. EYSENCK.

SEXUAL DEVIATIONS

Variations in Sexual Behaviour: A Psychodynamic Study of Deviations in Various Expressions of Sexual Behaviour. By Frank S. Caprio, M.D. Foreword by George W. Henry, M.D. (Pp. 344 + xxxi. 30s.) London: John Calder. 1957.

Divergence in expression of the sexual instinct is strange and often mysterious. Homosexuality in men and in women is familiar to every reader of novels. But other variations in sexual behaviour, such as exhibitionism, fetishism, sadism, masochism, transvestism, fellatio, cunnilingus—to mention only a few—may come as a shock to the practitioner. Yet he is sure to be consulted at some time, perhaps by the sadly disturbed spouse of a sufferer from one or more of the deviations from normal sexual life. The victim may be a psychopath or a schizophrenic; more often he (or she) is successful in work and socially adapted. Dr. Caprio's observations on aetiology and treatment are not of great practical value. Nevertheless, the book will be useful to those who know little of sexual deviation. It is written in a matter-of-fact style: case illustrations are numerous and there is an adequate glossary.

E. A. BENNET.

Since the war the publication of medical journals and books has much increased, no doubt in response to the increase in medical research. Not only do doctors write more, but they find they have to read more, and in consequence there are many more medical libraries than there used to be. All large hospitals, and very many small hospitals, now have quite considerable libraries, and a recently published small book provides a comprehensive guide to them. *Directory of Medical Libraries in the British Isles* has been compiled by a subcommittee of the medical section of the Library Association and is published by that association from Chaucer House, Malet Place, London, W.C.1 (13s., plus 6d. postage; 9s. 6d. to L.A. members). The book covers medical libraries in the whole of Great Britain and the Republic of Ireland, including a number of libraries owned by commercial firms. Notes on the larger libraries give details of what sort of books and periodicals are obtainable there, who may borrow them, the address and telephone number of the library, and the names of the paid or honorary staff in charge.

BRITISH MEDICAL JOURNAL

SATURDAY AUGUST 31 1957

DIAGNOSIS OF POLIOMYELITIS

The management of poliomyelitis is shared by general practitioner and specialist, and it is hard to say who has the more difficult task. The specialist indeed may have to diagnose the condition from other illnesses which are often obscure, and in treatment has to make decisions which are often controversial and difficult. But in a sense his work is technical and he has colleagues to help him and resources of a hospital behind him. The general practitioner faces a wide variety of illnesses, a few severe but most of them trivial; he must pick out the odd case which may be poliomyelitis. He has nothing to aid him except clinical acumen.

What type of illness should arouse his suspicion? In the minor illness of poliomyelitis there are no specific signs or symptoms. The patient complains of vague malaise, of aching in the limbs, perhaps of a sore throat, a head cold, or a "touch of flu"; headache is a common complaint of adults, but in the child there may be little other than tiredness and moping. During an outbreak of poliomyelitis these symptoms arouse suspicion, especially in contacts of the disease. The minor illness is the stage of viraemia; during this stage injections or undue muscular exercise may attract the virus from the blood stream into overactive nerve cells, with resulting paralysis of muscles, so that exertion and unnecessary injections should be avoided. After an interval of a few days, during which the patient may appear well, the major illness sets in with its signs of invasion of the central nervous system. The most obvious symptoms are headache, neck stiffness, and fever, and usually when these signs are present the diagnosis of meningeal irritation can be made easily. In very young children neck stiffness is difficult to assess; if one seizes a baby's head and tries to flex the neck, nearly every baby will respond with marked neck stiffness; the head is best rocked gently from side to side for a few moments and flexion tried when the baby is off its guard. Acute tonsillitis with cervical adenitis is a common cause of neck rigidity; the neck is certainly stiff, but this is due to the pain of the glands and not to meningeal irritation. Pain in

the trapezius or other muscles of the neck may occasionally produce neck stiffness in adults, and pneumonia or otitis media in children sometimes causes a meningism difficult to distinguish from the stiffness of meningitis. Not many cases of true meningeal irritation are missed at this stage; a fair number are diagnosed as such where careful clinical examination might reveal a simpler cause of the neck stiffness. True meningeal irritation may be due to many causes other than poliomyelitis and it may be difficult to make a diagnosis clinically. The child with tuberculous meningitis has probably been going downhill for a week or two and is often drowsy and apathetic, whereas the patient with poliomyelitis remains alert and apprehensive. The patient with pyogenic meningitis is probably more ill and has greater neck rigidity, though the signs may be very slight in babies. But in practice the differentiation from tuberculous or pyogenic meningitis is not usually very difficult, and in doubtful cases examination of the cerebrospinal fluid will be conclusive. There are a number of infections of the central nervous system in which only laboratory investigation can establish the diagnosis—mumps meningitis, Echo or Coxsackie virus infections, and canicola fever are examples; occasionally brain tumour or abscess may cause similar symptoms. If the general practitioner can establish the presence of true neck rigidity, that is usually as far as he can go at this stage.

When the stage of paralysis sets in, diagnosis is usually easy, but a few conditions may cause confusion. There are two main causes of immobility of a limb—weakness of the muscles and pain. Poliomyelitis is the only common cause of acute muscular weakness or paralysis. In acute polyneuritis the paralysis tends to be more symmetrical and there are often sensory symptoms, but the management of the two diseases is very similar. It is impossible on clinical grounds to say when a solitary facial paralysis is due to poliomyelitis or when it is a case of Bell's palsy, but virological investigations are often positive for poliomyelitis. Myasthenia gravis is a much rarer cause of muscular paralysis. It may present as a respiratory crisis, but even if the diagnosis is not made beforehand no harm will be done by sending the patient to a poliomyelitis respiratory centre. Hysteria is a fairly common cause of apparent weakness, and there is perhaps some increase during a poliomyelitis epidemic. Benign myalgic encephalitis, the so-called "Royal Free disease," is unlikely to be diagnosed without much observation and investigation.

Immobility due to pain commonly leads to a mistaken diagnosis of poliomyelitis. Though pain does

occur in the paralytic stage of poliomyelitis, it is not usually severe; agonizing myalgia is very unlikely to be due to poliomyelitis. Osteomyelitis in children is a fairly frequent cause of error. Often there are no localizing signs and only very careful examination of the limb will show that the child is afraid to move the limb because of pain. In younger children and infants septic arthritis may present a similar picture. Sometimes the cause of the pain may be inguinal, femoral, or axillary adenitis resulting from a septic focus in the limb; an abscess in the groin or about the shoulder-joint may cause unwillingness to use the limb. In babies and young children injury may be the cause of apparent paralysis; occasionally a fracture in a baby is overlooked, more often there is simply some muscular tenderness which passes off in a day or two. Acute or subacute rheumatism may cause immobility, but careful examination usually will show that there is no true weakness and that the pain is in the joints. Paralysis in poliomyelitis rarely comes on suddenly, and when there is a history that the patient's legs gave way while out walking or while bending or in some similar dramatic way the cause is almost certainly not poliomyelitis. It can be said that in the great majority of cases the diagnosis of the major illness of poliomyelitis is easy. That there are pitfalls can be exemplified by the diagnoses in three patients occupying adjacent cubicles in a hospital: one has staphylococcal septicaemia, one subacute rheumatism, and one canicola fever. All three were suspected of having poliomyelitis.

Respiratory embarrassment may be due either to paralysis of the muscles of respiration or to obstruction of the airway as a result of pharyngeal paralysis. Correct diagnosis between these two causes is vital. While restricted movement of the thorax is easy to diagnose clinically, the point to remember is that this restricted movement may be due not to paralysis of the breathing muscles but to the fact that the patient's pharynx is full of secretions due to pharyngeal paralysis, and that he is afraid to breathe because of the danger of inhaling these secretions. The treatment for true paralysis of breathing muscles is some form of artificial ventilation; the treatment for pharyngeal paralysis is to turn the patient on his face and allow the secretions to run out of his mouth. This simple measure may make all the difference between life and death if carried out in time. The diagnosis of pharyngeal paralysis is easy, provided the physician looks inside the mouth.

It is always difficult to forecast how any case will progress, and patients in the meningeal stage are probably safer in hospital. When paralysis has developed it is sometimes a little easier to give a

prognosis. Severe paralysis is usually severe from the outset, though every clinician has seen an apparently mild case progress to severe paralysis and possibly death. Patients who are first seen twenty-four to forty-eight hours after the onset of paralysis and whose paralysis is still mild are unlikely to become worse, and the question of whether to treat at home or in hospital arises. If the home is a good one, no harm will result from treating the patient at home. On the other hand, no harm will result from sending him to hospital. The main argument against sending a patient to hospital is the possible bad effect of the journey on the progress of the paralysis. But the stage of viraemia is past and it is unlikely that movement at this stage has any specific untoward effect. An ambulance journey has its hazards in any severe illness. In severe cases of poliomyelitis these hazards must be faced in the interests of the patient, and in desperate cases they can be mitigated if a skilful team of doctors and nurses accompanies the patient.

REPORT ON HALOTHANE

Anaesthetists throughout the world have been awaiting with interest the Medical Research Council's report on halothane published in our opening pages this week. It is notable in that never before has a new anaesthetic drug been submitted to such a thorough pharmacological and clinical investigation by experienced workers before it has become available for general use. The primary concern of the M.R.C.'s Committee on Non-Explosive Anaesthetic Agents, whose report it is, was to seek a new drug which would have the safety of ether as an anaesthetic agent yet be devoid of all risk of explosion in the operating theatre. This excellent report shows that, while halothane ("fluothane") has not achieved these heights of perfection, it has some useful properties.

The investigation has been made from three approaches—namely, pharmacology in animals, clinical investigation and experience in man, and finally a review of suitable apparatus for administration. Of the pharmacological investigation there are three important findings. First, halothane, like chloroform, has a specific action on the heart, depressing myocardial activity and reducing the cardiac output in direct proportion to the concentration used. Secondly, the fall in blood pressure with halothane is not primarily related to a block of the autonomic ganglia, but more probably to a direct depressant action on the vasomotor centre. Finally, the action at the neuromuscular junction is similar to that of D-tubocurarine, but even when used in high concentrations this effect is not very marked. The evidence

is lacking in one factor—namely, the action of the halothane directly on the peripheral blood vessels. All general anaesthetics temporarily depress the vasomotor centre on loss of consciousness; this gives rise to the increased flow of blood through the vessels of skin and muscle which is so troublesome for the surgeon. On the data available it seems possible that the hypotensive action of halothane may be due to the reduction in cardiac output, or to a direct vasodilator action on the peripheral vessels, or to both these changes.

In the clinical part of the report Dr. T. H. S. Burns and his colleagues are in complete agreement with the pharmacological findings in animals, and they draw special attention to three main points. First, halothane depresses respiration even during the early stages of induction of anaesthesia, and patients may become cyanosed if their respiration is not assisted. Secondly, in about one-quarter of the patients the systolic blood pressure fell to below 80 mm. Hg. In a small percentage of cases cardiac irregularities developed. Thirdly, the incidence of post-operative vomiting was no less than after other anaesthetics.

Many anaesthetists will now wonder whether or not to add this new drug to their repertory. Unfortunately the report gives little specific advice on this matter, but these and other trials to which this drug has been subjected, to which the M.R.C. report makes reference, suggest that it has a limited but useful part to play in modern anaesthesia. Its potency is similar to that of chloroform, and some of the side-effects are such that many clinicians will recognize a surprising similarity between these two drugs. To-day anaesthetic apparatus and the knowledge of the physiology of the unconscious patient are vastly different from what they were in the chloroform era. The fact that halothane is a respiratory and myocardial depressant would suggest that it is not suitable for deep anaesthesia and muscular relaxation. Moreover, it is unlikely to replace thiopentone sodium as a pleasant way of losing consciousness. Its main role, therefore, would appear to be as an adjunct to light anaesthesia. In this respect it may well replace trichlorethylene, because it is far more versatile. The hypotension and reduced bleeding will prove attractive to many anaesthetists, but often a price has to be paid for producing such perfect conditions. For the anaesthetist working in places where the supply of nitrous oxide and oxygen is limited, halothane may be found a useful substitute. But so great is its potency that it is essential to use a specially designed apparatus capable of delivering a known concentration of the vapour. Adequate means

of ventilating the patient's lungs must also be available. A suitable calibrated inhaler of the type described by Dr. H. G. Epstein in the report, or an adaptation for the Boyle's machine (now commercially available), would appear to fulfil the necessary criteria. At present the closed-circuit technique, the subject of a recent report in this *Journal*,¹ is best avoided by the inexperienced, because it is impossible to control the concentration of the inspired vapour in such conditions. In selecting premedication it is as well to remember that this drug is a strong respiratory depressant. The morphine group of drugs is best avoided or given only in very small doses. Large doses of atropine (1–2 mg.) have been advised in order to reduce the risk of sudden vagal stimulation on induction of anaesthesia. Part of the price the patient must pay, therefore, is to forfeit some of the ease of mind that routine types of premedication provide.

Provided halothane is used with caution under conditions where the concentration of the vapour can be controlled, it has a useful part to play. Specially designed apparatus for administration is essential. The main use of halothane may be in those operations in which bleeding is troublesome yet only a light plane of anaesthesia is required. For example, plastic operations and those on the ear, nose, and throat are well suited to this type of anaesthesia; it may also be found useful in cranial and thoracic surgery. On the other hand it is unlikely to gain favour in anaesthesia for cardiac surgery owing to its depressant action on the myocardium.

DANISH MEDICAL ASSOCIATION

This week-end the Danish Medical Association is celebrating its centenary. Its annual general meeting, annual representative meeting, and annual dinner on August 31 are to be followed the day after by a festival meeting in the University of Copenhagen attended by the King and Queen of Denmark. The President of the B.M.A., Mr. Weldon Watts, is presenting a gavel and block inscribed with the Association's fraternal greetings, and made from the wood of the mulberry tree which grew in Charles Dickens's garden where B.M.A. House now stands. Delegates from many other countries will be present on this auspicious occasion in the family of national medical associations, whose growth would surely be a matter of pride to the visionary founders of the Danish and of the other older associations were they here to witness it. The Danish Medical Association began in the provincial town of Korsør on the island of

¹ Marrett, H. R., *British Medical Journal*, 1957, 2, 331.

Zeeland, on September 1, 1857. Its founding was the outcome of informal meetings among doctors from the provinces during the preceding six years, a form of genesis which calls to mind the beginnings of our own Association. If the original aims of the D.M.A., stressing as they did that its main object should be to create conditions for medical practice in which the doctor's vocation could best be exercised, differed from those of the B.M.A., with their greater emphasis on fostering medical science, it may well be because our Danish colleagues were already partly familiar with the potential dangers of State medicine, for the provision of hospitals in Denmark as a social task was laid down by ordinance as long ago as 1806.

The D.M.A.'s present objects, as revised in 1935, are (1) to unite Danish doctors in watching over the interests of the profession, and (2) to act as the organ by which the medical profession exerts its influence on problems affecting the community in general. Its membership of 5,800, no less than 98% of the profession, is an impressive instrument for carrying out these objects. An active peripheral organization consisting of branches (each with its own small council) together with two associated special groups, representative on the one hand of younger doctors (hospital junior staff) and on the other of specialists, assures that an effective representation of professional opinion, both sectional and general, is brought to bear on the centre. A House of Delegates, corresponding to the B.M.A.'s Representative Body, consisting of 86 members elected by branches in proportion to their membership, meets once a year to decide policy and instruct its executive. The latter, the council, is a small body with a chairman, who is also president of the association, and seven members elected by the House of Delegates for a period of six years. The present chairman is Dr. Charles Jacobsen, a general practitioner in Copenhagen. Alongside the council, and bearing their share of the routine work, are several standing committees of a kind familiar to all associations. For the benefits of belonging to his national medical organization the Danish doctor pays an annual subscription equivalent to £10. That the Danish people too have benefited from the influence that the D.M.A. has exerted, in the terms of its second object, on "problems affecting the community in general," is evidenced by the pre-eminent position Denmark occupies, and has always occupied, in the field of social and preventive medicine. Such a position could hardly have been attained had not the various health authorities in Denmark been willing to co-operate with organized medicine in a relationship in which professional opinion led and informed lay helpers followed.

Last but not least we may refer to two journals published by the Danish Medical Association. First there is the *Ugeskrift for Læger*, a weekly medical journal which was launched in 1839, eighteen years before the association was formed. It has long held a distinguished place among the medical journals of the world. The second—a newcomer only three years old—is the *Danish Medical Bulletin*, a monthly journal published in English. This is a notable innovation, and a reminder, if one were needed, of how close in kinship our two nations are. Some Scandinavian publications in the English language are written in an idiom that is unmistakably foreign. Not so with the *Danish Medical Bulletin*, which is in remarkable fact setting a high literary standard to many to whom English is a native language. Still one more enterprise in medical journalism owing much to our Danish colleagues is the *Nordisk Medicin*, a weekly journal jointly supported by the four Scandinavian countries.

CEREBRAL CYSTICERCOSIS

Since Sir William MacArthur¹ and others established the importance of cysticercosis as a cause of epilepsy, there has been a tendency to overlook the other cerebral manifestations of the disease. E. R. Bickerstaff² drew attention to this in an article in the *Journal* two years ago. The disease is common in Latin America, Spain, and Poland, where it spread considerably during the war. This week Drs. C. Arseni and D. C. Samitca give a full report in the *Journal* (p. 494) of 65 cases seen in Rumania. Immigration has increased the incidence of the disease in Great Britain, and is likely to do so in the U.S.A. also.³

Eating measly pork allows the larva of *Taenia solium* to develop in the human intestine, but it does not lead directly to cysticercosis in man; this stage normally takes place in the pig. Cysticercosis follows the ingestion of the ova of *Taenia solium*, which are acquired from human faeces or possibly by regurgitation. These form cysts in the brain, muscle, and subcutaneous tissue. The chief manifestations of cerebral cysticercosis are epilepsy, mental disturbance, raised intracranial pressure, and loss of vision; focal signs and symptoms also occur. There are three main situations in which cysts may be detected in relation to the brain.⁴ In the cortex they behave in much the same way as a cerebral tumour, giving rise to generalized or focal epilepsy and to signs which vary according to their situation. The lesions may be isolated or spread throughout the cortex and white matter. Intraventricular cysts are commonest in

⁶ Stepień, L., and Choróbski, J., *Arch. Neurol. Psychiat.* (Chicago), 1949, 81, 499.

the fourth ventricle; they produce intermittent symptoms of raised intracranial pressure, which may be related to posture. Cysts together with proliferated meninges over the base of the brain also cause increased intracranial pressure by obstructing the passage of cerebrospinal fluid. A so-called racemose form, which may block the outlets of the fourth ventricle, is also found in the posterior fossa.⁵ Episodes of meningo-encephalitis may punctuate the history. Mental deterioration is produced by hydrocephalus or cerebral atrophy, or by the presence of the cysts themselves. Loss of vision may follow papilloedema or be due to infestation of the eye or visual pathways.

Diagnosis of the disease depends to a large extent on careful inquiry to detect the possibility of infestation. The time between acquiring the disease and the appearance of symptoms may vary from a few months to 20 years. During attacks of meningo-encephalitis there is a pleocytosis in the cerebrospinal fluid, in which eosinophils are found, together with a moderately raised protein. The Lange curve is of parietic type and the Wassermann reaction negative. Calcified cysts should be sought radiologically, for they are found in the brains of a third of those suffering from cerebral lesions and more frequently in the skeletal musculature. Subcutaneous nodules are sometimes available for biopsy. A complement-fixation test is said to be positive in just over half the cases examined. Ventriculography will assist in the localization of cerebral lesions.

The importance of making a correct diagnosis lies in the possibility of successful operative treatment. Most isolated lesions that behave like a tumour should be removed, and satisfactory results may be expected in more than half the cases.⁶ Surgery has little to offer those patients with severe oedema of the brain, to which children are particularly susceptible, or those with obstruction of the basal cisterns. Epilepsy is best controlled by anticonvulsant therapy in addition to any surgical treatment that may be possible.

DEPOPULATION OF A RURAL AREA

The depopulation of rural areas and their general social and educational backwardness are topics of much concern for a country which prides itself on its welfare achievements. Yet, apart from the broad demographic trends, little precise information is available on what is happening as a result of the exodus to the towns. It is partly to remedy this defect, at least for one corner of rural Devon, that E. D. Allen-Price, the medical officer of health for Okehampton, has put together some "micro-statistics" on the sociological consequences of population decline in his area during the pre-war years.¹ He calculated correlation coefficients between five sets of statistics: (1) the percentage rise or fall in the population of the twenty parishes of the Okehampton District between 1901 and 1931, (2) the mean intelligence quotients of the children of these parishes as given by Otis group intelligence tests supplemented in doubtful

cases by individual tests, (3) the standard deviations round the mean of these same test scores, (4) a specially designed score of the material and social attributes of each parish, and (5) the percentage of malnourished schoolchildren in each parish.

Some interesting correlation coefficients emerge. Thus, that between the social and material attributes of the parishes and the mean I.Q.s of the schoolchildren is given as $+0.8041 \pm 0.053$, and that between these attributes and the standard deviations of the I.Q.s as $+0.8324 \pm 0.046$. "With correlations such as these," claims the author, "there is no possibility of chance coming in at all, and one is forced to the conclusion that the intelligence of a community predetermines all the attributes which may be ascribed to that particular society." This is an important conclusion, though much depends on how the scores for social and material attributes were made.

Ten items altogether were used, some calculated on the basis of known or ascertainable statistics. A parish with a piped water supply to every house, for example, was awarded 20 points, one with "poor wells" 5 points. But for other items the method is sometimes open to question. Points were awarded for "general prosperity" assessed "on observation and conversations with bankers and merchants." Others were awarded for general impressions. Thus the exact meaning of the correlations may be rather obscure, and the work of J. D. Nisbet on the relationship between family size and I.Q. scores² suggests an alternative explanation. This is that the main differences in I.Q. data of the Okehampton schoolchildren were produced by the differences in the social and material environments of the parishes in which they were reared, rather than the reverse, entailing as this would assumptions about the inheritance of intelligence from the parent generation.³ In 50 years' time it may be possible to interpret these carefully compiled data with more certainty, particularly if some attempt is made to repeat the investigation. Meanwhile, in chronicling the changing countryside, Allen-Price has set an example that other medical officers of health may find inspiring.

MENTAL DEFICIENCY IN SCOTLAND

The Standing Medical Advisory Committee of the Scottish Health Services Council appointed in 1949 a Mental Health Subcommittee to inquire into and report on that part of "the mental health service in Scotland which affected mental deficiency." The report¹ is now published most opportunely, at a time when psychiatric interest is centred on the report² of the Royal Commission. The statement in the Scottish report that mental deficiency is essentially a social problem could be questioned, but not the fact that it has important social implications or that inadequate medical and social provisions put a heavy burden on households and on the community. Knowledge of the incidence of mental deficiency is inadequate because ascertainment in some

Scottish areas is unsatisfactory. Without better knowledge it is impossible to make estimates of the need for better treatment, whether in hospital or elsewhere. For reliable statistics, therefore, it is still necessary to go to the report³ of the Wood Committee, which inquired into mental deficiency in England in 1929. On the basis of those figures beds are available in Scotland for only half the patients who need them (10,000), and there are still 2,000 mental defectives occupying much needed beds in mental hospitals. Ascertainment is not necessarily just a first step to certification, but it should be a full assessment of each mentally defective individual and an estimate of his needs. To achieve this the Scottish report urges the establishment by the local health authorities of out-patient clinics to be staffed by hospital psychiatrists, general practitioners, and expert auxiliaries. In at least one area this is being done energetically and successfully.

There are only three hospitals (the subcommittee still calls them institutions) in Scotland of 600 beds or over, and the smallest has only 20 beds. Some of the buildings are old and very inadequate, but the subcommittee found the general standard was good. The report states that the main criteria for admission should be social maladjustment and instability in the feeble-minded and the need for continuous nursing or other care in the other grades. The subcommittee's views on ascertainment and on clinics are in accord with those of the Royal Commission, but it gives a hesitant support to the idea of voluntary admissions and is not in favour of psychopaths being admitted to the same hospitals as mental defectives. The Commission, on the other hand, recommended they should be admitted to any hospital that is able to give suitable treatment. Again, the subcommittee, like the Royal Commission, presses for the development of many more hostels by both hospitals and local authorities and finds it "inexcusable" that the one training hostel in the whole of Scotland has so few applications for admission. In general the report is critical of the arrangements for aftercare. Various organizations are responsible and it may be that the bringing together of these duties under the local health authority will help to increase the effectiveness of this work: that, in any event, is the recommendation of the Royal Commission. This report is an interesting one and should help to improve the standard of care for the mentally defective in Scotland.

ORAL PENICILLIN IN THE TREATMENT OF GONORRHOEA

The successful treatment of gonorrhoea by penicillin injected intramuscularly has led to many attempts to control the infection by giving the drug by mouth. The results reported have been conflicting. S. R. M. Bushby and A. H. Harkness¹ treated 62 patients with six doses of 40,000 units of penicillin at three-hourly intervals and found that two patients relapsed. G. O. Horne² noted one possible and two definite relapses among 42 patients who were given two doses of 0.5 mega units of calcium penicillin at intervals of three to six hours. A. Jacoby

and A. H. Ollswang³ claimed 82% of cures among 178 men who were given four doses of 100,000 units of crystalline penicillin G at hourly intervals. R. R. Willcox,⁴ using benzathine penicillin, found single doses of up to 4.8 mega units unsatisfactory; he also gave two doses of 2.4 mega units six hours apart to 28 patients, 4 of whom relapsed. Penicillin given by mouth is partially destroyed by the acid of the gastric juice, but a newer preparation of the drug, phenoxymethyl penicillin (penicillin V), is less affected by acid conditions. M. G. Rinsler and A. C. Cunliffe⁵ showed that after a single dose of 200,000 units by mouth the blood levels attained were, in general, equal to those attained after twice the dose of penicillin G, and that a detectable concentration was maintained for four to six hours. L. P. Sheil⁶ has recently reported a small series of 25 male patients with acute gonorrhoea who were given 400,000 units of penicillin V thrice daily for three days, together with urethral irrigations (presumably with the object of keeping the patients under observation). With this very large dose the results were good, there being only one relapse and one reinfection during the period of observation.

Many venereologists think that the treatment of gonorrhoea by oral penicillin is ill advised. Not only does it require a larger amount of the drug than the intramuscular route, but several doses have to be given, entailing further attendances by the patient if the treatment is to be completed under medical supervision. If given tablets to take himself, the patient may fail to carry out instructions carefully through forgetfulness or may cease treatment prematurely when his discharge abates. When a slow-release preparation of penicillin has been given by injection the physician does at least know that his patient has received the treatment prescribed and how long its antibacterial effect is likely to last. Sensitization reactions may occur when penicillin is given by mouth and can be very severe in type. Although the oral route may have ease of administration in its favour, it has little else to recommend it in the routine management of gonorrhoea. There is also the possibility that oral treatment, leading to low concentrations of penicillin in the tissues, may provide conditions favourable to the development of bacterial resistance to the drug. Comparisons of the sensitivity to penicillin of gonococci isolated in the United States in 1954 with those isolated in 1945-9 have not shown any evidence of the emergence of resistant strains.⁷ Despite this, an appreciable number of patients with apparently uncomplicated gonorrhoea are being seen who do not respond to 300,000 units of procaine penicillin given intramuscularly and who may relapse after re-treatment. Whether the cause of these unexpected failures lies in the gonococcus, the drug, or the patient remains to be determined. Fortunately the gonococcus is susceptible to a wide range of antibiotics, although a streptomycin-resistant strain has been reported.⁸

EXPLORING IN THE NORTHERNMOST ANDES

BY

HENRY BUNJÉ, M.D., M.R.C.P.

I have been lucky enough to go on two expeditions to the Andes, in 1954 and 1957. In 1953, while a lecturer in the University College of the West Indies, I heard a rumour that some people in the University planned a mountaineering expedition to the Sierra Nevada de Santa Marta in Colombia (Map 1). This range, the

MAP 1.—Map to show Jamaica and Colombia. The black triangle on the northern coast of Colombia marks the area of the Sierra Nevada de Santa Marta, which is shown in more detail in Map 2.

northernmost spur of the Andes, rises to nearly nineteen thousand feet (5,790 m.) within thirty miles of the sea—a unique geographical formation. It is within easy reach of Jamaica, being but ninety minutes' flying-time from Kingston southwards across the Caribbean to Barranquilla, the chief port of Colombia. While still out over the sea, one may see the snow peaks of the range rising from tropical jungles on the coast and from the swampy delta of the Mag-

dalena on their western side. The thought of exploring these mountains and meeting some of the primitive Indians living in the valleys was compelling. With no previous experience as an explorer, no knowledge of surveying, of Spanish, of physiological experiments at altitude or of mountaineering and, come to that, with no head for heights, my qualifications for applying to join the enviable company of mountaineers were meagre. However, I declared that I was prepared to cook, to carry, to take care of the base-camp, to take photographs, and to do as I was told. I was accepted.

First Expedition

This first expedition, led by Dr. Allan Cunningham, consisted of his wife, Dr. John Waterlow, Dr. Philip Hugh-Jones, and myself. We left on January 3, 1954, and flew to Barranquilla, then to Valledupar (Map 2) on the south-

MAP 2.—Sierra Nevada de Santa Marta, showing the principal peaks.

eastern side of the mountains in a broad dry valley bounded on the east by a 12,000 ft. (3,660 m.) escarpment overgrown with jungle and the home of the notorious and dreaded Motilone Indians. Along this Sierra de Perija lies the sometimes vague frontier between Colombia and Venezuela.

A truck took us and our baggage from Valledupar to the mestizo village of Atanquez—as rough and wild a road as any of us had ever been on. For four hours we lurched and plunged, forded rivers, and groaned up slopes, driven wildly by a youth with the improbable name of Alcibiades. Atanquez used to be an Indian village, but, retiring it is said from the inroads of missionaries, the Indians have left it for distant valleys. It is now the home of farmers, coffee-planters, and cattle-ranchers. It has a local industry in sisal, many emaciated stray dogs and scrawny chickens in the streets, rather more robust-looking pigs, lively children, and no plumbing. We saw last January, on our second expedition, that the growth of Atanquez had been considerable. There were more people, more taverns, more coca-colas, refrigerators, billiard-tables, radios, and juke-boxes, but no more plumbing.

From Atanquez one walks. A long slow climb precedes fording a river—potentially, no doubt, full of piranhas and anacondas, but we saw none. The end of this day's march is at the Indian village of Sogrome (Fig. 1). We had understood plainly that, at best, the Indians would be indifferent to our affairs. Though unlikely to be hostile, they would not be disposed to help us; but one sardonic consul went so far as to say that they would eat us. Thus dispirited, we approached their village for the first time with foreboding. Without their oxen as pack-animals, we could look forward to slogging up and down the valley carrying our own equipment. We found them to be hardy, industrious, quite willing to hire their animals, without qualms about long journeys, and perfectly trustworthy. There was no procrastination or unpunctuality. They inspected our camp, ourselves, and our utensils with a curiosity that was sometimes embarrassing but rarely impolite, and always without trace of "loitering with intent." They always asked permission before they removed even our discarded empty tins. On our second visit, while in camp near their village, we received a message that one of them was anxious to return a torch which we had dropped three years before and which had been kept safely against our possible return.

Second Expedition

On this year's expedition, also led by Cunningham, there were six of us, but only three who had been before. I enjoyed promotion—from porter to deputy physiologist. Waterlow and I had planned to conduct, as best we could, a balance experiment to learn something of possible changes in electrolytes in blood, urine, and faeces as we developed mountain sickness, became acclimatized to altitude, and recovered on the way down. (Incidentally, there is nothing like coming down, out of rarefied atmospheres, to feel increasingly energetic and well to realize that one had by no means "acclimatized" to altitude.) We recorded our food intake and collected nearly all our urine and faeces. It is debatable whether it is more tiresome making these collections "on the march" through the jungle, or when suffering from apathy and listlessness during the first few days at fourteen thousand feet. At our base-camp at this height we certainly had to guard against a befuddled state of mind and an impaired memory by writing results down at once and keeping notes up to date and insisting on an invariable routine to avoid mistakes.

The first time we really unpacked and settled down to several hours' work was in camp near Sogrome. The temperature was over 90° F. in the shade, and Major R. G. H. Allen, R.A.O.C., with the resourcefulness of his Corps, rigged us a shade of groundsheet on saplings. For our titrating, measuring, and labelling we had picked a corner of a hidden grove of *Erythroxylon coca*, the source of cocaine. The Indians deliberately plant these shrubs and tend them carefully. The groves are said to be much

FIG. 1.—A hut in the Indian village of Sogrome. Hugh-Jones was asked to examine the languid young woman on the left. He was obliged to do so in a dark hut while she sat on the floor and refused to remove any clothing. Her fiancé (with the hat) insisted on watching from the doorway. Under his left arm is his bag of coca leaves.

revered. We were a little concerned that they might resent our scientific mysteries amongst their coca, but they did not seem to mind our being there. The leaves are dried and the men carry them in bags slung across their shoulders (see Fig. 1) and chew handfuls of them all day long. It is a habit widespread throughout the Andes and, in our experience of observing these Arhuaco Indians, it certainly appears to impart a stamina enabling them to go for long marches without much sleep or food and without showing signs of flagging. A hill people, they are of necessity trained to this sort of energetic life, and have, indeed, a partly nomadic life moving up and down the valleys from village to village. Custom and not coca is probably the chief reason for their evident hardness.

We set up the base-camp laboratory about fifty yards from our tents and close to a gentle stream which drained one lake into another. Here the two of us did our work with a calculated air of aloofness; we insisted that nothing should upset our routine lest we make mistakes. While at work we

made it a rule, before embarking upon discussion or posing questions, to ask permission to speak. We believed this lessened our errors and enabled us to overcome our lethargy and make the initial effort required to work when suffering from even minor degrees of mountain sickness. It was apparent that the three of us who had been before were this year less seriously affected by altitude than the newcomers. It is difficult to understand why. The facility for more rapid acclimatization in those of experience is well known, though the mechanism is not understood. It was of particular interest to notice it in the three of us who had been within a few hundred feet of sea level for the whole of the three years since our previous visit in 1954. It was not only that we seemed to fare better than the others, we felt that we were better than we had been the first time. There is little chance that our physiological studies will in any way tell us why.

The Mountains

The main purpose of the expedition on both occasions was to explore the peaks and, more particularly the second time, to survey peaks on two unexplored eastern ranges. In 1954 Cunningham made the first solo climb of

FIG. 2.—On the glacier approaching the summit of Ojeda. The distant peak is El Guardián. The base-camp was to the left of the furthestmost of the three lakes in the foreground.

FIG. 3.—Panorama of the range explored in 1957 (4-5 on Map 2). Los Hermanos is the peak second from the left. On the right is La Reina—18,160 ft. (5,535 m.)

El Guardián (Fig. 2) of 17,175 ft. (5,235 m.). This year he and his brother, Mr. Frank Cunningham, scaled for the first time a peak of similar height to the east of the main group and which they have called Los Hermanos (Fig. 3). From the summit the north face drops over a thousand feet nearly sheer into an unexplored valley the far side of which rises to another unknown range. Beyond that this mountainous wall faces the Caribbean, which can be seen through the haze across lesser rock peaks and the jungle of the coast. The same impressive range, also with an exceedingly steep north face, is part of the longest mountain barrier of the Sierra Nevada de Santa Marta and rises westwards to three named peaks. These are Ojeda and, the highest pair of the lot, Cristóbal Colón and Simón Bolívar, of 18,947 ft. (5,775 m.). The range takes its name from the port of Santa Marta on the Caribbean. It is less often known as the Sierra Nevada de Los Taironas, after the people of that name who were contemporaries of the Inca. The remains of their buildings, causeways, and carved stones, now overgrown by jungle, may be seen on the northern coastal slopes.

There have been fewer than a dozen expeditions to these mountains. In their valleys live tribes of Indians of singular dress and language, their numbers dwindling and upon whom civilization fast encroaches. Lost cities and legendary treasures of the Taironas await discovery. Unclimbed peaks and unmapped territory challenge the mountaineer, the surveyor, and the explorer. Our other colleague, Mr. A. D. Scott, claims the discovery of what may be referred to as "mineral wealth." The speed of access from Jamaica and the ease with which one may return to a fully equipped laboratory in the University there greatly assist the study of the effects of altitude—at any rate, up to 18,000 feet (5,490 m.). The scenery and climate are wonderful. Can it be wondered at that a third expedition is planned by the same company?

