THE AETIOLOGY OF CANCER AND ALLIED DISEASES DEVELOPMENT OF A CONCEPT BASED ON RECENT EXPERIMENTS DEALING WITH A CELL-FREE TRANSMISSION OF MOUSE LEUKAEMIA

BY

LUDWIK GROSS, M.D., F.A.C.P.

From the Cancer Research Unit, Veterans Administration Hospital, Bronx, N.Y., U.S.A.

It has long been suspected that cancer and allied diseases may be caused by transmissible viruses. This concept appeared particularly plausible as a hypothetical explanation of the obscure aetiology of various forms of leukaemias, lymphosarcomas, and Hodgkin's disease. The course of either disease in humans with the accompanying fever; the frequent temporary improvements followed by relapses; the general systemic manifestations, including the gradual loss of weight and anaemia; the striking, though rare, reports of familial incidence in humans and in animal hosts, were consistent with the assumption of a chronic infectious nature of these diseases.

The main difficulty, however, in accepting the infectious concept of the aetiology of malignant tumours, including leukaemias, has been the well-established observation that in humans, and in animal hosts, tumours are not transmissible from one host to another, at least not in a manner similar to that observed in other infectious diseases. When speaking of a communicable disease we are conditioned to think automatically of a disease spreading from one host to another within the same generation; by contact (smallpox), through infected food or carriers (typhoid fever), through airborne droplets (common cold, influenza), etc. In each case both the infecting and the infected hosts belong to the same generation; a brief interval of time, most frequently not exceeding a few days, or weeks at the utmost, elapses between the individual cases forming successive links in the chain of a conventional transmission of the common communicable disease.

In the typical cases the human observer can actually follow the spread of a communicable disease, tracing it in either direction, back to the infecting carrier, or ahead to the infected host. Thus, a child suffering from chicken-pox, or measles, for instance, could readily cause a rapidly spreading epidemic, progressing from one child to another in the neighbourhood. Similarly, a mouse infected with the salmonella organism would spread typhoid rapidly to other mice within the same cage. Malignant tumours, including the various forms of leukaemias, are obviously not transmissible in such a manner. A leukaemic or sarcomatous chicken could be placed for the balance of its life in close quarters with a flock of healthy chickens; a leukaemic mouse, or a mouse bearing a large, perhaps even ulcerated mam-

mary carcinoma, could be placed in the same cage with a group of healthy mice; yet no transmission of the disease would occur in either case. A similar observation has been repeatedly made, over the period of decades, in human tumours and leukaemias. It appeared logical to conclude, therefore, that malignant tumours, including leukaemias, are not transmissible diseases.

Thus the viral theories of cancer, advanced now and then during the past decades, appeared to be doomed at the onset, and fell in disrepute when confronted with common observations in clinical medicine and experimental laboratories. Actually, however, upon reviewing clinical and experimental observations thus far accumulated, it does not seem necessary to conclude that cancer and leukaemias are not caused by transmissible agents. It can only be concluded that malignant tumours do not appear to be transmitted from one host to another in the conventional manner hitherto observed in the common communicable diseases.

"Vertical" Transmission of Oncogenic Agents

The transmission of oncogenic agents from one host to another may take place in a different manner, not usually observed in the common infectious diseases. Instead of spreading "horizontally" among hosts of the same generation, a potentially pathogenic agent may instead be transmitted from a carrier host to the host's offspring, thence to the offspring's offspring, thence, in turn, to the next generation, and so forth. Such a transmission would obviously require much more time than that observed in those communicable diseases which spread in the conventional manner within the same generation. The term "vertical transmission" or "vertical epidemic" was suggested (Gross, 1944) to designate the transmission of potentially pathogenic agents from one generation to another, usually through germinal cells, occasionally through mothers' milk, as in the case of mouse mammary carcinoma (Bittner, 1936). The agent, though potentially pathogenic, would remain latent for a long period of time, often perhaps throughout the entire life-span of a given carrier host. During such an interval of time the potentially pathogenic agent would remain frugal and moderate in its requirements, causing no harm to its carrier host. Thus the host would remain in perfect health, while carrying and transmitting the seeds of the disease.

In some of the hosts, however, particularly in those reaching middle age, the agent may become activated. Triggered by intrinsic or extrinsic stimuli, the hitherto latent and harmless agent would then change into a formidable pathogen, causing rapid multiplication of

*Special University Lecture in Pathology delivered at the London School of Hygiene and Tropical Medicine on May 16, 1958, entitled "Viral Aetiology of 'Spontaneous' Mouse Leukaemia: its Possible Implications for the Problem of Cancer." Aided, in part, by grants from the Damon Runyon Memorial Fund and the American Cancer Society.

cells harbouring it, and killing its carrier. In most instances, however, activation of the agents would not occur. The hosts would remain in good health, even though they would carry the agent and transmit it to their offspring.

The triggering factors responsible for the activation of the hitherto latent agents would be of varied nature, generally non-specific. Essentially, these triggers would be either intrinsic (metabolic or hormonal) or extrinsic (such as x rays and other forms of ionizing radiation energy, certain chemical poisons, physical factors such as prolonged irritation, etc.).