Nova et Vetera

ROYAL MYSTERIES

The Princes in the Tower and Other Royal Mysteries. By Sir Arthur Salusbury MacNalty, K.C.B., M.A., M.D., F.R.C.P., F.R.C.S. (Pp. 212. 18s.) London: Christopher Johnson. 1955.

Sir Arthur MacNalty has long occupied some of his learned leisure in exploring certain byways of history. Many of these can be traced only by those who combine experience in practical medicine and in critical biography. The number of those who have both skills can be counted almost on the fingers of one hand. On several occasions, such works by Sir Arthur have been noticed in these columns. In this work he surveys nine mysteries and on each throws some light. He gives most space to that monster, Philip II of Spain. For over 40 years (1556-98) he misruled his vast empire, which included Spain and its American possessions, Sicily, Naples, and Southern Italy, the Duchy of Milan in northern Italy, the Netherlands, and Franche Comté. He approached his great task with the mind of a petty and spiteful police official, jumped by a turn of the wheel of fortune to direct one of the largest empires in history. Yet he busied himself with the most minute details of office administration, loved writing and reading dispatches, but using murder as a regular instrument of policy. By meticulous religious observance he concealed from his Spanish subjects—and doubtless from himself—his innumerable misdeeds. Among these was his doing to death of his insane son and heir. Sir Arthur devotes considerable attention to this and certain other of Philip's atrocities. They are characterized by an extraordinary indifference to human life, difficult to reconcile with his apparently sincere attachment to his religion.

Despite all this, and although his policy in the end brought his empire to ruin, Philip was the idol of his countrymen.

In many matters he was a parallel to Henry VIII. (Sir Arthur has himself carefully analysed the medical history of Henry.) From Henry's policy England was happily rescued by his great daughter, Elizabeth. Philip had no such heir and the power of Spain suffered a steady decline which has lasted to our time.

Of Sir Arthur's other cases, the most interesting to English readers is perhaps Queen Caroline Matilda of Denmark, youngest sister of George III. She was transported at 15 into an atmosphere of madness, political intrigue, and vice. She imperilled her reputation, became a State prisoner, went into exile, and died at the moment when there were prospects of recall to her throne and children. Surrounding Caroline Matilda were some thoroughly sinister figures, most of them without any redeeming feature. Yet the central villain of the caste had at least a wish for the betterment of the Danish people, though it was just this trait in his character that brought his downfall.

Caroline Matilda was born posthumously in 1751. She was the youngest of a large family. Her eldest brother later ascended the throne of England, Scotland, and Ireland as George III. The little princess was reared strictly and in comparative seclusion by her mother. There was an entire lack of sympathy between mother and daughter, and, in addition, the princess came to lose all respect for her mother. In 1760 George III became King, and, as sister of the reigning monarch, Caroline Matilda became a political pawn in the game of international diplomacy. Five years later a proposal for a marriage between Caroline Matilda and Christian, Crown Prince of Denmark, was put forward. King George at first considered Caroline Matilda too young and suggested her older sister, Louisa Anna, who was about the same age as the prospective bridegroom. The Danish ambassador found that this lady's health was poor, and advised his sovereign to press for Caroline Matilda. George III at last agreed but postponed the marriage by reason of her youth.

At that time most European Courts were modelled on that of Versailles, and Denmark's also was a clumsy imitation. It was idle and dissolute. The King spent large sums on the arts and science, but his administration was corrupt, the peasants were little but serfs, and the monarch often indulged in bouts of drinking and other unseemly behaviour. Yet like some even worse sovereigns, such as Philip and Henry, he remained popular with his oppressed subjects.

In 1766, the young King Christian VII of Denmark, aged 17, at last married Caroline Matilda, aged 15. Christian was a perverted, restless, vicious, and schizophrenic dwarf, and the marriage was most unhappy from the first. There were intrigues at Court, of which the demon of the piece was the King's German medical adviser, Johann Friedrich Struensee. He was an able physician but of a character born for plot and counterplot. He ultimately obtained political ascendancy in Denmark and personal ascendancy of that country's unfortunate queen. Both relationships ended in tragedy. The one bright spot in the melancholy drama is the gallant good sense of the British ambassador to Copenhagen, who did all that was possible to avert disaster. The poor young queen was separated from her children and she died in exile and almost in solitude. These and several other historical tragedies are related in Sir Arthur's sombre but most readable collection. They induce the reflection, "Who would be a monarch, and, above all, an absolute monarch?"

CHARLES SINGER.

Dust in Card Rooms, the Third Interim Report of the Joint Advisory Committee of the Cotton Industry, has been issued by the Ministry of Labour and National Service. The report discusses the results of tests made on a device for removing dust from carding engines before that dust is able to enter the atmosphere. The results are analysed statistically, and photographs of the machines under test are included. The report is obtainable from Her Majesty's Stationery Office (price 2s. 6d. net).

Chloroquine Naphthoate for Malaria

SIR.—The intensely bitter taste of many antimalarial compounds is an obvious disadvantage in their use as therapeutic or protective drugs, particularly in children. The two chloroquine salts (diphosphate and sulphate) used at the present time are almost as bitter as quinine, and medical practitioners in the tropics have often expressed the need for a more palatable though equally effective drug. Chloroquine naphthoates, of low solubility, have little if any taste. It was thought that these salts might be of practical value, especially as early pharmacological tests¹ suggested that their resorption after oral administration was almost as good as that of more soluble salts.

A brand of chloroquine methylene-beta-hydroxynaphthoate has been produced and marketed for over a year by a foreign firm. Another brand of the same compound was more recently prepared by a British firm under a provisional name of chloroquine "embonate" and forwarded to Nigeria for preliminary trials, pending a large-scale production. The results of these trials are of interest and call for early and widespread reporting.

Chloroquine embonate, a completely tasteless salt, was administered in single doses of 100 mg., 200 mg., and 300 mg. of base respectively to three groups of approximately 30 naturally infected African schoolchildren and its action assessed according to the method used in Nigeria for the past six years and recently described by us (*Journal*, July 6, p. 23). A comparable group of children was given a single dose of 100 mg. base of chloroquine sulphate ("nivaquine"). The results tabulated below refer mainly to *P. falciparum* with about 15% of *P. malariae* appearing as a mixed infection.

Field Trial of Chloroquine Naphthoate and Chloroquine Sulphate on 121 African Children Naturally Infected with Malaria

Drug and Dose	Number Examined	Number Cleared	Mean Clearance Time and S.E. (in days)	Remarks
Chloroquine embonate:				
100 mg.	30	8 (26.6%)	2.22 ± 0.58	Clearance times relate to all forms except gametocytes of <i>P. falciparum</i>
200 "	32	21 (65.6%)	2.14 ± 0.14	
300 "	29	18 (62.1%)	2.22 ± 0.15	
Chloroquine sulphate:				
100 mg.	30	30 (100%)	2.13 ± 0.02	

The results of this trial, judged by the comparative percentage of clearances, indicate that weight for weight chloroquine embonate is only about 1/4 to 1/5 as active as the sulphate. The absence of difference between the results of the 200 mg. and 300 mg. dose of the new compound is of interest. Detailed comments on these results might be premature and more research is indicated. The similarity of the mean clearance times of the four groups suggests that a proportion of children have a low resorption threshold with regard to chloroquine embonate, but that when an adequate amount of the drug is resorbed its activity is only a little slower than that of chloroquine sulphate.

Whatever the explanation of the disappointing results obtained with chloroquine embonate the trial shows that the schizontocidal activity of this compound is much below that of more soluble salts of chloroquine. There can be little doubt that the present "tasteless" brands of chloroquine are unsuitable for treatment of malaria. It might be argued that chloroquine naphthoate could be reserved for suppression only. But the actual effective dosage of this compound used as a suppressive and its reliability remain to

be investigated. Nor do the above results, showing a high proportion of actual failure to clear asymptomatic parasitaemia, suggest any validity for this contention. Moreover, the presence on the market of the two types of chloroquine compounds, one for suppression only and the other for suppression and treatment, is unwelcome, as it will add to the present confusion of proprietary names and various dosages of synthetic antimalarials.

We understand that a series of field trials of chloroquine methylene-beta-hydroxynaphthoate carried out lately by Clyde in Tanganyika² substantially confirmed our findings. According to the latest information the results of our and Clyde's trials have led to the discontinuation of the production and marketing of chloroquine naphthoates. Nevertheless, a warning of the unreliability of these compounds for the treatment of acute malaria is timely and of some importance.—We are, etc.,

Poliomyelitis Vaccine

SIR.—In connexion with the statement from the Ministry of Health consisting of questions and answers relating to poliomyelitis vaccine (*Journal*, August 17, p. 405), I should like to take exception to a statement contained in the last answer, which in my experience is untrue. It is there remarked that the majority of paralytic cases recover completely. My experience in Darlington is not, of course, very considerable, but, having followed up some 50 patients who during the last five years have been under my care at Hundens Hospital, Darlington, I have found that hardly any are left without residual disability of some kind. Even though there is no recognizable or ascertainable residual paralysis of a once affected limb or muscle group, the patient complains of early fatigue when undertaking any more than usual activity. Thus, a child soon tires in play with other children and a youth finds that he cannot compete with the same facility as before with his fellows in games and sports, except perhaps at swimming, which for obvious reasons is not prejudiced to the same extent. Mild cases without paralytic complication do, of course, recover completely, but in my opinion the capacity for extra effort is always diminished when paralysis has occurred.—I am, etc.,

Darlington.

JOSEPH V. WALKER.

Listerial Meningitis

SIR.—The 11-day-old infant referred to by Drs. C. S. Shaw and Dr. C. Turk (*Journal*, August 10, p. 351) was originally reported as a diphtheroid meningitis.^{1,2} Clinically she resembled the 10-day-old infant described by Edmunds *et al.*³ The mode of onset was similar—a convulsion. The cerebrospinal fluid was turbid, and an identical organism was cultured in pure growth from both the cerebrospinal fluid and blood. The infant was treated with systemic and intrathecal streptomycin and oral chlortetracycline and responded well. Like their patient, the fits were only partially controlled by sedation and continued for six days. The patient was discharged well on the 14th day, but during the next four weeks she developed hydrocephalus, due to a block in the aqueduct of Sylvius; this was treated by a Torkildsen's ventriculocisternostomy. In view of the original suspected nature of the organism, it was interesting that the mother gave a history of clinical diphtheria at the age of 10 years and had been kept in hospital subsequently for three months as a nasal carrier.—We are, etc.,

Polioencephalitis

SIR.—Dr. B. Snell and his colleagues (*Journal*, July 20, p. 126) have done well to focus attention on the unusual course which polioencephalitis may sometimes follow. The following case summary also exhibits some highly uncommon features which I have not before encountered.

A girl of 14 was admitted on January 4 with a history of concussion following a blow on the head a month previously, and of "muzziness of vision" for a fortnight. A few days before admission she had developed an influenza-like attack, but early on the morning of admission her mother had found her "unconscious" in bed. When seen the patient was stuporous. She was febrile, there was moderate neck stiffness, the pupils were unequal but reacted to light. The tendon jerks were sluggish and there was no obvious paralysis. The patient insisted on lying on her right with conjugate deviation of the head and eyes to the same side. Lumbar puncture showed 75 cells per c.mm., roughly half being polymorphs. The chemistry was normal. A blood count showed a leucocytosis. Postural drainage and tube feeding were instituted at once. During the next 24 hours stupor deepened into coma and the left pupil became immobile. Frequent generalized convulsions set in, more marked on the left side; these alternated with bizarre attacks of twitching of the muscles of the neck. Within a few days frequent haemorrhages from the vagina and epistaxis occurred, so that tube feeding had to be discontinued and intravenous feeding employed instead. After some 16 days in coma the patient began a slow return to consciousness. It then became evident that, though she could swallow fluids, she could not manage semi-solids, a sign which, in my experience, is almost pathognomonic of poliomyelitis, and with the C.S.F. findings, the only suggestive evidence of that disease to appear so far. As she gradually came round she disclosed motor aphasia, paralysis of conjugate movements of eyes to the left, weakness of the left motor 5th and paresis of the left 7th cranial nerves. Within the next month or so all these cleared up and the only residual paresis was that of the left 6th nerve. On March 7 she was discharged, by which time that too had recovered.

Had not polio virus type 1 been isolated from the stools, we should have been very reluctant to diagnose this case as poliomyelitis, particularly when, on coming up for review some time later, her mother reported that after discharge she had developed a temporary behaviour disorder, had become emotional and aggressive, and had actually struck her sister, to whom, normally, she was devoted. A few weeks ago this seemed to have disappeared and the patient is now reported quite normal.—I am, etc.,

Isleworth, Middlesex.

G. E. BREEN.

Smoking and Lung Cancer

SIR.—It was with interest that I read the letter from Dr. Antonis Georgeades (*Journal*, August 3, p. 298), in which he makes certain suggestions regarding the effect of various types of tobacco in regard to lung cancer. Although it has not yet been established by scientific methods whether smoking of Virginia cigarettes is responsible for the increase in the incidence of cancer of the lung and other diseases, such as heart and other complaints, I think that unbiased medical experience and the knowledge of the chemical composition of several varieties of tobacco speak in support of the views I have expressed elsewhere.¹ (1) The tremendous increase in the death rate from lung cancer has been mainly observed in countries where Virginia tobacco is smoked in the form of cigarettes and not, so far as it is known, in the countries where other varieties of tobacco are used (the so-called Oriental or black tobacco). (2) Virginia tobacco is artificially cured by heating (flue-cured), while other types of tobacco are sun-dried. (3) Virginia tobacco leaf has an excessively big stem which represents about 22% of the whole weight of the leaf and is constituted almost completely of cellulose. This stem, after being moistened, pressed, and cut, is put into the tobacco blend used for cigarettes. Such a great quantity of cellulose in the Virginia cigarette might produce more tobacco tars than a cigarette containing less cellulose. (4) Tobacco used in Virginia cigarettes is usually treated with various foreign substances in order to keep its moisture (for the sake of keeping the

cigarette soft), and in the U.S.A. many more substances are added for the so-called casing and the flavouring of tobacco. (5) Virginia tobacco contains a high percentage of nicotine, which no one can doubt is a powerful poison and is responsible for the increase in the incidence of diseases of the heart, the circulatory system, the stomach, etc. As it is known, the percentage of nicotine in Virginia and other similar tobacco varieties amounts to about 2% (in some cases it is even higher), while in other varieties it is much lower—e.g., Oriental tobacco contains about 1% nicotine. According to my conclusions it is more likely that the relationship between lung cancer and smoking incriminates Virginia tobacco rather than tobacco in general.—I am, etc.,

ALBERT W. BAUER.

London, W.1.

REFERENCE

SIR.—The cigarette has a social value. It is the first step towards friendship, the next being a meal at the club, and finally a drink at home. Anything which encourages friendship is to be cultivated. It is the "chain" smoker who is the victim; he has not the money but he carries on, never giving any away. These addicts are to be pitied. There can be no doubt that tobacco, especially if smoked in a pipe, is a solace and conducive to literary work. The comfort greatly exceeds that of cigarettes. Cigars occupy the same position as the pipe. Our leading citizen does not appear any the worse for them. There is the tale of the two literary giants who met at a pub one evening to wine and pipes. Not a word was spoken. Well into the night they parted, each declaring how much they had enjoyed the evening. I had published 125 articles including letters in twenty years, while smoking 4 oz. in a pipe every ten days; not one was returned. Fifteen years ago I stopped smoking; only 25 articles found their way into print—many returns. It may be *anno domini*, but I think not. Dr. Doll and Professor Bradford Hill do not mention snuff.—I am, etc.,

London, S.W.16.

A. P. BERTWISTLE.

SIR.—I once had the privilege of being taught by Professor Learmonth. When one of us suggested a rather improbable diagnosis, he used to say: "If you saw a bird sitting on a fence, which is it more likely to be, a sparrow or a hoopoe?" Sir Ronald Fisher's suggestion (*Journal*, August 3, p. 297) that cigarette-smoking and lung cancer are both influenced by the individual genotype is a "hoopoe."

Perhaps the point can be made clear by analogy. Earlier this year a survey¹ showed that during the period from November, 1951, to September, 1956, there had been eight recorded deaths from poliomyelitis among medical men in Great Britain. If doctors were dying from poliomyelitis at the same rate as adult males in the general population, not more than one death would have been expected to occur. There are, if chance is excluded, three possible explanations which suggest themselves: first, that persons in the higher social classes are rather more at risk of contracting poliomyelitis than those in the lower social classes; secondly, that doctors are specially at risk either of contracting poliomyelitis or, having contracted it, of dying from it; and thirdly, that there is a genetic predisposition to poliomyelitis linked with a genetic inclination to take up medicine. There is no published evidence from this country to support the first explanation. The second explanation is the sparrow, and the third is the hoopoe.

Incidentally, Sir Ronald Fisher's "massive and recalcitrant" fact, "that lung cancer has been increasing more rapidly in men relatively to women," is neither so massive nor so recalcitrant. It is, one would expect, the sum total of exposure of women to the carcinogen over the past 40 or 50 years which is significant. The rate of increase in their mortality from lung cancer is not very different now from that of men; between 1955 and 1956 the mortality from lung cancer increased 5.36% in men and 4.08% in

women. In any case, why should there not be a sex difference in susceptibility?

The total increase in cigarette consumption over the 50 years from 1900 to 1950 in this country has been from approximately 0.2 to 3.9 lb. (91 to 1,770 g.) per person per annum (Board of Trade statistics), a percentage increase of 1,850. According to the Hulton readership survey figures, women use less than a quarter of the cigarettes consumed in Great Britain even now, so, even after allowing for alterations in the age groups, Sir Ronald Fisher's memory is not an accurate guide to the increase ("certainly small") in cigarette consumption among men in this country over the past 50 years.—I am, etc.,

Garboldisham, Norfolk.

Smoking and Chest Diseases

SIR,—About 10 years ago I visited a patient whom I found sitting up in bed smoking a foul-smelling pipe. A week later the same patient discharged himself from hospital because he could not tolerate the smoky atmosphere. Since that time I have kept records of similar cases, which always occur in people suffering from chronic bronchitis and emphysema. These people know that the inhalation of tobacco smoke upsets their chests, yet they produce their own and have not sufficient intelligence to understand that it is their own smoke which is the cause of their persistent cough and bronchitis. These people waste the time of chest physicians and clutter chest clinics and doctors' surgeries, when they should be attending a psychiatric department. I believe this to be a constant occurrence in bronchitic and emphysematous subjects, which might be termed "the half-witted smokers' syndrome."—I am, etc.,

Leeds, 8.

DAVID A. HERD.

The Houssay Syndrome

SIR,—We were interested to read the article by Drs. R. J. Calvert and G. Caplin (*Journal*, July 13, p. 71), describing the development of the Houssay syndrome in a diabetic patient with resulting reduction of insulin requirements. The example which we describe below would appear to demonstrate a somewhat similar endocrine association with a differently operating mechanism, since diabetes appeared at the age of 61 in a female affected with pituitary infantilism.

The patient was referred for the investigation of glycosuria in March. She had lost 2 stone (12.7 kg.) in weight over a period of two years, during which time she had been troubled with polyuria, thirst, and pruritus vulvae. Apart from the smallness of her stature and that fact that she had never menstruated, her past history was not revealing. Two maternal cousins had suffered from diabetes. The patient was of normal proportions in relation to her height of 4 ft. 4 in. (1.3 m.), and was of average intelligence. The skin was dry and thin and the pubic and axillary hair was absent. The breasts, external genitalia, vagina, and uterus were hypoplastic. Physical examination otherwise revealed no abnormalities. Radiography of the skull showed marked destruction of the dorsum sella and posterior clinoid processes, the anterior clinoids being grossly decalcified. The visual fields were not involved. The fasting blood sugar was 190 mg.%. The glucose tolerance after 50 g. of oral glucose gave the following results: ½-hour reading, 230 mg.%; 1 hour 200 mg.%; 1½ hours, 190 mg.%; 2 hours, 180 mg.%. No urinary gonadotrophins were detected at a level of 3 mouse units per day. The urinary ketosteroids measured 2.6 mg. per 24 hours and the 17 ketogenic steroids 7.3 mg. per 24 hours. Examination of the oral mucosa and of the leucocytes showed genetic female characteristics. The patient's diabetic condition was established on 20 units of insulin zinc suspension daily and an 8-line Lawrence diet.

The hypopituitarism obviously had been of long duration in view of the lack of growth and of secondary sexual

features and the non-development of menstruation. Improvement of the pituitary state would be unlikely at the patient's age and there were no clinical or biochemical features to indicate excessive adrenal cortical activity. Joslin *et al.*¹ consider that the association of clinical diabetes and hypopituitarism should be rare. They quote an example of a diabetic patient's insulin requirements dropping after the development of hypopituitarism; gross destruction of the pituitary fossa was also present in their patient. The recent trials by some clinics of hypophysectomy in the diabetic state perhaps adds further significance to our case report.—We are, etc.,

Effect of Pregnancy on Colitis

SIR,—The individual tree which impresses the G.P. can be lost in a forest of statistics, or so I felt reading your annotation in the *Journal* of July 20 (p. 151) on the effect of pregnancy in colitis. A patient of mine, a woman of 36, had a subtotal colectomy for severe ulcerative colitis with septicaemia and remained well for four years until her child was born. So well did she come through her confinement that she was shown as a "model" case. "But," she told me, "they missed the point: I coped well on the physical plane but not at the emotional level," and worsening nervous stress with diarrhoea then began.

Wittkower¹ has pointed out that the obsessively tidy often develop ulcerative colitis. This woman, over-sensitive, houseproud, and finicky, has been driven to distraction by the normal untidiness of her small son, and the dread that one day he might see the messy toilet of her colostomy. Further pregnancies cannot be contemplated: her only child has been a disappointment, and one source of the panic for which I was called in, and into which her anxiety had grown.—I am, etc.,

Ilford, Essex.

Dyspareunia

SIR,—Dr. Mary Pollock is, of course, quite right in saying that dyspareunia "will often lead to mental disharmony" (*Journal*, August 17, p. 409). It is not clear, however, why hyperaesthesia in the female should be a more potent cause than the iatrogenic anaesthesia in the male that would accompany the treatment she advocates. It was, I think, Blair Bell who told of the reproaches he received from a husband whose wife had used cocaine ointment to alleviate dyspareunia. Although lignocaine is more modern than cocaine, it seems equally likely to disturb a very old-fashioned relationship.—I am, etc.,

London, W.1.

A. PINEY.

Sterilization of Dressings

SIR,—I have been given the opportunity of reading Dr. R. M. Savage's article,¹ to which he refers in his letter (*Journal*, July 27, p. 235), and there seems to be no doubt from his interesting experiments that tulle gras will sterilize in an autoclave, provided—and this is the important point—that the moisture content is within certain limits. It seems probable, therefore, that sterility can be obtained under the controlled conditions, such as presumably must be the case during the manufacture and subsequent sterilizing of the tulle gras, and that therefore the tulle gras as supplied by the manufacturer in sealed tins may well be sterile before being unsealed.

It is, however, particularly with the subsequent fate of the tulle gras that I am concerned. Such tins as are supplied by the manufacturer are only rarely used up immediately after opening, and therefore require to be resterilized before being used again. It is during this resterilization that the

moisture content is obviously quite unknown and one cannot be certain of the sterility of the contents when reautoclaved.—I am, etc.,

West Hartlepool.

The Forgotten Thomas Splint

SIR,—Mr. G. P. Arden's letter (*Journal*, July 13, p. 101) has given me great pleasure. May I add a note to his reminder of the worth of the Thomas splint? During the first world war, by June, 1916, some 80% of the casualties having open fracture of the femur were fatally injured, many dying during transport or at the casualty clearing station—they died of shock due to pain. At the urgent insistence of Sir Robert Jones, the Thomas splint was made available at the advanced dressing stations in the battle of the Somme, July, 1916, and thenceforward it was used almost exclusively for men so injured and was applied as near as possible to the firing line. By the end of the war, 1918, the mortality of these cases had been reduced to 20%. Colonel Crile, of the United States Army, gave his opinion that the Thomas splint had done more to prevent death from shock than any other single measure. It was held to be the greatest life-saving tool of the first world war. First-aid instructors not familiar with it may feel some diffidence, but with practice first-aiders can be taught to apply the splint with accuracy and care, even by touch in the dark with their gas-masks on.—I am, etc.,

London, W.C.1.

M. A. DOBBIN CRAWFORD.

REFERENCE

- ¹ Jones, R., in F. Watson, *Hugh Owen Thomas: A Personal Study*, 1934, p. 76. London.

SIR,—May another word be said on the forgotten Thomas splint, on a point raised in Mr. Richard Harrison's letter (*Journal*, August 3, p. 298)? The size of the ring presents no real problem, provided it is large enough. In the R.A.M.C. the teaching is to ensure that the ring is big enough for the largest thigh. Such a splint is easily and efficiently accommodated to a smaller thigh by "padding the ring" adequately, between it and the leg, laterally and if necessary antero- and postero-laterally. For this purpose intact shell dressings are ideal and may still remain useful for their primary function.—I am, etc.,

London, S.W.1.

A. G. D. WHYTE.

Stove-in Chest Injury

SIR,—I was interested to read Mr. L. Henry's article on stove-in chest (*Journal*, August 10, p. 339). My interest was mostly stimulated by the fact that we have recently had to deal with an exactly similar case, except that there were no other serious injuries. Had there been any such complications I feel sure our treatment would have been even more justified.

Our patient was a middle-aged man who had been involved in a head-on collision, during which the steering-wheel of his car had stove-in the front of his chest, in addition to which he had sustained a "rudder-bar" injury to the left talus. On admission he was shocked and suffered considerable respiratory distress. Examination revealed obvious paradoxical respiration. As in Mr. Henry's case, x-ray examination was of no help in assessing the extent of injury to the thoracic cage. It did, however, eliminate the presence of any serious intrathoracic damage. Within one hour of admission the patient had been taken to the theatre, and under local anaesthetic, through a 1½ in. (3.8 cm.) incision, wire was passed around the third costal cartilage to the sternum. Manual traction gave immediate relief, which was sustained by traction of 2½ lb. (1.1 kg.) over pulleys suspended from a Balkan beam. The patient was nursed in a sitting posture.

This is not an attempt to add anything new to our knowledge of stove-in chest injuries, for, as Mr. Henry points out, the principle of traction to stabilize the floating sternum

has been described. I do feel, however, that Mr. Henry's recommendation to use his method cannot sustain close scrutiny. This would mean general anaesthetic and a fairly prolonged and complicated procedure in a patient who is shocked, suffering from severe respiratory distress, and, furthermore, in need of urgent relief. The advantage of increased mobility cannot, in my opinion, outweigh the disadvantages, for even if subsequent operative procedures requiring general anaesthetic were required the traction methods could still be implemented.—I am, etc.,

Stockport.

Sea-snake Bites

SIR,—Dr. H. A. Reid's account (*Journal*, July 6, p. 26) of his experience of being accidentally bitten by a sea-snake (*Enhydryna schistosa*) was a most valuable contribution to the literature on the subject. Certain sea-snakes in Malaya are aggressive even when unprovoked. I was extremely cautious when making a very close approach to any one of them. When I was last in the north of Malaya, dealing with the treatment of snake-poisoning (*Journal*, July 16, 1955, p. 204), I developed a crude but sufficiently effective method of my own to render the sea-snakes motionless and disciplined for identification or photography. One day I had 20 sea-snakes on a table for photographing. The amount of general wriggling going on among them made it too difficult for the photographer to bring them into sharp focus. I therefore started drumming along their backs gently with a wooden stick, increasing the force as the cephalic end was approached to a degree strong enough to immobilize them each within a minute. Within a period of five minutes they spontaneously recovered their original movements. This drumming method is not effective with land-snakes. The potential danger which one has to face in this way seems to me sufficiently far-reaching to justify the adoption of the above method, which could be tried and modified to suit individual requirements.—I am, etc.,

London, W.C.1.

ABDUL WAHAB ARIFF.

Blood Group Chimeras

SIR,—Dr. C. C. Bowley and Mr. I. Dunsford (*Journal*, August 17, p. 408) state that, "so far as the development of immunological tolerance due to exposure to foreign red cells is concerned, the literature [references given] contains confirmation that the foetus can bleed into the mother [my italics], but the reverse phenomenon of maternal haemorrhage into the foetus has not yet been recognized so far as we are aware."

Actually, this problem of the cells of the mother entering the circulation of the foetus *in utero* is being actively investigated by interested workers in the department of pathology, St. Margaret's Hospital, Epping, at the present time. Very simply: the foetus *in utero*, when less than five millimetres in length, may be unable to react to the cells of the mother if "injected" at this stage. However, within a week of "term" the infant *in utero*, being the recipient of its mother's cells, reacts like an adult—i.e., the infant constructs antibodies. Somewhere—at present the phase of immunological tolerance cannot be timed—between the under-five-millimetre foetus and the infant near term tolerance will follow receipt by the foetus of the mother's cells. We are looking for a Rhesus-positive grandmother. As "pointers" we use a Rhesus-negative mother who has had eight healthy children by a homozygous Rhesus-positive husband. Having found our grandmother, we will take all the precautions suggested by Dr. Bowley and Mr. Dunsford—i.e., have the father genotyped, etc.

I think it is doubtful whether the ABO group differences would give such complete protection against the production of anti-Rhesus agglutinins as Dr. Bowley and Mr. Dunsford suggest. Without detracting in the least from the brilliance of Professor Rogers Brambell and Mr. N. A. Mitchison (or from Dr. Bowley and Mr. Dunsford) we seem to be in the position of Lieutenant Backsight-Forethought, whose mental processes were so carefully examined in that classic of the first world war *The Defence of Duffer's Drift*.—I am, etc.,

Epping, Essex.

FRANK MARSH.

Acute Immediate Reactions to Penicillin

SIR,—I agree with Dr. Martin O. Raven (*Journal*, June 1, p. 1305) and Dr. Cassie E. Williams (*Journal*, June 15, p. 1419) that penicillin should be given subcutaneously with a small needle. I think it was Dr. H. M. Hanschell who taught me at Albert Dock Hospital in 1932 that no injection should ever be given intramuscularly, and that if deep injection was necessary it should be given deep subcutaneously on top of the muscle. I believe this to be correct for the following reasons: (1) Hypodermic injections are easier to administer. There is therefore less danger of breaking the needles. (2) The needle is less likely to damage a blood vessel or nerve, because it travels a shorter distance. Abscess formation is therefore less common. As most injections are given by nurses whose knowledge of anatomy is not detailed, this is important. (3) The injections are less painful, as they do not cause tension on the muscle sheath.—I am, etc.,

Tennant Creek,
N.T., Australia.

S. V. HUMPHRIES.

Teeth of 5-year-old Children

SIR,—The article on teeth of 5-year-old schoolchildren by Lady Mellanby and her colleagues (*Journal*, August 10, p. 318) prompts me to record some figures which I have been collecting for another purpose. These figures apply to all the toddlers who attended a child welfare centre in Moss Side during the period November, 1956, to June, 1957. This area has a very unstable population of English, Irish, Jamaicans, Poles, Ukrainians, and Indians.

Two hundred children are concerned, aged 2-5 years, mostly 3 and 4. There were 116 children not in need of dental treatment and who had not had any treatment previously. The remaining 86 showed 66 teeth previously extracted; 28 teeth previously filled or painted; 369 teeth with active caries: total number of diseased teeth 463, which averages 5.5 diseased teeth per child. Of the 200 children, there were 130 who attended the clinic regularly, 78 whose mothers reported taking vitamin supplements during the antenatal period, and 109 children said to be taking cod-liver oil and orange juice now. For comparison, of 200 mothers attending the antenatal clinic, 12 had 28 or more teeth all sound, 41 were not in need of treatment, 15 had a complete set of dentures. The remaining 132 mothers had 766 carious teeth between them, an average of 5.7 carious teeth per mother. All those needing treatment were referred to the local authority dental clinic, which serves several maternity and child welfare centres, and they report 57% of children and 23% of mothers attended. A very small proportion sought dental treatment privately.

Toothbrushes are used sparingly in this area, but the toddlers are almost always sucking lollies or eating soft biscuits and buns. Most of the mothers are interested only in "taking out teeth for pain"—and children who have once attended the dental clinic are likely to default in future, once their teeth have been blackened with silver nitrate. Even for toddlers the cosmetic effect is important if working-class parents are to be "sold" the idea of conservative dentistry and the state of teeth of the 5-year-old schoolchild is to be improved.—I am, etc.,

Manchester. 15.

DAPHNE SASIENI.

Halothane

SIR,—Dr. H. Rex Marrett (*Journal*, August 10, p. 331) is to be congratulated on his large series of halothane anaesthetics without a mishap. His technique with the Marrett closed circuit shows that remarkable economy in the consumption of halothane can be achieved in this way. With care and close attention, the method is evidently safe during spontaneous respiration. It would be interesting to know how Dr. Marrett measured the percentage of halothane in his circuit (2% to 2.4%) with such accuracy. So far, I have been unable to discover a practical method of doing this in a closed circuit. Hitherto, also, I have found that the maintenance of any definite vapour strength from a vaporizer

included in the circuit is not easy, as no safe upper limit is imposed on the vapour strength, each time round the circuit adding more halothane, unless very low settings on the vaporizer tap are used.

Brennan¹ has shown that very high concentrations, exceeding 10%, can easily be produced when "bag-squeezing" methods are used. Indeed, a fatality appears to have been caused in precisely this manner.² As Dr. Marrett points out, however, during spontaneous respiration (and in the absence of muscle relaxants) excessive concentrations of halothane are 'signalled' by respiratory depression, and the vaporizer can be turned off before assistance is given to aid the respiratory excretion of halothane. However, I feel that when controlled or assisted respiration is to be used it would be dangerous to use a vaporizer in the circuit of a closed circle absorber. Rather, halothane should be vaporized by the gases supplied to the circuit. In a series of about 200 cases (to be reported elsewhere) of thoracic (including cardiac) surgery, I have used halothane with controlled respiration and carbon dioxide absorption with soda lime. In order to limit the percentage of halothane, the supply of fresh gases has been passed through a calibrated vaporizer. Since it became available, the "fluotec" has been used for all cases. Using this technique I have found that, with input flows of 2 litres/min., 1.5% to 2.5% halothane is usually needed (the calibration of the fluotec used has been checked at this flow rate). After induction with thiopentone and D-tubocurarine chloride, followed by intubation, controlled respiration can be maintained for the longest thoracotomies with halothane and oxygen. Used in this way, curare and halothane do not cause the severe hypotension and vasomotor collapse reported by Johnstone.³ Other relaxants tried have been less satisfactory in thoracic work. Since repeat doses are not needed, respiration at the end of the operation is not depressed.

In addition to noting the early vasodilatation and reduced bleeding reported by others, Dr. Marrett states that higher concentrations of halothane cause vasoconstriction during surgical anaesthesia. Surely this should cause a rise in blood pressure, which has not so far been reported or observed to my knowledge. Perhaps Dr. Marrett could give us more information concerning the blood-pressure levels seen during his series.—I am, etc.,

Malignant Melanoma

SIR,—A man aged 64, coal-miner by occupation, was admitted to the Rotherham Hospital as an emergency on June 6, and a diagnosis of irreducible epigastric hernia, possibly involving a loop of bowel, was made. Laparotomy disclosed that the epigastric hernia was nothing more than some extra-peritoneal fatty tissue, but, curiously enough, the liver was found to be grossly enlarged and covered with hard black nodules. All other organs were normal. A piece of liver tissue was sent for biopsy to confirm the obvious diagnosis of malignant melanoma. Search of the records of an operation for enucleation of the right eye performed on the patient in this hospital on May 9, 1953, revealed a pre-operative diagnosis of "acute secondary glaucoma as a result of a contusion injury causing vitreous haemorrhage a fortnight ago." A biopsy report was, "Sections show malignant melanoma of the posterior chamber of the eye with retinal detachment."

A malignant melanoma of the eye followed by secondaries in the liver after a variable length of time is perhaps a well-known condition. But the interesting thing in this case, I feel, is the remarkable coincidence of an injury to the eye four years before, which also was the site of a malignant melanoma, and that this time the patient was admitted as an abdominal emergency with an irreducible epigastric hernia, and the liver was full of malignant melanoma.—I am, etc.,

Merchant Shipping Medical Scales

SIR,—By a lucky chance I got an offer to act as a ship surgeon of a small ship for a month recently. The ship was the cable ship *Edward Wilshaw*. This ship has a complement of 106 souls, made up of 18 British officers, 10 British petty officers, 40 Zanzibari seamen, 20 Indians comprising the engine room staff, and 18 Goanese the victualling staff. As the numbers exceed 100 she is, by Ministry of Transport regulations, required to include a surgeon in her complement. The crew is a mixed one composed of Europeans, Africans, and Indians, recruited mostly from England, Zanzibar, and Bombay.

The previous doctor showed me the surgery, the arrangement of the drugs and instruments in the surgery, and the hospital or sickroom, which consisted of three berths and a bathroom. After going through the drugs, instruments, and the equipment on the first day of my arrival, I began to wonder at what looked to me a complete lack of planning and thought as to the suitability and the necessity of many of the articles provided. After a little search I got a copy of the merchant shipping medical scales, according to which the equipment is provided. On going through this book I came to the conclusion that it must have been drawn up forty or fifty years back, with a few additions made every few years. In fact I got an old copy without date, a copy dated 1945, and one dated 1953, and, though the matter has been rearranged, there was very little addition except the antibiotics, and practically no or very few deletions. This in my opinion has led to a great number of unnecessary drugs and instruments carried.

There are very few made-up mixtures, but there is a large assortment of drugs to be made up as and when required, and the necessary equipment to make up prescriptions is provided. For example, there were a pair of scales, different sizes of measure glasses, palettes, spatulae, and the like. There was also a very large mortar and pestle, which did not show any sign of having been used, and the same could be said about the pair of dispensing scales. This may have been useful some 30-40 years back, as the doctors then used to know a certain amount of dispensing, but the present-day doctor does not do so. He mostly prescribes tablets or made-up mixtures, ointments, liniments, eye drops, ear drops, etc., and in fact hardly ever writes a prescription to be made up by a chemist. In fact, to make up a prescription by weighing things when the ship is in motion must be experienced to find out how difficult it is. The surgical instruments are enough to carry out a major operation, including a trephine. I think this is expecting the impossible from any doctor. He is alone in these small ships and has no help of any sort, not even a dresser. He has had neither the training nor the experience to take on such an operation, otherwise he would not accept such a job except in exceptional circumstances. In fact, in my opinion, any doctor trying to undertake an operation of the magnitude of an abdominal operation or an operation for decompression of the brain under conditions available in a small ship and in the space of a sickroom or a hospital provided would be doing an act amounting to murder. Many may think this to be a rash statement, as they may have heard of successful operations done at sea with the second officer acting as the anaesthetist, or the chloroform-bottle-holder, as he was called in the days gone by. Would such a risk be justifiable, however, in these days of antibiotics? Would it be in the ultimate interest of the patient?

To take a practical view of what can be expected of a doctor of a small ship carrying, say, a hundred to two hundred persons on board, he must be able to treat all the minor complaints to which the human body is liable, such as colds, fevers, digestive and respiratory complaints, and carry a passenger suffering from a more serious complaint to the nearest port. In case of an accident he ought to be able to give first aid, set up a fracture temporarily, and treat a burn, also until the patient can be landed at the next port. He must be able to treat an acute abdomen by antibiotics and with Ryle tube and intravenous drip, and treat a case of accidental poisoning. The most that can be

expected of him in the way of a surgical operation is an amputation in case of a crush injury in machinery. The medicines, equipment, and instruments must be such as would suffice the above needs and no more. More would be a waste. It would be futile and completely unnecessary to expect him to compound prescriptions on the high seas. Everything must be ready-made so far as is possible, except in rare cases where solutions could be diluted in fixed proportions from tablets or stronger solutions.

To go into full details would be impossible in the compass of such a letter. I feel very strongly, however, that a revision is necessary and would lead to a big economy to the order of 50%, and it would be in the interests of the ship's owners if the Ministry of Transport appointed an expert committee which should include one or two doctors who have done a period of service in such a ship to go thoroughly into the question of revising the medical scales on a thoroughly practical basis.

I wish to thank Captain C. C. Muscleston, the commander of the ship, for his encouragement to put my thoughts in writing.—I am, etc.,

S. D. KARVE.

Mombasa.

Breast-feeding

SIR,—During my professional lifetime mothers have been instructed to feed their babies two-hourly, four-hourly, on demand, on one breast, or on two breasts at each feed. Whatever the method, if their babies have been reasonably good suckers, most mothers have succeeded; some have succeeded with one baby and not another, whilst a minority have failed with every baby. Probably the most convenient way for the average mother is to feed the baby off alternate breasts every four hours; each nipple then has an eight-hour rest, and a sore nipple can be spared even longer if the baby will sleep on at night; more important still is the fact that if, through fatigue or other cause, the milk should be a little short the second breast can be used instead of a bottle or spoon. Although some babies will want three-hourly feeding, at least for a while, and some mothers do best by using both breasts each time, it seems to me that every mother should be encouraged to give a good trial to what may be termed the method of choice.—I am, etc.,

Beckenham, Kent.

Suxamethonium Chloride and Muscle Pain

SIR,—When Dr. H. C. Churchill-Davidson published his original observations on muscle pains after suxamethonium chloride (*Journal*, January 9, 1954, p. 74), I had already stopped using the chloride salt and had used the bromide ("brevital M") in over 2,500 anaesthetics, and had had no complaints from my patients. Since then I have used suxamethonium bromide in over 8,000 anaesthetics. Although patients are not provoked to complain, all have been seen and talked to, and, with the exception of two, none have complained—these two were both from the same ward, both from the same operation list, and both so striking that the ward sister greeted me with: "What have you been doing to my patients? The two cases from yesterday are complaining of terrible pains in the chest." That remark in itself indicates how unusual such pains were. Subsequently I discovered that I had used a bottle of suxamethonium bromide on Monday that had been prepared on the Thursday previous. Whether or not the pains are due to some product of deterioration I do not know, but I have experienced no trouble since then. Neither have I had a case of prolonged apnoea since I started using suxamethonium bromide, though I did have one with suxamethonium chloride.¹

I find it difficult to comprehend that any scientifically trained person uses a ready-made solution of problematical strength in preference to a freshly prepared solution of known potency. However, it appears to be so, but it would be interesting to know whether muscle pains are as common after the use of suxamethonium bromide as they are after suxamethonium chloride, as my experience tempts me to suggest that they are not, and I think that some of the

disadvantages of suxamethonium chloride—e.g., prolonged apnoea—may be due to the products of its decomposition.—I am, etc.,

Lethbridge, Alta, Canada.

Hepato-lenticular Degeneration

SIR,—In your annotation on hepato-lenticular degeneration (*Journal*, August 3, p. 283), you state that there is now some evidence that improvement may follow treatment with dimercaprol (B.A.L.).

Within the past year reports have been published^{1,2} on the results of treatment of Wilson's disease with a new chelating agent, penicillamine, which proved more active in increasing copper excretion than B.A.L. Penicillamine is effective by mouth, and in preliminary trials it has not shown any toxic effects. The number of patients suffering from hepato-lenticular degeneration who have been treated with penicillamine is small, and it is too early to make a final assessment of its influence on the clinical course of the disease. However, the immediate and marked effect on copper output suggests that penicillamine may be a considerable improvement on other chelating agents.—I am, etc.,

Mass B.C.G. Vaccination

SIR,—In his letter (*Journal*, August 17, p. 410) Dr. E. F. James is concerned with the efficacy of B.C.G. vaccination and with whether tuberculosis morbidity is now sufficient to justify its extensive use, rather than with the optimum age for mass vaccination. The latter was the question discussed in my paper (*Journal*, July 6, p. 20). As regards the value of B.C.G., the accumulation of evidence in favour of the efficacy of the vaccine is against Dr. James, but he may be right in his opinion that at present the morbidity from tuberculosis is so low in County Tyrone that mass vaccination is not indicated there.

Similarly, the declining tuberculosis rates elsewhere encourage the view that mass B.C.G. vaccination may eventually be no longer required in many other communities, including England and Wales. Nevertheless, in England and Wales a total of over 49,000 cases of tuberculosis were notified in 1950; in 1955 the figure was about 38,000. The corresponding figures for the age group 15–24, which the present vaccination scheme might be expected principally to affect, were 13,000 and 9,000 respectively.¹ Thus in England and Wales the declining tuberculosis notifications remain sufficient to indicate that the current mass vaccination scheme may remain a valuable measure for some years.

One of the features of tuberculosis morbidity in recent years has, it is true, been the increase in the middle-aged and elderly. However, unless Dr James's view—that tuberculosis has become less severe in children and young adults—is taken to mean that tuberculosis at that time of life is no longer a significant disease, an appreciable prevalence of infectious tuberculosis in the middle-aged and elderly constitutes a threat to the health of young people. While this state of affairs exists it would seem wise to continue to vaccinate schoolchildren here, preferably before the onset of the stresses of adolescence.—I am, etc.,

London, N.W.11.

St. Luke's Tide Services

SIR,—With regard to Dr. J. B. Gurney Smith's communication (*Journal*, August 10, p. 356) referring back to the Bishop of Lichfield's invitation (*Journal*, July 13, p. 105) to doctors to preach in churches on St. Luke's Day, he reminds us that there is in being the Union of St. Luke. This

is an Anglican organization, I understand, and is no doubt useful; but healing is interdenominational. The Christian Church, the body of Christ, is rent by divisions on theological issues and it seems that the ministry of healing—by which I mean co-ordinating spiritual, mental, and physical considerations in health and disease—could be an instrument in the hands of Christians to bring about unity.

Some of us in the north are trying to form a clergy-medical association formed of clergy and doctors (and including allied professions as associate members) of all denominations. The aims are to promote Christian ideals among medical and nursing personnel, to encourage closer co-operation between clergy and doctors so as to keep the medical mind informed in spiritual matters and the clerical in scientific, and to study the role of spiritual considerations in healing and keeping whole, and, while using all orthodox medical, surgical, and psychiatric methods of treatment, to foster scientific examination of and research into the deeper spiritual processes involved. Such a clergy-medical association, being a body for scientific investigation, might well arise under the umbrella of the B.M.A., for this is an age of enterprise in research, and "findings" from local groups might prove very surprising and useful in treatment. While sympathizing with the spiritual affinity which prompts sectarianism, I feel that, for the ultimate good both of the science of medicine and our Christian vocation, we should be non-sectarian in our search after truth.—I am, etc.,

Morpeth.

JANE H. THOMPSON.

Operations for Varicose Veins

SIR,—Dr. K. Sanders is, I'm afraid, a little premature in describing (*Journal*, April 6, p. 822) the thrombophlebitis in the leg of his patient as a cure. This he does after three weeks. However, when he examines his patient after six months he most likely will be disappointed to discover that the vein has recanalized. No cure is possible in "extensive varices from ankle to groin" unless sapheno-femoral ligation is carried out.—I am, etc.,

Sydney, Australia.

C. H. WICKHAM LAWES.

Medical Association for the Prevention of War

SIR,—I note from the *Observer* of June 30 that the Medical Association for the Prevention of War has been proscribed by the Labour Party as a Communist-dominated organization. Perhaps others may, like myself, have been misled into joining it. I wrote to the secretary after seeing the article in the *Observer*, but so far have had no reply.—I am, etc.,

Newcastle upon Tyne.

ALAN GILSTON

*In *The Communist Solar System* (Hollis and Carter, Ltd., with a foreword by Mr. Herbert Morrison), the following paragraph describes the organization to which Dr. Gilston refers: "The formation of a 'Medical Association for the Prevention of War' (M.A.P.W.) was announced in the *Daily Worker* of June 6, 1951. It was soon obvious that this innocent-sounding body was yet another Communist front organization. In practice, like the French 'Union National des Médecins pour la Paix,' the Danish 'Doctors' Anti-War League,' and similar organizations in other countries, the M.A.P.W. has close links with the World Congress of Doctors for the Study of Contemporary Living Conditions, a Communist international organization founded by the World Peace Council."—ED., *B.M.J.*

Case of Mistaken Identity

SIR,—Much confusion has been caused by the fact that my name is so similar to that of Dr. Geoffrey (H.) Bourne, of the London Hospital. I have nothing to do with ageing, except in so far as my own metabolic processes are concerned, nor have I any interest in hair-growing, beards, or other such appurtenances of senility.—I am, etc.,

London, N.W.1.

GEOFFREY BOURNE.

Obituary

Sir CHARLES READ, P.R.C.O.G., M.B., F.R.C.S.
F.R.C.S.Ed., F.R.A.C.S.

We record with great regret the death of Sir Charles Read, President of the Royal College of Obstetricians and Gynaecologists and Director of the Institute of Obstetrics and Gynaecology of the University of London. He died suddenly while on board his yacht at Dartmouth, aged 54 years.

Charles David Read was born in Dunedin, New Zealand, on December 22, 1902. He was educated at the Southland and Otago Boys' Schools, and graduated M.B., Ch.B. at the Medical School at the University

[Bassano, Ltd.]

of Otago in 1924, being medallist in clinical medicine. After holding the posts of house-physician and house-surgeon at Dunedin Hospital, he came over to work in Britain, and during the next few years he took the F.R.C.S. of Edinburgh, the M.R.C.O.G., and the F.R.A.C.S. He joined the staff of a number of hospitals in and near London, and for some years was obstetrical and gynaecological

tutor first at Charing Cross Hospital and then at the Westminster Hospital. But his main hospital attachment was to the Chelsea Hospital for Women, which he served to the time of his death. Charles Read's exceptional capabilities quickly made themselves apparent, and for many years past he led a life of great activity. He was elected F.R.C.O.G. in 1940 and F.R.C.S.Eng. (*ad eundem*) in 1951. On the retirement of Professor James Young in 1950 he was appointed Director of the Institute of Obstetrics and Gynaecology of the British Postgraduate Medical Federation, and as such joined the staffs of Queen Charlotte's and the Hammersmith Hospitals. He examined for the R.C.O.G. and for the Universities of Birmingham and Glasgow. A vice-president of the Section of Obstetrics at the Royal Society of Medicine, he also served as vice-president of the Section of Obstetrics and Gynaecology at the Annual Meeting of the B.M.A. in 1950. He served on the Consultants and Specialists Committee of the B.M.A. for two years (1955–6) and was a member of the Negotiating Committee and of the Medical Whitley Council Staff Side, Committee B.

Two years ago he was elected President of the Royal College of Obstetricians and Gynaecologists, and he received a knighthood at the Birthday Honours this year. His fame was world-wide, and among the foreign learned societies of which he was an honorary fellow was that of the American Association of Obstetricians, Gynaecologists, and Abdominal Surgeons.

F.C. writes: "Whom the gods love die young." At the early age of 54 Charles Read passed all too suddenly from

this life. He had not infrequently forecast to his best friends that he would never reach old age, and indeed he had a serious warning some few years ago. This did not deter him in the least from the exercise of his amazing abilities and his inspiring leadership. He was a big man in every sense of the term: a superb surgeon, an excellent clinician, a really great teacher, a wise, progressive, and tolerant administrator, a generous and loyal friend and colleague. For a man of his vast physique, his energy and his surgical skill were alike phenomenal; his patience was exemplary.

Following a highly creditable early career in New Zealand, he arrived in Britain in 1926 with very slender means at his disposal; he was shortly afterwards appointed house-surgeon to the Chelsea Hospital for Women at the nominal salary obtaining in those days. Quite apart from these financial disabilities, newcomers from overseas must have found the England of the nineteen-twenties even more difficult to understand than did her own native inhabitants. Charles, however, adapted himself admirably; he was well received by all classes of the community. Victor Bonney and others soon recognized his outstanding ability and efficiency; he was always willing to observe, to listen, and to learn; his leadership came later, in the natural course of development. For the next few years he held with distinction appointments on the junior staff of various hospitals. *Inter alia*, he was obstetric and gynaecological registrar and tutor to two of our more famous undergraduate medical schools in turn. These institutions did not avail themselves of his subsequent services; but it is probable that the outcome was all to the good, as Read's interests have been essentially global, with special reference to the Commonwealth; his academic *métier* has been postgraduate teaching.

During the two years prior to 1931, when he was appointed surgeon to out-patients at the Chelsea Hospital for Women, he was responsible for such pathological investigations as were then available there. In this short space of time, and with the slenderest of assistance, he laid the foundations of a pathological museum which soon became famous in the gynaecological world. Throughout the war he held the fort at Chelsea in all senses of the term. As soon as he was appointed full surgeon he ensured that every surgeon should have an equal number of beds—a characteristically generous gesture; in earlier days the junior of the surgeons to out-patients had one bed only. On the retirement of Mr. Aubrey Goodwin in 1954 he became senior surgeon to a hospital which he has always regarded as his alma mater in this country.

As was inevitable in his case, Charles Read had a very large private practice in gynaecology and obstetrics: his reputation was truly international. But he never on any occasion neglected his hospital work on this account, whether the treatment of patients, teaching, or attendance on committees was concerned. He paid many professional visits to the United States of America, where he was most highly appreciated. It is fair to say that he has done as much or more than any man of his time to cement a healthy international relationship in that direction.

As President of the Royal College of Obstetricians and Gynaecologists since 1955 he was tremendously successful. In public life he was always at his best as a chairman. He was invariably well informed, lucid, and definite; although he spoke with authority, his courtesy, patience, and sense of justice never failed. It is all too sad to realize that he will not see with mortal eyes the new College which he had done so much to plan.

Sir Charles was twice married, and there are two sons of each marriage. Lady Read, to whom we offer our heartfelt sympathy, has been a wonderful partner. David, his eldest son, is well embarked in the medical profession, though not in the same branch as his distinguished father.

It is of some consolation to know that his domestic and social life has been so happy. He enjoyed yachting almost as much as he enjoyed his work, but he longed to have an

opportunity of revisiting his native country, New Zealand. Our democracy can ill afford to lose one of its few great men: may his benevolent and inspiring influence remain for many years to come.

We are indebted to Professor J. C. McCURE BROWNE for the following appreciation: Charles Read was appointed Director of the Institute of Obstetrics and Gynaecology in October, 1950. No happier choice could have been made, for with his world-wide reputation and his remarkable personal charm he immediately became the guiding force in the Institute, and at the same time drew the three branches together into a coherent body. Every member of the staff has felt the impact of his personality, experienced his kindness and understanding, and enjoyed his delightful sense of humour. He was admired for his professional skill and revered for his friendly and unassuming way with even his most junior colleagues. As a diagnostician he was extraordinarily shrewd. His knowledge of gynaecological pathology was surprising. As a surgeon his work had to be seen to be believed: a fine economy of movement combined with an unhurried precision made him a swift and masterly operator.

As the administrative head of the Institute he was wise, able, fair, and intensely active. The numerous visitors from centres at home and abroad were always made welcome by Charles in the most informal and friendly way, and in no small measure this, together with his outstanding professional ability, had gone far to make the Institute known all over the world. The students, representing so many nationalities, found him unfailingly courteous and helpful, yet their obvious admiration never caused him to mount any pedestal. He remained what he always was, a modest and friendly man. In 1952 he had a serious illness which gave warning that he should reduce his activities. This he did for a while, but his abounding energy and strong sense of duty soon made further calls on his reserves, to which he responded with characteristic courage. He could not do otherwise, for to Charles each day was too short and each moment precious.

His election as President of the Royal College of Obstetricians and Gynaecologists and the knighthood so recently conferred on him were but fitting recognition of his great achievements, and it is indeed tragic that he has been cut off so suddenly at the very height of his career. He will be remembered with affection as a man of vision, vigour, and enthusiasm whose passing has deprived us all of a beloved colleague and friend. It is pleasant to reflect that his last days were spent with his family, in his favourite recreation of cruising in his yacht, but it is hard to realize that he will never again slip moorings in the Hamble River, nor delight us with surgery made easy by the deft touch of a master.

A. J. JEX-BLAKE, D.M., F.R.C.P.

Dr. A. J. Jex-Blake, who died in Nairobi on August 16 at the age of 84, was on the staff of St. George's Hospital and the Brompton Hospital before he went out to Kenya shortly after the first world war.

Arthur John Jex-Blake, who was born on July 31, 1873, came of a well-known family. His father had been headmaster of Rugby, and his aunt, Sophia Jex-Blake, was the leader of the movement to open the medical profession in Britain to women and the founder of the London School of Medicine for Women. His sisters too achieved great scholastic distinction, for one was the principal of Lady Margaret Hall, Oxford, and another was mistress of Girton College. After this, the questioner lost interest in him. Jex-Blake visited me at the Ministry of Health during the war, and it was good to see him and to renew our friendship. He loved flowers, the classics, and beautiful things, and, though he forsook striving for some of the higher prizes of his profession which his early career promised him, he was happy in his life in a far country.

JOHN F. LAMBIE, M.B., Ch.B.

Dr. John Lambie, who was for many years a well-known general practitioner in Glasgow, died in that city on August 19 after a long illness. He was 80 years of age.

John Francis Lambie was born on September 19, 1876, and was educated at Glasgow High School and at George

to the D.M. in 1913. After holding house appointments at St. George's, he was awarded a Radcliffe travelling fellowship by the University of Oxford, and spent the next year or so working in Vienna, Copenhagen, and Baltimore. He returned to St. George's as an assistant in the dental, ophthalmological, nasal, and aural departments, and in 1905 was appointed assistant physician. A year or two later he became physician to out-patients at the Victoria Hospital for Children in Chelsea, and in 1909 he was elected to the staff of the Brompton Hospital as an assistant physician. At about this time also he worked as an assistant school medical officer for the L.C.C.

Although Jex-Blake tended to take a special interest in respiratory diseases, and was the author of a textbook on tuberculosis, he wrote on several other subjects and was an assistant editor of Gray's *Anatomy* for a number of editions. In 1913 he gave the Goulstonian Lectures before the Royal College of Physicians on "Deaths by Electric Currents and by Lightning"; these lectures were published in this *Journal* and have been regarded ever since as one of the most authoritative accounts of the subject.

During the first world war Jex-Blake served in the R.A.M.C.(T.) as a major, and after the war he returned to St. George's as a full physician. But he did not stay long in Britain, for he went to live near Nairobi in 1922. He practised there as a physician, but paid many visits to London. He took an active part in the work of the B.M.A. in Kenya, being president of the Branch on four separate occasions, his last term of office expiring in 1944.

Dr. Jex-Blake married in 1920 Lady Muriel Herbert, daughter of the fourteenth Earl of Pembroke. She died in 1951. There was one daughter of the marriage.

Sir ARTHUR MACNALLY writes: I have heard with regret of the death of Arthur Jex-Blake. His passing recalls the days at Brompton Hospital, when I soon learned to appreciate his gifts as a scholar-physician. He had already achieved a high reputation at Brompton and St. George's Hospital as clinician and teacher. His case-notes and letters were written in his small, neat handwriting, which was modelled on that of his chief, Sir Humphry Rolleston, whom he greatly admired. Both men had the same wide outlook on life and medicine. Both were men of good will and generous deeds.

In 1920, when the Tuberculosis Committee of the Medical Research Council was being planned, I asked Jex-Blake to dine at my club to meet Sir Walter Fletcher. We needed an able clinician on the committee, and Jex-Blake was our first choice. It was then he told us that he was going to be married and intended to live in Kenya. This meant that London was to lose an outstanding authority on diseases of the lungs, but the gain to Kenya in having a consultant-physician of Jex-Blake's calibre was immense.

He said once to me that he was overshadowed by the fame of his aunt and sisters. It was automatic with him to say when he saw the question hovering on the lips of a new acquaintance: "Yes, I am the nephew of Dr. Sophia Louisa Jex-Blake and the brother of the principal of Lady Margaret Hall, Oxford, and of the mistress of Girton College." After this, the questioner lost interest in him.

Jex-Blake visited me at the Ministry of Health during the war, and it was good to see him and to renew our friendship. He loved flowers, the classics, and beautiful things, and, though he forsook striving for some of the higher prizes of his profession which his early career promised him, he was happy in his life in a far country.

Watson's College. Going on to Glasgow University, he graduated M.B., Ch.B. in 1900. He was a noted athlete in those days, and along with John Dykes was instrumental in reviving the Glasgow High School Rugby Club. He lived to see it become one of the most powerful clubs in Scotland, and had the honour of becoming its president. His eldest son Lindsay followed in his footsteps and was capped several times for Scotland. For many years John Lambie was a member of Pollokshaws parish council and was a justice of the peace for the city of Glasgow. He took an intense interest in the welfare of his profession, and was a member of the British Medical Association for over fifty years. During that period he became chairman of the Glasgow Local Medical and Panel Committee; and he was chairman of the Glasgow Division, president of the Glasgow and West of Scotland Branch, and ultimately chairman of the Insurance Acts Scottish Subcommittee of the B.M.A. His work on central committees was again chiefly devoted to the interests of the general practitioner when for over ten years he was a member of the Insurance Acts Committee, the Central Ethical Committee, and the Representative Body. Before the inception of the National Health Service he was a member of the Negotiating Committee, and its prolonged discussions made a lasting impression on him without changing his antipathy to any State-organized medical service. He retired from general practice before the introduction of the National Health Service, but continued to carry on work as a part-time regional medical officer until failing health made him give up work. Dr. Lambie was a widower and is survived by three sons and a daughter.

W. M. K. writes: John Lambie was a man of high principles, both in his private and in his professional life, but this did not prevent him from being a congenial and lovable companion. During the difficult war years, those who travelled with him found him young of heart and always willing to participate in any social relaxation. He was a contemporary and great friend of Dr. J. B. Miller and the late Professor A. W. Harrington, and it was always a joy to be in their company, especially at a football match and listen to their caustic comments on the deterioration of modern Rugby, intermingled with an argument about which of the trio was the oldest. By all his friends John Lambie will be remembered as a very great gentleman, a wise man, a strong man, and a kind man.

P. J. ATKEY, M.R.C.S., L.R.C.P., D.P.H.

Dr. P. J. Atkey, who died on August 8 at the age of 90, was in general practice at Southampton for many years. After retiring to Woking, he continued working, though not regularly, until about five years ago.

Percy James Atkey was born in Sussex on January 28, 1867. From Haileybury College he went on to St. Thomas's Hospital, qualifying M.R.C.S., L.R.C.P. in 1891. After holding resident posts at St. Thomas's he worked for a time as a ship surgeon, and in 1896, during an epidemic, he was a temporary medical officer at the Gloucester Smallpox Hospital. In that year he took the Cambridge D.P.H. In 1897 he settled in practice at Southampton, where he was in partnership for a long time with Dr. A. B. Harman, being joined subsequently by Dr. Robert Henry and Dr. P. R. Browning, all of whom have predeceased him. At Southampton he became medical officer and surveyor for the Board of Trade and medical officer to the Canadian Pacific Steamship Company. During the first world war he added to the duties of his practice by undertaking much work in the British Red Cross hospitals in the locality. He retired in 1926, and two years later went to live at Woking. From the time he settled there he was always ready to help other doctors in the district, and for many years he was the appointed factory doctor for the area. During the second world war he worked for the Surrey County Council at infant welfare, pre-natal, and school clinics, and for the Ministry of National Insurance. For over twenty years,

until 1953, he was honorary secretary of the Woking district of the Royal National Lifeboat Institution. A keen sportsman, he played a good game of tennis and badminton in his day, and, as a young man, Rugby football for St. Thomas's Hospital and the Harlequins. He leaves a widow and two daughters.

J. D. REYNOLDS, M.B., D.T.M.&H.

Dr. J. D. Reynolds, who was for nearly a quarter of a century a member of the Uganda Medical Service, died at Kampala, Uganda, on August 7. He was 59 years of age.

John David Reynolds was born in 1898 and studied medicine at the Queen's University of Belfast, where he graduated M.B., B.Ch. in 1921. Three years later he entered the Colonial Medical Service and was posted to Uganda. In 1928 he took the D.T.M.&H. of the English Royal Colleges. He was honorary secretary of the Uganda Branch of the British Medical Association in 1929-30, and in 1931 attended the Annual Meeting of the Association at Eastbourne as the representative of his Branch.

J. G. B. writes: "J. D." as Dr. J. D. Reynolds was known by most people locally, went out in 1924 to the Uganda Medical Service, with which he served until 1947. For the last thirteen years of his career he was medical officer in charge of the European and Asian Hospital in Kampala, where his skill, kindness, and twinkling wit established for him a reputation greatly to be envied. Since his retirement from Government service he had been in general practice in Kampala. He leaves a widow and three grown-up children.

W. A. HOWITT, M.R.C.S., L.R.C.P.

Dr. W. A. Howitt died at his home in Birmingham on August 12 at the age of 86.

The son of a doctor, William Adlington Howitt was born in Nottingham on April 21, 1871, and later succeeded his father and practised medicine from the house in which he was born until his retirement to Birmingham in 1951. Receiving his earlier education in Nottingham, he later went to Caius College, Cambridge, and St. George's Hospital, qualifying M.R.C.S., L.R.C.P. in 1896. He had a particular interest in gynaecology and obstetrics, and was for many years an honorary surgeon at the Women's Hospital and Samaritan Hospital in Nottingham, retiring from these appointments in 1934, when he was made an honorary consulting surgeon. His real devotion, however, was for general practice, where his kindness and his strict ethical code endeared him not only to his patients but to the colleagues with whom he worked. Even after his retirement he often came to Nottingham and visited many of his old patients again as their friend. He was a very active member of the Nottingham Medico-Chirurgical Society, of which he was secretary in 1900, and fifty years later he was elected an honorary life member, an honour of which he was very proud. During this half-century he was a regular attender at the meetings and participant in the discussions, where his sagacity and experience lent weight to his remarks. He took a kindly interest in the younger generation of his own profession and was always keen to help the younger consultants as they came along, taking a lasting interest in their careers. The helpful advice which he gave to many will be remembered with gratitude.

F. S. BRERETON, C.B.E., M.D.

Lieutenant-Colonel F. S. Brereton, the author of many popular books for boys, died on August 12, aged 85.

Frederick Sadleir Brereton was born on August 5, 1872. From Cranleigh School he went on to Guy's Hospital, qualifying M.R.C.S., L.R.C.P. in 1894. He obtained the Brussels M.D. in the following year. Gaining first place in the competitive entrance examination, he was gazetted a surgeon lieutenant on the Army Medical Staff in 1896.

While at Netley he was awarded the Martin gold medal for medicine and the Parkes bronze medal for hygiene. In 1898 he was attached to the 2nd Scots Guards, and served with them in the South African War until 1902, when he retired from the Army with the rank of captain.

Brereton settled at Southport, and from that time until the outbreak of the first world war he wrote a number of books of adventure for boys: most of them had a historical flavour and had titles such as *With Shield and Assegai*, *With Rifle and Bayonet*, *In the Grip of the Mullah*, and *Foes of the Red Cockade*. In 1914 he was recalled to the R.A.M.C., and later became secretary to the committee responsible for the preparation of *The Medical History of the War*. In 1919 he published a book entitled *The Great War and the R.A.M.C.* This narrated events of the first two months of the war: the failure of horse transport, the success of the then new unit the casualty clearing station, and the excellence of the British field ambulance were some of the subjects discussed in the book. He was appointed C.B.E. in the 1919 Birthday Honours, when he held the rank of temporary major and brevet lieutenant-colonel, and in the same year he was created a commander of the military Order of Avis by the President of Portugal. Two years later he was appointed an officer of the Order of the Crown of Italy.

After the war Brereton returned to the writing of adventure stories, his later books bearing titles such as *Under Haig in Flanders* and *With Allenby in Palestine*. He wrote some 30 or 40 of these books. In 1920 he was living at Boxmoor, in Hertfordshire, but later moved to Hemel Hempstead. He became a member of the Hemel Hempstead borough council and a justice of the peace. *Hemel Hempstead Through the Ages* was another product of his pen. In 1898 he married Miss Ethel M. Lamb, of Birkdale, Southport, and had one son and one daughter. Mrs. Brereton died in 1948.

A. FERGUS HEWAT, M.D., F.R.C.P.Ed., F.R.F.P.S. The obituary of Dr. A. Fergus Hewat was printed in the *Journal* of August 17 (p. 415).

Dr. W. GILLIES ANNAN writes: I cannot allow the sudden death of Dr. A. Fergus Hewat to pass without adding my humble contribution to the well-merited tributes which have already been paid to him. I had the very great pleasure and privilege of working under his able guidance, first as an undergraduate, when he was clinical tutor in the late Professor Lovell Gulland's wards, and later as his house-physician in the Chalmers Hospital, Edinburgh. Initial impressions were perhaps a trifle terrifying, but under his somewhat stern exterior there lay a wealth of human understanding which served to endear him to all. His intolerance of all that savoured of disloyalty, insincerity, inefficiency, and self-aggrandizement was intense, while his admiration of the direct opposites knew no limits. In this era of "trumpet blowing" and "window dressing" it was always most refreshing to renew personal contact with Fergus Hewat, whose modesty and humility, relative to his own many achievements, had to be encountered to be believed. Typical of him was his reply when I wrote to offer my congratulations on his election as President of the Royal College of Physicians of Edinburgh. After thanking me for my letter, he said that it was merely tangible evidence of advancing years. One honour which he greatly cherished was the presidency of the Edinburgh Academical Club. Many famous men have occupied that eminent position, but I venture to suggest that none have done so with more distinction, and acceptance to all, than Fergus Hewat. I met him at North Berwick last summer and noted with deep regret that he was failing. The old booming voice had gone and the handshake was weaker, but the same kindly nature and sincerity of purpose was even more evident and I came away from our short but delightful interview with a renewed faith in human nature. The world is the poorer by his passing, and the Edinburgh medical school and the Edinburgh Academy have suffered the loss of one of their greatest and most loyal and lovable sons.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending August 10 (No. 32) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
§ Includes puerperal pyrexia.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications (uncorrected) in England and Wales in the week ending August 17 were as follows, with the figures for the previous week in parentheses: paralytic 176 (183), non-paralytic 191 (145), total 367 (328). Total cases in Scotland were 3 (9), Northern Ireland 22 (8), and Eire 9 (4).

The following counties had the largest numbers of cases: Devon 18 (Exmouth U.D. 9); Essex 37 (Harlow U.D. 7, Colchester M.B. 5); Kent 36 (Maidstone M.B. 4, Hollingbourne R.D. 5); Lancashire 15 (Liverpool C.B. 3); Lincs (Lincoln C.B. 12); London Administrative County 28 (Lewisham M.B. 5); Middlesex 19 (Harrow M.B. 8, Heston and Isleworth M.B., 3); Nottinghamshire 9 (Nottingham C.B. 4); Southampton 15 (Portsmouth C.B. 6, Gosport M.B. 3); Staffordshire 11; Warwickshire 33 (Birmingham C.B. 11, Coventry C.B. 4, Nuneaton M.B. 6); Yorkshire W. Riding 15 (Leeds C.B. 6).

Week Ending August 17

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 278, whooping-cough 1,205, diphtheria 1, measles 6,620, acute pneumonia 223, acute poliomyelitis 367, dysentery 238, paratyphoid fever 15, typhoid fever 1.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1948-56 are shown thus - - - -, the figures for 1957 thus ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The number of notifications of infectious diseases fell in England and Wales during the week ending August 10. The falls included 1,956 for measles, from 9,885 to 7,929, 234 for whooping-cough, from 1,284 to 1,050, 178 for scarlet fever, from 475 to 297, 100 for food-poisoning, from 444 to 344, and 51 for dysentery, from 325 to 274, and the only rise of any importance was 68 for acute poliomyelitis, from 260 to 328.

The largest decreases in the incidence of measles were 277 in Yorkshire West Riding, from 1,040 to 763, and 191 in Leicestershire, from 593 to 402; the largest exception to the declining trend was a rise of 41 in Dorsetshire, from 98 to 139. A small decline in the incidence of scarlet fever occurred throughout the country. The largest fall in the number of notifications of whooping-cough was 45 in Kent, from 153 to 108. Whooping-cough is at the lowest level it has been for almost two years. Seven cases of diphtheria were notified during the week, being 3 more than in the preceding week. The areas with multiple cases were Yorkshire North Riding, Thornaby on Tees M.B. 3, and Warwickshire, Birmingham C.B. 2.

The number of notifications of dysentery was the lowest for almost three years. The chief centres of infection during the week were Lancashire 47 (Liverpool C.B. 11); Yorkshire West Riding 26 (Leeds C.B. 10); Durham 23.

The largest outbreak of food-poisoning was 69 in Blackpool C.B.

Universities and Colleges

UNIVERSITY OF LONDON

The following candidates have been approved at the examination indicated:

M.D.—Part I: J. A. M. Ager, A. J. Bowdler, M. J. Cassells, J. V. Dadsell, J. E. Davies, J. A. Dossett, D. A. M. Ellis, R. Emery, P. L. Fieldus, N. S. Galbraith, Katherine A. Grice, M. H. Hambling, R. A. Osborn, Nancy I. Swift.

APOTHECARIES HALL OF DUBLIN

On July 19 the diploma of L.A.H. was conferred on the following candidates:

R. Antebi, J. C. Daly, Ida Dixon, S. K. El Dairy, E. J. Fleming, J. P. Gallagher, Helen Gavin, H. A. Gelfer, O. Gundersen, J. D. Harrington, J. B. Hession, T. F. L. Keane, D. A. Mhaikar, J. Morley, N. C. O'Brien, Bridget O'Neill, D. O'Tierney, F. O. C. Peters, K. A. Robertson, L. C. van Oudenhoove, N. P. Walsh.