Viral Aetiology of Cancer and Leukaemia

On the basis of this working hypothesis, one could regard the development of a malignant tumour or that of leukaemia as the result of an activation, perhaps accidental, of oncogenic agents, hitherto latent, and carried by the host. Fortunately, in most instances no activation of the oncogenic agents would occur during the life-span of the host, even though such agents would be transmitted to the host's offspring. Thus only now and then malignant tumours or leukaemia would develop in some of the members of those families in which the agents would be transmitted from one generation to another. Such instances, however, representing only unhappy "accidents" in the otherwise harmonious relationship between the host and its usually well adjusted and latent oncogenic agents, would often be separated by two or three generations of healthy carrier individuals. In humans, therefore, two cases of leukaemia or other malignant tumours representing successive links in the generation-to-generation transmission of the same oncogenic agent might frequently be separated by a century or two. It is quite obvious that the tracing of the "vertical" host-to-host transmission of oncogenic agents in man would be extremely difficult.

The concept of vertical transmission of oncogenic agents may be new as applied to tumours. Actually, however, there exist in nature numerous examples of pathogenic agents transmitted from one generation to another. A virus disease of the silkworm, pebrine, is transmitted through the eggs from one generation to another (Pasteur, 1865). The mosaic disease of lettuce, tomato, or potatoes is caused by viruses transmitted from one generation to another through the seeds, or in the case of potatoes through the tubers; these viruses may remain latent for long periods of time (Kunkel, 1928). The infected plant may grow next to a healthy one, yet no transmission of the virus will occur among hosts of the same generation, unless an intermediary carrier, such as an insect vector, is interposed. In certain instances the vertically transmitted agents may be so adapted to their own hosts that they will not cause harm to their own carriers but may become pathogenic when transmitted to other breed or species. The Rocky Mountain spotted-fever rickettsiae, or the tularemia organisms, for instance, are transmitted in the tick, through the eggs of these insects, from one generation to another. They cause no harm to their carrier hosts, but may become pathogenic and cause disease when transferred to other species, such as humans.

The temperate phage may also be transmitted from one generation to another in certain lysogenic bacterial clones (Lwoff, 1953). The phage may remain perfectly harmless to its hosts, as a prophage. In very rare instances it may spontaneously become pathogenic, destroying its own host by lysis. The activation may be prompted at will, however, by certain inducing agents, such as ultra-violet (Lwoff *et al.*, 1950) or x-ray irradiation (Latarjet, 1951).

It is obvious that the vertically transmitted pathogenic agents can readily escape detection, since they are sub-microscopic, and since they only occasionally cause symptoms of disease.

Transmission of Tumours by Filtrates

It is difficult to determine the nature of an obscure disease with the rather limited means available in an experimental laboratory. One of the first steps consists usually in an attempt to transmit the disease from one host to another.

It should be stressed that there are no particular criteria to indicate, *a priori*, whether a given disease is caused by a transmissible agent. In many instances, when studying a new and obscure disease, the investigator may be confronted with symptoms appearing to develop "spontaneously." Yet the disease may be communicable, even though it may be quite difficult to trace the mode of transmission of the pathogenic agent. If experimental transmission succeeds in the laboratory by means of inoculation of filtrates, it can be assumed that the investigated disease is actually caused by a transmissible filterable agent, presumably of viral nature. It still remains to be determined, however, how the actual transmission of the agent occurs under natural conditions of life (Tables I and II).

The discovery by Ellermann and Bang in 1908 that leukaemia in chickens could be transmitted by cell-free extracts provided the first experimental support of the concept of viral nature of leukaemia. Even though the cell-free transmission was accomplished only in the fowl, it strengthened the suspicion that in mammals also leukaemia may be caused by similar filterable agents.

"Spontaneous" Mouse Leukaemia

Leukaemia occurs as a spontaneous disease in various strains of mice. In some strains, such as C3H or C57 Brown, it develops only occasionally. In other strains it is more frequent, and in two outstanding inbred strains of mice—namely, C58 and Ak—leukaemia develops spontaneously in up to 90% of middle-aged animals. (Over 25 years ago mice of the strain designated by the symbol C58, and bred by MacDowell and Ritcher (1935), were observed to die with large spleens; it was then realized that mice of this particular strain develop leukaemia spontaneously. On the other hand, Furth and his associates (1933) developed purposely a high leukaemic strain of mice by breeding selectively relatives of leukaemic mice and continuing such selective inbreeding through a number of successive generations; they designated this particular leukaemic strain by the symbol Ak. Leukaemia, usually of the lymphatic type, develops in middle-aged Ak mice of both sexes, though the onset begins slightly earlier in females. The incidence of spontaneous leukaemia in a sample of 500 Ak females was in our laboratory 94% at 8.6 average age (Gross, 1958b). It begins to develop approximately at 4 to 4½ months of

age; this incidence rises rapidly, reaching its peak at 7 to 9 months, then declines gradually.

The development of spontaneous leukaemia in over 85% of middle-aged mice in certain inbred lines of mice, such as C58 or Ak, raised immediately the question whether a virus transmitted from one generation to another in certain families of mice may not be actually responsible for the development of this disease. The existence of a leukaemic agent, though long suspected, was not established, however, until the experimental conditions were recognized under which mouse leukaemia could be transmitted by filtrates. All previous attempts to transmit mouse leukaemia by filtered extracts failed prior to 1951 (Gross, 1958b). Transmission of leukaemia in mice appeared possible only when live cells were transplanted from a leukaemic mouse to another host usually of the same or of a genetically related inbred line.