Medical News

Red Cross Deficit.—A deficit of £84,977 is reported by the British Red Cross Society for the year 1956. The chairman of the society's executive committee, LORD WOOLTON, states that it needs a more regular income and ought not to have to depend on precarious flag days. The Red Cross also needs more members to help in the voluntary work which it does in peacetime. Referring to last year's achievements of the Red Cross as "an inspiring triumph for the practical application of great humanitarian ideals," Lord Woolton emphasized in particular "the vast organization for relief given to refugees from Hungary and Egypt."

Psychopharmacology Service Centre.—A clearing house of information on psychopharmacology is being established by the Psychopharmacology Service Centre of the National Institute of Mental Health—a department of the Public Health Service of the Federal Government of the United States. An extensive collection of the literature in this field, including pharmacological, clinical, behavioural, and experimental studies of the ataraxic, psychotomimetic, and other centrally acting drugs, will be classified and coded to enable the staff to answer a wide variety of technical and scientific questions. As soon as enough materials have been assembled the Centre plans to offer bibliographic and reference service as well as the preparation of critical and analytic reviews of special topics in the field. In order to accelerate the growth of the literature collection the Centre invites persons working in this field to provide three copies of any papers that deal with their work—whether reprints, pre-publication manuscripts, progress reports, informal mimeographed reports, papers read at meetings, or abstracts. Letters outlining work in progress would also be welcome. Any restrictions that authors may wish to place on the Centre's use of their papers will be strictly observed. All materials should be addressed to the Technical Information Unit, Psychopharmacology Service Centre, National Institute of Mental Health, 8719, Colesville Road, Silver Spring, Maryland, U.S.A.

General Medical Council.—The General Medical Council's "Recommendations as to the Medical Curriculum" were published in the *Supplement* of June 8 (p. 327) and there was a leading article commenting on the recommendations in the same issue (p. 1351). The recommendations have now been published and are obtainable from the Registrar, General Medical Council, 44, Hallam Street, Portland Place, London, W.1 (price 1s. 6d.).

Tuberculosis Pool.—In England and Wales the known tuberculosis population is large, and apparently still increasing, according to a report by Dr. W. P. D. LOGAN and B. BENJAMIN, of the General Register Office (*Tuberculosis Statistics for England and Wales, 1938-1955*, H.M.S.O., 4s.). As to respiratory tuberculosis, the whole tuberculosis population (known and unknown) is estimated at 375,000 persons, of whom perhaps 45,000 are sputum-positive and therefore infectious. Non-respiratory disease (not all of bovine origin) adds 36,000 to the tuberculous population. The authors of this report comment, "These statistics indicate that the problem of control of tuberculous infection is still a large one and any complacency as a result of the dramatic decline in mortality and the progressive reduction in notification is not justified."

The Society of Apothecaries of London.—At a recent meeting of the Court of Assistants Dr. Reginald Fisher was elected Master, and Dr. W. S. C. Copeman and Dr. R. R. Trail as Wardens.

COMING EVENTS

Nutrition of Young.—The Scottish Group of the Nutrition Society is holding a symposium on "The Nutrition of the Very Young" in Dundee on September 21. The papers

will be both on infants and on young farm animals. Further particulars from Dr. J. DAVIDSON, The Rowett Research Institute, Bucksburn, Aberdeenshire.

College of General Practitioners.—First annual Pfizer lecture of Northern Home Counties Faculty, 8 p.m., September 26, University College Hospital Medical School, London. Lady Isobel Barnett will speak on "Why don't we live to be a hundred?" Lecture open to all medical practitioners; apply for tickets to Dr. D. G. WILSON, 19, Chiltern Avenue, Bushey, Herts.

World Congress of Gastroenterology.—May 25-29, 1958, at Washington, D.C., followed by the 59th annual meeting of the American Gastroenterological Association, May 30-31. Further details from the secretary-general, Dr. H. M. POLLARD, University Hospital, Ann Arbor, Michigan, U.S.A.

First Catholic World Health Conference.—Brussels, July 27 to August 3, 1958, in connexion with the Brussels World Exhibition. The conference includes congresses of the International Association of Catholic Physicians, the Catholic International Committee of Nurses and Medical Welfare Workers, the International Federation of Catholic Pharmacists, and the International Federation of Catholic Hospitals. Further details from the secretariat of the C.W.H.C., 8, rue Traversière, Brussels.

Third International Congress of Allergology.—Paris, October 19-26, 1958. Simultaneous translation of papers into English, French, German, and Spanish. Details from the secretary, Dr. B. N. HALPERN, 197, Boulevard St. Germain, Paris, 7.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Friday, September 6
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. G. Scadding: clinical demonstration.

APPOINTMENTS

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—G. L. Ashford, M.B., Ch.B., D.P.M., Consultant Psychiatrist and Deputy Medical Superintendent, Little Plumstead Hospital; I. S. Lister, M.B., B.Chir., Surgical Registrar, United Norwich Hospitals; B. D. Shrivastava, M.B., B.S., D.O., Ophthalmic Registrar, Norfolk and Norwich Hospital; M. P. Awon, M.Sc., M.B., B.Ch., Registrar in Obstetrics and Gynaecology, and S. Kanagasabay, M.B., B.S., Orthopaedic Registrar, Peterborough Group of Hospitals.

MANCHESTER REGIONAL HOSPITAL BOARD.—A. Ashworth, M.B., Ch.B., F.R.C.S., Additional Consultant Urologist to North Manchester, Salford, South Manchester, and Booth Hall and Monsall Hospitals; J. C. Herapath, M.D., M.R.C.P., Maximum part-time Consultant Geriatrician to Blackpool and Fylde Group of Hospitals; J. F. Dunn, M.B., Ch.B., D.P.M., Whole-time Assistant Psychiatrist to Lancaster Moor Hospital.

BIRTHS, MARRIAGES, AND DEATHS

DEATHS

Brander.—On August 16, 1957, at Dumfries, John Brander, M.D., F.R.C.P., D.P.M.

Christie.—On August 12, 1957, at 12, Rosslyn Terrace, Glasgow, William Walls Christie, M.D., aged 93.

Connolly.—On August 14, 1957, at Basingstoke and District Hospital, Victor Lindley Connolly, M.C., M.B., B.Ch., D.P.M., of 68, Bounty Road, Basingstoke, Hants.

Czyzewski.—On August 12, 1957, at Oldchurch Hospital, Romford, Essex, Wacław Jan Józef Czyzewski, M.D., D.M.R.D., aged 47.

Dodson.—On August 17, 1957, at Edinburgh, Henry Reginald Dodson, M.B., Ch.B., of 2, Sighthill Neuk, and 8, Gilmore Place, Edinburgh.

Ellis.—On August 15, 1957, Francis Hamilton Ellis, M.B., B.Chir., of Campion Road, Putney, London, S.W.

Fell.—On August 3, 1957, Richard William Fell, M.B., C.M., of 44, Dalmeny Avenue, Cliftonville, Kent, aged 89.

Gibbard.—On August 11, 1957, in a nursing-home, Major-General Thomas Wykes Gibbard, C.B., C.B.E., M.B., late Royal Army Medical Corps, aged 92.

Graham.—On August 8, 1957, Cecil Irving Graham, F.R.C.S., aged 80.

Holcombe.—On August 10, 1957, Roy Stanley Holcombe, M.B., B.S., of Chingford, London, E., and Sydney, N.S.W., aged 59.

Howitt.—On August 12, 1957, at Northfield, Birmingham, William Adlington Howitt, M.R.C.S., L.R.C.P., aged 86.

Jex-Blake.—On August 16, 1957, in Nairobi, Kenya, Arthur John Jex-Blake, D.M., F.R.C.P., aged 84.

McLachlan.—On August 15, 1957, at Bristol Royal Hospital, Angus Elrick William McLachlan, M.B., Ch.B., D.P.H., of 9, Cooks Folly Road, Bristol, 9, aged 58.

Reynolds.—On August 7, 1957, John David Reynolds, M.B., B.Ch., D.T.M.&H., of Kampala, Uganda, aged 59.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Fibrous Cavertitis

Q.—What is the aetiology, treatment, and prognosis of fibrous cavernitis (Peyronie's disease)?

A.—The aetiology of this disease, first described by Peyronie, a court physician to Louis XV, in a treatise on factors influencing delayed ejaculation, remains unknown. The condition consists of a desmoid thickening, analogous to that observed in Dupuytren's contracture, affecting the tunica albuginea of one or both corpora cavernosa and the investing fascia of the penis. Histological studies fail to support an infective origin, and there is no clinical correlation with previous venereal disease. Earlier theories of an association with gout, diabetes, and arthritis are nowadays discounted. The condition, which manifests itself with greatest frequency between the ages of 40 and 70, probably represents an involutionary change possibly predisposed to by repeated minor traumata during coitus. Replacement of the elastic tissue by fibrous tissue, such as occurs in other vascular structures with advancing age, may be influenced by endocrine disturbances, metabolic changes, or malnutrition. There is some evidence, as in the case of Dupuytren's contracture, to suggest that vitamin-E deficiency may play a part, but the frequent association of the two conditions has also been considered indicative of a fibro-plastic diathesis.

With regard to treatment, both surgical excision and radiotherapy have their advocates. Many cases, however, display a tendency towards spontaneous resolution, but regular treatment with alpha-tocopherol (vitamin E) in doses of 100 mg. three times a day certainly does no harm and may possibly accelerate the healing process. Alternatively, good results have been reported following the direct injection of hydrocortisone 25-50 mg. into the lesion at twice-weekly intervals up to a total of 15 to 20 injections.

The prognosis is difficult to determine, as it seems probable that many minor lesions are never reported and the likelihood of spontaneous resolution is thus unknown. In general it would seem best to postpone active treatment by surgery or radiotherapy for several months so that any evidence of improvement in the meantime can be assessed.

Xanthoma Tuberosum

Q.—Has recent knowledge of cholesterol metabolism thrown any fresh light on xanthoma tuberosum multiplex and its relationship to arteriosclerosis?

A.—Subjects presenting with xanthoma tuberosum have raised serum cholesterol levels, but not all subjects with hypercholesterolaemia exhibit xanthoma tuberosum. The plasma cholesterol is not free, but is bound to two major protein fractions (α and β globulins), yielding the conjugated proteins called the α and β lipoproteins. Thus it is possible to describe an individual's serum cholesterol value in mg.% or to describe it in terms of its partition between the α and β lipoproteins. When this α : β lipoprotein ratio is obtained on subjects presenting with xanthoma tuberosum, one frequently finds that practically all the cholesterol is present as β lipoprotein, giving a ratio expressed as a percentage in this case of α : β :0:100 (normal α : β :35:65).

These α and β lipoproteins have been shown by ultracentrifugal methods to be unhomogeneous, and the β -lipoprotein has been fractionated by this technique into a wide spectrum of lipoprotein subdivisions, which are characterized by their densities of flotation constants (that is, S_0 20-20-40, etc.). These subdivisions of the β -lipoprotein have different chemical compositions, though all are associated

with the same β -globulin protein. It has been shown that the β -lipoproteins with the highest S_0 values have the highest content of neutral fat and the lowest content of cholesterol and protein, whereas the β -lipoproteins of low S_0 values have the highest content of protein and cholesterol and the lowest content of neutral fat.

Under physiological conditions, and in the presence of the heparin-induced clearing system, it seems that in normal plasma there is a gradual transformation of the higher S_0 β -lipoproteins in the lower S_0 lipoproteins. In subjects presenting with xanthomatosis tuberosum there may be a block in this catabolic reaction at a certain lipoprotein level which may lead to an accumulation of S_0 12-20 β -lipoproteins in the subjects' plasma, and the available experimental evidence seems to support the view that the cholesterol and other substances found in the xanthomatous lesion originates from the plasma cholesterol—possibly from this S_0 12-20 β -lipoprotein. Some American workers think that the plasma cholesterol level is only weakly correlated with the plasma S_0 12-20 β -lipoprotein levels, and these workers maintain that this particular class of plasma lipoprotein correlates better with the degree of atherosclerosis than does any other measurement such as the plasma total cholesterol or α : β ratio. Thus they claim that the increased severity of atherosclerosis in subjects with xanthoma tuberosum is due to the accumulation of the S_0 12-20 lipoproteins in the subjects' plasma.

The postulated block in lipoprotein metabolism in xanthoma tuberosum can be partially overcome by stimulating the formation of extra clearing factor in plasma by the parenteral administration of heparin. This treatment lowers the subjects' S_0 12-20 β -lipoprotein concentration (and lowers the serum cholesterol) and causes the xanthoma lesions to regress or in some cases even to disappear. Whether this treatment continued indefinitely will alter the prognosis of this disease remains a problem for the future.

Jaundice During Testosterone Therapy

Q.—Is jaundice a known complication of testosterone therapy? If so, how should it be treated?

A.—The occurrence of jaundice in patients under treatment with methyl testosterone is now a well-recognized, though rare, complication. It has not been observed in patients treated with testosterone (either as implants or as injections of the various esters). If jaundice occurs treatment with methyl testosterone must be stopped. If it is necessary to continue androgen therapy, injections of a long-acting form of testosterone (for example, the oenanthate), implantation of testosterone, or sublingual testosterone may be used. Otherwise it would be better to withhold further treatment until the jaundice has subsided.

Action of Antihistamines

Q.—What is the precise mode of action of antihistamine drugs in reversing allergic phenomena such as urticaria?

A.—The antihistamine drugs are competitive antagonists of histamine—that is, they are able to compete for the same receptors on the cell surface with which histamine normally combines. The reaction between receptors and antihistamine drugs is reversible, and depends on the concentration of the antihistamine drug in the extracellular fluid. If the concentration in the extracellular fluid falls, the antihistamine drug dissociates from the receptors and ceases to act; thus its action cannot be expected to last for more than a few hours after administration.

The effect of antihistamine drugs in urticaria is due to antagonism towards histamine released from cells. There is good evidence that both in typical anaphylaxis and in allergic reactions histamine is released as a consequence of the reaction of antigen with cellular antibody. It seems likely that much of the histamine thus released originates from the mast cells, which congregate in interstitial tissues, particularly in the neighbourhood of blood vessels. The effectiveness of antihistamines may depend on the proximity

of the histamine-releasing cells and the cells on which the histamine acts. Thus in urticaria and hay-fever, where histamine is probably released from cells somewhat distant from the locus of action, the antihistamines are fairly effective. On the other hand, in bronchial asthma, where histamine is released from cells in very close proximity to the site of action, or possibly from the smooth-muscle cell itself, the antihistamines are relatively ineffective.

Backache and Muscle Tone

Q.—Do flabby musculature and poor posture predispose to "slipped disk"? If so, what prophylactic measures are suggested for a sedentary male of average weight aged 35 years?

A.—It would be tempting to suppose that flabby musculature and poor posture do predispose to a slipped disk, but many of these patients are fairly vigorous and often very muscular men with good posture. The reason they have trouble is that they undertake strenuous or even violent work. The man of sedentary occupation with poor posture and poor muscle is probably liable to postural backache but not unduly predisposed to disk prolapse. For such backache the maintenance of good muscle tone is valuable. It is probably best achieved by some physical work as a hobby rather than by trying to maintain muscle bulk by repetitive and tedious exercises.

Syringe Lubricants

Q.—Is there any danger of precipitating embolism if syringes lubricated with silicone grease are used for intravenous injections?

A.—Three grades of silicone are used for the lubrication of syringes. These are MS.510/50, MS.510/500, and MS.550. These substances are non-toxic and are chemically inert. Further, the blood coagulation time is prolonged if carried out in a test-tube treated with silicone, since the platelets do not adhere to the glass walls. The normal practice is to smear a small quantity by means of an impregnated rubber pad on to the sides of the plunger, and to remove the excess with a swab. The plunger is replaced in the barrel, and worked up and down until a thin film is adherent to both the inside of the barrel and the outside of the plunger. The syringe is sterilized by dry heat. There is no danger of embolism if these precautions are taken, and indeed this practice has been in use in a number of syringe services for a number of years. The use of silicone to lubricate the assembled syringe before sterilization with steam is dangerous, since it prevents a free flow of steam to all surfaces of the syringe.

Catarrh

Q.—A patient already partially deaf as a result of previous otitis media (12 years ago) has recurrent attacks of Eustachian catarrh which last most of the winter. Treatment with decongestants does not help at all, and Eustachian catheterization only for a day or two. What can be done to help him?

A.—The key to such problems lies in the nasopharynx, very rarely in the Eustachian tube. Even in adults adenoids may persist and be an important factor, particularly collections round the Eustachian openings. Chronic sinusitis, nasal polypi, rarely a deflected nasal septum, the stuffy nose of allergy, or of so-called vasomotor rhinitis, may all be responsible by producing postnasal discharge or congestion. He should be advised never to blow his nose in the conventional manner, but freely, "à la paysanne." If, as seems likely, fluid is present in the middle ear, the drum should be incised early, and the ear inflated by catheter or by Valsalva's method. Finally, in an obstinate case, irradiation of the opening and lumen of the pharyngeal portion of the Eustachian tube by means of deep x rays should be considered, or the patient may be advised to live in a warm, dry climate.

NOTES AND COMMENTS

Bathroom Aids for Elderly Arthritics.—Miss DOROTHY A. SHARPE, F.R.C.S. (London, W.1), writes: Referring to "Any Questions?" July 20 (p. 171), a further very simple and effective aid for those who can use hands and/or arms which I have devised for myself (in addition to a high stool) is this. I have got two strong double hooks fixed in the ceiling or wall, similar to those used for children's play and climbing ropes, one at the near side of the top end of the bath, and one opposite where I want to get in. I hang from each hook a strong roller towel (of turkish towelling) of whatever length suits best. Then when sitting on the stool with legs in the bath I can hook one arm through the towel opposite and one through the end one (or this can be grasped if hands are strong), and, taking the weight on the arms and elbows, it is easy to lower myself into the water, and conversely to pull myself out on to the edge of the bath and then the stool.

Gastric Analysis in Suspected Cancer.—Mr. W. WEATHERSTON WILSON (Wigan) writes: Your expert's answer ("Any Questions?" June 15, p. 1430) is contrary to my experience. I have looked up my cases of gastric ulcer for the last three years which have had gastric analysis done. Of 38 patients with carcinoma, 33 show no free acid on gastric analysis. Of 20 patients with benign gastric ulcer only 5 show no free acid. As a diagnostic measure, taken of course in conjunction with the clinical history, the x-ray examination, and other customary ancillary investigations, I have found gastric analysis helpful. I submit that my view is substantiated by the figures I have quoted. Perhaps I should add that by "gastric analysis" I mean the titration with Töpfer's reagent of the gastric contents aspirated at half-hourly intervals following the ingestion of 50 ml. of aqueous alcohol. "No free acid," therefore, means a pH of more than 3.5.

OUR EXPERT replies: An accuracy of over 17% in what may well have been a selected series of late cases gives little support for an investigation in a region where more precise methods are available.

Early Symptoms of Parkinsonism.—Dr. G. W. M. MACKAY (London, N.2) writes: The late Sir Walter Langdon Brown told me of the following very early symptom, of which he himself was told by an Irish doctor—not named. It is this: The patient becomes aware of increasing difficulty in turning over from side to side while in his bed, without there being any obvious cause. It is a symptom to which I have subsequently found it worth while to pay attention.

Collected Articles from the "British Medical Journal"

The following books are available through booksellers or from the Publishing Manager, B.M.A. House. Prices include postage.

Emergencies in General Practice (26s. 6d. inland; 26s. overseas).

Refresher Course for General Practitioners, Volumes 2 and 3 (26s. 6d. inland each, 26s. overseas).

Clinical Pathology in General Practice (22s. 3d. inland, 21s. 9d. overseas).

Any Questions?, Volumes 2 and 3 (8s. each).

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: Attitology, Westcent, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the British Medical Journal alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Director, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. MEDICAL TRAINING AND RESEARCH IN INDIA TO-DAY

BY

A. W. WOODRUFF, M.D., Ph.D., F.R.C.P., D.T.M.&H.

Wellcome Professor of Clinical Tropical Medicine, London School of Hygiene and Tropical Medicine, University of London; Physician, Hospital for Tropical Diseases, London

Among the centenary anniversaries of Indian events taking place this year one which has received but little prominence but which nevertheless marked a vitally important milestone in the history of the Indian peoples was that of the founding of the Universities of Calcutta, Madras, and Bombay. These with their constituent medical colleges formed the van of a company which has grown steadily during the past century, which has played a fundamental part in the establishment of modern India, and which now has a record of which it may be justly proud. The founding of these universities, and the events leading up to their founding, may have been one of the factors causing the mutiny, which current historical investigators generally regard as being the result of stresses engendered by the impact of westernizing influences on Indian culture and social structure of the time. Though in 1857 the development of the universities was resented by some, all welcomed one of the results which it made possible 68 years later, when, in 1925, responsibility for India's health and education was handed over entirely to Indian Cabinet Ministers and Members of Council.

The next major step in the establishment of Indian Medical Services as they exist to-day was the setting up by the then Viceroy of a committee under the chairmanship of Sir Joseph Bore. This committee carried out a great labour during the two years of its existence and in 1945 issued a report which has been as far-reaching in its consequences as it was wise in its recommendations and which envisaged the development of a State medical service upon a gigantic scale. This service was to be built up over a period of forty years, and in spite of much preoccupation with constitutional changes a vast amount of work has been done towards carrying out the recommendations.

To run the health service as envisaged by this committee will require many more doctors, nurses, and ancillary medical staff than India now has and still more than she had in 1947, when there were approximately three for every 20,000 of the population. The distribution of these doctors in the country also presents a problem in that approximately 75% of them are practising in urban areas, whereas the population of the rural portion of India is approximately eight to nine times that of the urban. It was apparent therefore that if the recommendations of the Bore Committee were to be carried out increased facilities for undergraduate and postgraduate medical training would have to be created.

These facilities are now being provided in a four-point programme: (1) by building new medical schools; (2) by expanding, improving, and upgrading older ones; (3) by the establishment of the All-India Institute of Medical Sciences to provide teaching and research facilities in all the major branches of medicine; and (4) by establishing special teaching and research centres for medical problems of particular importance in India.

New Medical Colleges

In 1947 there were 17 medical colleges in India and now there are 42. Admissions of students to medical colleges increased from 2,500 in 1950 to 3,500 in 1955, and it is anticipated that during each of the next five years approximately 2,500 doctors will qualify. There are at present approximately 70,000 qualified medical practitioners in India, which is almost the same as in Great Britain, whereas the population of India is approximately seven times that of Great Britain. The sum of Rs.6.5 crores (£50m.) has been earmarked by the Indian Ministry of Health for the establishment of new medical colleges during the next five years, but expansion of existing colleges and their associated teaching hospitals has been given priority over the establishment of new ones and £150m. has been allotted for this purpose together with the provision in these institutions of departments of preventive medicine and psychiatry. This sum is also to provide funds for the completion of the All-India Institute of Medical Sciences and the upgrading of some departments for postgraduate training and research within existing medical colleges. It is proposed that every department within medical colleges will maintain a whole-time research unit.

Among India's new medical colleges that at Nagpur must rank among the finest; both in conception and in execution it is outstanding. The spacious, three-story building rises over a plinth area of 84,000 square feet (7,800 square metres) and possesses a fine colonnaded front, while the proportions are pleasing and the light stonework makes a brilliant spectacle in the Indian sun. The building was put up at the very economical price of £315,000. The college together with the new teaching hospital stand adjacent to one another on a site of 189 acres (75.5 hectares) which was chosen because of its proximity to that area of the town in which the poorer class of the population lives. Within the site there are bungalows for some of the senior members of the staff, students' hostels, a nurses' home, and recreation grounds.

Construction of the college was begun on January 2, 1948, and completed in December, 1952. There are at present 500 students, of whom approximately 15% are women and 25% are in receipt of grants.

The associated Medical College Hospital is of 800 beds and has cost £1,750,000, a price which is less than half that being spent on individual teaching hospitals elsewhere in the Commonwealth. Yet the accommodation, though without luxury, is fully adequate for its purpose. Students at Nagpur spend nine months after qualification as residents in the College Hospital and a further period of nine months is spent in charge of a village dispensary. Three months of the latter period are allotted to rural public health work. A centre for training in tuberculous disease is to be attached to the College Hospital, as a joint enterprise sponsored by the Government of India, the Madhya Pradesh State Government, and by the World Health Organization. This co-operation appears to apply throughout to the medical organizations in Nagpur.

At Indore, Madhya Bharat, another new medical school and hospital have been erected. Both are very well built, and are equipped with the object of combining utmost utility with economy. A special feature of the hospital is an excellent haematological laboratory, beautifully equipped with the most modern apparatus.

All over India new colleges are springing into being, many of them—as at Nagpur—in places where there had previously been training schools for medical licentiates: at Patiala in the west, at Dibrugarh, Assam, in the east, and at Jabalpur near the centre of the subcontinent. The Government Medical College, Patiala, was opened in October, 1953, and is affiliated to the Punjab University. The new college building consists of an administration block and self-contained blocks for the departments of anatomy, physiology, pathology, and pharmacology; there is also a spacious library. A 500-bedded teaching hospital associated with the college was opened in 1954 and it is intended that by the end of 1958 a further 250 beds will have been added. Hostels for 200 male and 50 female undergraduates have been provided, and the average cost of board and lodging amounts to 40–45 rupees (£3–£3 7s. 6d.) a month. Societies and sports have not been neglected, and there is provision for cricket, hockey, tennis, and badminton. The medical colleges at Dibrugarh and Jabalpur were opened in 1952 and 1956 respectively.

Older Medical Schools and Colleges

Along with these and other new colleges and hospitals, older members of their company continue to do very good work. In Calcutta the British-Museum-like Medical College Hospital is testimony of its earlier foundation and stands impressive and solid in dignified grey stone weathered by 100 summers and monsoons through which it has served alike the needs of the sick and of its medical students. At Hyderabad, Deccan, and at Madras, long-established hospitals and medical colleges combine modern teaching and outlook with balance and stability springing from a tradition founded upon sound principles. For the British visitor to Madras it is pleasant to enter the office of the Dean of the Medical College, and see the photographs, which have been carefully preserved, of previous administrators and medical superintendents.

The All-India Institute of Medical Sciences

In the four-point programme for the extension of medical facilities in India, the establishment of the All-India Institute of Medical Sciences occupies a very important place and is

designed to be a pivot on which many other medical activities will centre. The Institute was founded in 1956 under an Act of Parliament of the Indian Government, and its stated aims and objects are: (a) to develop patterns of teaching in undergraduate and postgraduate medical education in all its branches so as to demonstrate a high standard of medical education in all medical colleges and other allied institutions in India; (b) to bring together in one place educational facilities of the highest order for the training of personnel in all important branches of health activity; and (c) to attain for India self-sufficiency in postgraduate medical education.

The Institute opened in 1956 with an undergraduate medical course accommodated in the already existing Safdar Jang Hospital, New Delhi. There are also to be nursing and dental colleges, and it is planned later to add others for pharmacy and the training of public health engineers. It is proposed that in both the undergraduate and postgraduate fields high standards should be established not only as a stimulus and demonstration to the rest of the country but also to promote the output of medical graduates who will develop into leaders of the profession and who will take their places in the different medical colleges throughout India. It is also proposed to establish rural and health organizations as integral parts of the Institute, with the aim that they should provide training for medical men and nurses, and facilitate research into community health problems. Although a postgraduate course in orthopaedics has been started with a limited number of students, it is probable that other postgraduate courses will not begin until two years hence. Of the 50 undergraduate places at present available in the Institute, five are reserved for students of the scheduled castes and tribes.

At Calcutta a regional postgraduate medical college is being formed on the pattern of the British Postgraduate Medical School, London.

Special Research Institutes

Research institutes devoted to the study of particular diseases or subjects have also been created. In association with the long-established University of Delhi there is the Vallabhai Patel Chest Institute in which research on chest diseases is allied to training for a Diploma in Tuberculous Diseases. Under the Colombo Plan, the British Government has donated a sum of approximately £11,850 to the Institute and to this the United States Government under their technical co-operation programme has added approximately £2,800. Indeed under the Colombo Plan much has been done to aid in the developments here being discussed.

Medical visitors to India are very quickly confronted with appreciations of the legacy of knowledge, research, and training in medicine left by the British. One of the fields, however, which has remained relatively more difficult to approach in research is that concerning psychological disease in Indian people. The complex system of religious beliefs and social customs which form the background to their upbringing can be understood only with difficulty by those who have not been so brought up, and as is to be expected they play an important part in the genesis of psychiatric disturbances. Problems of mental health in India are being tackled at the All-India Institute of Mental Health, Bangalore, where it is aimed to train psychiatrists, psychiatric nurses, and other personnel required in India; it is also aimed to educate the public in measures calculated to promote mental health. Of special interest is the plan to train workers to deal with problems in social pathology, including crime, delinquency, prostitution, alcoholism, vagrancy, and beggary.

The Institute is composed of 15 departments grouped around the central department of clinical psychiatry which includes mental deficiency and psychosomatic medicine. Among ancillary departments are those for child and adolescent psychiatry, psychotherapy, mental health education, neurophysiology, and statistics and sociometry. Students may study for the postgraduate Diploma in Psycho-

logical Medicine of the University of Mysore, and in 1956 13 were admitted to the two-year course. This Institute is broad in its concept and ambitious in its aims, which cover not only negative aspects of mental health but as Rajkumari Amrit Kaur, formerly Minister of Health in India, has stated: "The positive aspect, namely, that of training the normal man of average mental calibre to gain control over his emotional equipment and intellectual power so as to promote the growth of an integrated personality." The task is large but is being tackled with so much enthusiasm that it is inconceivable that what is accomplished can be less than important.

In addition to these institutes, there is one for leprosy, and there are the Indian Cancer Research Centre, a Virus Research Centre at Poona, an Institute for Drug Research at Lucknow, and it is proposed to set up institutes of biology and for research into occupational health. Mention of the Institute for Drug Research brings to mind the demands which have been voiced by many sections of the Indian people for a revival of the indigenous systems of medicine—the Ayurvedic and the Unani—and of homeopathy. The Government of India has appointed committees to study and report on these systems, and research aimed at assessing their various merits is in progress. Current opinion and pronouncements from leading Indian politicians indicate that it is unlikely that India will reject modern scientific medicine on any significant scale to return to the older systems and the whole pattern of recent medical developments supports such a view. Nevertheless, investigations are proceeding to determine to what extent indigenous systems can be developed and regulated for medical relief in the country, and in the interests of humanity it is to be hoped that in this as in all medical matters politicians and administrators can be constrained to accept facts instead of expressing and attempting to legislate on the basis of their personal opinions.

Among the institutes, as in the case of the medical colleges, those which have been long established continue to serve, and to serve well, the people of India and medical science generally. At Conoor, South India, the Nutrition Research Institute, originally founded by Sir Robert McCarrison, continues with an output of first-class work which will compare favourably with that from any similar institute in the world. The All-India Institute of Hygiene and Public Health, Calcutta, was established in 1933 and aims at the provision of first-class advanced instruction in the methods of preventive and social medicine, suited to India's peculiar problems. Its large staff includes eight professors. The Institute is affiliated to the University of Calcutta, from which its students may obtain Diplomas in Public Health, Maternity and Child Welfare, Dietetics, Industrial Health, Nutrition, the degree of Doctor of Science (Public Health), and the Mastership in Engineering (Public Health). Near Calcutta the Institute runs two rural community controlled practice units which are used both for teaching and for research. Long-established Indian research institutes which have gained international recognition in the field of preventive health include the Central Research Institute, Kasauli, the Haffkine Institute, Bombay, and the King Institute, Guindy.

Indian Council for Medical Research

No mention of medical institutions in India would be complete without paying tribute to the Indian Council for Medical Research. It would be presumptuous to attempt to review its achievements within an article of this kind, but it would only be just to say that through its conferences, publications, and the active support it gives to innumerable workers its stimulating influence permeates the whole of the Indian subcontinent.

Special tribute must also be paid to the work of the World Health Organization in India. It is everywhere active, supporting investigations into the causes of ill-health and providing measures to prevent it. Its special concern is with tuberculosis, nutrition, and maternity and child wel-

fare, and for the latter it has given its support in staff, in funds, and in kind to centres throughout the country. It is currently engaged in tackling the important problem of preventing anaemia, which causes so much ill-health, particularly among pregnant women in India and throughout the tropics.

The impression gained by visiting a large number of Indian medical establishments is one of tremendous and enthusiastic development, of confidence in the future and in the value of continuing co-operation between India and Britain in medical training and research, and of genuine appreciation of the medical legacy of the past era. Mistakes have been made, but there appears to be a very general feeling that the past is the past and that to err is human. Between British and Indian great mutual respect and good will have grown up, and this fund of good will is everywhere apparent in acts of kindness and hospitality which are continually being shown to the British visitor to India.

The experience on which this paper is based was obtained during a recent visit to India as a consultant to W.H.O., to whom I wish to express my gratitude for the facilities provided and for permission to publish. I wish also to thank Colonel M. L. Ahuja, Medical Adviser to the Indian High Commission, for much helpful advice and information.

THE PATTERN OF HEALTH ORGANIZATION IN CANADA

BY

ALEX. MAIR, M.D., D.P.H., D.I.H.

Professor of Public Health and Social Medicine, University of St. Andrews

AND

GORDON H. M. HATCHER, M.D., D.P.H.

Special Lecturer in Medical Care Administration, Department of Public Health, University of Toronto

The problems besetting young medical graduates in Great Britain to-day are well known. It has become increasingly difficult for them to enter general practice. Hospital registrars remain dissatisfied and unhappy, while the profession itself is involved in yet another of its recurring crises, in which it would appear that financial readjustments to inflationary trends can only be achieved by prolonged and acrimonious debate with politicians, and, what is perhaps more deplorable, by a further loss of public esteem. It is indeed a sad day when the affairs of the medical and dental professions become the subject of a Royal Commission (*Manchester Guardian*, February 21, 1957). Moreover, the appointment of the Willink Committee (*British Medical Journal*, 1955) "to estimate, on a long-term basis and with due regard to all relevant considerations, the number of medical practitioners likely to be engaged in all branches of the profession in the future, and the consequential intake of medical students required" would seem to add still further to the feeling of uncertainty with regard to the future of the profession in this country.

During a visit by one of us (A. M.) to Canada a few years ago, it was thought that a brief outline of the medical services and opportunities of that country would be of particular interest to colleagues at home. In the prevailing circumstances, and the renewed interest in emigration, particularly to Canada, it would seem appropriate to tell this story now. We certainly do not wish to underestimate the many difficulties confronting the medical practitioner in establishing himself in Canada. Nor, as modern Jeremiahs, do we seek to lament, "Is

there no balm in Gilead; is there no physician there? " Rather, this is an attempt to illustrate not necessarily a better but a different approach to medicine from that practised in Great Britain.

Canada in 1956, including the Yukon and North-west Territories, had a population of 16,080,791, mostly in the ten provinces of Newfoundland, Prince Edward Island, Nova Scotia, New Brunswick (the four Atlantic Provinces), Quebec, Ontario, Manitoba, Saskatchewan, Alberta, and British Columbia. Medical and health organization, as in Britain, has been influenced by traditions of social and governmental organization as well as by the evolving pattern of disease. Public health organization, as distinct from hospital and general-practitioner services, had its origin at a time when communicable disease and sanitation were of paramount importance. It is therefore not surprising that in public health Canada has followed very closely the outline and spirit, even to the extent of reflecting the actual wording, of the English Public Health Act of 1875.

In its governmental organization it would not be entirely correct to liken a Canadian province to Scotland or Northern Ireland, each with its own measure of self-government or devolution. Rather, the relationship of the various provinces is more akin to that of the United States, where the Federal Government legislates for broad national or general purposes, while the constitution provides individual states (or provinces) concurrent or even exclusive jurisdiction over specified matters, including education and most health services developed to date. Constitutionally the Dominion or Federal Government is charged with the major governmental tasks, and it is only by subsequent judicial interpretation that the individual provincial governments have assumed unto themselves greater administrative and judicial responsibilities. This is the exact converse of the United States constitution, where the legal powers are vested in the individual states, but judicial interpretation has later extended the powers of the Federal or central authority.

Most important, the Federal Government holds the major powers regarding taxation and thus acquires more revenue than the Provinces. One other major difference is that in Canada, as in Britain, legislative and executive powers of government operate through the cabinet or parliamentary system, whereas in the United States the President or State Governors and their administrations exercise administrative functions separately from the legislative functions of the Federal or State Congresses. Canada has an appointed Upper House or Senate like our House of Lords, although it has no hereditary nobility. There is no upper chamber in most of the provincial governments. The upper chambers can hold public hearings on proposed legislation passed by the lower chambers. Members of the upper chambers are appointed for life by the Crown on recommendation of the government of the day, an alternative to the hereditary principle which, it is believed, finds increasing support in different political parties in Britain.

Before proceeding to describe the governmental health organization it must be emphasized that most of the health and medical services in Canada are not directly operated or even very closely supervised by the Central Government. The pattern of their services can be classified under four administrative headings: (1) public health services; Federal, provincial, and local; (2) hospital services; (3) private practitioner services, both general and specialist; and (4) independent voluntary health agencies.

Public Health Services

Federal

Historically most public health responsibilities in Canada have developed as provincial activities. The only mention of health in the British North America Act of 1867, which forms the basis of their Constitution, assigned charitable institutions to the Provinces, and marine hospitals, quarantine, and immigration to the Dominion. The Federal Government has since developed extensive responsibilities for food and drug administration and control; narcotic drugs; veterinary matters; the health of Civil Servants, immigrants, merchant seamen, Indians, and Eskimos; and sanitary conditions in interprovincial and international transport.

Most of these activities are concentrated within the Department of National Health and Welfare, the health portion of which was established in 1919. The major responsibilities for bovine tuberculosis and brucellosis continue to be the concern of the Department of Agriculture. The health of members of the armed Forces falls into the sphere of the Department of National Defence, while the medical care and welfare benefits of ex-Service men suffering from disabilities connected with their service come under the Department of Veterans Affairs.

Vital statistics are collected locally and provincially, and their compilation later into national figures is effected by the well-known Dominion Bureau of Statistics, which is within the Department of Trade and Commerce and not the Department of National Health and Welfare.

In the Act establishing the Federal Department of National Health and Welfare in 1944 this Department is charged with the responsibility for the health, welfare, and social security of the people of Canada, except for those matters within the exclusive jurisdiction of the provincial governments or which are by law assigned to other Federal Departments. In line with the spirit of this Act and the assumption of Federal health responsibilities, the Dominion Government began in 1948 a major programme of special grants-in-aid to the provincial health departments, and through them to hospitals, and to other health agencies within the provinces in order to improve and extend medical and health services. These grants are two or three times as large per capita as the corresponding health grants in the United States, but they still make up only a small proportion of the total provincial and local health expenditure. These measures were announced as the first step towards a nation-wide health insurance programme to be administered by the provinces, and financed jointly by the Dominion and each of the provinces. This programme has been discussed for many years, but its implementation has not yet really begun. These grants commit the Dominion Government to joint planning with each province to meet the major health needs within that province. In this way a national health policy is gradually being evolved with the Federal Government assuming a greater role in the health services of the future.

The first step in the national health insurance programme will probably begin early in 1959. This will likely be an extension of insurance for hospital care (excluding the services of doctors both in and out of hospital) for virtually the whole population of such provinces as enter into such an agreement with the Federal Minister of Health. The Federal Government legislation* authorized contributions of approximately 50% to hospital insurance plans administered by the provinces.

The three western provinces and Newfoundland already have programmes in operation that will likely require only some modification to meet the requirements of Federal financial aid (Hatcher, 1955). Other provinces, notably Ontario, the largest (one-third of the Canadian population) and most highly industrialized, have recently passed the enabling legislation and are negotiating the terms of Federal assistance.

*Bill 320, 5-6 Elizabeth II. The House of Commons of Canada. King's Printer, Ottawa. April, 1957.

election in June, 1957, of Canada's first Conservative Federal Government in 22 years may lead to some changes in detail and timing, but now seems unlikely to change the basic pattern of these developments.

The terms offered by the Federal Government after a recent Dominion provincial conference, and embodied in recent legislation, include: (1) that a majority of the provinces with a majority of the Canadian population must participate; (2) that virtually the entire provincial population must be included; (3) that deterrent cash payments by hospital in-patients must be small enough not to cause financial hardship; and (4) that within a reasonable time out-patient laboratory and radiological diagnostic services for all income groups must be offered together with the hospital in-patient services, to help prevent unnecessary hospitalization.

It should be emphasized that the majority of Canadian hospitals are under voluntary boards, and even the local government hospitals do not usually employ salaried clinical staffs. These arrangements for hospital insurance have not and probably will not change the voluntary nature of the hospitals, except that most of their increases will not come through the hospital insurance programme. There will undoubtedly follow increased rationalization of hospital services, with attempts to meet minimum standards of service in all areas based on regional planning. Even with these developments, this does not mean that Canada will necessarily follow the pattern of the National Health Service in this country. Indeed, considering the extent to which private non-profit-making and commercial health insurance agencies have succeeded on a fee-for-service basis in providing cover in case of illness† it is unlikely that it would. Probably some years will elapse before the Government moves to provide physicians' services as additional benefits.

Provincial

Most Canadian Provincial Government health services are integrated into a single health department headed by a provincial cabinet minister. It is interesting to recall that the Province of New Brunswick was the first government in the British Empire to recognize the public importance of health by appointing as early as 1917 a cabinet minister as head of such a department. This example was followed by the Federal Government shortly thereafter. Among the major responsibilities of Canadian provincial health departments are the following:

1. *The licensing, supervision, and payment of money grants to all public general hospitals within each province.*—Practically all their general hospitals come into this category.
2. *Finance and in many cases the actual operation of the mental and tuberculosis hospitals in each province.*—In this regard one perceives great similarities in 1 and 2 to the responsibilities of local authorities in this country prior to the advent of our National Health Service in July, 1948, except that the province rather than the city or county is the "authority."
3. *The provision of specialist consultation services—for example, pathology, bacteriology, and serology—and the direction of general policies for environmental sanitation and the prevention of disease are carried out by provincial public health departments.*—Some of these responsibilities are delegated by the province to local health departments, especially health visiting and sanitary inspection. In all the provinces, except Alberta and Ontario, medical officers of health and health visitors are provincial "civil servants." In these two provinces and in all the large cities public health staffs are local authority employees as in this country.
4. *Provision of special assistance to private practitioners, especially in isolated areas, assistance in obtaining medical and health services to needy families, and the development of adequate medical and hospital services for the whole population.*—This miscellaneous category includes the provision of provincial laboratory and diagnostic services, which may be used by practitioners free or for a nominal charge. It also provides certain special medical-care programmes such as insurance for hospital

†It is estimated that such programmes cover about one-quarter of the total costs of physicians' services now, and a similar proportion of hospital costs, excluding physicians' services. This is in addition to the Government hospital and medical care plans.

bills in the Provinces of Newfoundland, Saskatchewan, Alberta, and British Columbia, and for physicians' services in parts of two provinces. It provides medical care for the indigent population (our old Poor Law recipients) in two provinces (Newfoundland and Saskatchewan). In four others (Ontario, British Columbia, Nova Scotia, and Alberta) the government has contracted directly with the professions to provide this care. Special provision (hospitalization and/or physicians' services) is also made for all income groups for certain forms of chronic illness such as cancer in both Alberta and Saskatchewan, for poliomyelitis in most provinces, and for maternity hospitalization but not for physicians' services in Alberta.

Special mention should be made of Canadian workmen's compensation programmes. These are operated separately from the provincial health department in all ten provinces by government boards or commissions. Funds are collected entirely from employers. A workman is not entitled to sue an employer for damages arising out of industrial illness or accident. In turn the Canadian disabled workman is entitled to cash compensation in lieu of loss of wages, based on two-thirds to three-quarters of his average earnings prior to disablement subject to a maximum that is above average wages in most provinces and to a minimum which is above subsistence. Moreover, he is also entitled to comprehensive medical treatment services, including some of the most advanced rehabilitation programmes in Canada. He may choose any private practitioner, but later, depending on the disability, the Workmen's Compensation Board may refer him to a specialist or consultant. To varying degrees in different provinces, these boards exercise careful supervision of the quality of medical care being provided. Payment is made in such cases to doctors, hospitals, physiotherapists, and rehabilitation officers according to a schedule of fees. There is no limitation to the amount that may be spent on any one case.

In the western hemisphere this programme is unique. Only domestic servants and certain agricultural workers are excluded. Despite the comprehensive nature of its benefits, the administrative and other charges on employers are much less than in most American jurisdictions, because in the absence of litigation all the money is used for the administration and award of benefits to the disabled workmen. The programme dates from its inception in one Canadian province in 1913, and workmen, employers, doctors, and government alike attribute much of its success to the exclusion of courts and insurance companies from its operation. By contrast it is well to remember that the National Insurance (Industrial Injuries) Act, 1946, has not entirely removed the unpleasant features of former Workmen's Compensation Acts in this country. Since 1948 in Britain there has been a steep rise in the number of claims at common law against employers for negligence resulting in injury—legal proceedings which must still to some extent detract from the harmony essential between men and management in industry.

Local Authority Health Services

Local government is relatively weak in Canada by comparison with that in Britain, and no doubt is due to the inherent difficulties of attempting to administer large areas of sparsely populated country. The county system or its equivalent exists as a major local government unit in only three provinces, Ontario, Nova Scotia, and Alberta. So-called counties with limited powers exist in other provinces also. The basic unit of local government in most provinces is still the separate city or town in urban areas and the township or municipality in rural areas. As in the widely scattered and thinly populated parts of the Highlands and Islands in Scotland, these units, in terms of population, are too small for efficient local administration, and this has handicapped the development of local public health services. In the smaller provinces, as already mentioned, many of these services have of necessity to be provided centrally by the province.

In all provinces the old principle of the English and Scottish Public Health Acts of last century is still to be found in the appointment of general practitioners as part-time medical officers of health for small rural municipalities or

townships. It is only within the past fifteen years that most provinces have taken the initiative in organizing large areas of local public health administration under full-time medical officers of health, and staffed by health visitors. Sanitary inspectors attached to these units are rarely professionally trained but they have usually taken special correspondence courses organized by the Canadian Public Health Association or by a provincial health department.

With regard to the functions of local public health departments, the major part of the work of a medical officer of health is concerned with sanitation, immunization, school health services, and certain aspects of health visiting in respect of tuberculosis and other communicable diseases. Practically no treatment is provided and the work is largely isolated from the general-practitioner and hospital services.

Local public health administration in Canada to-day is going through a critical stage. With grave limitation of professional activities and with only limited contact with other health agencies, the medical officer of health finds, as in Britain, that the traditional fields of sanitation and control of communicable disease are shrinking. Private practitioners are becoming increasingly competent in the provision of maternity and child welfare and other preventive health services. Bovine tuberculosis and typhoid fever have been largely eliminated through the pasteurization of milk and the purification of water supplies by filtration and chlorination; so too has diphtheria by the widespread use of toxoid. Either provincial governments will have to find and develop a more significant role for the local medical officer of health in the planning and administration of medical care and hospital services within the provinces or local and provincial public health work will cease to have much attraction for competent professional people.

Although most Canadian provinces have established health departments in cities and rural health units to cover the population in the outlying areas, closer study reveals that many of these outlying units are understaffed or staffed by general practitioners who are working on a part-time basis. The local medical officer of health in Canada does not enjoy the respect that his professional colleagues accord to clinical consultants and specialists, and in consequence his remuneration is less than that of either general practitioners or clinicians.

Hospital Services

Mention has already been made of the mental and tuberculosis hospitals. There were approximately five mental hospital beds per 1,000 population in 1953, and, as in Britain to-day, these hospitals are grossly overcrowded. Mental hospitals are usually owned and operated by the provincial government, and in all provinces, with the exception of British Columbia, they are administered through the provincial health department. Provision has also been made recently to establish special psychiatric units in general hospitals, a policy, of course, which is becoming increasingly popular in this country. Up-to-date statistics on tuberculosis hospitals in Canada are somewhat confusing owing to the recent and continuing fall in the tuberculosis death rate throughout the country. In some provinces tuberculosis mortality in 1955 was under 5 per 100,000 population, although the average throughout the Dominion was 9. In the country as a whole there are now more than seven beds per tuberculosis death. Canadians look forward confidently to the day when these hospitals may be put to other uses, particularly for the care of the chronic sick, the needs of which in Canada may appear more clamant than those of geriatrics in the mother country. Elsewhere the tuberculosis problem is not so favourable. The problem is still serious in Newfoundland, while the mortality rates in the Indians and Eskimos are still five to six times those of the white population.

Most general hospitals in Canada are classed as public general hospitals under provincial legislation. In one small province most of them are owned and operated by the provincial health department. In the mid-western provinces and in some large cities local governments or groups of local

governments own and operate general hospitals. However, most of the public general hospitals are owned and operated by lay or religious boards, similar to our former voluntary hospitals, and are operated as corporate non-profit-making bodies quite separately from the government. They are public also in the sense that they are open to all classes and races of patients. They are also eligible for government financial assistance and subject to government licensing and regulation.

There are approximately 5½ general hospital beds per 1,000 of the population under provincial supervision and nearly 6 if we include the Federal hospitals for ex-Service and armed Forces personnel.

The public general hospitals in most provinces are eligible for two kinds of government grants. The first is from the province through the health department. It amounts to so many cents per patient per day or so many dollars for public ward bed, or in some cases it may be a grant in the form of a lump sum. Secondly, in the majority of provinces the local authority or municipality in which an indigent patient resides is required by provincial law to pay to the public general hospital so many dollars per patient per day of care given to the particular patient. In provinces which still operate this traditional method of financing hospital care the greater part of the hospital revenue derives from payments made by individual patients who are able to pay at the time they are receiving treatment, or by voluntary and commercial insurance companies on their behalf.

Private Practitioner Service

Canada had 15,651 doctors in active practice in 1954, giving a ratio of one doctor to 948 persons. In England and Wales (Census, 1951) there were 42,285 doctors in practice, giving a ratio of one doctor to 980 persons. A recent survey of practitioners and specialists in Canada (Department of National Health and Welfare, 1955) shows the number of general practitioners, general practitioners in one or other specialty, specialists, and others (see Table I). It will be seen that there are 6,246 doctors practising as specialists, of whom 4,182 have higher degrees. The figures given are exclusive of 380 doctors who are in the armed Forces, but include 708 immigrant doctors who have entered Canada in the three years since 1951.

TABLE I.—Canadian Doctors, 1954

Type of Work	Certificated*	Non-certificated	Total June, 1954
Private practice:			
General	389	6,378	6,767
Specialist	3,375	1,175	4,550
Other medical work:			
Specialist†	807	889	1,696
Other	24‡	2,614	2,638
Civilian physicians: total	4,595	11,056	15,651

* By the Royal College of Physicians and Surgeons of Canada.
† Does not include administration.
‡ All are on postgraduate study courses.
Note.—By certification is meant the possession of one or other of the higher degrees in a particular specialty as in this country.

Although the total number of doctors for the whole of Canada has risen from approximately 5,500 in 1901 to 16,031 in 1954, there has been very little change in the population/doctor ratio, being 972 in 1901 and 948 in 1954. The Provinces of British Columbia, Ontario, and Quebec have since 1911 shown consistently more favourable ratios—777, 858, and 1,005 respectively—than any of the other provinces. The under-doctored areas would appear to be Newfoundland with a ratio of 2,117, New Brunswick with 1,436, Nova Scotia with 1,280, the Yukon and Northwest Territory with 1,688, and the rural areas in almost all provinces.

Age Distribution

The median age of doctors in Canada, which had ranged between 43.4 and 44.2 years since 1931, dropped to 42.8 years in 1954, which is the same as that for England and

Wales in 1951. The proportion of medical practitioners in Canada in 1951 aged 25 to 54 years was 74.7%, while in England and Wales in the same year it was 78.3%. In Canada by 1954 the percentage of practitioners 65 years and over had dropped from 11.4 to 9%, while the proportion aged 25 to 54 years had increased to 76.7%, suggesting that the increasing numbers of young graduates from Canadian medical schools and young immigrants from abroad are tending to lower the mean age of medical practitioners in the Dominion. A comparison of age structure of doctors practising in the two countries in 1951 is given in Table II.

TABLE II.—Ages of Doctors in Canada and in England and Wales in 1951

Age in Years	Canada		England and Wales	
	No.	%	No.	%
25-34	28	0.2	1,513	3.5
35-44	3,564	25.2	12,537	29.3
45-54	3,953	27.9	11,046	25.8
55-64	3,059	21.6	9,923	23.2
65 and over	1,946	13.7	5,088	11.9
Total	1,533	11.4	2,732	6.3
Total	14,163	100	42,839	100

Graduates of Canadian Medical Schools

Graduates from Canadian medical schools amount to almost 900 a year compared with more than 2,000 annual accessions to the *Medical Register* in England, Wales, and Scotland (Hood, 1953). The number graduating from Laval Medical School, Quebec, has increased considerably. The first 54 medical students graduated from the new medical school at the University of British Columbia in 1954. A further 30 graduates are expected this spring as a result of the extension of the medical training at the University of Saskatchewan to a full medical course.

Migration of Medical Graduates

Very little information is available from Canada about emigration of doctors. Data which are available for emigration from Canada are complicated by extensions of stay for postgraduate training and by decisions to remain in the United States after taking postgraduate training there. Information is available regarding immigration to Canada since 1951. For the three years to 1954, 708 immigrants have gone to Canada to practise medicine.

The bulk of these immigrants were in the 25-34 and 35-44 age groups (see Table III). Of the total of 708, 79.5%

TABLE III.—Immigrant Doctors to Canada Since June, 1951, and Still in Canada at June, 1954, By Age Group, for Provinces

Age Group	N.E.	P.E.I.	N.S.	N.B.	Que.	Ont.	Man.	Sask.	Alta.	B.C.	Yukon and N.W.T.	Total
Under 25	1	—	—	—	—	—	—	—	—	—	—	2
25-34	26	2	4	7	46	70	21	29	37	50	3	295
35-44	9	4	7	4	14	92	30	44	34	30	—	268
45-54	—	—	—	—	3	29	7	10	11	5	—	72
55-64	—	—	—	—	1	2	10	2	4	—	—	21
65-69	—	—	—	—	—	1	—	—	—	1	—	3
70+	—	—	—	—	—	—	—	—	—	—	—	—
Not given	7	—	—	—	4	20	3	2	6	4	1	47
Total	45	6	16	12	69	222	64	87	93	90	4	708

were aged 25 to 44 years. Almost a third of the group were resident in Ontario; only 69 had settled in Quebec. One-third are now in general practice and the majority of the remainder are in the "other" category comprising those employed by hospitals in duties equivalent to specialists or senior registrars.

Procedure for British Medical Graduates Who Intend to Emigrate

Licensure in Canada is a provincial responsibility, although most provinces have reciprocity with each other through a common licensing examination, or rather series of examinations, known as the "Dominion Councils." These examinations cover the usual medical school subjects. A few pro-

vinces have reciprocity with the *British Medical Register*, while others, notably Quebec and British Columbia, present obstacles to the British immigrant doctor in the form of residential requirements or very high fees.

The licensing body in each province, vested with authority by the provincial legislature over medical practice requirements, is independent of both medical school faculties and health departments. In some provinces the secretary of the Provincial Medical Association is the registrar of the licensing body. Most doctors from Britain wishing to practise in central or western Canada should be prepared to sit examinations in the clinical subjects at least, and a year's internship in an approved Canadian general hospital is of value and sometimes mandatory. For further details a letter should be addressed to the Registrar, College of Physicians and Surgeons, in the capital city of the province.

The licensing bodies are not to be confused with the Royal College of Physicians and Surgeons of Canada (in Ottawa), which grants specialist certification and Fellowship, and is not a licensing body at all. The right to treat patients in hospital is accorded by the board of that hospital, and to an increasing extent is granted only in accordance with specialist qualifications. The immigrant doctor wishing to perform surgery or administer anaesthetics in one of the better hospitals in a large centre of population should consider obtaining specialist qualifications. British medical graduates possessing specialist degrees or qualifications should certainly inquire of the Royal College of Physicians and Surgeons of Canada about their status in Canada.

Specialists in Canada who restrict themselves largely or wholly to a given specialty do not depend entirely on referrals from other physicians, but will see patients unreferred. This is particularly true in paediatrics and obstetrics, and in other specialties where the patient feels herself or himself competent to identify the portion of her or his anatomy that requires attention.

Those planning to enter general practice in Canada should remember that domiciliary midwives are almost unknown outside Newfoundland, and that it is difficult to build a good general practice in most parts of Canada to-day unless one is competent to do one's own obstetrics. It is exceptional for a physician to purchase the goodwill of a practice. The customary method is simply to put up one's plate. Group practice is uncommon in the larger centres of Eastern Canada, but physicians lacking the resources to develop a practice of their own at once might start as an assistant or junior partner of an established practitioner. Either form of association would be invaluable in learning Canadian ways, and the Canadian Medical Association (St. George Street, Toronto) or its Provincial Divisions would be helpful in finding such a position.

Independent Voluntary Health Agencies

The names of the independent voluntary health agencies are legion and no attempt is made here even to enumerate them, much less to mention their pioneering work in demonstrating health needs and developing effective patterns of lay, government, and professional co-operation to meet these needs. Tuberculosis, mental health, crippled children, and bedside nursing have had special voluntary agencies for many years, and more recently cancer, heart disease, rheumatism, and arthritis are health problems for which there are special voluntary agencies. The practising doctor should co-operate with these agencies in order to give his patients the best possible service. In the area in which a doctor establishes practice he should inquire about the voluntary agencies that are active and how his patients can use their services.

Special mention should be made here of the voluntary insurance plans providing practitioner services. These are to be distinguished from the Blue Cross plans which pay hospitals for services rendered, and from commercial insurance companies that pay cash amounts to the patients on certification (usually a special form or a receipted bill) by the doctor who rendered the services.

Except for parts of the Maritimes and Quebec, in every province there is at least one voluntary insurance plan for medical services in the home, surgery, and hospital, sponsored by the Provincial Medical Association. Medical practitioners are asked to enter into a contract with this plan, agreeing to accept payment from the scheme directly on submission of a bill by the physician to the plan for services rendered by him to an insured patient. The schedules of fees used by the plans are close to the minimum recommended by the Provincial Medical Associations, and, with some variations from province to province, physicians agree to accept these fees as payment in full for their services. In Quebec, Ontario, Manitoba, and the Maritimes, Blue Cross plans also pay physicians for services in hospitals only, on a somewhat similar basis, although the physicians more often make additional charges to the patients. About one-quarter of all payments to physicians in Canada are now made through voluntary or commercial insurance companies. Through the extension of such plans the Canadian Medical Association hopes to anticipate a Government health service.

In conclusion, it is generally accepted that there are immense opportunities for young people, both lay and medical, who wish to emigrate to this young and vigorous Dominion. Nevertheless, in the last resort it must remain a highly individual and personal matter involving difficult decisions of adjustment to a new climate no less than to a new culture. As Dr. Geggie (1955), a Canadian returning home after seven months in Britain, wrote: "Lest the picture look too bright, let me point out that no doctor, except the dead one, knows security in Canada. The foreign doctor must be willing to conform with Canadian ways and to cater night and day to a very demanding public. Nor is a higher degree, including British degrees, of any great assistance. The Canadian doctor has to prove himself to his public—and a very discerning public it is."

Summary

An outline is given of the administration of the health services of Canada. Reference is made to recent hospital insurance developments.

A PRESCRIPTION FOR HEALTH*

BY

R. W. LUXTON, M.D., B.Sc., F.R.C.P.

Consultant Physician, Crumpsall Hospital and the Christie Hospital and Holt Radium Institute, Manchester

Some years ago an advertisement for a famous retail chemist included the arresting phrase "Prescriptions dispensed with deadly accuracy." I make no such claim for to-day's prescription, because, on this subject of health, the thinking of the medical profession is worse than inaccurate, it is confused. We doctors know a good deal about disease, but not much about health; indeed, we have to be more *interested* in disease than in health. Symbolic of the confusion is our describing as the "National Health Service" what is actually the "national ill-health service." Typical also is the fact that we regard health as merely the absence of disease. At this meeting of doctors and clergy I would urge that we look on health not as the absence of something wrong, but as the presence of something right. Health is the whole man at his best. A real health service will arise when there is understanding and collaboration between all those whose vocation is to bring man to manhood—doctors, clergy, educationists, social workers, and many others, including politicians.

These introductory remarks you may regard as the letter-heading of the prescription form. If you will

*Read at a meeting organized by the Churches' Council of Healing during the Annual Meeting of the British Medical Association, Newcastle upon Tyne, 1957.

Governmental public health services operate at Federal, provincial, and local levels. These services at the local level are poorly developed by comparison with those of Great Britain.

Hospital services, both voluntary and provincial, have many features in common with the situation as it existed in this country prior to the advent of the National Health Service, except that financing is more of a public responsibility in Canada, and administration of the institutions more often a voluntary function.

Private practice perhaps displays features of combined general and specialist service to a greater extent than was ever the case in this country.

In 53 years there has been little change in the population/doctor ratio in Canada.

Particulars of numbers, age, and province of settlement are given for immigrant doctors between 1951 and 1954.

We are grateful to Dr. Joseph Willard, Director of the Research Division of the Department of National Health and Welfare, Ottawa, for making available to us much of the statistical information and for his suggestions in the writing of this article. Of course, responsibility for the opinions expressed is our own.

ADDENDUM.—To make terms and titles intelligible as regards the Health Service in Great Britain, some licence may be evident in terminology. The Canadian equivalents are: health visitor = public health nurse; local authority = local government; senior registrars = senior interne; general practitioner = physician (usually an all-embracing term in Canada).

pardon a play on words, they indicate the *premises* on which the prescription is written, and are commonly the only section to be legible. The illegible portion includes the list of ingredients with doses, an instruction to the dispenser, an instruction to be passed on to the patient, the name and address of the patient, and, finally, the name of the prescriber. Of the many ingredients which could be introduced into a prescription for health, I have chosen six—wholesome food, sound habits, right environment, creative work, the promotion of active resistances, and daily meditation. Before discussing other sections of the prescription, I will give some consideration to each of the six ingredients. To do so is not only sound therapeutics, it is sound homiletics.

The Ingredients

Wholesome Food

It is clear to science that the human engine requires certain general categories of fuel if it is to function—proteins, fats, and starches, and also vitamins—and that physical and even mental diseases, disorders of nutrition, will arise if these needs are not met. Further, lack of balance in the intake of normal foodstuffs can sometimes promote physical disease. For example, the excess of fatty foods in our civilized dietary

may be a factor in disease of the coronary arteries. Indeed, the food eaten in our towns and cities is probably as unnatural, as unsuited to the physical nature of man, as is the city environment, with its polluted atmosphere, its sunless streets, its hard pavements. Within limits, without being faddy, the healthy man must be selective in what he eats. Of course, all we eat is selected—very few sane adults have been forcibly fed in this country since the days of the suffragettes.

However, if it is important to select the right foods for the body, it is equally important to select the right foods for the mind. Although forced feeding of the body has gone out of fashion since the suffragettes demonstrated which is the dominant sex, forced feeding of the mind has vastly increased. From all sides modern man has his five senses bombarded with information dressed up to stimulate his appetite—press, radio, television, advertisements, novels and journals, cinema. Propaganda has become a fine art, and ideas are forced into one's mind willy-nilly, as by a kind of psychological stomach tube. Some of the ideas are wholesome, many are fatuous and futile, but some are rank poison which demand immediate diagnosis and outright rejection. The first ingredient then is wholesome food.

Sound Habits

A habit is a settled tendency or practice. It achieves its end with an economy of effort to mind or body as the channel of action becomes worn by repetition. It is like a reflex in the field of behaviour, and once initiated may become almost as uncontrollable as a physical reflex. What habits of body and mind should be ingredients in the prescription for health? I will consider three such habits, although you will easily think of others.

1. *Adequate Sleep*.—Rhythm is a feature of nature manifested, for example, as night and day, sleeping and waking, systole and diastole. Most animals need to sleep, and I have even caught a trout napping. Many people suffer from a chronic lack of sleep without knowing it. A consulting physician not infrequently sees patients whose main complaint is persistent lethargy. After a thorough examination has offered no clue to causation, inquiry into the patient's sleep habit may reveal that this item is being squeezed out of his programme. In some cases the net result of a five-guinea examination has been an instruction to go to bed early. Moreover, some have stated subsequently that the consultation was worth the fee.

2. *Regular Exercise*.—Muscles are meant for action, but civilized man is becoming car-bound and exercise has become effort. When muscular inactivity is combined with an unbalanced diet, two common killing disorders may result—obesity and coronary disease. Dr. J. N. Morris and his colleagues, working for the Medical Research Council, made an interesting statistical study of many thousands of the drivers and conductors of double-decker buses of London Transport. In general, their social background was the same, but the drivers suffered more from coronary disease in two respects: the incidence of the disease was higher and the type of disease they developed was more dangerous. Morris suggests that the essential difference is one of physical activity: the conductor spends much of his time struggling around inside his bus, whereas the driver has a sedentary occupation away in front and is grateful for an opportunity to stretch his legs. Morris found a similar situation in Post Office workers; as regards disease of the coronary arteries, the peripatetic postman fared better than the sedentary telephonist. Thus our motor-cars may be shortening our lives insidiously and without threat to the no-claim bonus. Physical exercise should be a regular daily habit. Walking is excellent. I find that skipping 150 times every morning after shaving is useful—you can make all the motions without a rope. Golf, gardening, and walking are valuable if made habitual. Energetic trout fishing seems to have a special appeal for the medical mind, and since Isaac Walton described it as "the contemplative man's recreation" it must likewise be divinely designed for bishops. The

mind, too, needs regular exercise. Mental sclerosis and psychic obesity are as real as their physical counterparts.

3. *Self-discipline*.—As a habit, self-discipline is really important for health. I will mention only one minor aspect—the quantity of food we eat. Many people take about a third more food than they need. Obesity has definite perils, well recognized and financially estimated by insurance companies. Obesity is not always due to lack of self-discipline, but of all the muscular exercises designed for its cure the most effective is performed half-way through each meal, and consists in the placing of both hands firmly against the edge of the table immediately anterior to the waistcoat and imparting a sustained pushing movement. Lack of self-discipline leads a man insidiously into slavery—slavery to food, to alcohol, to tobacco, to sex, even slavery to his job. To be a slave to anything is unhealthy—unwholesome. The healthy man is streamlined both physically and mentally. When he has something really big to live for, self-discipline merges into self-realization.

Right Environment

The medical profession is becoming steadily more aware of the significance of environment for physical and mental health. Diseases associated with certain occupations form a medical specialty. A topical and important example of disease due to environment is the chronic bronchitis of our industrial cities, caused largely by pollution of the atmosphere by smoke from the domestic chimney, from industry, and from transport. Long-continued bronchitis may result in emphysema, heart failure, and death. In 1951 the mortality from chronic bronchitis was 40 times greater in England and Wales than in Denmark, and 20 times higher than in Norway or Sweden. 4,000 people died as a result of the London fog of 1952, and the country was deeply disturbed at the time. But only the *concentration* of that tragedy made a dent in our armour-plated public conscience. All over the country the tragedy continues. Annually thousands die precisely the same death. Fortunately, some of the more thoughtful and energetic local authorities have now realized that in Britain "we must fight for the air we breathe to be made as pure as the water we drink." Those authorities need our encouragement and support.

Creative Work

Every person has creative power, and if his daily work is useless a man becomes subtly frustrated and demands more wages, more leisure, more amusement. Similarly, many women remain discontented because they accept a safe but dull job in an office when they should be using their whole creative personality as a home-maker, or as a nurse, teacher, or social worker. To the prescription for health, a creative job adds both punch and palatability.

Promotion of Active Resistances

The body becomes impervious to some forms of disease because it has developed a resistance thereto by its own effort. Many infectious fevers give this immunity and prevent a second attack. Active resistance can be engendered artificially and safely by inoculation of both child and adult, and thus, in Britain, diphtheria and smallpox have been almost eliminated and we have good hopes for poliomyelitis. Can we do something of the same sort for the *minds* of children? In the clinic, by instilling the appropriate vaccine under their skin, we can protect them against diphtheria, whooping-cough, and smallpox. In the home, by instilling absolute moral values under their skin, we can protect them against slipshod standards of work, against lying and petty theft, against sexuality and homosexuality. The mind can acquire active resistances. Wilfred Trotter, one of our great surgeon-philosophers, pointed out that the mind can react to an alien idea as vigorously as the body can react to a foreign protein. For proof you need only to raise the subject of osteopathy with your doctor.

Daily Meditation

Everyone recognizes that there are diseases of the body and diseases of the mind. Many thoughtful people believe that there are also diseases of the spirit, important in themselves and capable of producing pronounced secondary disorders of body and mind. Spiritual disorders include pride, jealousy, greed, self-pity, resentment, self-indulgence, and chronic fearfulness. As an example of the latter I may tell you of an eminent surgeon who had a patient with a dangerous and painful illness requiring an operation involving serious risk. She showed great courage and endurance, in contrast to her husband, who was a worrying little man, fussy over trifles and consumed by fearfulness. Many times during those difficult weeks he telephoned or visited the surgeon about trivialities. Eventually the patient reached a stage of convalescence. One day, again by special appointment, the husband came to the surgeon and asked, "Mr. Jones, do you think I ought to get a bath-chair?" The harassed surgeon answered crisply, "You can if you like, but I don't think she's strong enough yet to push you around."

The prescription for health, therefore, must include ingredients which deal effectively with these disorders of the spirit, such as wholesome spiritual food, plenty of spiritual exercise, the right spiritual environment, spiritual discipline, a creative job in the spiritual field. There is, however, one ingredient which I believe is fundamental—daily meditation.

Educating the Hypothalamus

I cannot overstate the importance of the habit of quiet meditation for health of body, mind, and spirit. Modern man's life is grossly abnormal. Our days are spent in continuous activity and our senses stimulated incessantly, so that we have neither time nor opportunity for quiet. We search for the Kingdom of Heaven in every quarter except where we are told on excellent authority that it happens to be—within us. We need to meditate daily on great truths. We need to explore our own lives, our motives, our plans, in the clear light God provides as we sit quietly and unhurriedly in His presence.

The daily life of human beings has been described as existing on two planes, horizontal and vertical. On the horizontal plane is the succession of events, mostly trivial, which form our daily routine. The vertical plane is the plane of values. We understand why we are dropped on to the horizontal plane of trivial daily affairs only when we relate the horizontal plane to the vertical, and see our lives against the background of values such as honesty, great-heartedness, love, courage, purity, hope, and faith. In meditation the horizontal plane of routine meets the vertical plane of eternal values. The spiritually healthy man lives close to the line where his horizontal and vertical planes intersect.

Meditation is best undertaken in the morning, immediately after waking, with body and mind refreshed and the day unspoiled. It means going to bed earlier, to exchange that last languid half-hour at night for the first refreshing half-hour next morning. It is the critical act which makes every day significant. It is a time which saves time, for it clarifies what is important. As a daily habit it transforms the way you live, your ambitions, your interests, your methods. It has been practised by seers for centuries, and is powerful to-day in the lives of those who explore its secrets and accept its discipline. It is essential now as never before, for it is potent in the upward struggle of mankind. Apart from extremely busy periods, the average doctor or clergyman should have at least half an hour of such meditation daily; when exceptionally busy he needs longer.

It is imperative that modern man should cultivate this God-directed quietness. It is the only firm foundation for serenity, for the quiet mind. And by a quiet mind I do not mean an inactive mind. Daily meditation is the best means I know for educating the hypothalamus—the primitive part of the brain concerned with emotional reactions. Man's

cerebral cortex—his intellect—is overdeveloped but his "feeling" reactions are atavistic. He is an intellectual giant, delighted with his science, but a spiritual pygmy. I am reminded of a picture in a journal showing two cannibals sitting on the beach of a tropical island. They were watching with anticipation a large iron pot which was steaming appetizingly over the fire, when one cannibal remarked to the other, "Isn't science wonderful: a missionary can have his breakfast in London and be here in time for dinner."

Infectious Health

The modern and enlightened view of health is as wholeness—a sound body, a sane mind, and a victorious spirit. Many doctors, scientifically highly competent, are in this respect uneducated, largely because their own spiritual development has been neglected. In my view the main single factor which leads to "wholeness" is a vital and valid religious experience based on moral standards and refreshed by disciplined daily meditation. By "meditation" I do not mean "dreaming on religious themes." Meditation presupposes a clarification of thought and feeling. In the ultimate, it is the expectant waiting upon God's will of a man whose self-will is broken. It may start with moral standards, pass into contemplation, and end in spiritual adventure and exciting discovery. It is vital and infectious religion, the source of infectious health. If, like infectious disease, infectious health is due to a germ, then meditation is the incubator.