Transmission of Mouse Leukaemia by Filtrates Inoculated into Newborn Mice

A few years ago it was unexpectedly found in our laboratory (Gross, 1951a) that naturally occurring "spontaneous" mouse leukaemia could be transmitted by filtered extracts, provided that certain experimental conditions were met. Thus, newborn, less than 16 hours old, mice of a low leukaemic but susceptible inbred strain—namely, the C3H inbred line (with an incidence of spontaneous leukaemia less than 0.5%)—could be successfully inoculated with filtered extracts prepared from spontaneous Ak leukaemia.

Leukaemia developing in C3H mice following inoculation of the leukaemic filtrates was usually of the lymphatic type, and resembled essentially that which develops spontaneously in mice of the Ak strain. Of a total of 328 newborn C3H mice inoculated with filtrates, 28% developed leukaemia at an average age of 10 months. This compared with an incidence of less than 1% among 166 litter-mate controls (sister and brothers), either not treated or inoculated simultaneously with heated (65° to 68° C. for half an hour) leukaemic extracts, and surviving to an average of 16 months (Gross, 1951-8).

Surprisingly, among the inoculated C3H mice, some developed, instead of leukaemia, bilateral parotid gland carcinomas, and a few developed subcutaneous fibrosarcomas (Gross, 1953). These results were later confirmed and extended by Woolley and Small (1956), Furth *et al.* (1956), Rudali *et al.* (1956), Dulaney *et al.* (1957), Hays *et al.* (1957), and Kassel and Rottino (1958).

One of the initial difficulties in transmitting mouse leukaemia by filtrates was due to the difference in susceptibility among the strains used for inoculation of the extracts (Gross, 1955); furthermore, it soon became evident that the results of individual experiments may vary to a considerable degree, depending on the extract used. Of 70 leukaemic filtrates, each prepared from a different donor, and tested in our laboratory, 18 were found to be completely inactive on inoculation tests (Gross, 1957b).

Selecting a particularly potent extract, and passing the agent serially through several successive inoculations of newborn hosts, made it recently possible to develop a very potent filterable mouse leukaemia strain (Gross, 1957a). Filtrates prepared from this passage virus can now be inoculated into suckling C3H mice 1 to 14 days old, inducing leukaemia in up to 97% of the inoculated mice after a latency of only three to four months (Gross, 1958a).

It is quite interesting that leukaemic filtrates inoculated into C3H mice less than 16 hours old induce leukaemia, and in some instances parotid gland tumours, whereas the same filtrates inoculated into suckling C3H mice 1 to 14 days old induce leukaemia but not parotid tumours (Gross, 1958a). It appears, therefore, that in order to induce parotid tumours, newborn, less than 16-hours-old, C3H mice have to be inoculated with the leukaemic extracts.

Previous attempts to transmit Ak leukaemia by inoculation of filtrates into adult C3H mice were seldom successful. After the potency of the leukaemic agent has been increased

through serial cell-free passage, it is now possible, however, to induce leukaemia also by inoculating passage leukaemic filtrates into adult C3H mice; the incidence of induced leukaemia is approximately 37% after a latency of seven months (Gross, 1958a). Suckling, 1 to 14 days-old, C3H mice, however, are substantially more susceptible to the inoculation of the leukaemic filtrates than adult hosts.

It is apparent, therefore, that the induction of different types of tumours requires the use of a suitable recipient strain for inoculation of the leukaemic extracts. Moreover, the cell-free extracts must be inoculated into newborn mice less than 16 hours old, if the full array of the different types of tumours is to be induced.

The development of leukaemia in some of the mice inoculated with the filtrates, and that of parotid carcinomas or subcutaneous fibromyxosarcomas in others, raised immediately the fundamental question whether a single agent may be able to cause different types of tumours, or whether several distinct agents were present in the leukaemic extracts.

One could assume that one agent may be able to induce different types of tumours. It is also possible to speculate, however, that certain tumours, at least, may carry, either accidentally or for a good reason, a number of distinct oncogenic agents. Under proper experimental conditions some of these hitherto latent agents may assert themselves, inducing a wide spectrum of different tumours. Such a hypothesis would explain the puzzling results of experiments reported by Graffi *et al.* (1956) and Friend (1957).

Development of Leukaemia Following Inoculation of Newborn Mice with Cell-free Extracts from Transplanted Mouse Tumours

The use of newborn, less than 1 day old, mice for inoculation of oncogenic agents, so successful in studies on cell-free transmission of mouse leukaemia (Gross, 1951-3), soon became a useful tool, and proved a source of unexpected findings also in other laboratories.

Thus, Graffi and his co-workers prepared filtered extracts from Ehrlich ascites mouse carcinoma, and from several other mouse tumours. These extracts were then inoculated into newborn mice of a low leukaemic inbred strain (designated by the symbol Agnes-Bloom and having an incidence of spontaneous leukaemia less than 1%); newborn non-inbred mice designated by symbols M and W were also injected. As a result, 34% to 75% of the inoculated mice developed a myelogenous form of leukaemia, after an average latency varying from 113 to 224 days. The most potent extracts were those prepared from Ehrlich carcinoma and from three closely related mouse sarcomas. Of 332 control mice inoculated with either normal organ extracts from mice, rats, chickens, or rabbits, or with rat-tumour filtrates, less than 1% developed leukaemia (Graffi *et al.*, 1956).

Friend inoculated cell-free centrifuged extracts from Ehrlich ascites carcinoma into newborn Swiss mice. After a latency of 14 months, some of the inoculated mice developed a form of myelogenous leukaemia. This leukaemia was found to be transmissible by intraperitoneal inoculation of filtrates into young adult Swiss mice, inducing leukaemia after only several weeks (Friend, 1957).

It is quite possible, therefore, that there exist different forms of mouse leukaemia, caused by distinct though probably related viruses, requiring different experimental conditions for cell-free transmission. Certain leukaemic agents may require newborn hosts for transmission; others may also infect adult hosts of a suitable line. In this respect, mouse leukaemia would not be different from the various forms of chicken leucosis (Furth *et al.*, 1933; Burmester *et al.*, 1946; Beard, 1957).

Electron Microscopical Studies of the Mouse Leukaemia Agent

Electron microscopical examination of the leukaemic filtrates in drop preparations, shadowed with chromium,

revealed the presence of spherical particles, varying in average diameter between 60 and 70 m μ (Gross, 1956).

More detailed studies were possible on thin sections of the leukaemic tissues. In collaboration with L. Dmochowski, sections were prepared from thymus, cervical glands, and livers from C3H mice in which leukaemia was induced by inoculation of the leukaemic filtrates. Characteristic spherical virus-like particles, most of them averaging approximately 100 m μ , and showing dense centres, were found in large numbers in the cytoplasm and in extracellular spaces (Dmochowski and Grey, 1957). Examination of normal mouse tissues did not reveal the presence of similar virus-like particles; additional studies are necessary, however, to clarify this point further. It is possible that the particles visualized in drop preparations represent the dense centres of the large particles observed on the sections. Technical differences in the manner of preparing the drop preparations compared with ultra-thin sections may also account for the difference in size of the particles.

Multiplication of the Parotid Tumour Agent in Tissue Culture

In a series of experiments Stewart and her associates (1957) at the National Cancer Institute succeeded in demonstrating the survival and possibly also multiplication of mouse-leukaemia-derived parotid tumour agent in tissue culture media. After passing the agent through monkey kidney, or chicken chorion allantoic membrane culture media, inoculation into newborn, less than 12 hours old, (C3H $\times$ AKR) F₁ hybrid mice induced in up to 51% of the mice the development of parotid tumours and other neoplasms after a latency varying from 2½ to 10 months. Control mice injected with fluids from uninoculated tissue cultures failed to develop tumours. More recently Eddy and her associates (1958) at the National Cancer Institute made the remarkable observation that the mouse-leukaemia-derived agent passed through tissue culture media induced multiple malignant tumours, most frequently sarcomas, following inoculation into young, less than 4 weeks old, Syrian hamsters.

Attempt to Transmit Radiation-induced Leukaemia by Filtrates

One of the greatest difficulties in the proper interpretation of results obtained with experimental transmission of tumours and leukaemia by means of filtrates has been the fact that in many instances morphologically similar tumours could be obtained with chemical carcinogens, hormones, or ionizing radiation.

The fact that ionizing radiation, hormones, or carcinogenic chemicals may be able to induce tumours and/or leukaemia does not necessarily imply, however, that these tumour-inducing factors are similar in their pathogenic action to oncogenic viruses.

Theoretically, at least, it may be possible to assume that carcinogenic chemicals, hormones, or ionizing radiation may induce leukaemia in mice indirectly only, by activating latent viruses carried in an inactive form by apparently healthy hosts.

In order to determine whether radiation-induced leukaemia could be transmitted by filtrates, the following experiment was carried out (Gross, 1958c).

Leukaemia was induced in mice of a low-leukaemic strain (C3H)

by fractionated total-body x-ray irradiation (150 r once a week for four to six consecutive weeks). Up to 50% of the irradiated mice developed leukaemia after seven to nine months. An attempt was then made to recover from such mice an oncogenic agent; filtered extracts were prepared from livers, spleens, and thymic lymphosarcomas from the leukaemic donors; the filtrates so prepared were then inoculated into newborn C3H mice. Of 148 inoculated mice, 16 (11%) developed leukaemia after approximately one year, and 7 (5%) developed parotid gland tumours (Gross, 1958c). Similar results have been recently obtained by Kaplan (1958) on C57 Black mice. These experimental findings suggest that mice of a low leukaemic strain may carry a latent leukaemogenic agent of a low pathogenic potential. When triggered by repeated total-body x-ray irradiation such an agent may become pathogenic, and induce leukaemia in its hosts. Once activated, this agent may then, at least in some instances, be separated from cells by filtration, and transmitted by inoculation into newborn hosts of a susceptible strain.

There may exist a large variety of tumours which, although similar in their morphology, may be individually distinct. It is entirely possible that ionizing radiation, hormones, or chemical carcinogens merely activate latent oncogenic viruses; their tumour-inducing action could thus be compared to the experimental induction of bacteriophages in lysogenic bacteria (Lwoff, 1953). Accordingly, oncogenic viruses could be compared to temperate bacteriophages, transmitted from one generation to another in lysogenic bacterial hosts, only very occasionally killing their carriers (Gross, 1954; Latarjet, 1954).