We doctors, with our science and art, are highly privileged in our power over body and mind. But the most health-giving thing one man can do for another is to infect him with a vital Christian experience. Thus the clergy must never underestimate what they can do for individuals and for the nation if they are adventurously true to their vocation. The primary purpose of Jesus Christ was spiritual—to transform human nature. His healing miracles were not fundamental, they were incidental. Some clergymen to-day become absorbed in, almost obsessed by, "faith healing" of the body. They must not forget that at the core of their vocation they already hold the pearl of great price.

The Vehicle

People will say: "Your prescription for health is most unpalatable. It would make me ill. You prescribe going to bed early, although I never got over my boyish liking for staying up. You prescribe at least half an hour of meditation on great truths at a time of day when I always sleep the best. I just cannot swallow it." Now a prescription is usually made up with some substance which unites all the ingredients into a takable whole. It is known as the vehicle. It carries everything along elegantly and harmoniously, and, in a word, "makes it go." There is a vehicle which unites these unpalatable ingredients. It has been variously described as an ideology, the single eye, the pure intention. It is the one big idea which integrates every other idea. To define that big idea, I cannot better the New Testament: To love God with all your heart and soul and mind and strength, and your neighbour as yourself. The pure intention is to obey the Holy Spirit. When you meditate you seek instruction from the Holy Spirit. If you cannot see what I mean, read J. B. Phillips's book *New Testament Christianity* and the new book by Campbell and Howard, *America Needs an Ideology*.

Plain Speaking

To return to the prescription. When the ingredients and the vehicle have been prescribed, there follows an instruction to the dispenser written in Latin—the language of his craft—telling him to make up a mixture or a pill. Next comes the "signature," abbreviated to "sig." The signature is not the name or initial of the doctor, but the instruction to be given to the patient, such as "one tablespoonful to be taken three times a day after meals." It is a recognized part of the dispenser's duty to transmit these instructions to the patient clearly and in plain English.

As members of two great healing professions, the clergy and doctors are dispensers of health to other people. We receive our own instruction in the language of our craft, be it theology or medicine. Do we always transmit our message to people in plain English? The plainest speech comes from *example*—what we are and what we do. Why should people take a doctor's advice on health when he is obviously living in an unhealthy way himself? The *Lancet*, in a leading article on an address by Mr. Harold Dodd, comments: "In their endeavour to make more and more patients fit to be operated on, surgeons have sometimes forgotten their equally important task of keeping themselves fit to operate." Too many doctors are pale, tense, and harassed, and driven by a sense of duty. This driving sense of duty is useful only until it is replaced by a better incentive, for it is a source of strain to the doctor and to all who work with him. A ward sister noticed that whenever she exhibited a very strong sense of duty, her nurses exhibited an equally strong sense of "off-duty."

Further to exemplify our failure to speak plainly: most of us are satisfied that cigarette-smoking predisposes to chronic bronchitis and lung cancer; how can the man in the street take notice of our warnings when he observes that his doctor and his vicar are no less addicts than he is himself?

That is where the more primitive levels of our brain need education—we theorize with our cerebral cortex, but in relation to these ingrained habits we think with our hypothalamus. One man read in a magazine that smoking caused lung cancer, and he was so upset he decided there and then to give up reading. Even our speech is not plain. When we ought to be surgical we are diplomatic. As a doctor I find myself using soothing phrases when I should be probing the wound, smoothing over when I should urge clear decision. And many a man has faced a major physical operation because his doctor has avoided a minor spiritual operation such as an honest examination of the patient's emotional attachments. A distinguished surgeon has written a much appreciated lecture entitled, "Is your gastrectomy really necessary?"

Again, how much of what is customary to the man in the pulpit is gibberish to the man in the pew? I was told of a patient in the chapel of a mental hospital who, after listening for a time to the chaplain, was heard to remark, "There, but for the grace of God, go I." Of course, as in that instance, the fault may be at the receiving end. But, as custodians of spiritual truth, do the clergy transmit their message in plain English? Religious problems, regarded as intellectual, are often rooted in moral compromise. Similarly, intractable health problems, physical and mental, may be due to sustained moral conflict. That is precisely where the parson fails with his intellectual arguments and the doctor with his pills and potions. That is precisely why spiritual diagnosis is almost as important to the doctor as to the priest.

The Prescription as a Charter for Freedom

I have now considered the prescription for health. But what of its purpose? Health is to be judged more by quality of life than by length of days. You may become a "teenager" in your second century and still have missed the whole point of being alive. The prescription is not merely a recipe for longevity, it is a charter for freedom. In its human aspect the vocation of doctor, clergyman, and educationist is to set man free and to offer him the key to life-long liberty. If you will allow me, I wish to quote from a B.M.A. Lecture given before the University of Oxford Medical Society in March, 1956, for what was said there relates with special force to this joint gathering of doctors and clergy.

"The doctor's primary function is to set people free—it is our greatest achievement and a wonderful privilege. What is disease but bondage?—bondage to arthritic joints, to paralysed limbs, to the limitations set by coronary disease or a malignant growth. Similarly psychological disease is bondage—for example, the bondage to severe depression or to a fixed delusion. Now we are able to set people free from certain physical and mental diseases

mainly when we uncover the scientific truth about these disorders. The truth makes men free. But there is another kind of truth which is just as necessary if man is to be free—spiritual truth—the truth which liberates a man from the diseases of the spirit which I have mentioned—pride, fearfulness, self-pity, self-indulgence, resentment. The truth of the intellect (scientific truth) and the truth of the spirit are *both* aspects of the truth which makes men free. . . . There are laws of the spirit just as absolute as the laws of science."

One final point. I have said that to be healthy the individual must have his life united around a great positive idea. I believe that if a nation is to be healthy it must be integrated around a great, positive ideology. Our own nation needs a great theme of life which every home acknowledges and which the world understands. Man is primarily a spiritual being: for wholeness he must have a spiritual ideology with a moral backbone. In a day when almost half the world's population is organized under a ruthless, materialist ideology, for very survival the other half must be united by an ideology which is spiritual, positive, and universally acceptable to all men who are willing to obey God. With that in mind, I offer this prescription for health. It is tentative and needs addition. It is certainly not prescribed with deadly accuracy, indeed it may already have reminded you of the notice in the window of another retail chemist which read, "We dispense with accuracy." But, taken regularly and in adequate dosage, I believe the mixture can cure man's fundamental disease—materialism—first in the individual and then in professions, governments, and nations.

THE DISAPPOINTED
UNDERGRADUATE*

BY

B. W. DAVY, M.D., D.P.H., D.P.M.

Health Service Officer, Cambridge University Health
Service; Honorary Physician, Psychiatric Department,
United Cambridge Hospitals

"This man's work during the past term has been no more than fair but he appears to have found himself, which, after all, is what he came here to do." These words, quoted from a Cambridge tutor's report on one of his pupils, record a stage in one undergraduate's development which clinical experience amongst undergraduates suggests is too commonly not reached.

Some undergraduates prove unable to profit fully from the opportunities a university offers and so fail significantly to develop their academic, cultural, and social potentialities—in other words, to find themselves.

The man (or woman) who has found himself is recognizable as someone who is beginning to see more clearly the nature and extent of his gifts and skills and of his weaknesses and inexperience, and recognizes the opportunities, the responsibilities, and the handicaps which arise from them. He is developing a growing confidence in his judgment and with it the skill and the courage to express an opinion and to defend it. In short he can face the demands and the opportunities of his life unhandicapped by fear. He is laying a sure foundation on which to build and is gaining the insight necessary for realistic planning.

By contrast, to the undergraduate who has not found himself the world is a difficult place. He is for ever misinterpreting the causes of his difficulties, blaming himself, his fellow men, his material circumstances, for his frustrations. His discontent is not the healthy dissatis-

*Based on a paper prepared for the First International Conference on Student Mental Health, Princeton, New Jersey, September, 1956.

faction with an imperfect world which spurs on to effective action, it is the unhealthy brooding over a disappointing, denying world which breeds an aggressive resentment or a dispirited apathy and provides a treacherous foundation upon which, by unrealistic planning, he is likely to build unwisely. Disappointment with the results serves only to confirm the fears and the resentments. This is the disappointed undergraduate, the subject of this paper. He falls into no single diagnostic category. He may have a character disorder, a neurosis, or, rarely, a psychosis. In the more severely ill the disappointment is but one of a number of overt symptoms. It is with those not overtly ill, the milder neuroses and character disorders, that this paper is particularly concerned.

Outwardly there may seem to be nothing amiss. The academic record is often satisfactory, sometimes outstanding. The social performance is, superficially at least, adequate. Tutors' reports, though sometimes severely critical, occasionally guarded, or perhaps a little puzzled, may be complimentary, even enthusiastic. But beneath the surface there gnaws a discontent which must not be underestimated. For many the university course is their first experience of adult life and it has disappointed them and defeated their efforts to adjust to it: confirming not correcting false attitudes, strengthening not dispelling prejudices, inflaming not soothing resentments, quenching earlier enthusiasms.

Because some of them present no overt or commonly appreciated academic, social, or medical problems these people are in danger of going unrecognized, by teacher and doctor alike, as in need of help. The undergraduate himself may be the one who is least aware of the nature of his need. He has usually achieved some measure of adaptation to his difficulties, maintaining an uneasy equilibrium between his ambitions and emotional needs on the one hand and what he interprets as the inadequacies of himself and his environment on the other.

Clinical experience of these people when they do reach treatment suggests that, although some of them present tough therapeutic problems, others can be relatively easily freed from their misconceptions and their resentments, so that they find and enjoy their place in university life, and profit from it in a way hidden from them before. Non-medical university staff have at least as large a part to play in this as doctors.

Two common examples serve as illustrations. The first is the man or woman who has always been a big fish in the home pool and who believes that his parents, his school, and his tutor expect him to maintain this supremacy over others when he plunges into the university sea. He becomes very anxious, depressed, and desperate when the difficulty—usually the impossibility—of doing this becomes clear. The second is the man who has been too intensively taught at school so that he has never recognized how dependent he is on the critical, selective abilities of his teachers and upon their constant guidance, correction, and encouragement, so that the independence thrust upon him by the university paralyses him. Taken early by tutor or doctor, these attitudes can be influenced by explanation and reassurance, but the longer they persist and the more often they are aggravated by apparent confirmations of shortcomings and failures the more firmly established they become.

In consequence it is essential to ask in any university how commonly undergraduates are failing to find themselves and yet are passing unnoticed as in need of help.

The Problem in Cambridge

An attempt to answer this question was made in the Cambridge University Health Service. In Cambridge there is no routine psychological appraisal of students. At the routine physical examination, offered to all undergraduates in their first year, the examining doctor records his impressions of each undergraduate's psychological state, so far as he is able to judge it during the course of a short interview. But this record is insufficient for the assessment of the prevalence of the disappointed undergraduate, not least because it is made during his first year and no routine examination is made after that year.

During the course of an investigation,† still in progress, into the life and work of about 500 undergraduates—the freshman intake of five men's colleges who joined the University in 1952 and graduated in 1955—it had been noticed how clearly the unhappiness and discontent of some of them was revealed in the answers they gave in questionnaires they had been asked to complete. These questionnaires therefore seemed a promising field for investigation.

The men had been asked to complete two long questionnaires, one in their first, the second in their eighth—that is, their penultimate—term, to attend for routine physical examination, and to take an intelligence test. Additional information about each man was available in the form of examination results for each of his three years and tutors' progress reports given twice during that time.

It was the second questionnaire, because it was completed towards the end of the man's university career, which was primarily examined for evidence of dissatisfaction and failure to adjust to university life. It had taken a man about an hour to an hour and a half to complete and was designed to discover as much as possible about his two and a half years' experience of Cambridge life and work and his reactions to them. Questions, of which there were a hundred or so, were both closed and open-ended, and covered a man's work and his reactions to his work and to university teaching methods; his future hopes and plans; his academic, social, athletic, and personal successes and failures; his health and personal habits; and his personal reactions and relationships. With a few exceptions the questionnaires appear to have been completed conscientiously and with interest, and examination reveals considerable internal consistency within questionnaires. They were therefore considered a reasonably reliable source of information about attitudes and reactions to Cambridge life and work.

Of those invited to complete and return the second questionnaire, 92% did so. They were all within a few months of taking their final examination and so already had behind them a fair record of having achieved something at least of what they had joined the University to do. The overt failures had already been eliminated during their first two years. About 4% went down before completing their three years either on account of academic failure or for family or other personal reasons or, rarely, for disciplinary reasons. There are relatively few overt failures, because, unlike many universities, in which the majority of applicants are accepted and those who prove unsuitable for a university career are eliminated during the first year, Cambridge colleges are able to accept only a fraction (perhaps one in twenty) of those who apply for admission. Competition is therefore fierce and selection methods are important.

Incidence of Expressed Disappointment

For the purpose of this paper an unselected sample of 200 of the 400 questionnaires returned was examined.

The question which was first analysed asked: "In what way has your time at Cambridge disappointed or failed you?" For the purposes of this investigation this was regarded as an invitation to the man to criticize Cambridge or complain about it and so, no matter what his reply, if a

†Assisted by grants from the Pimsent Darwin Fund, Cambridge, and from the Medical Research Council.

man accepted this invitation he was arbitrarily included in the "disappointed" group (called group D). This arbitrary allocation is open to criticism, but the impossibility of assessing what a man really meant by answers such as "I don't think, on the whole, that it has" or "It hasn't—so far" made necessary an arbitrary method of differentiating group D from the "satisfied" group (called group S). Only those who answered by a direct negative or by a line drawn through the answer space were included in group S.

With these criteria, 108 men fell into group D and 92 into group S. It is not of course suggested that all or even many of the 108 men in group D were emotionally disturbed. Although the bitterness expressed in some of the answers left little doubt that all was not well with the writers, in the majority of cases the significance of the answers, examined alone, could not be assessed.

Only a small proportion of group D gave vague answers of the kind "It hasn't—so far." The complaints of the majority fell into a few well-defined categories. For example, nearly half the "disappointed" men said that they were disappointed with their fellow undergraduates. They complained that they are uncultured, their conversation boring, their interests limited and unintellectual; or that they are uncouth, or, conversely, that they are snobs, poseurs, given to the forming of cliques, out of touch with real life, leading artificial, sheltered lives. (Investigation of individual statements of this kind would almost certainly reveal a number of men with emotional difficulties in personal relationships with contemporaries sufficient to be a severe handicap. These statements are more noteworthy because they are made after more than two years' experience of Cambridge life.)

The next largest group (about 20%) said that they had too little contact with senior members of the University, complaining that they received too little direction and encouragement in their work or that the seniors were socially aloof and insufficiently interested in undergraduates. (Clinically the man who regularly criticizes his teachers is a familiar figure. He misinterprets the intellectual freedom of the university as lack of interest and slackness on the part of his seniors, of whose direction and encouragement he feels constantly in need. The growing pains inseparable from the development of a critical ability of his own and the achievement of independence of mind he interprets as evidence that he is being badly taught and needs a change of teachers, or that he is unsuited to his subject and must change it, or that he was mistaken to aim at a university education and had better admit himself beaten and go home.)

Less commonly expressed disappointments were lack of women, or the difficulty of meeting them in Cambridge (4%) (perhaps with justification, the proportion of men to women in the University is over 10 to 1); failure to develop a firm religious faith whilst in Cambridge (6%); specific complaints about work, teaching methods, and lectures (5%); and general dissatisfaction with an individual college or with the University as a whole (6%) or with themselves (11%).

This very mixed collection of "disappointed" young men, group D, was then compared in various ways with those in group S, on the assumption that, although only a proportion of those in group D were likely to be seriously discontented, and although not all of those in group S could be considered as inevitably contented and emotionally unhandicapped, it was probable that group D would contain more truly discontented men and that in consequence the emotional characteristics of the group as a whole might differ significantly from those of group S as a whole.

Emotional Characteristics of the Two Groups

It was decided first to test whether there was other evidence that the group D men were less contented than group S men, because it could be argued that, in accepting the invitation to complain and criticize, all the undergraduates in group D were doing no more than the young have always done, with or without invitation—that is, criticizing that which is older and more senior.

In one question in the second questionnaire the undergraduate had been offered a list of emotional states, including contentment, depression, self-confidence, maturity, optimism, pessimism, energy, apathy, enthusiasm, tension. He had been asked to indicate whether he felt these "never," "rarely," "occasionally," "frequently," or "constantly."

A previously agreed combination of frequent or constant contentment, optimism, self-confidence, enthusiasm, and other positive emotions combined with rare depression, apathy, etc., was scored as "up" (125), while the reverse constellation of emotions was scored as "down" (42). In between was an indeterminate group (33). Men were sorted into these three groups by the application to their answers of the previously agreed criteria of "up," "down," and "intermediate," and without knowledge of how they had answered the question inviting them to criticize their time at Cambridge (Table I). The distribution of "up" and

TABLE I

	"Down"		Intermediate		"Up"		Totals	
	No.	%	No.	%	No.	%	No.	%
"Disappointed" men	32	29	19	18	57	53	108	100
"Satisfied" men	10	11	14	15	68	74	92	100
Totals	42	20	33	16.5	125	63.5	200	100

Significant: χ^2 (2 degrees of freedom) = 15.129; 0.001 > P.

"down" men in group D and group S was examined: 11% of group S as against 29% of group D were "down," and 74% of group S and only 53% of group D were "up."

A further question related to anxiety. The undergraduate had been asked to indicate how often he felt anxious about a number of named topics, including trifles, his work, his health, his relations with others, his work and future, what others thought of him, and so on. Once again he had been offered a choice of "never," "rarely," "occasionally," "frequently," and "constantly." A man who said that he was constantly worried about one or more topics or was frequently worried about trifles or about any three or more

TABLE II

	Anxious		Not Anxious		Totals	
	No.	%	No.	%	No.	%
"Disappointed" men	59	55	49	45	108	100
"Satisfied" men	27	29	65	71	92	100
Totals	86	42	114	58	200	100

Significant: χ^2 (1 degree of freedom) = 11.945; 0.001 > P.

items was classed as anxious (Table II). Group S contained 29% of anxious men, group D 55%.

When these two questions are taken together and group D and group S examined for men who are both "down" and "anxious" the difference between the two groups is more striking. In group S 6 out of 92 (7%) were "down" and "anxious" compared with 25 out of 108 (23%) in group D.

The Disappointed Undergraduate's Recognition of his Need

Because it could be argued that it is the privilege of healthy youth not only to complain and to criticize but also at times to affect unusual and even uncomfortable poses and emotions it was decided to examine the questionnaire for evidence of emotional stress.

The question chosen for this purpose asked: "Have you ever sought the advice of an older, more experienced person outside your family (e.g., doctor, clergyman, schoolmaster, college tutor) about any nervous or other psychological problem?" The answers offered the man were "no," or "no, but I would have liked to have done," or "yes." It seemed not unreasonable to assume that a significant difference between group D and group S in their replies to this

question would suggest that the prevalence of "down-ness" and anxiety in group D was, to some extent at least, real and felt by the undergraduate.

Of the 200 men, 143 answered "no," they had never sought advice of this kind; 34 answered "yes" (29 had sought advice during their time at Cambridge, 5 at an earlier date); and 16 answered that they had not sought advice but would have liked to have done (14 at Cambridge, 2 earlier). Seven men left the answer blank and have been included with the 143 who answered "no." This was done on the grounds that although they may include some who did in fact seek or want help, this cannot be assumed and all must be scored as negative answers (Table III).

TABLE III

		"Dis-satisfied" Men		"Satisfied" Men		Totals	
		No.	%	No.	%	No.	%
"Yes"	Before Cambridge	2	2	3	3	5	2.5
	At Cambridge	20	18	9	10	29	14.5
"No, but would have liked to have done"	Before Cambridge	2	2	—	—	2	1.0
	At Cambridge	11	10	3	3	14	7.0
Total of those who felt a need to seek advice		35	32	15	16	50	25
"No"	Question not answered	68	63	75	82	143	71.5
		5	5	2	2	7	3.5
Total of those who gave no indication of feeling a need to seek advice		73	68	77	84	150	75
Totals		108	100	92	100	200	100

Significant: χ^2 (1 degree of freedom) = 6.039; 0.05 > P > 0.01.

In group S 77 (84%) had not sought advice, 12 (13%) had sought advice, and 3 (3%) would have liked to have done so. In group D 73 (68%) had not sought advice, 22 (20%) had sought advice, and 13 (12%) would have liked to have done so.

If the answers of those in group D who are also "down" and "anxious" are compared with those in group S who are also "up" and "not anxious" the differences are again even more marked: 25 were "disappointed," "down," and "anxious" and 52% of them had not sought advice, 24% had sought advice, and 24% would have liked to have done so. The "satisfied," "up," and "not anxious" group contained 51 men and 84% of them had not sought advice, 14% had sought advice, and only 2% (one man) would have liked to have done so.

It is important to know more about the uses made of psychological help and the value derived from it. It is probable that the material available is insufficient to provide more than limited information, but further analysis of it will be made during the course of the main investigation.

Objective Evidence of Disappointment

Other data about the 200 men under investigation, in the form of examination results and tutors' reports, were also examined to see whether or not the disappointed man reveals himself by doing less well in his examinations than his more satisfied colleague or by attracting the adverse comments of his tutors. The figures do not support this, although there are some differences between the two groups. Tutors appear more likely to be very enthusiastic or very critical of the group D man than they do of the group S man about whom they more commonly make an average report. There was some evidence that in examinations the man in group D more commonly exceeds expectations, arbitrarily assessed, than does the man in group S.

Both the tutors' reports and the examination results are in keeping with clinical impressions that, although some disappointed men try the patience of their tutors and do badly in examinations, others, not uncommonly as compensation for emotional difficulties, may put all their energies into

work and obtain a better mark in examinations than a more balanced work programme would have earned for them.

There is, however, no evidence that more than a few disappointed men reveal their disappointment easily. In some cases there was a marked discrepancy between the tutor's assessment of a man and the man's view of himself and his situation.

Estimated Incidence of Disappointment

The clinical concept of the disappointed undergraduate is therefore given some support by the answers to a general questionnaire. There is also some broad indication of the frequency of emotional maladjustment, because if it can be assumed that the men who are both "down" and "anxious" have some degree of emotional maladjustment (and in fact about half of them have either sought psychological advice or would have liked to have done) then 31 out of the 200 fulfil these criteria. This may not be considered altogether unlikely when it is appreciated that these men say of themselves that, in addition to being frequently or constantly anxious, they uncommonly feel content, self-confident, mature, optimistic, energetic, or enthusiastic and, on the contrary, commonly feel depressed, pessimistic, apathetic, apprehensive, tense, and under a strain. Of these 31 men, 25 give some indications of the ways in which they felt Cambridge University life had disappointed or failed them.

This gives a figure of 12-15% of these 200 men likely to have emotional problems needing help and, as we have seen, half of them give some indication of perhaps being aware of this, although half of these did not seek the advice of which they felt in need. (The numbers seeking or needing psychological help is large by conventional British standards. In the total sample of 200 men, 29 said that they had sought advice while at Cambridge and 14 that they would have liked to have done so, a total of 43 (21.5%). In Britain this figure might be considered unexpectedly high for an ancient university. Some still hold to the belief that emotional problems are uncommon and should in any case be dealt with by the individual unaided save in exceptional cases.) It is perhaps not without significance that of the "disappointed" men who felt in need of psychological advice nearly 40% of them did not seek it (13 out of 35). The comparable figure for the "satisfied" men is only 20% (3 out of 15). The "disappointed" man is perhaps more likely to feel that no one is able, or will want, to help him.

Possible Correlates of Disappointment

It was tempting to search what seemed to be promising data for aetiological clues, but the temptation had to be resisted for the time being as irrelevant to the purposes of this paper. Some points noted, however, may be mentioned; some were half expected, others surprising. Those who described their parents as suffering with "nerves" were a little more likely to be found in group D, as were those who expressed dissatisfaction with their school or national service life. Those in group D were more likely to have experienced a change in their religious life while undergraduates, either strengthening or weakening their faith, compared with those in group S, who changed less commonly. There was no difference between the two groups in the proportions of those who attended day-school or boarding-school, although there was a suggestion that those who had attended the smaller and less-well-known public and State schools were more commonly to be found in group D. Rather surprisingly there was no difference between those who had already done their national service and those, two years younger, who had come to the University straight from school. Equally surprising was the similar distribution between the two groups of those who gained their place in the University as the result of a written scholarship examination and those who were admitted after interview. These various points are provoking and invite further investigation.

Conclusion

The disappointed undergraduate is, of all the emotionally handicapped, the most likely to go unrecognized and unhelped. Efforts to draw attention to him and to make him aware of the nature of his difficulties and of how he may be helped to deal with them are apt to be criticized by some university teachers and even by some doctors as improper interferences in the affairs of healthy men, calculated only to create difficulties where none existed, to encourage the morbidly introspective, and to attract the overdependent. Yet to some tutors, chaplains, hostel wardens, and doctors the disappointed undergraduate is a familiar figure to whom they have long been accustomed to give effective explanation and encouragement. But some men and women undergraduates never receive the help they need and leave the university with unsolved emotional problems which could have been resolved and which are apt to be a source of unhappiness to themselves and their families and of friction in their professional and social contacts.

In consequence the early recognition of the disappointed undergraduate and the provision of appropriate help is one of the important problems of student mental health.

Primarily the need is for a wider acceptance that some undergraduates, though not overtly ill, need psychological help which they should not feel ashamed to seek; that the availability of the various sources of skilled help should be known to undergraduates; and, most important of all, that tutors, chaplains, wardens, doctors and others should know each other and co-operate with each other. In this way men and women in need are most likely to make contact with the source of skilled help appropriate to their problem.

I am indebted to the governing bodies of the five Cambridge colleges (which must remain nameless) who allowed me to ask their freshmen to take part in the investigation and to the men who subsequently volunteered; to Mrs. Marjorie Sisson, M.R.C. research assistant, for much laborious work and many valuable suggestions and criticisms; to Mr. R. G. Carpenter, statistician to the Cambridge University Medical School, for assistance with the statistics; and to Sir Alan Rook, Senior Health Service Officer, Cambridge University Health Service, for his advice and encouragement.

TREATMENT OF PRE-EXAMINATION STRAIN

BY

NICOLAS MALLESON, M.D., M.R.C.P.

Physician-in-charge, Student Health Association, University College, London

Every year the physician at a university health centre will be called upon to treat a substantial number of students suffering from nervous strain in the period before and during major examinations. Both in their clinical features and in the principles underlying their management, these cases have enough in common to warrant description as a "syndrome." And description here may be of some value, not for university physicians who know all about it already, but for the ordinary practitioner who, if he is on the look-out for cases, may find one or two a year among the young people on his panel. Knowing how to go about it, one can give quite a lot of help not only in lessening symptoms, but, *pari passu*, in improving efficiency and the prospects of passing the examination.

As important examinations draw near almost every-one experiences a certain amount of tension and apprehension; that is only natural, and is probably a valuable spur to increased study. Pre-examination strain can be defined as the condition wherein the nervous tension is of such a quality that it diminishes the efficiency of study and impairs the prospects of success. The severity can vary from a modest insomnia with daytime tiredness to extreme paralyzing alarm.

Incidence.—It is in the nature of the condition that no accurate estimate of its incidence is possible; the number of subjects seeking medical aid must be a product not only of the numbers at risk but also of the availability—or rather the approachability—of that aid. At University College Student Health Centre we have tried assiduously to nourish a reputation for being approachable. As a result some 10% of students facing their major examinations (finals, B.A., and B.Sc., second M.B., librarianship diplomas, etc.) come to us with strain symptoms. For lesser examinations (intermediates, part I, crucial sessionals, etc.) the figure is less, perhaps 3%. In British universities and technical colleges there are some 170,000 full-time students, and nearly half a million doing degree or diploma-type courses part-time. Even if one excludes schoolchildren (whom I presume can suffer much the same at the G.C.E.), the number of cases going largely unhelped at present must be very great; this cannot be an uncommon condition.

Clinical Features

Presentation

There are three principal ways in which cases usually present themselves. (1) The largest group (the most easily recognized group, perhaps 50%) come with the classic symptoms of overt anxiety which they themselves clearly associate with the impending examinations. There is sleeplessness, persistent daytime apprehension, with thoughts continually turning pessimistically to the examinations, difficulty in retaining and recalling recently learned material, and in consequence a growing sense of desperation and hopelessness. (2) The next most common presentation, perhaps 30%, is of an increasing torpor frequently associated with nocturnal insomnia, though often with dropping to sleep over the textbooks during the day. Here the student may not at first recognize that his symptoms are causally related to the impending examinations. He comes for medical help, often directly requesting a stimulant; his torpor "happens" to have come at an awkward time. (3) The third group, perhaps 20%, present with a physical symptom; usually it is something clearly psychosomatic like vertical headache or nervous dyspepsia.

The Leading Symptom: Fear

The main subjective symptoms are usually those of anxiety, familiar to all practitioners. Insomnia, tension, obsessional thinking, tearfulness, bouts of depression, somatic conversion symptoms, and particularly headache are the principal complaints. But anxiety as normally met with in general practice is something diffuse, related to personal inner problems. Here there is a quite specific fear related directly to the approaching examination.

The fear felt by the student is two-handed. There is a fear of failure, and there is a fear of the examination itself. Usually they go hand in hand, but sometimes they are quite distinct. Students who know they have first-rate ability can be troubled almost as severely as poor students with only an outside chance; they fear the examination, not its outcome. It is perhaps true that the worst cases are usually among the weaker students, but exceptions are very numerous.

The Secondary Symptom: Study Difficulty

The soldier suffering from fear before an impending attack, or the airman facing his first flight after a crash, can, if he is tough enough, screw his courage to the sticking point and get through the dreaded incident. The student's problem is more complicated. To pass his examination he must be moderately calm at the time, and he must do a certain amount of consistent study and revision in the weeks preceding. But in fact it is almost impossible to study effectively when in the grip of a pervading anxiety. As soon as a person sits down with his books and clears his mind to receive intellectual matter, it is flooded with obsessional fears of the coming examination or its outcome. These can be pushed aside, but only with persistent effort. As he begins reading, the effort imperceptibly relaxes, and in a few minutes the fears have crowded back, displacing intelligent concentration once again.

Extreme study difficulty can amount to nothing short of panic. The student tries to study but cannot hold off his fear. He begins to feel desperate, not only because of the examination but because he feels his mind is failing him. He tries to remember what he read before lunch; he cannot recall it. He reproaches himself for stupidity. His head is hammering, so he decides to have a rest. But he can think only of the examination. This spiral of fear leading to study difficulty can get a normally steady and unneurotic chap into a really parlous condition.

Such study panic is the extreme. In most cases the vicious circle, though constantly present, does not get so utterly out of hand. The holding back of fear consumes mental energy—not enough completely to prohibit study, but enough to tire the student and to diminish his efficiency. Three or four hours' work produces a lesser result than he expects. He then counters this by trying to do longer hours. In consequence he gets increasingly tired as well as increasingly anxious. It is the student's innate capacity to hold back anxiety that determines the type of principal presentation, whether overt anxiety or daytime torpor.

There is a less common but interesting form of study difficulty, sometimes to be found among those who present with psychosomatic symptoms and little insight. It is to be compared with the classic *belle indifférence* of hysteria. The student, when asked about his impending examination, says he is certain that it cannot be responsible for his symptoms, for he isn't at all worried about examinations—quite the reverse. Indeed, he wishes he could get a little more worried, as he really can't bring himself to get down to any revision.

Lack of Insight

A few of the cases in which torpor preponderates over frank anxiety, and a good many of the cases with psychosomatic symptoms, have no insight into the nature of their trouble. The majority of students, even those with physical symptoms, are very ready to accept that worry about the examinations is the cause of their trouble; indeed, they have usually thought so themselves and the doctor's opinion comes only as confirmation. But there is this small group who not only do not know it for themselves, but steadfastly refuse to accept it: they may listen to one's advice, they may even take one's medicines, but clear on their faces is written stark disbelief. The condition here is really a sort of conversion hysteria. The secondary gain is a sort of insurance; failure, if it should come to that, can be blamed on the illness. Illness, after all, can save his self-respect, and a doctor's certificate can save his place in the university. Small wonder if a hard-pressed student half welcomes the onset of his headache or dyspepsia.

Examination Panic

Every university teacher has known the able, even brilliant, student, who, out of the blue, panics and leaves his examinations uncompleted. The form of such an acute panic varies. Sometimes the student is seized by a blinding and incapacitating headache. Sometimes he finds himself suddenly un-

able to think logically or to recall facts—what he calls a "mental black-out." Sometimes he has a vasovagal syncope, and is unable to get over the subsequent sense of giddiness and weakness. Sometimes he just feels the paper is hopeless and is overwhelmed by a sense of fear amounting to an intolerable claustrophobia.

A careful history of these cases, in my experience, nearly always reveals that they have suffered from classic pre-examination strain or from *belle indifférence* in the weeks before; examination panic seldom really comes "out of the blue." In reality the examination has only acted as a last straw to a back already bent.

Severe Psychiatric Disturbance and Suicide

Students who seem normally stable and unneurotic can get into a quite distracted condition over examinations. But once the examination is over, even if it has resulted in failure, they quickly regain their usual composure. The only serious psychiatric emergencies I have encountered in students over examinations have always arisen in people known to be mentally unstable anyway, the examination merely triggering off a crisis which has for some while been brewing. In judging how seriously one should regard a student's symptoms, in particular whether one should intervene by forbidding the examination, or by arranging admission to a mental hospital, one should weight the past history and personality more heavily than the current picture. And by and large one need not be too apprehensive. Certainly one does read newspaper reports of students who have committed suicide because of their examinations. But examinations are common things, and so is suicide. In seven years at University College (student population 3,400) I know of four suicides, only one of which was associated with an examination, and that in a student known to be deeply disturbed for several years previously and who had certainly been a suicide risk on more than one occasion before. I have written to a number of my colleagues at other universities, and find that they have had very much the same experience.

In general, I think it is safe to regard pre-examination strain as a circumscribed condition of minor medical, though of major social, importance, and one that can be safely and often most fruitfully handled by the ordinary practitioner.

The "Pathology"

I have seen many students, wont to attend college every day in a sports jacket and jersey, troop in for their written papers brushed sleek and squeezed uncomfortably into stiff collars. This is apocryphal. People so easily fear examinations because they feel that not only their technical knowledge is a bar of judgment but their lives and characters too. As I see it, the whole process whereby the newborn infant is progressively trained into a socially acceptable adult is one of judgment: "good boy; bad boy." Judgment is necessarily deep in the personal experience of all of us from the cradle onwards; it is therefore deep in our culture too: "Judge not lest ye be judged." There can be but few people who never have those anxious day-dreams about being on trial, protesting innocence and proving alibis. The examination, as a student meets it, comes as the quintessence of all judgment situations. It is because of this, I believe, that the fear of examinations so easily becomes disproportionate to their reality importance. This is the psychopathology of the condition.

Management

The treatment of these cases of pre-examination strain is in some respects in contrast to the usual psychotherapeutic handling of anxiety in general practice. There the essential is to get the patient to verbalize his anxiety in order that he can see his way to managing his own problems with as little direct intervention from the doctor as possible. The patient's crisis is usually a subjective one, and if he can be brought to see it as such the problem partly dissolves. But with these cases the problem is a real one. The examination is really coming, usually within a week or two. "Characterological"

insight, even if there were time to achieve it, is not of much help. The doctor must stride in boldly, pull the floundering student back on to a steady path, and stay beside him with unbounded confidence, so that he does not get lost again. The examination crisis is so short-lived, and so curiously unique in life's stresses, that here a frankly surrogative approach is necessary in a way that it can seldom be in other psychiatric upheavals.

The cornerstone of treatment then is to give confidence. But, unlike most incidents in which the doctor is involved, the patient does not seek the confidence that his health is being preserved and protected. He wants confidence that his mental efficiency is being boosted to the uttermost so that he has the greatest possible chance of passing the examination. He is only too ready to put his health in second place temporarily. Right from the beginning the doctor must acknowledge that he recognized this and say that efficiency is his aim too. If he fails to do that the student will always half distrust his advice as ulterior; "health," he will feel, is his doctor's realm—even his fad.

Contact with the Student

To give confidence it is essential to maintain contact with the student right up to and over his examination period. It is only by a close and repeated contact that the student can come to feel that the doctor is standing with him. It is best to make firm appointments each time. Once a week is usual, but they may be needed more often as the examination draws near. Though often the consultation need only be very short, looking after these cases certainly takes time. It is worth remembering that an avoidable failure, meaning another full year's university attendance, costs somebody—the student's father or the taxpayer—the best part of £400, let alone the disappointment and distress of the student himself.