Should this hypothesis prove to be correct, it would then logically follow that individuals with symptoms of tumours or leukaemia would represent only a small fraction of those actually carrying the seeds of either disease. This concept would also explain the striking though not too frequent cases of familial occurrence of tumours and leukaemia not only in animals but also in humans. Although in most instances cancer or leukaemia occurs in man only sporadically, yet numerous instances, some of them striking, have been recorded in which malignant tumours and/or leukaemia developed in two or more members of the same family, either within the same or in successive generations. Cases of either tumours or leukaemia developing in brothers, brothers and sisters, or in a child and in one of its parents, grandparents, aunts, uncles, or cousins, have been recorded by numerous observers. One of the most striking families

has been reported by Anderson (1951): five out of eight siblings developed leukaemia when 5 to 8 years old.

Vertical transmission of potentially pathogenic agents should not be confused with inheritance. The differentiation is not always easy. When observing a disease appearing in several descendants of successive generations within the same family of hosts, a casual observer may consider such cases to be caused by some obscure inherited genetic factors. Yet inheritance is conditioned by genetic factors, transmitted in an orderly and foreseeable manner, and is not acquired. Vertically transmitted diseases, on the other hand, are caused by viral agents, and represent a form of infection. The potentially pathogenic agents had been most probably at one time acquired, even if this might have happened in individual families many thousands of years ago; transmitted, since that time, from one generation of their hosts to another, invisible and completely adapted, such agents represent examples of "perfect parasites," causing in most instances no harm to their hosts. Only now and then, prompted by obscure reasons, they may change into formidable pathogens, causing symptoms of fatal disease and destroying their hosts. Such "accidents," however, would be usually separated by several generations of apparently healthy carrier-hosts.

It is quite possible that not only in animal species but also in humans malignant tumours, including the various forms of leukaemias, are caused by oncogenic agents seeded in millions of apparently healthy hosts and transmitted from one generation to another (Gross, 1954).

EFFECT OF INSULIN AND GLUCAGON ON TUMOUR GROWTH

BY

J. M. SALTER, Ph.D.

R. DE MEYER,* M.D.

AND

C. H. BEST, M.D., F.R.S.

The Banting and Best Department of Medical Research,
University of Toronto, Toronto, Ontario, Canada

During the past few years we have been working on certain problems related to both insulin and glucagon (Salter and Best, 1953; Salter *et al.*, 1957a, 1957b; Davidson *et al.*, 1957). There is considerable evidence in the earlier literature that insulin may cause some inhibition in the growth of malignant tissue (Piccaluga and Cioffari, 1925; von Witzleben, 1925; Silberstein *et al.*, 1927; Gomes da Costa, 1931).† The results of experiments carried out in this laboratory are in general agreement with these earlier reports. We find that, although the effects of giving insulin to rats bearing the Walker carcino-sarcoma vary considerably, a small but significant inhibition of the growth of this tumour is produced in most instances. The findings presented in this preliminary communication show, for the first time, that glucagon alone also produces a significant inhibition in the growth of this tumour, while the simultaneous treatment with both glucagon and insulin consistently causes an inhibition that is considerably greater than the sum of their individual effects.

Methods

Female Wistar rats weighing approximately 150 g. were used in all experiments. The animals were fed powdered Purina chow containing 5% corn oil.

Walker carcino-sarcoma tissue was collected from several donor rats, pooled and macerated with three parts (by weight) of 0.9% saline until the resultant brei would pass through a 23-gauge hypodermic needle. Each animal was then injected in both gastrocnemii with 0.2 ml. of the suspension. Treatments were started three days after the inoculations. At this stage the tumours were just palpable. In every experiment all rats had palpable tumours at the start. Protamine-zinc insulin (P.Z.I.) was injected once daily at 3 p.m. Crystalline glucagon suspended in 0.9% saline was administered subcutaneously at 9 a.m., 3 p.m., and 9 p.m. The rats were sacrificed after 10 to 15 days of treatment. The back legs were skinned, carefully disarticulated at the hip-joint, and removed. Tumour weights were determined by subtracting from the weight of the tumour-bearing leg the average weight of the normal hind limb in rats of the same size. The doses of insulin and glucagon and other relevant data are given in the Table.

Results

The results of the experiments are also presented in the Table. In Experiment 1 the administration of insulin inhibited the growth of the tumour by 10%, while in

*On leave of absence from Professor J. P. Hoet's Department, University of Louvain, Belgium.

†Our former colleague, Dr. Spencer Monroe, now of the Sloan-Kettering Institute for Cancer Research, has recently discussed with us his observations on the dramatic inhibition by insulin of the growth of Rous sarcoma in chickens.

Experiment 5 no inhibition was discernible. In a large series of other trials not reported here, insulin consistently produced a small but significant slowing of the tumour growth. This inhibition occurred only when the food intake of the treated animals was restricted to the level of the controls.

The retardation of growth of the tumour induced by glucagon alone has varied from 20 to 40%. This inhibition can be attributed, in part, to the reduction in food intake and the adverse effect of glucagon on the growth of the rat as a whole (Salter *et al.*, 1957b). Although the rats treated with both insulin and glucagon lose less weight than animals given glucagon alone, inhibitions of tumour growth of 60-70% have been obtained invariably. The inhibition is not therefore proportional to the weight loss. In each experiment the carcinostatic action of the combined therapy has been much greater than the sum of the individual effects of the two substances.

Discussion

The data show that both insulin and glucagon produce some inhibition, which is, on the average, about 10% for insulin and approximately 30% for glucagon. Together

Fig. 1.—The upper animal was treated with both glucagon and insulin. The tumours present in the back legs are barely discernible, while those in the control animal, immediately below, are obviously much larger.

that a prolonged remission may have taken place, but there is no proof as yet that this can actually be made to happen.

Hypoglycaemia still presents a serious problem, but the experience we have gained enables us to control the level of blood sugar better than was possible initially. A long-acting glucagon would be of great value in these studies.

If we consider for the moment only the control animals and those which have received insulin and glucagon together there have been in all 67 controls and 77 treated with the two substances. The inhibition of tumour growth produced by glucagon and insulin together has been remarkably consistent, but a great deal of further work will have to be done on this tumour and on others to determine the maximum extent and duration of the inhibition and the frequency with which it takes place in various species of animals. Dr. E. S. Goranson, of the Ontario Cancer Institute, working with one of us (J. M. S.), has already repeated our experiment, and has found that an extensive inhibition (80%) is exerted by insulin and glucagon together on the growth of the Novikoff tumour in rats. There was a negligible difference in the weight of the control and test animals at the end of the experiments. Studies of various other tumours are under way.

Fig. 2.—The tumours of the rats from Fig. 1 are shown after surgical exposure (circled in white). The tumour on the right is from the glucagon-insulin treated rat. The inhibition evident here is slightly greater than usual, but we have seen even more pronounced inhibition in some instances.

they exert from 60 to 70% inhibition of growth of this particular tumour (Figs. 1 and 2).

We have thus far only established that the inhibition persists while insulin and glucagon are being administered. Cessation of treatment is followed by resumption of growth of the tumour. There has been a suggestion in a few cases

It is abundantly clear that these findings demand, and that they will probably stimulate, an even more vigorous exploration of the metabolic effects of insulin and glucagon given together. No attempt will be made here to review the controversial literature on this subject. If glucagon supplements the peripheral action of insulin on normal

tissue, the effects of the two together in "starving" the tumour may be supplementary. Equally plausible suggestions may be based on the possible katabolic effects of glucagon on the tumour itself. Both mechanisms could be involved.

The field of tumour growth is notorious for the frequency of pitfalls. We have seen no indication that the effect we are investigating is due to a contaminating infectious agent or to other artifacts. These may, of course, emerge later and necessitate a change in the interpretation of our findings. We have obtained glucagon from two sources—Indianapolis and Toronto. The various lots of insulin have been made in Toronto.

It is obvious that, if this phenomenon of the extensive inhibition of tumour growth by insulin and glucagon together is observed in a large number of other tumours in various species of animals, a clinical trial of the substances may become very tempting. Some aspects of the investigation would be easier to control in the hospital than in the experimental laboratory. Clinically the two substances could be given by continuous intravenous drip and the hypoglycaemia which has plagued us could be detected at an early stage. Frequent blood-sugar estimations have not been considered advisable in the small animals. A sufficient number to establish low blood sugar as the cause of death in the insulin-treated animals which succumbed have been made. A great deal more should be learned in experiments on animals before any clinical study is seriously considered. An inhibition which persists only during the administration of the substances would be of limited clinical interest. The obvious possibility of using other substances to supplement the inhibition produced by insulin and glucagon is being explored.

We are indebted to Mrs. H. Vilup, Mrs. C. Hooper, and Mr. Gunther Brunet for their efficient technical assistance. This work has been supported in part by funds from the Foster Bequest of the University of Toronto and the National Research Council of Canada. We wish to thank the Connaught Medical Research Laboratories for the insulin and some of the glucagon which we have used. Our major source of glucagon has been Eli Lilly and Company.

Dr. A. J. DALZELL WARD, medical director of the Central Council for Health Education, said at a recent press conference on the dangers of the common housefly, "Eggs laid last autumn are now hatching out. It takes about 12 days for the egg to hatch and another 12 days to reach maturity. During its brief life the housefly can lay about 900 eggs. Within a couple of months or two generations, therefore, some 800,000 (certainly half a million) flies can come from one fly. In other words one fly can have 800,000 grandchildren." Dr. Ward went on to describe prophylactic measures against the housefly. Obviously the best way to stop this menace to health was to prevent them breeding, he said. The lids of dustbins should be tight and not battered. The bottoms of dustbins should be kept clean and dry, and if possible sprayed with insecticide, preferably one containing D.D.T. It was a good thing to line the bottoms of dustbins with newspaper and renew this whenever they were emptied. As much rubbish as possible should be burned and the remainder, if burning was not possible, kept wrapped and covered until disposed of.

The housefly could and did travel as much as 10 or 12 miles (16-20 km.) from its breeding-place.

OOPHORECTOMY IN BREAST CANCER AN ATTEMPT TO CORRELATE CLINICAL RESULTS WITH OESTROGEN PRODUCTION

Medical and Surgical Units, St. Bartholomew's Hospital, London

The treatment of metastatic breast cancer by surgical castration is the oldest rational method of palliation for this disease (Beatson, 1896). In the series reported by Thomson (1902) and Lett (1905) objective signs of growth regression in pre-menopausal women were observed in 25% of cases. On the other hand, and in sharp contrast, growth regression was limited to a single instance in a series of 25 post-menopausal women.