Drugs

Drugs are seldom, if ever, the most important part of treatment. But, used sensibly—that is, in modest doses—they can be of great help. To be able to give an indication of how often medication is necessary I have turned back the records of the 68 cases treated at the unit here in the last year: 37 (54%) were given hypnotics—usually quinalbarbitone, $\frac{1}{2}$ or $1\frac{1}{2}$ gr. (50 or 100 mg.); 28 (40%) were given basal sedation—usually amylobarbitone, $\frac{1}{2}$ or $\frac{3}{4}$ gr. (25 or 50 mg.) three times a day (15 were having hypnotics); and 18 (26%) were given stimulants—usually caffeine, 5 gr. (320 mg.), sometimes one or two "drinamyl" tablets; 9 (13%) had no drugs given them at any time. These crude figures are a little misleading in that in many cases the drugs were added late in the series of consultations. On occasion, administration of two methylpentynol capsules ("oblivon") half an hour before the examination, particularly before vivas, is helpful.

I personally see no objection, clinical or ethical, sometimes to giving students drugs before examinations. No amount of pills will make a student more intelligent or more knowledgeable than he is. All one can possibly hope to do is in some measure to counteract any undue nervousness or psychogenic torpor from which he is unlucky enough to suffer. There are certain practical difficulties, however, and they must be borne in mind. First, there is no evidence that any drug improves high-grade intellectual performance; there is plenty to suggest that most preparations can, at times, impoverish it. In prescribing, one must cautiously balance the possible gain through reduced nervousness with the possible loss due to intellectual blunting. Second, anxious students are unreliable; unless the idea of a carefully chosen optimum dosage is explained they are very apt to double the dose simply because all doctors are known to be pernickety. Third, as pharmacological tolerance develops and tension and insomnia heighten as examinations draw nearer, dosage has often to be increased. One must therefore start with the smallest possible dose, so as to allow elbow-room. Lastly, and most important, no drug should be given for the first time on the night before or on the day

of an examination, for failure then will certainly be blamed on an untoward effect of the doctor's pills.

Managing the Consultations

The detailed form of one's therapeutic interviews, their time, the medicines given, what problems one discusses, cannot of course be preordained; they must vary with the patient and with the doctor. Here I wish only to suggest a sort of general pattern that can be varied as occasion dictates.

As with all psychiatric cases, it is essential that the first interview be a fairly long one, and the student be given time to speak out his major worries. An ordinary "surgery" consultation is seldom adequate; it is best to give a special appointment. The student should be asked about his academic career, and about his studying difficulties, and about the examination itself, and the sort of consequences of possible failure. He should be given the opportunity of cataloguing somatic symptoms if he has any, and then a modest physical examination to allay fears of real illness should be undertaken. In so far as symptoms are not organic, their psychogenic nature should be clearly and categorically, but sympathetically, stated.

In the first interview I like usually to explain that pre-examination strain symptoms are common, and say confidently that their treatment is straightforward. I explain that I shall keep in close and regular contact with the student and shall guide him as necessary to get the very greatest amount of effective revision done and to keep him clear and fresh for the examination itself. Often I explain the psychopathology of the common anxiety about "judgment" in much the same terms as I have described it above. Many students, particularly the more intelligent and insightful, feel helped if they have some explanation of why they are feeling so disproportionately nervous. I try also to describe the sort of floundering and anxiety that strained students feel when trying to study. It helps the student and gives him confidence in you if he recognizes the symptoms described as his own—no one likes feeling exceptional in his troubles.

The most important part of treatment is to give guidance about working hours and technique. If the first interview has already gone on some while the student may not be able to absorb it, and another appointment in two or three days' time is necessary.

To help in regulating his study one should inquire carefully about how much work the student is attempting daily, asking for his average daily programme in some detail. In nearly every case the student is attempting more than six hours a day—often much more. The fact that he is in difficulties with his study can then be taken, *ipso facto*, that this is too much for him in his present circumstances. Indeed, though the evidence about normal learning is scanty, I doubt whether the ordinary person can effectively swot for more than five or six hours a day; certainly most *anxious* students cannot. The usual problem in regulation, therefore, is to urge a reduction in the hours of work attempted. (For the case with *belle indifférence* the opposite is true, and a firm programme, beginning small and steadily increasing daily, is necessary; but these cases are not common.)

The anxious student will never really consent to reducing his work unless given convincing reasons in terms he can understand: this is the sort of thing I say, and as I do so I draw this little graph:

"There is a lot of misconception about this studying business. Most students have not really been taught the principles behind really effective working. This is a graph showing the amount a person learns against the number of hours he works in a day.

If he doesn't do any work, he learns nothing [I put a mark at 0]. If he does an hour's work he learns say that much [I put a mark at 1]. If he does two hours' work he learns about twice as much [I put a mark at 2]. If he does more work he'll learn still more [I put a mark at 3]. Now, if he tries to do 23½ hours' work in the 24, he'll be so exhausted that he'll hardly remember anything: what he learns will be somewhere there [I put a mark at 4]. If he did less work he'd learn more [I put a mark at 5]. Now, whatever the exact shape of this curve, it must be something like this—it must have a crest [I draw in the curve]. This point X [I mark it] is the very maximum anyone can learn in the day [I draw the horizontal line to M]. And this represents the optimum, the best, amount of work to do [I draw the vertical line to O]. The point X is the best possible compromise between adequate time at the books and fatigue. Fatigue is an absolutely real thing; one can't escape it or try to ignore it. If you try to, if you press yourself willy-nilly to work past the optimum (and any fool can prop his eyelids up and do 14 hours a day), you can only get on this downward slope and achieve less than the best—and then get exhausted and headachy and lose your power of concentration. That is what all these symptoms of yours are—just the perfectly natural consequences of passing the crest and being on the downward curve.

"The skill in being a student consists in getting one's daily study as near the optimum point as possible. I cannot tell you, *ex cathedra*, what the optimum is. It differs with the type of work, it differs from person to person, and even in the same person it varies from week to week. You must try to find your own. Every day you study, bear this principle of the optimum in mind. When you feel yourself getting fatigued, if you find yourself repeatedly reading over the same paragraph and not taking it in, that's a pretty good sign you've reached the crest for the day and should stop.

"Most ordinary students find their optimum at about five hours a day. Yours may be a little more or a little less—but if you get five hours' good consistent work in every day, you will be doing well."

Regarding this last paragraph one must stretch a point. A really obsessional hard worker, one perhaps aiming at 12 hours a day, may simply be unable to accept the suggestion of five or six hours; he will think one is potty and ignore all advice. I will then sometimes say "eight or nine," and be content with achieving at any rate some reduction—one has to feel one's way.

Having at the first or second interview fully explained the principle of the optimum, one should give another appointment not more than a week hence. Nearly always one will find there is quite substantial improvement. One should have the student describe his new work routine and should discuss it sympathetically, using the opportunity again to impress the optimum principle upon him. At all subsequent interviews one should spend a few minutes in just this way—confirming that the study routine is kept within his *de facto* capacity.

In this highly surrogate relationship the student is helped if one gives, each time, certain other measures of assimilable advice. I have several little "lessons" which, much compressed, run like this (the order in which one calls on them, if at all, must vary with the circumstances):

1. "Now, what are you doing with yourself when you aren't working?" (He tells me: it is usually nothing at all except to sit in a chair and worry.) "Here is another misconception. People too easily think of the mind as if it worked like the body; it does not. If one wanted to conserve physical energy to cut the maximum amount of firewood, one would lie flat on a bed and rest when one wasn't chopping. But the mind cannot rest. Even in sleep you dream, even if you forget your dreams. The mind is always turning. It gets its relaxation only by variety. That is what makes mental rest. When you've finished your optimum hourage you must stop, cleanly and briskly. You must not then sit around in the chair thinking about the work—that only tires without any learning. You must get out and do something. I don't mind what—whether it's playing squash, taking out the girl friend, or reading Peter Cheyney—anything so long as you are actively doing something else but work. The college is full of chaps who come up for their final term and decide to cut everything but work out of their lives. Before halfway through they are so flat and stale that their concentration has fallen to a fraction and they are downright depressed. So keep up normal activities outside working hours."

2. "About revision. The mind is like a storeroom—its efficiency depends not only on what is in it but on how well catalogued and accessible it is. In revising when the examination is near you must *never* try to learn new material. You cannot assimilate it—it lies on the top, and you'll drag it into your answers, even if it is quite irrelevant. In storeroom terms, you can't get it neatly packed in the racks; it lies in the passage-ways and keeps tripping you up as you hurry down. In revision you must go over only the stuff you know: not the stuff you are really bad at. There are bound to be some parts of the syllabus you don't know; leave them be, it is too late to bother with them now. Revision should tidy up the loose ends. It is to get the stuff you do know really polished up and accessible."

3. "You've got to accept some gaps in your knowledge. Trying to know absolutely everything in the syllabus can be a student's downfall. The best you can do is to be like everybody else. And that means that you know your way around about two-thirds, and are quite at sea in a third. When you open your examination papers you find three questions you can do, one that isn't quite as bad as it first looked, and one that is hopeless. It is the same for all the others as for you. The truth is there is always a bit of luck in examinations: if the questions fall out the other way you may be stumped; but you've got to take that risk. You only work yourself into a state if you try to cover all the gaps."

4. "How much work should one do on the day and night before the examination? Ideally, none at all. You pass the examination on what you already know, and on your mental freshness and composure when you go in. Heavy study on the day before can add very little to your knowledge; and if you go in jaded and tired in consequence you've made a very bad swap. Nevertheless, the pressure on the day before is sometimes so tense that really a couple of hours' work is soothing to the nerves and restful to the conscience. If so, do a couple of hours—but not more, and not in the late evening. Broadly speaking, the essential thing is to plan a nice full day, with company, well in advance; particularly go to a movie or something specific like that in the evening."

Such little talks, lacing one's clinical contacts, the study regulations one gives, and the modest medication, very seldom fail to be helpful; often they are crucially helpful. Any measured assessment of one's efficacy is difficult. All one can say is that the students we treat for pre-examination strain at the Student Health Centre have a pass rate very much the same as the college average: and, seeing they are the ones who come in trouble, the work seems to us well worth the effort we put in.

I should like to acknowledge my indebtedness to Dr. Arnold Linken, assistant physician to the Student Health Association. Not only has he carried the burden of much of the clinical work upon which this article is based, but by regular discussion and case conferences he has been jointly responsible for the clarification of our ideas on this condition.

A new British Standard "Cupboards (Wall-fixing) for Poisons and Dangerous Drugs" has been prepared at the request of the Hospital Equipment Standards Advisory Committee to provide a cupboard of approved design and layout for the storage of poisons and dangerous drugs. In accordance with the Dangerous Drugs Regulations, 1953, each cupboard has an inner independently locked compartment for dangerous drugs, opened by a second key; to minimize the risk of errors in the administration of drugs this compartment is placed at the lower left-hand corner, whatever the size or shape of the cupboard. The cupboard lights up automatically when the door is opened, and a red warning light shows until both inner and outer doors are closed and locked. Materials, dimensions, construction, and finish are specified for both metal and wooden (block-board) cupboards, and plans and elevations illustrated for both narrow and wide cupboards. Provision is made for firmly attaching the cupboard to a wall, but the actual means of attachment is not included, as requirements will vary according to circumstances. Copies of the Standard, B.S. 2881: 1957, may be obtained from the British Standards Institution, Sales Branch, 2, Park Street, London, W.1, price 3s. 6d. net.

INFLUENCE OF ENVIRONMENT ON SURGERY*

BY

F. A. R. STAMMERS, C.B.E., T.D., Ch.M., B.Sc., F.R.C.S.

Honorary Consultant Surgeon, United Birmingham Hospitals; Professor of Surgery, University of Birmingham

I always make a point of inquiring of postgraduate students from abroad about the conditions under which they work in their own countries, and one soon realizes that those conditions are often very different from our own, sometimes fundamentally so. Sometimes it is a matter of different diseases, such as yaws or bilharziasis, with a background of anaemia and hypoproteinaemia; or a different incidence of familiar diseases, as, for example, the high incidence of gall-bladder disease in Scandinavia, or the relative rarity of varicose ulcer in Persia; sometimes it is a matter of national wealth or the state of social advancement of the particular country, there being, in some, extreme wealth and extreme poverty side by side, whilst in others the whole organization is backward; or, yet again, it may be the effect of geography on communications. At any rate, it soon becomes obvious that such environmental circumstances may modify, even dictate, what a surgeon can do or should do with regard to the management of the different types of surgical disease he encounters. This was somewhat vividly impressed on my own mind when, a few years ago, one of my best registrars, thinking he would like to practise surgery in the Colonial Service, went for interview, and found that they wanted him to go into the hygiene side of the Service, since "he would save more lives thereby," which in those backward areas is, of course, true; and, again, when a man working in Rhodesia reported in a letter that he was treating children with tuberculous meningitis as out-patients because there were no beds.

I think that it is a good thing, from time to time, to give a little thought to this question of environment, and that our students, housemen, and registrars should be made to realize that the environment in which they choose to work, or may be called upon to work, may be so different from the one in which they received their medical education that their attitude to their work and their management of cases may need to be completely different. Let us consider a few examples.

War Surgery

Wars have always been a stimulus to surgical progress, and many of the great surgeons of the past received their first inspiration on the field of battle. In our own time we have witnessed two world wars, as well as smaller ones in Korea and Malaya. War brings us right up against fundamentals, and the environment of war has many facets, such as terrain, climate, communications, and type of warfare, which combine in different ways to produce changing circumstances, often demanding a change in management of wounds. Let me enlarge further.

The *History of the Great War (Medical Services)* recounts how from appalling sepsis, spreading cellulitis, and septicaemia during 1914 and 1915 the surgeons learnt that bold excision of wounds, particularly of dead and devascularized muscle, together with removal of in-driven pieces of clothing or equipment, was the best way of saving life and limb; that these wounds should neither be packed nor stitched; that efficient splinting should be used; that there was an important time factor showing that war wounds were contaminated up to between six and eight hours and then, after

that, became truly infected; they even discovered the value of the principle of delayed suture.

All these fundamental factors were learnt before there were any sulphonamides, antibiotics, readily available blood or blood substitutes, or any knowledge of fluid and electrolyte balance. After the war was over, all this was written up in great detail, yet I suspect that the truly rock-bottom fundamental reasons for the behaviour of these wounds was not fully appreciated. At any rate, it would appear that these lessons were not passed on, and by the time the second world war started the official history was out of print and there was literally nothing to guide young surgeons entering the Services in 1939. These young men naturally argued that their own particular hospitals employed the latest advances in everything, and that what they had been taught in the casualty department and on the accident services, especially since sulphonamides had been discovered and blood banks could be organized, was in advance of what was available during the previous major war.

Textbooks of surgery and bedside teaching, however, did not speak of the circumstances under which war wounds were sustained, but when those circumstances were suddenly reintroduced there was no readily available literature for reference. All had been forgotten and everything had to be relearned or, rather, the reasons behind the varying behaviour of wounds under the changing circumstances of war had to be rediscovered. Books describing the surgery of the Spanish Civil War had recently been published, and were seized on as a fair description of the latest advances in war surgery; yet when applied to wounds in the environment of France, the desert, or North Africa these methods proved unsatisfactory, not to say dangerous. The explanation was that most of the Spanish Civil War casualties were picked up off the streets of Barcelona and other towns and were in hospital within half an hour or so, often less. Under such conditions of continuous medical supervision it was safe to apply closed plasters, but in a major war, where there were long delays in collecting casualties, gross contamination of wounds, enforced evacuation following the first surgical treatment, often for long distances, such methods were absolutely wrong.

As a result of different environment an interesting and major difference of opinion developed between Eighth Army surgeons with their experience in the desert and those of the First Army in North Africa, because basic factors had not been accurately analysed. The Eighth Army surgeons had been delighted with the behaviour of wounds in the desert, and attributed this to the sulphonamides combined with Eighth Army judgment. They began to feel that the excisions of the first world war were unnecessary and, indeed, mutilating; and a directive was issued stating these principles. Many hundreds of miles further west the new First Army was meeting with a very different experience in a very different environment, and their surgeons found that the behaviour of wounds in the wet, cold weather, on the highly cultivated soil of North Africa, demanded bold excision as learnt and practised in the first world war.

The two armies met in Sicily, and the surgical consultant, an Eighth Army surgeon, laid down the principles evolved in the desert, feeling sure that with sulphonamides, together with the earliest supplies of the new wonder drug penicillin, all would be well. Environment, however, won again; no longer were men fighting in shorts and open shirts or even stripped to the waist as in the desert; no longer was the terrain dry sand, but the mud of a highly cultivated soil, and there was a great shortage of beds and long delays in treating wounds. The old spreading cellulitis, osteomyelitis, septicaemia, reappeared, and I well remember A. L. d'Abreu

*A paper read before the North of England Surgical Society at the Royal Infirmary, Newcastle upon Tyne on April 10, 1957.

writing to me from Sicily, describing it all and saying, "I am a confirmed exciser," and later, in Italy, so were we all.

It is quite certain that, in war, environment dictates what is the best management of wounds, yet in order to apply the optimum treatment it has to be appreciated that this environment is not constant, but is ever changing, according to the many different factors already mentioned, and that, with an appreciation of these (one of the most important functions of the consultant), the behaviour of wounds can be foretold and the best management planned.

The important thing to grasp is that any really major catastrophe, such as an earthquake, a collapsed building, or a serious train smash, may introduce just those same factors of contamination, delayed treatment, long exposure, dehydration, and blocked communications, and thereby demand the same sorts of modification of management.

Before leaving the subject of battle casualties and their management according to the circumstances of the moment, I must recall how, in spite of these two major experiences in 25 years, once again there was evidence that some of the lessons had been forgotten as early as the Korean War. I saw some of the early casualties in the American Naval Hospital in Boston, and was disappointed to find that none of the wounds had been treated by delayed primary suture.

Return to Peace

After 1945 one saw peace-time surgery built up. I suppose that teaching hospitals have never been so fortunately placed with respect to equipment, laboratories, and technical assistants as they are to-day, and surgery has positively leapt forward in the past decade, and the pace quickens even now. Unfortunately, the development of new specialties tends to fragment surgery, and the danger is that such specialties may have to be housed in outlying hospitals for lack of room in the main ones. This is not good, for it results in isolation, and this, in turn, during the second and third generations of such specialties, may lead to stagnation. Besides, really alert and progressive specialties are by no means constant or definitive in their boundaries, which inevitably overlap, and it is essential that they be with others. It seems to me that the one solution to this important problem is to have under the common roof of the teaching hospital token units, of say 10-20 beds each, of all specialties, where they will keep in touch with general medicine and surgery, as well as rubbing shoulders with each other. All of them, general medicine and surgery as well as these new specialties, should be exploring the growing edge of their own subject, and a common place of work is a general stimulus.

The main medium of exchange of ideas is the conference habit and the seminar, in which the North American centres are so pre-eminent. Such an arrangement is mutually beneficial, and such an organization establishes a haven for the whole. I think that such things as the endocrine approach to the late stage of breast and prostatic cancer, the newer vascular surgery wedded to that of the past 25 years, the ding-dong match between medicine and surgery in the treatment of hypertension, the newer heart surgery, all stem from such organization and the meeting of keen young minds. Such advances would probably have occurred even though units were in isolation; but they might easily go awry, and there would not be that whole body of knowledge freely available to all, nor those frequent discussions that are so valuable and fruitful.

Even more important is the influence that such an environment of progress, free criticism, exchange of knowledge and experience, and of striving after something better has on housemen and surgical trainees; and certainly not less important is the effect on the medical student, who senses this spirit of inquiry and self-criticism, and learns not to accept without questioning all that is taught, and realizes that there is far more to discover than is already known.

Research Laboratories

Whole-time university clinical departments were not always generally popular, yet I think they may claim to have

achieved something; for, in spite of the slight doubt that may still linger in the minds of some, they have received kindness and co-operation from their part-time colleagues. I think their most useful recent contribution is the building up of laboratories near to the wards, wherein young trainees can worry out problems suggested to them by some bedside or operating-theatre experience. Of course, this means that their ward duties must be so arranged that they can spend two or three half-days each week in the laboratories. One well-known surgeon once told me that he foresaw that all such laboratories would eventually fall into the hands of tame physiologists, but there is no fear of this provided one takes note of the many problems suggested by bedside and theatre experience. The reason why these laboratories are so essential is that problems that never come into the experience of preclinical departments can be investigated. Surgery is an applied science and probably the highest form of it, and there are plenty of practical problems for investigation.

Here, then, is another most potent factor in the general environment or atmosphere of the modern teaching hospital, and I am delighted to find senior registrars of non-professional firms now asking for laboratory space in order that they may work on some problem of their own choosing. Of course, one must have technicians to help, and, as the work increases, maybe science graduates for biochemistry and electronics too. As in the major schools in the United States, it should be possible for a man of senior registrar grade to break off for a year of research, without losing salary, status, or seniority, even though for that year he may be called a "research fellow." Modern experience of selection committees discloses the most interesting fact that the trump cards for an applicant to hold are several teaching hospital posts, a year or two in good regional hospitals, a year or more on a professorial unit, and a year on research, either in his own school or in a major centre at home or abroad.

This description of what I conceive to be the best general pattern for a well-balanced and progressive teaching hospital would not be complete if I did not pay tribute to the contribution the bright intelligent student, especially the B.Sc. student, makes to the general atmosphere of enthusiasm. He brings the latest information from the pre-clinical sciences, and adds greatly to its application to practical surgery.

Of course, we must guard against teaching hospitals becoming too highly specialized in patent surgery, dependent on more and more elaborate machines that require more and more technicians to work them. Such would indeed be a bad environment in which to teach undergraduates and train young surgeons. Indeed, it would savour somewhat of the tendency in university life to-day to worship at the altar of research at the expense of teaching: let not the latter become a shrine instead of one of its prime functions. We all recognize that clinical teaching to-day needs to be based more and more on fundamental knowledge and principles than on masses of facts, giving the student a background of knowledge from which he can argue out for himself solutions to problems as he meets them in patients: in other words, a more positive application of physiology, pharmacology, and pathology to ward work. In the past we have been too inclined to teach the facts of our own particular subject, leaving the students to discover whether these facts have any relationship to what they have already learnt in the pre- and para-clinical subjects. Rather should we ourselves adopt this more basic knowledge and point the way to its application to the solution of the patient's illness.

Teaching of Anaesthetics

One final remark regarding medical schools concerns the teaching of anaesthetics. A large proportion of surgical procedures to-day demand a type of anaesthetic that must make it difficult to find opportunity to instruct the student on the kind of anaesthetic that he may be called upon to administer should he practise in small towns or country places. For some years now, we in Birmingham have arranged for final-year students, on a voluntary basis, to

spend two weeks working with doctors in general practice. The scheme has been highly successful, and has resulted in some useful criticism from both sides. Recently, a doctor spoke highly of the student attached to him, but said that he seemed quite ignorant of how to set about giving a simple anaesthetic for the stitching of a laceration or the opening of an abscess in the local cottage hospital. Personally, I believe that the time has come when the teaching of practical anaesthetics should be given during the pre-registration year. The teaching hospital may not necessarily be the best place for this, since much of modern surgery demands complicated machines and polypharmacy that the general practitioner would never be called upon to use. A busy casualty department, on the other hand, does offer an opportunity for learning about the simpler anaesthetics, and our senior anaesthetist makes use of this environment for teaching: but not all students can pass through his hands.

Environment of the Theatre

The periodic appearance of sepsis in wounds and the rising incidence of the penicillin-resistant staphylococcus make all hospitals anxious. Heneage Ogilvie has even suggested that the discovery of antibiotics will in the long run prove a curse, but I do not suppose there are many who would wish to return to pre-penicillin days. What is needed is a more intelligent use of the many antibiotics that are now available, and it certainly behoves us to put our house in order so far as aseptic discipline is concerned. The difficulty is that 99 times out of 100 one can flout the rules yet meet disaster on the 100th. It is then difficult to be sure what is the specific weakness in our technique. Blower *et al.* (1955) and Cook *et al.* (1957) both point to blankets as a strong factor in harbouring the staphylococcus as well as other organisms which will infect the noses of the staff and, in turn, the wounds of patients; and those from St. Bartholomew's Hospital (Shooter *et al.*, 1957) confirm Seddon's work on theatre ventilation just after the war. At the same time, the M.R.C. report on cross-infection in 1943 deserves restudy.

In large hospitals the modern tendency to increase the tempo of work in order to keep pace with the waiting-lists and to avoid waste of time in view of the financial cost per patient per day most certainly increases the risk of cross-infection, which is the reason why sepsis is less common in the smaller hospitals. But I believe that some of the worst offenders against theatre discipline are the surgeons themselves; and any disregard for fundamental principles is inevitably passed on to registrars, housemen, and students.

Permeable masks, uncovered noses, outdoor shoes and trousers for momentary onlookers, popping in when fully dressed to have a last word with the registrar before going, are all cardinal sins. The dresser scrubbing up for the case should change completely just as the rest of the team; but extravagance of linen is the usual excuse for not insisting on this. A very great danger is the physician who wants a word with his surgical colleague. In full lounge suit he leans round the door, talking into his handkerchief and polluting the atmosphere. A small loud-speaker from the annexe or off-duty room should permit these conversations without the potential danger.

Ventilation should certainly be checked. Many hospitals are thought to have positive pressure in the theatres when in fact they have not.

This is all a very difficult story, with many more facets to it than I have time to mention, but the red light has flickered, and the all-important thing for the safety of the patient is to stick to a rigid theatre discipline, the chiefs being the most earnest exponents of it: it is a matter of medical morals.

Demands of Newer Surgery

So far I have dwelt on the two extremes of environment as it concerns the surgeon—the battlefield and the near-ideal teaching hospital of 1957: there lies a vast territory in between. It may be just a matter of new activities in old buildings, where keen young men have to work with limited facilities. For instance, a surgical friend of mine who has

done much work on peripheral arterial disease had performed an excision of an abdominal aortic aneurysm and replacement by a graft. The operation went well, but several days later it was obvious that a leak had developed and that a second and emergency operation was necessary. The difficulty was to find a theatre, of which there were only three, for it was in the morning and all were busy with routine lists. After some effort he managed to persuade one of the other surgeons to cut short his list so that the emergency could be dealt with. Now, there we find something really fundamental: first, that many modern operations can be undertaken safely in modern hospitals, where, in case of a complication, a theatre and its full team can quickly be made available; and secondly, and as a corollary, a major procedure of uncertain duration but potentially protracted is more safely managed if it is the only operation on that particular list.

If we now pass from major hospitals on to hospitals without really senior assistants, without generous laboratory services such as in some country town institutions, or where special nursing would be difficult to obtain, it can be seen that certain of the more intricate and protracted types of operation, especially those pregnant with potential complications, cannot be undertaken with safety and should not be attempted. The older members of the staff would know this, but a young and newly appointed man, fresh from the hot-house of high-powered surgery, might well be tempted to "have a go," yet the slightest hitch would spell disaster.

Surgery in Backward Countries

Going further afield, I well remember how, at a selection committee for a post in one of the outposts of the Commonwealth, a candidate said that one of his chief interests was the surgery of portal hypertension, yet I knew from personal experience of a similar environment during the war that the nursing there consisted of a few English sisters in charge of illiterate natives, who could not possibly keep fluid charts or take blood pressures; that many of the anaesthetics were given by the native pharmacist; and that the resident staff was small and not very experienced. Blood in large quantities would be impossible to obtain, and repeated electrolyte estimations difficult to arrange.

Difficulties of language can make history-taking tedious and inaccurate. For two years of the war I was in Sierra Leone, where there are many tribes and many languages. On one occasion a soldier from one of the smaller tribes, using one of the rarer languages, could be communicated with only through five different interpreters, using five different languages. It can well be imagined that under such circumstances only very straightforward diagnoses were possible, especially when translation into English produced such expressions as "belly palaver" or "my head he hurt me." These natives live in primitive conditions, often several hundred miles from the hospital, so that there is no possibility of aftercare or follow-up, and in such an environment there is no place for exotic surgery; indeed, it would be a disservice.

A colostomy would be quite insupportable for those living in mud huts with palm-leaf roofs, sleeping on the mud floor of the only room with the rest of the family. Amputations are tragedies in a country where there are no artificial limbs and where custom demands that you either earn your food or take the consequences. Prolongation of life in victims of advanced cancer by x-ray therapy, or attacks on the endocrine glands where there is no chance of follow-up or outpatient supervision, is not kind, helpful, or practical, and therefore not ethical.

Nevertheless, a surgeon's life in these parts is fascinating and full of interest, for he must be something of a jack-of-all-trades. In preparation for such a life it is obvious that he must have served on a fracture and orthopaedic unit, on a genito-urinary unit, and have gained some experience in ophthalmology and ear and throat work. He will find a host of new diseases, and, if he is so minded, plenty of opportunity for research of a practical kind, such as studies

on fluid and electrolyte needs in the tropics, the widespread incidence of hypoproteinaemia, and the response to chemotherapy of tropical diseases. His advice will be accepted with child-like faith and gratitude, marred only, maybe, by a large admixture of superstition, the medicine man with his bones and incantations being only just round the corner. The tropical coastal climate of West Africa makes operation wounds go soggy if ordinary dressings are applied. We found the best thing was the old-fashioned cracker dressing, and the patient either lay naked or was covered by a sheet only.

An excellent description of life and medical service in West Africa is to be found in the writings of Albert Schweitzer.

Colonial Medical Schools

So far as British Colonies are concerned, serious attempts to raise medical standards have been made, and the new medical schools, together with their new hospitals, at Makerere and Ibadan are experiments worthy of success. It is terribly important, however, to keep these environmental features to the fore, and to realize that for some years ahead it will be the public-health side of medical work and a greater number of doctors that are most needed. The vast majority of those trained in these schools are destined to practise "up country," and there surgery must be simple and curative. For some time now the Government, through the Ministry of Health, has been trying to persuade senior registrars to work for a year or more in one or other of these two places, and I would commend it for serious consideration. I realize that the difficulty so far has been that men at this stage of their career dare not risk being out of the swim of things at home. Yet so important is it to help these countries that somehow it must be planned that volunteers for such work would receive some credit for it, and a combined second year in some major centre in America or elsewhere has been suggested as an assurance to a man willing to take the risk; but, of course, this is not very easy to arrange, and for the family man it is difficult to carry out.

One does not have to stay in backward countries to see patterns very different from our own. On four occasions Russians have visited Birmingham, and we were all greatly impressed by Dr. Kupriyanov and his ingenious pieces of apparatus for bowel and vascular work. However, Russia is very short of doctors—so much so that the medical schools have been taken away from the universities and put under the Ministry of Health with the object of manufacturing as many doctors as possible. Whilst one of the Russians was watching me operate I pointed out the complete flaccid state of the diaphragm under the influence of relaxants, and afterwards asked him if they used relaxants in Russia. He replied that they had not enough doctors in Russia to allow specialist anaesthetists and that they used spinal and local analgesics extensively. Such a state of affairs must modify one's outlook on modern surgery very greatly.

Conclusions

I have wandered somewhat, yet I feel that all these ramblings carry a message. Keen students and housemen tend to think that what they see in their own teaching hospitals is the complete and last word in everything, practised in the only possible way: they will find that this is not so. Surgical trainees may imagine that they will always have exactly the same facilities as during their training: they may easily have to work with much less. Those who go abroad to work must be prepared to find quite fundamental differences in disease, in equipment, in public services, and in the general outlook of the people, and they must train themselves to be a jack-of-all-trades. Something must be done to provide adequately trained and skilled staff for the new Colonial medical schools. In our schools at home I believe that the teaching of anaesthetics needs

replanning. Finally, I believe the time has come when senior registrars should be able to spend, as part of their training, a year or more in research without loss of salary or status, and then to return to clinical work without loss of seniority.

GENERAL PRACTITIONER RESPONSIBILITY IN GYNAECOLOGY*

BY

J. K. RUSSELL, M.D., M.R.C.O.G.

Senior Lecturer in Obstetrics and Gynaecology, University of Durham

A. J. G. NEWTON, T.D., M.B., Ch.B.

General Practitioner, Morpeth, Northumberland

R. P. ROBERTSON, M.B., D.Obst.R.C.O.G.

General Practitioner, Amble, Northumberland

AND

J. B. LILLY, M.B., B.S.

General Practitioner, Warkworth, Northumberland

In February, 1956, we began a twelve-month field study of gynaecology in a general practice in Northumberland. We report here the results of our investigation, which was designed to enable us to do three things: (1) find out how many patients in the course of one year sought advice because of gynaecological symptoms or signs; (2) record the relative frequency of the various gynaecological conditions; and (3) study together the management of these cases, with particular reference to the part to be played by the general practitioner.

Material and Methods

The practice, situated 25 miles north of Newcastle upon Tyne on the edge of the Northumberland coal-field, is centred on a community engaged for the most part in mining, farming, and fishing; some 300 patients are women and children of R.A.F. personnel. There are three partners in the practice, and a full-time secretary is employed. Of 7,300 patients, 3,000 are females over the age of 12 years.

For the purpose of the investigation the three partners kept a separate record of all gynaecological consultations. Their notes, together with any hospital records, were produced for discussion at regular monthly meetings which all four of us attended. By agreement with the other consultant gynaecologists on the staff of the Royal Victoria Infirmary, all patients referred from the practice for a gynaecological opinion were seen by one of us (J. K. R.). In this way we were able to build up month by month a complete picture of the numbers and types of gynaecological conditions occurring among patients in the practice.

As a result of these monthly meetings, at which all the facts of each case were brought forward for consideration, we were able to discuss and formulate our views on the sphere of responsibility of the general practitioner in the management of most of the commoner gynaecological conditions.

During the twelve-months period covered by the investigation 178 women presented with gynaecological symptoms or signs (Table I).

*Read in the Sections of Obstetrics and Gynaecology and of General Practice at the Annual Meeting of the British Medical Association, Newcastle upon Tyne, 1957.

TABLE I.—Symptoms and Signs in 178 Women

	Total No. of Cases	No. Referred to Gynaecologist
Abnormal bleeding	68	36
Discharge	26	21
Prolapse	11	11
Dysmenorrhoea	15	5
Pruritus	10	8
Sex problems	6	4
Menopausal symptoms	4	0
Contraception	4	0
Infertility	4	4
Miscellaneous	30	4

Vaginal Discharge

We are impressed by the frequency of vaginal discharge, by the mental and physical distress it can bring to a patient, and by the tendency for it to recur unless treatment is preceded by careful and thorough investigation. So often in our experience discharge is external evidence of some underlying lesion in the genital tract. Temporary improvement may follow the use of pessaries or vaginal douching, but permanent relief is not likely to be achieved until the lesion is corrected and normal vaginal physiology restored. These facts are well illustrated in a case treated in the Royal Victoria Infirmary in 1953.

A gravida-3 aged 28 first consulted her family doctor because of vaginal discharge in 1952. After a fortnight's course of pessaries the discharge became less in amount, but within a month it was as bad as ever. She received a further supply of the same pessaries and this time used them for a month. Again the discharge became less, and she was quite comfortable for three months, then she had to consult her doctor because of vulval irritation and discharge. A different type of pessary was prescribed and she was advised to bathe the vulva with a weak antiseptic solution. Very little improvement followed this treatment, but the patient decided against seeking further advice. By the autumn of 1953 the discharge had become much heavier and was more offensive and causing considerable irritation. She consulted her doctor, who referred her to the gynaecological department of the Royal Victoria Infirmary. On examination she was found to have a large granular cervical erosion with one or two small mucous polypi at the external os; a copious mucoid discharge issued from the cervix. In the lower part of the vagina the discharge was mucopurulent, and a swab showed a mixed coccal infection. The patient was admitted to hospital and the cervix, after removal of the polypi, was cauterized. For four weeks she had quite a heavy brown discharge, but by six weeks it had gone. Two years later she became pregnant and was booked for delivery in the Princess Mary Maternity Hospital. She confirmed that there had been no further trouble from the discharge.

Of 26 patients whose main complaint was vaginal discharge, 21 were referred to the gynaecological clinic. One patient refused to come to hospital, one left the district shortly after consulting her doctor, and the other three were treated at home without reference to hospital. Sixteen of the 21 referred patients were found to have underlying lesions in the genital tract (Table II). In one case the cervical erosion bled to the touch and looked very active; the patient was admitted at once for cervical biopsy, which showed only chronic cervicitis. It is known that an offensive vaginal discharge can be the first clinical evidence of carcinoma of the cervix, and we do not believe that the general practitioner should be the person to decide whether a cervical lesion warrants further investigation.

The temptation to prescribe pessaries or vaginal douches without proper investigation of the cause of the discharge is likely to result in a sequence of treatments, none of which will give the patient more than temporary relief. We suspect that many women after a variety of treatments will decide to put up with the discharge rather than keep troubling their doctor. It seems to us that any woman

whose discharge causes her to consult her general practitioner should, after examination, be referred for a gynaecological opinion.