From 1910 onwards the usefulness of surgical castration was seriously questioned. For over thirty years it was generally discredited, and it was not reinstated until 1942 (Farrow and Adair, 1942) and Beatson's original and cautious claims were confirmed (Adair *et al.*, 1945; Sicard, 1947; Dargent, 1949). Objective remissions in post-menopausal cancer were again shown to be very uncommon.

The therapeutic purpose of surgical castration in pre-menopausal breast cancer is to arrest the progress of the disease by removing the source of ovarian oestrogen production. The palliation induced by this surgical manoeuvre is clearly and intimately related to the regressions which are frequently observed during the "physiological castration" of a natural menopause in breast cancers which, arising during the pre-menopausal period, have already metastasized by the time the patient enters the menopausal phase (Clemmesen, 1948; Hadfield and Holt, 1956).

Laboratory studies of the effectiveness of oophorectomy in abolishing oestrogen production have not been numerous. Bio-assays or biochemical estimations of urinary oestrogens have been reported by Smith and Emerson (1954), Dao (1953), Bulbrook and Greenwood (1957), and McBride (1957), and studies of vaginal cytology were published by Struthers (1956). These investigations revealed that, whilst surgical castration does not abolish the excretion of oestrogens, it does significantly reduce the excretion in pre-menopausal women.

None of the above authors attempted to correlate the immediate and long-term fluctuations in urinary oestrogens with the clinical consequences of the operation. In the present communication this correlation has been attempted.

Material and Methods

All clinical regressions recorded have been based exclusively on observable objective improvement in superficial lesions or in deep lesions visualized by radiography, and all clinical assessments were made without prior knowledge of the biochemical estimations.

Oestrogen-excretion studies were carried out in hospital. Patients were divided into two groups. Those

* Food intake restricted to this amount. † All deaths due to hypoglycaemia.

Figure represents weight of carcass exclusive of tumour.

in the first group had been oophorectomized before this investigation began and no pre-operative oestrogen levels were available. In the second group pre- and post-operative values were determined and the change in oestrogen excretion induced by the operation could be clearly defined.

After discharge all patients attended hospital at monthly intervals, whenever possible bringing a 24-hour specimen of urine. Some were readmitted for several days for clinical assessment and further oestrogen estimations. In a few cases the 24-hour urine specimen was collected from the patient's home. All patients were warned against the use of the several aperients which interfere with oestrogen analysis.

Vaginal smears were taken from the majority of patients and were graded as showing high, moderate, or low oestrogenic activity.

Chemical Methods.—Urinary oestrone, oestradiol-17 β , and oestriol were measured by the method of Brown (1955a) or by the modification proposed by Brown, Bulbrook, and Greenwood (1957a). Results are expressed in $\mu\text{g./24 hours}$ for each oestrogen, or as their sum. Analyses are shown as zero when the amounts of each oestrogen were less than the calculated limits of sensitivity of the method (Brown, Bulbrook, and Greenwood, 1957b). In Case 10, 17-oxosteroids and 17-oxo-genic steroids were estimated by the methods of Norymberski, Stubbs, and West (1953) and Gibson and Norymberski (1954), and pregnanediol by the method of Klopper, Michie, and Brown (1955). The results of both analyses are expressed in mg./24 hours .

1. Clinical Effects and Hormone Excretion After Oophorectomy in Pre-menopausal Women

All patients in this group had a regular menstrual history up to the time of operation. Analyses were carried out on 230 urine specimens from 24 patients in whom progressive metastatic breast cancer had developed after oophorectomy. The mean daily amount of oestrogen was calculated for each patient. These amounts showed no correlation with the time after oophorectomy, and the amounts shown in Table I are the overall means for the 24 patients studied from 1 to 60 months after operation.

TABLE I.—Oestrogen Levels 1 to 60 Months After Oophorectomy in 24 Pre-menopausal Women (230 Analyses)

	Oestrone	Oestradiol-17 β	Oestriol	Total
Arithmetical mean	1.8	0.6	2.9	5.3
Standard deviation	1.0	0.8	2.2	2.6

Results expressed in $\mu\text{g./24 hours}$.

Table I shows that in this group of women the level of oestrogen excretion was much lower than has been found during the normal menstrual cycle.

Four patients treated by oophorectomy for metastatic breast cancer were studied individually at intervals after operation. These patients had shown a regular menstrual history up to the month of operation. In two cases pre-operative oestrogen levels were not estimated, and it was assumed that these were within the normal range (Brown, 1955b). The detailed results are shown in Figs. 1 to 3.

Case Reports

Case 1 (Fig. 1).—This patient was a single woman aged 36. Eleven months after mastectomy, metastases appeared in the ribs, spine, and pelvis; no ovarian or other soft-tissue deposits were detected. Bilateral oophorectomy was carried out. Oestrogen analyses were started two weeks after operation, and up to one month after operation the mean amount of oestrogen was only $2.8 \mu\text{g./24 hours}$. A substantial fall

in oestrogen excretion from the pre-operative level may be assumed to have taken place accompanied by objective

FIG. 1.—Case 1. Excretion of oestrogen after bilateral oophorectomy. In all figures the day of operation is marked with a vertical arrow. Oestrogen excretion is shown as total oestrogen—the sum of the oestrone, oestradiol-17 β , and oestriol values. In Figs. 1-6 each vertical column gives the mean of a duplicate determination on a 24-hour specimen of urine. Open circles on the abscissa indicate no detectable oestrogen.

remission of the disease for four months following operation. Intermittent analyses from two to three months showed an increase in the mean oestrogen level to $3.9 \mu\text{g./24 hours}$. The patient was readmitted to hospital seven months after oophorectomy, and cortisone therapy was initiated, and for a period of three months only trace amounts of oestrogen were detected. In spite of this, from the fourth to the tenth month after oophorectomy there was progressive growth in the skeletal metastases.

Case 2 (Fig. 2).—This patient, aged 53, married, had been menstruating regularly until 10 to 12 months before she was first seen; during that time she had serious menorrhagia.

FIG. 2.—Case 2. Excretion of oestrogen after bilateral oophorectomy.

On admission she had gross pseudo-inflammatory malignant extension in the left breast, hard axillary glands on the same side, and the liver was palpable one fingerbreadth below the costal margin. No skeletal metastases were detected. There were multiple uterine fibromyomata. Hysterectomy and bilateral oophorectomy were performed. Examination of the liver at operation showed multiple metastases in the right lobe. The mean total oestrogen in the first month after oophorectomy was $5.8 \mu\text{g./24 hours}$. Analyses at 7, 10, and 11 months later showed similar values, suggesting that at no time had oestrogen excretion reached zero. Over this period the breast became shrunken and softer, the skin reaction faded, and the nodes decreased in size.

Case 3 (Fig. 3).—This patient was aged 54 and married. Over the previous eight years, and after a left radical mastectomy, the intermittent appearance of clavicular, intercostal, sternal, costal, and supraclavicular swellings had been treated by deep x rays. When admitted to hospital she had pelvic bone metastases and a left pleural effusion. Admission interrupted an otherwise regular history of menstruation. The vaginal smear indicated high oestrogenic activity. Urinary excretion of oestrogen was irregular but showed a normal excretion pattern of the individual oestrogens and a total amount within the normal range (Brown, 1955b). 17-oxosteroid excretion was normal and relatively constant at 3.4 mg./24 hours . Operation revealed metastatic deposits in both ovaries. Oophorectomy produced an arrest in growth but no objective regression for a period of three

months, associated with a reduction in mean oestrogen excretion from 15.5 to $3.9 \mu\text{g./24 hours}$, and a change in the appearance of the vaginal smear from high to moderate activity in the first two months after operation. The pre-operative lesions were virtually unchanged over the three-

FIG. 3.—Case 3. Excretion of oestrogen before and after bilateral oophorectomy.

months period and a return to active growth and the reappearance of other skeletal secondaries was preceded by a slight rise in oestrogen excretion ($5.3 \mu\text{g./24 hours}$) and a return of the vaginal smear to one of high oestrogen activity. Intermittent analyses from the fourth to the sixth month after operation showed an irregular excretion around a mean value of $3.2 \mu\text{g./24 hours}$. The patient died seven months after operation. Post-mortem examination revealed diffuse carcinomatosis; secondary deposits were found in the adrenal glands.

Case 4.—This patient, aged 44, married, had a history of recurrence of growth after a previous mastectomy similar to that described in Case 3. Oestrogen excretion before operation showed a similar picture—irregular excretion but a normal pattern and total amount; the mean pre-operative level was $14.4 \mu\text{g./24 hours}$. Clinically, oophorectomy had no effect, but regression of the lesions was obtained by irradiation from one to three months after operation. Oestrogen levels were investigated only at the fourth month. At this time oestrogen was still present, although in amounts ($3.3 \mu\text{g./24 hours}$) well below the mean pre-operative level. The patient died seven months after operation. Post-mortem examination showed diffuse carcinomatosis.

Summary of Findings in Pre-menopausal Group

The mean excretion of Cases 3 and 4 before operation was about $15 \mu\text{g./24 hours}$. Similar figures have been given for pre-menopausal women with breast cancer (Birke *et al.*, 1958) and for normal women (Brown, 1955b). The results shown in Table I, and Figs. 1 to 3, afford further evidence that oophorectomy in pre-menopausal women removes a major source of oestrogen production. Although well marked in Cases 3 and 4, the reduction in oestrogen excretion was not accompanied by objective remission of the disease.

The range and mean levels of oestrogen excreted after oophorectomy demonstrate that adrenal secretion of oestrogen is always detectable after operation and can vary within wide limits. The results obtained in the first few days after operation (Case 3) suggest that the adrenal glands contribute to excretion before oophorectomy, and this component may be temporarily increased by operative stress.

The finding that adrenal secretion of oestrogen is usual after oophorectomy would afford at least a rational explanation for the clinical failure of the operations in Cases 3 and 4, but remission of the disease was obtained in Cases 1 and 2, although oestrogen was always detectable in the urine. The levels of oestrogen in the latter cases do not differ from the levels found in the group with progressive disease (Table I).

2. Clinical Effects and Hormone Excretion After Oophorectomy in Menopausal