Abnormal Bleeding

Sixty-eight women sought advice because of some variation from the accepted monthly bleeding pattern. We have placed these women into groups, depending upon the type of abnormal bleeding, and for each group have shown the number of women who were referred to the gynaecological clinic (Table III). Table IV shows the ages of the 68 women, and the numbers in the various groups who were

TABLE III.—Type of Abnormal Bleeding in 68 Women

	Total No. of Cases	No. Referred to Gynaecologist
Metrorrhagia	34	25
Menorrhagia	28	10
Oligomenorrhoea	6	1

TABLE IV.—Ages of 68 Women who Sought Advice Because of Abnormal Vaginal Bleeding

Age Group	Total No. of Women	No. Referred to Gynaecologist
Under 21	4	0
21-30	14	4
31-40	18	7
41-50	23	16
Over 50	9	9

referred to hospital. These two tables illustrate clearly the tendency to refer women with metrorrhagia and women in the older age groups.

Under the heading metrorrhagia we have included women with irregular bleeding patterns and post-coital and post-menopausal bleeding. Of the 34 women in this group, four were found to have carcinoma of the cervix or body of uterus. Metrorrhagia in a parous woman over the age of 30 and bleeding beyond the menopause are always worrying symptoms. These patients should invariably be referred at once to a gynaecologist. Once hospital investigation has excluded malignant disease many of these patients require periodic consultation with haemoglobin checks. This continuing surveillance could well be carried out by the family doctor.

Metrorrhagia between the ages of 15 and 25 years does not have the same sinister clinical significance. In this age group the general practitioner must use his clinical judgment and discretion in deciding which cases ought to be referred to the gynaecologist. By carrying out periodic haemoglobin checks, and by ensuring that anaemia is recognized and treated, the practitioner can make a major contribution to the management of metrorrhagia in younger women. The development of anaemia in spite of iron therapy would be an obvious indication for referring these younger women to hospital.

In the management of menorrhagia the family doctor must be guided by the patient's age, medical history, and physical condition. When the patient is over 30 years, or the menorrhagia is severe enough to cause anaemia, we suggest that it would be wise for the doctor to refer the patient to hospital.

Other forms of abnormal bleeding are relatively infrequent. Patients with primary or secondary amenorrhoea, and others with scanty infrequent periods, do not present the same pressing clinical problem as do those women whose periods are heavy and irregular. It is generally considered reasonable to wait until a girl has reached the age of 18 before she is referred to hospital on account of primary amenorrhoea. In cases of secondary amenorrhoea it is likely that the family doctor will himself establish the diagnosis; when the patient remains anxious and the diagnosis is in doubt then the opinion of the gynaecologist should be sought. We imagine that many patients with scanty infrequent periods do not seek medical advice; some, however, will consult their doctor because of childlessness, others may be genuinely perturbed by their failure to menstruate monthly. These women should be referred to hospital.

Other Signs and Symptoms

Prolapse.—Patients with prolapse present no great problem; they ought all to be referred for a gynaecological opinion.

Dysmenorrhoea.—Fifteen women sought advice chiefly because of dysmenorrhoea. In 10 cases the dysmenorrhoea was of the primary type in younger women, and only one of these patients was referred for a gynaecological opinion. We prefer to leave these women with primary dysmenorrhoea under the care of the family doctor as long as possible in the belief that mild analgesics and reassurance are safe and good treatment. Early reference to hospital may well add to a girl's anxiety that there is something wrong with her reproductive organs. We know that certain of these cases do not respond to simple treatment at home. The family doctor, in referring such intractable cases to hospital, can often supply a wealth of information about the patient's background. Four of the five cases of secondary dysmenorrhoea were referred to hospital. The problem here is of a different nature and we consider it advisable for the practitioner most often to refer these cases for an opinion, as there is more likely to be some underlying pelvic pathology.

Frigidity and Dyspareunia.—Four patients sought advice because of dyspareunia, and two because of frigidity. These are small numbers, and from our knowledge of women patients in the practice we suspect that these complaints are commoner but the women hesitate to bring them into the open. The patients with dyspareunia were referred to hospital and in each case a gynaecological cause for the complaint was found and treated. The two patients with frigidity were not sent for a gynaecological opinion. Whether such cases should be referred to a psychiatrist is, we believe, open to doubt. The family doctor, with his knowledge of the patient's background, is well placed to help in this type of case. The clinical history of one of the patients suffering from frigidity illustrates this point.

At the age of 19, much against her will, the patient was persuaded to have intercourse in the back of her fiancé's car. She was greatly upset by this episode and asked her doctor (A. J. G. N.) whether she ought to break off the engagement. She was advised not to do this. Soon after marriage she became pregnant. In an attempt to avoid further pregnancies she and her husband practised coitus interruptus. The patient began to lose weight, found that she was always "on edge," could not concentrate, failed to derive any pleasure from intercourse, and eventually difficulties arose between her and her husband because of her refusal to have intercourse. After a number of years she confided to her doctor that she was very frightened of further pregnancies. Arrangements were made for her to have proper contraceptive advice, and there was a dramatic change in the family circumstances. The patient put on weight, looked fitter, took a much greater interest in her house and family; and she and her husband seemed to be very happy.

Contraceptive Advice.—Four women wanted contraceptive advice and were referred direct to a local contraceptive clinic. This is a very small number, and we do not know what interpretation to put on the finding. We purposely avoided giving advice unless it was sought, and in some measure this may be responsible. It may be that the women or their husbands seek advice elsewhere, and do not believe that they need to bring this matter to their doctor. When advice is sought we do not consider that the patient need be referred to a gynaecologist. In the absence of a local contraceptive clinic the practitioner ought to be prepared to give the necessary advice.

Pruritus Vulvae.—Ten women sought advice because of pruritus vulvae and all but two were referred to the gynaecological department. Both patients treated at home had short histories; one had a herpes of the vulva and the other an acute infection of a Bartholin gland. In each case there was a satisfactory response to treatment. Three of the eight patients referred to hospital were found to have lesions of the vulva—leucoplakia, kraurosis, and chronic infection of a Bartholin gland. The other five patients, on investigation, proved to have irritating discharges caused by vaginal or cervical conditions. It is tempting for the patient and the family doctor to use a sequence of local applica-

tions for pruritus vulvae, and we have known women be referred direct to a skin department for fractional x-ray treatment to the vulva. This pattern of treatment may well obscure the original cause of the pruritus by introducing secondary factors such as chemical irritation or sensitivity to specific drugs. Unless the history is short and there is an obvious vulval condition to account for the itching we have no hesitation in advising that these patients be referred for a gynaecological opinion.

Infertility.—The four patients who consulted their doctor because of involuntary childlessness were all referred to hospital. In spite of the small numbers, we have chosen to discuss the part to be taken by the family doctor in the management of these cases, for in the clinical approach to this problem great care and tact are necessary, otherwise much unhappiness can be brought to the childless couple. When advice on childlessness is sought the general practitioner should emphasize that the problem affects husband as well as wife and both must be referred to the infertility clinic. Once the investigations have been completed someone must decide how the findings are to be presented to the couple and what prognosis is to be given. On the whole we believe that this ought to be done by the gynaecologist, yet the family doctor must be fully aware of the significance of what has been found and what has been said to the couple, who may at any time want to discuss the matter with him.

Menopausal Symptoms.—Four women complained of a variety of symptoms generally associated with the menopause—flushings, headaches, emotional upset, and abdominal distension. Patients in this age group with these symptoms, but who also complained of irregular bleeding, have been included under the heading "abnormal bleeding." The four patients were not referred to hospital, but were treated with small doses of oestrogen and mild sedatives by their own doctor.

Miscellaneous Group.—This group consists of 30 patients whose reasons for seeking advice are not listed above. Some wanted to know whether they were pregnant, others suffered from anaemia following recent childbirth or abortion, a few complained of premenstrual tension, and four others drew their doctor's attention to abdominal swellings which turned out to be fibroids or ovarian cysts. These four patients were referred to hospital for surgical treatment.

Discussion

In our approach to this subject we have assumed that the general practitioner is a doctor charged with the overall care of his patients. Neither by training nor by experience is he a surgeon, a gynaecologist, a chest physician, or a radiologist, but he is entitled at any time to call in the assistance of his specialist colleagues when he considers this step necessary in the interest of his patient. Most often this specialist assistance is but an episode in the continuing care of the patient, yet unless the general practitioner, in his training, has received clear guidance about where his and the specialist spheres of responsibility lie, the patient may be caused much unnecessary suffering and anxiety.

We have given details of the various gynaecological complaints which brought patients in one practice, during a period of twelve months, to seek the advice of their doctor; we have discussed the part to be taken by the general practitioner in the management of these cases.

Our experience has convinced us that the main contribution of the general practitioner, in so far as he is dealing with gynaecological cases, lies in his appreciation of the significance of various symptoms and signs, and in his knowledge of when to seek specialist assistance. On the one hand, too early reference to the gynaecologist in hospital may serve to focus undue attention on a complaint which can well be managed by reassurance and simple treatment at home under the care of the family doctor. We have in mind the young girl with primary dysmenorrhoea or menorrhagia. He should have no difficulty in deciding which of these cases do ultimately require to be seen by a gynaecologist.

On the other hand, failure to refer certain cases at once may result in delay in the diagnosis of important pathological conditions in the pelvis. For example, irregular bleeding or offensive discharge in parous women are sinister features, particularly if the woman is over 30, and may be the earliest evidence of malignant disease in the genital tract. In other types of case the general practitioner, by instituting treatment without reference to a gynaecologist, may obscure and even complicate the clinical picture. We have already stressed the need for careful hospital investigation in most cases of discharge and pruritus before any treatment is begun. In this category we would also include the use of endocrine therapy by the general practitioner. We believe that there is a limited yet important place for hormone treatment in gynaecology and that cases suitable for treatment require careful selection and supervision. With very few exceptions the decision to give endocrine treatment should be left to the gynaecologist. The patient with menopausal symptoms such as we have described above and the younger woman suffering from premenstrual tension seem to us to be the type of case where the family doctor might himself prescribe endocrine treatment.

Whereas in this study we were content to record the number of patients who consulted their doctor because of gynaecological conditions, we know that this does not present the total picture of gynaecological responsibility within the practice. There are occasions when the family doctor will consider it his duty to offer advice. We made no record of the number of occasions on which this circumstance arose, but we are well aware of the responsibility of the general practitioner in this respect. The family steadily progressing over the years towards becoming a problem family, perhaps because of a rapid sequence of pregnancies and poor circumstances, presents a challenging problem. We appreciate that there are people whose religious views debar them from giving or receiving advice on family planning; their views must be respected. The general practitioner who watches such a situation unfold must exercise considerable discretion. We have known families in this practice who at one time would readily have qualified for the title "problem family," yet five years later, once the older children were out earning money, have improved their physical circumstances out of recognition and seemed then to be very happy. We have seen standards fall steadily in other families where the mother has suffered from some physical handicap. Such a mother may well survive the hazards of successive pregnancies, but those who come into daily contact with the family will bear witness to her failing ability as a good mother. Whether the family doctor, in the absence of any request, should make a positive move towards helping such women is never an easy decision to make.

There are other occasions on which the doctor, in the absence of any request from the patient, may think it advisable to suggest investigation or treatment, but it has been our experience that when advice has to be offered in this way by the family doctor it is seldom so readily taken up as when it is actively sought by the patient.

Repeatedly during our year's study we had evidence of the respect that the patient has for her family doctor, and of the importance she attaches to his opinion. Many patients, after a visit to hospital, would call on their doctor and discuss with him what had been said at hospital. Complete reliance was placed upon his ability to interpret the opinion of the gynaecologist in regard to treatment and prognosis. This presupposes a very close link between general practitioner and specialist—much closer, we suspect, than generally holds in medical practice to-day.

Much of what we have learned from this study of gynaecological responsibility in general practice is of interest and great importance in relation to undergraduate teaching. So many textbooks and teaching programmes, although they deal adequately with the common gynaecological disorders, fail to guide the student in regard to the relative parts to be taken by practitioner and specialist in the management of these disorders. Too often the student must guess the stage at which a patient should be referred for specialist opinion.

We consider that investigative work of the type we describe should be undertaken at regular intervals, for the practice of medicine is constantly changing. In this way the general practitioner might periodically review his sphere of responsibility and thus ensure for his patients the highest standard of medical care.

Summary

The results of a field study of gynaecology in a general practice in Northumberland are reported.

Details are given of the various gynaecological complaints which brought patients in this practice, during a period of twelve months, to seek the advice of their doctor. The part to be taken by the general practitioner in the management of these cases is discussed.

There is a need in teaching to define more clearly the spheres of responsibility of practitioner and specialist in the management of patients with gynaecological complaints.

We are indebted to Professor Evers for his helpful advice and encouragement.

THE TEACHING OF DERMATOLOGY TO UNDERGRADUATES*

BY

F. F. HELLIER, O.B.E., M.D., F.R.C.P.

Senior Clinical Lecturer in Dermatology, Leeds University

It is a common experience for a dermatologist called out in consultation by a general practitioner to be met with the remark, "Of course, I know nothing about skins," uttered almost with an air of boasting. Many a sound practitioner will adequately cope with cases of heart failure or pneumonia, but is only too willing to surrender patients with the most trivial skin disease to the specialist. This is largely due to inadequate study of dermatology as a student, the unsatisfactory state of which in many medical schools has been shown by Peck (1955).

Need for Training in Dermatology

A comprehensive and thorough training in dermatology is an essential part of undergraduate medical education for two reasons. Firstly, skin diseases form a substantial part (about 10%) of everyday general practice; many doctors have told me that if they could go back to their medical school the first subject they would study would be skin diseases. It is surely reasonable to equate roughly the proportion of student time given to dermatology with the proportion of skin diseases in practice. Even the budding surgeon or general physician would benefit by a sound knowledge of dermatology. Too much attention is given to dramatic highly specialized subjects such as neurosurgery and cardiac surgery, and much time is wasted in theatre attendance at other operations which have little bearing on general practice and the knowledge of which should be acquired by postgraduate study. The elements of dermatology should form part of the basic training of all doctors. Secondly, the study of skin conditions displays better than any other the fundamental processes of disease, such as inflammation and repair, the effect of allergy on bacterial infection, and the influence of the mind on the reaction of tissues and disease.

Dermatology must not only be given its proper share of the students' time, but it must also have its proper status in his mind. It must be presented so that he sees it as an integral part of medicine, like cardiology or neurology, and not as some curious specialty set apart. For example, in the introductory clinical course instruction should be given

*An address given to the Dermatologists Group of the British Medical Association on May 9, 1957.

in the examination of the skin just as much as in that of the heart or nervous system.

Lectures.—I will not tackle the vexed question of whether students should or should not be given lectures, but will assume that some at least are to be given. These should certainly not be factual rehashes of textbooks but should seek to cover some aspect or reveal some principle which the student could not get from his ordinary reading. A lecture on rosacea might serve to show how a final disease picture may be the result of the interplay of several factors—gastric, endocrine, psychological, etc.; whilst a lecture on skin tuberculosis would teach the evolution of bacterial allergy and help the student to understand what happens in tuberculosis elsewhere in the body. Such lectures fully illustrated by slides could usefully be given early in the student's clinical years, but they should not be used to try to teach him masses of facts about skin diseases he has not yet seen.

Period in Skin Department

Later in his clinical training—but not too near his final—the student should spend three months in the skin department; this need not be a whole-time appointment but could be fitted in with some other subject (in Leeds it coincides with orthopaedics), but the student must devote a substantial part of his time to dermatology. During this three months he must attend the out-patients clinic regularly at least three times a week. The object of this is threefold: he must see a sufficient number of cases so that he can begin to acquire that comprehension of skin diseases and knowledge of what he is looking at which only comes with experience; he must learn to make his own rational diagnosis and not just turn over the pages of some skin atlas till he sees a picture which fits the patient; and he must watch the dermatologist really dealing with cases and providing an example, and I hope an ideal picture, which the student can carry with him and imitate in later life.

The first of these objects can only be achieved by frequent attendances in the ordinary out-patients clinic. It cannot be replaced by the didactic demonstration of a few selected cases, though this may be a useful adjunct at times. A student does not really grasp the difference between psoriasis and nummular eczema until he has seen many cases of each; in the selected demonstration method he is only likely to see such cases once or twice. Some selection will still be necessary to weed out an endless procession of warts, etc., from the teaching material.

Teaching the student to think and to make a rational diagnosis is the supreme aim of all teachers and for various reasons the most difficult to achieve. It cannot be done with big classes where most of the students not on the front bench sit like fledglings with open beaks waiting for the teacher to drop a nice factual worm into their mouths. With a small group of about six one can practise the Socratic method and each student in turn can tackle a patient. It is time-consuming and limits the number of patients that can be seen at a session, but it is rewarding. A further development of this is for each student to interview a selected patient in a side-room and then to present his case to the class. This can only be done in a very limited way in an average English clinic, but under ideal conditions where there are plenty of instructors it is an excellent method. I have seen it used very successfully in the Maryland Hospital in Baltimore, where each student discusses his case individually with an instructor.

Finally, the student must have the opportunity of seeing the dermatologist really dealing with cases and not just giving a demonstration, of hearing how he takes a history and watch how he carries out his examination. A great responsibility rests on our shoulders to set a good example; we must take the history carefully, we must examine the patient all over; we must do a general examination, not neglecting a rectal examination where indicated; and there must be no short-cuts. The student will also see something

of how we approach the psychological side, and, not least, he will see how we deal with a difficult patient and get rid of a garrulous one without being rude. Each one of us looking back will remember some chief whose manner and methods we consciously or unconsciously imitate, and we must realize the rather sobering fact that we ourselves are now the ones who may be copied.

During his time in the out-patient clinic the student will attend on one or more occasions the special clinics, such as those devoted to leg ulcers, lupus vulgaris, ringworm, minor operations, etc. Above all, he will take part in the daily treatment clinic and learn how to put on elastic adhesive bandages and how much ointment it takes to cover a given area of skin.

Besides the work in the out-patient clinic, he will become clerk to a number of in-patients in the same way as on the general medical firms. This will not only give him deeper knowledge of his own patients' skin conditions which he will read up, but will also enable him to develop an intimacy with a skin patient and learn what having a skin condition means to the patient in a way that cannot be done with out-patients.

Arrangements in Leeds

At some stage the student should systematically cover all the common skin diseases. Some students benefit from set lectures, but this is not a good method for the majority. In Leeds we favour a rather informal tutorial carried out by our senior registrar, who is called the dermatological tutor, during their three-months skin appointment. This occurs once a week and is illustrated by coloured slides and is part lecture, part discussion, and systematically covers the major skin diseases. An alternative is for the student to read systematically himself. Some students will do this, but many will not, and so the method of "assigned reading" may be used. The class is given some subject to read up and the next morning they are quizzed for 10 minutes on their subject. Here, again, time and adequate instructors are required.

The question of incentive is an important one. Idealists say a good teacher will attract the students, and if they do not attend it is his fault and the students cannot be blamed. But students do not always recognize what is in their best interests, and many live to regret their failure to attend certain clinics or take certain subjects seriously. Some form of examination is essential not so much as a test of knowledge but as a stimulus to the student to work. Any subject which is not represented in the final examination loses status in the strictly practical eye of the student, and this attitude is likely to persist even apart from examinations. On the other hand, one does not want to increase the heavy burden of the student at his final examination. I feel our arrangements in Leeds are reasonable. There is one compulsory skin question in the finals, set and corrected by a dermatologist, or rather by two dermatologists, one internal and one external; in the clinical examination one short case is a skin condition on which the student is examined by a dermatologist and a general physician. Edinburgh has a somewhat similar system, as they have a class examination at the end of each clinical appointment and dermatology falls into line with all other clinical subjects.

What I have suggested here is practical and possible and suited to the British type of medical education. These are the basic requirements, though one could suggest many other useful additions such as discussion groups, visits to industries with an occupational skin risk, etc. A student trained as I have outlined would be turned out with an adequate practical knowledge of skin diseases and at the same time a grounding in basic ideas which would support him when he has forgotten most of the details he has learnt. Finally, such a student would have an interest in skin patients and an ability to treat them which would give him lasting satisfaction in his later medical career.

Reviews

PRINCIPLES OF THERAPEUTICS

The Principles of Therapeutics. By J. Harold Burn, M.A., M.D., F.R.S. (Pp. 278+ix. 27s. 6d.) Oxford: Blackwell Scientific Publications. 1957.

Professor Burn has made such distinguished and important contributions to science, not only in the sphere of academic but also in that of applied pharmacology, that the publication of a book based on his lectures to the medical students at Oxford must be received with great interest. It is not easy to determine how much pharmacology medical undergraduates should be taught; nor is it easy for the expert to describe what he has selected in a short and simple, yet interesting, manner. Professor Burn has been outstandingly successful in the selection of his pharmacological subject-matter and in the brevity and lucidity of its presentation. This is particularly the case in those chapters in which he describes the experiments on which our knowledge is based of drugs acting on the neuromuscular apparatus. Since Oxford students do not receive any other formal instruction in therapeutics the book attempts to link pharmacology with therapeutics, and it is unfortunate that the therapeutic instruction given is not always satisfactory. For example, few physicians would agree with the following: "Thiamine by mouth is very valuable for treating lumbago and other forms of muscular pain. Large doses such as 100 mg. four times a day are required; in the course of two or three days relief is obtained from severe attacks. Finally, thiamine in similar large doses is valuable for the treatment of trigeminal neuralgia, the neuritis of pregnancy and Bell's palsy." Again, while it is recognized that elaborate instruction on insulin therapy is inappropriate for fourth-year students, the following homoeopathic advice, given without qualification, is hardly adequate: "Insulin treatment is begun with 5 units before breakfast and again before supper. After four days the urine is examined for sugar and if necessary the dose of insulin is increased to 10 units." Further, in diabetic coma, besides "enormous amounts of insulin" the intravenous infusion of dextrose is recommended "in the ratio of 2 g. of dextrose for 1 unit of insulin." Were such advice to be followed the patient might well crystallize out, like Lot's wife, into a pillar of sugar. It is a pity that unsound advice of this nature should spoil an important and interesting book, and when a new edition is called for, as must surely be the case, Professor Burn might well take a practising physician into consultation.

D. M. DUNLOP.

MEDICAL EDUCATION

Meditations on Medicine and Medical Education: Past and Present. By I. Snapper, M.D. (Pp. 138+vi. \$3.75.) New York and London: Grune and Stratton. 1956.

Dr. Snapper, a native of Amsterdam, has practised and taught medicine in Holland, China, and the United States. His opinions on medical research and education are therefore based upon a wide personal knowledge and well merit attention. The book is divided into three parts. The first gives an interesting picture of the early physicians and surgeons who practised in and around New Amsterdam (afterwards New York) during the seventeenth century. The second part describes the great influence of Leyden as a medical centre during the early eighteenth century, and stresses the decisive effect of Boerhaave's teaching on his own and succeeding generations, especially in Edinburgh and the United States. It is in the third and concluding essay that we find Dr. Snapper's meditations which lead him to certain definite conclusions. He notes the fallibility of doctors. "The medical profession, both practitioners and academic teachers, since time immemorial has always been highly satisfied with its own accomplishments." He regrets the threatened separation of medical research from practical medicine. "Unfortunately, in the minds of many medical

authorities, the ill-conceived dogma of a schism separating bedside medicine and research has gained a strong foothold again," and, still stronger, "Unfortunately, some modern leaders, like the Knidians, despise empirical medicine." Finally he laments the neglect of the clinical demonstration in the United States. "The very kind of demonstration which made Leyden the center of medical education in the first decades of the eighteenth century—has for the last three decades been anathema to the teachers of medicine in the United States." While admiring the great work of Abraham Flexner for medical education in America he comments, "It is understandable that Flexner did not wish to appreciate the importance of professorial demonstrations." Dr. Snapper holds the balance well between European and American methods of teaching medicine, and his opinions deserve to be well considered.

ZACHARY COPE.

ANAESTHESIOLOGY

Manual of Anaesthesiology for Residents and Medical Students. By Herman Schwartz, M.D., S. H. Ngai, M.D., and E. M. Papper, M.D. (Pp. 170+xii; illustrated. 32s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1957.

This latest addition to the American Lecture Series contains, as the introduction puts it, "what every young anaesthesiologist should know." It is based on the authors' own course of didactic teaching for their residents, a universal feature of the training programme of the American anaesthesiologist. His young British counterpart, too, is certain to derive benefit from the clear and concise, if somewhat limited, account of basic anaesthetic knowledge. An equally good title for this book might have been "Basic Anatomy, Physiology, and Pharmacology for the Anaesthetist," although there is more than a sprinkling of sound clinical information as well. In this country teaching in these basic subjects is rarely given, and is not easy for a registrar to obtain. He must cull the information for himself, not without difficulty, from a range of specialist textbooks. However, the small size of the book, coupled with the large type, necessarily limits the scope of the material, and the reader must clearly understand that it is no more than what the authors themselves call a "teaching guide." This is particularly important in the case of candidates for higher examinations in Britain. The essay type of answer required in this country needs a deeper understanding than is generally contained within simple lists and tabulations of causes and effects. Teachers too are certain to find this book useful, for it summarizes for them in excellent fashion the minimum of basic scientific knowledge essential to the proper practice of anaesthesia.

W. W. MUSHIN.

WARD BOOK OF TREATMENT

Current Therapy, 1957. Latest Approved Methods of Treatment for the Practising Physician. Edited by Howard F. Conn, M.D. (Pp. 731+xxx. 77s.) Philadelphia and London: W. B. Saunders Company. 1957.

Those of us who run departments have often tried to maintain a ward book of directives for the treatment of the common diseases. Such a book ensures that those prescribing treatment, often inexperienced prescribers, will be aware of the methods considered best, and it ensures that sizable groups of patients will be treated by the same method and adequate data will be available when the methods come to be appraised. The difficulty is to keep such a ward book up to date, and unless the chief or one of his permanent assistants has the administrative type of mind the book rapidly falls behind the times. *Current Therapy*, of which previous editions have been reviewed in these columns, is just such a book, and it gives programmes for the treatment of all the common diseases, prepared by some 300 experts. It has 750 quarto pages printed in double column and weighs over 2 kilos. At the end there is a list of poisonous substances commonly found in household articles such as polishes, solvents, cleaning agents, and cosmetics, and also a list of the principal active ingredients of some 2,000 commercial

products, including such exotic items as "bug-blast aerosol" and Parson's "kal-zoo ant and roach killer." Only a wealthy country like the U.S.A. could afford to publish a new edition of such a book every year, in which 30 to 50% of the material is new or rewritten, and the rest of the English-speaking world are the sharers of their bounty. Noteworthy in the present edition is the attitude of caution adopted towards both the corticoids and the tranquilizers. It is evident that protracted maintenance therapy with corticoids in anything more than 25 mg. cortisone or the equivalent dose of allied compounds a day is fraught with great risks.

Although the book is large, the contributors confine themselves strictly to therapy and do not stray into medical diagnosis. The sections I have sampled are admirable, and it is most helpful to know the best current American practice in the treatment of common diseases such as myocardial infarction, ulcerative colitis, rheumatoid arthritis, and asthma. In conclusion one must congratulate the editor on the skill with which he has chosen his contributors and marshalled their contributions. This is certainly an annual volume which the hospital library should be persuaded to subscribe to.

L. J. WITTS.

HISTOLOGY FOR STUDENTS

A Student's Histology. By H. S. D. Garven, B.Sc., M.D., F.R.S.E., F.R.F.P.S.G. (Pp. 649+xii; illustrated. 55s.) Edinburgh and London: E. and S. Livingstone Ltd. 1957.

The special merit of this pleasant book lies in its excellent account of the normal microscopic structure of bone, muscle, alimentary canal, liver, and central nervous system. Not only is the texture of tissues and organs thoroughly dissected, layer by layer, to the ultimate cellular level, but the correlation with function is kept well to the fore so that the beginner soon realizes the need for studying the partnership. Dr. Garven has designed an admirable handbook for the work bench, rich in unambiguous diagrams and many beautiful drawings. There are, of course, a few criticisms which might be made the basis for a second edition. I would wish to see the problem of endothelium revised in the light of the recent work of Short and McGowan; an account of the mysterious centripetal recession of the red bone marrow; something about the crystalline structure of bone, the ageing of lymph nodes, the curious glands in the wall of the extra-hepatic bile ducts; Jean Oliver's fascinating study of the isolated nephron; Keith Richardson's work on the mammary glands; and various odds and ends that startle the reader into realizing that histology is by no means a settled affair. Something to this end has already been achieved through some excellent suggestions on further reading and a pithy list of investigators who have given their names to histological terms or made notable contributions. The few mistakes in spelling can easily be rectified in the next edition; the index appears to be adequate, and the price is not excessive by modern-day standards. May I implore Dr. Garven to explain how the spleen contracts?

G. R. CAMERON.

PATHOLOGICAL HISTOLOGY

Pathological Histology. By Robertson F. Ogilvie, M.D., D.Sc., F.R.C.P.Ed., F.R.S.E. Foreword by A. Murray Drennan, M.D., F.R.C.P.Ed., F.R.S.E. Fifth edition. (Pp. 482+xi; illustrated. 52s. 6d.) Edinburgh and London: E. and S. Livingstone Ltd. 1957.

The issue of a fifth edition of this textbook since 1940 tells its own story: it is without question useful for the student, especially perhaps at the revision stage. Though it is more than an atlas, the colour photomicrographs are the salient feature. They are of a high order; not only have they been taken from good and representative sections, but their reproduction is of the high standard that we have learnt to associate with these publishers. The text is clear, and good accounts are given of conditions that have assumed increasing importance in recent years—for example, lupus erythematosus; the illustrations of L.E. cells are outstanding. A

few criticisms might be met in the next edition. Fig. 205, of primary liver-cell carcinoma, is uninformative. Hutchinson (p. 106) should read "Hutchinson." Cerebral medulloblastomas (p. 384) are no longer held to occur, and it would surely be preferable to transfer the account of these tumours to the section dealing with gliomas. It is tempting to suggest the inclusion of other material—for example, the much commoner chromophobe adenoma of the pituitary in addition to the eosinophil (beautifully illustrated), but problems of choice are both individual and difficult. These suggestions should not be held to detract from the general value of this work, which is truly a bargain at its price.

DOROTHY S. RUSSELL.

SURGICAL PHYSIOLOGY

Physiologic Principles of Surgery. Edited by Leo M. Zimmerman, M.D., and Rachmiel Levine, M.D. (Pp. 988+xv; illustrated. £5 5s.) Philadelphia and London: W. B. Saunders Company. 1957.

There has long been a need for a book of this type. Surgeons used to be practical anatomists, and in that stage of its development surgery was rightly considered to be dependent more upon anatomy than any other of the basic sciences. To-day many surgeons feel that the future progress of surgery will occur as a result of the advances in the physiological and biochemical fields and that surgeons should think at least as much in a physiological as an anatomical way. We are well supplied with good books on surgical anatomy, but until now the physiological principles of surgery, unlike those of medicine, have not been the subject of a comprehensive work of this type.

The editors and their team of contributors have succeeded in producing a valuable book which covers the subject in a comprehensive manner and which should pass through many editions. It is recommended.

PERSONALITY THEORIES

Theories of Personality. By Calvin S. Hall and Gardner Lindzey. (Pp. 572+xi. 52s.) New York: John Wiley and Sons, Inc. London: Chapman and Hall Ltd. 1957.

The authors, pupils of Tolman, Allport, and Murray, have attempted to present a picture of the major theories of personality, with the aim not of their critical evaluation but of demonstrating their positive aspects. They have succeeded better than anybody else before them. In a valuable introduction they point out that personality theory owes much more to medical than to academical psychologists. It has occupied a dissident role in the development of psychology, being functional and motivational rather than experimental. The main criterion of the value of a personality theory, the authors submit, is the amount of important empirical research it has produced. They refuse to adopt an omnibus definition of personality. Personality theories are general theories of behaviour, of which the following are presented: those of Freud and Jung, and their social psychological derivatives; furthermore the theories of Murray, Lewin, Allport, Goldstein, Sheldon, Eysenck and Cattell, Hull, Rogers, and Murphy. The presentations are without exception well informed, lucid, and fair. Although the authors have found something to admire in each of those theories, they regard every one of them as in need of considerable improvement before it could be considered even moderately adequate in terms of formal criteria, such as explicitness of statement and adequacy of definition. In a final chapter they compare the presented theories with regard to their originators' basic assumptions about the determinants of behaviour. The authors enter a plea for increased sophistication on the part of the psychologists concerning the nature and function of theoretical formulation, but they remind critics that the only telling argument against an existing theory is an alternative theory that works better.

This book deserves a place in every psychiatric and psychological library. Teachers and students will find it equally helpful.

THE AIM OF MEDICAL EDUCATION

In 1800, writes Dr. Charles Newman,¹ the aim of a physician's education was to produce "a cultured and highly educated gentleman with, quite secondarily, an adequate knowledge of medicine." Little actual medical knowledge was necessary or indeed available, and until 1812 the Royal College of Physicians required for its licentiates only six months' practice in hospital. The good physician owed his skill and his status principally to experience and wisdom, not to knowledge. Diagnosis based on the history given by the patient; physical examination was but an afterthought and restricted to observation of the pulse, the tongue, drawn blood, and the excretions. What the patient complained of was more important than what the doctor found. So the psychological factors in causation and their influence upon the progress of the disease were stressed to the neglect of the nature of physical changes and their possible significance. Then in the early part of the nineteenth century "technology began to supplant wisdom," and though this led to steady advance in the understanding of disease it was accompanied by the "gradual eclipse of the patient"; there arose "a tendency, born of physical signs, to ignore what the patient complained of, or feared, or thought about his illness, in favour of the doctor's finding of what was 'really' there." The growth of the physician's technical skill and so of his capacity to treat disease effectively did not give the profession a higher status in the community or inspire a greater respect: the qualities which do this, it appears, are not technical ability or academic knowledge, but integrity, wisdom, and sympathetic understanding. Since the beginning of the nineteenth century medical education has been steadily moving away from methods designed to educate the doctor professionally and develop his intellect, and increasingly towards those directed to equipping him as a technician. Knowledge there must be for the wisdom of experience to work upon, but a vast assembly of facts, free from any framework of reference that will make them intelligible, are still thrust on the student.

Dr. Newman gives an interesting account of how the unfortunate medical student came to acquire some of his technological burdens, in particular anatomy

¹ *The Evolution of Medical Education in the Nineteenth Century*, 1957, Oxford University Press. Price 30s. net.

and the premedical subjects. "Botany was included because to recognize vegetable drugs was essential when doctors gathered their own herbs. It was based upon the same argument as that which required early dentists to know all about the manufacture and working of steel (they had, within the memory of people still living, to make their own instruments)." In physics it was thought that the student should learn mechanics and heat so as to be able "to advise on common domestic questions of nuisance-preventing, warming, ventilation and the like" (General Medical Council, 1886). Dr. Newman remarks: "The underlying trouble about the premedical sciences was that in spite of all the discussion about details, no one ever thought out what they were being included for." Much the same might with equal truth be said about other parts of current medical curricula.

If the whole of the present technological training of the doctor is to be regarded as essential, then there is little hope of providing a more adequate professional education in which the intellect will have something to feed upon. One of the assumptions which has stood in the way of a reduction of technological training is the nineteenth-century obsession that the aim of medical education is to train the "safe general practitioner." This concept was written into the Medical Act of 1886, and, as Dr. Newman points out, it is not "the failure to reach the whole objective that matters, but the fact that the objective itself may not have been the best aim of medical education." To-day we have moved much nearer to agreeing that the aim of training is to turn out a "basic" doctor, able to go on learning for himself and equipped for further training in any direction he may choose. This concept has received some slight statutory recognition in the compulsory pre-registration year of resident hospital appointments, and in the tardy realization that even general practice is a fit subject for post-graduate study.

The broad plan of the curriculum was laid down by the General Medical Council in 1867. A "logical" order of subjects was decided by its committee on medical education in 1869, and was, in substance, the opinion of Acland. This basic pattern has persisted to the present day, but from the latter part of the nineteenth century one specialism after another has been added to it. It was the concept of training the "safe general practitioner" which justified each addition as it was proposed. Acland's "logical order" of premedical, preclinical, and finally clinical subjects has the fundamental disadvantage that the student cannot intellectually grasp the relevance to medical practice of each successive phase. The various stages are not clearly linked steps to a defined objective but arbitrary obstacles to be overcome, and the student's acceptance of the need for what he learns is no more than an act of faith, a blind acceptance of authority,
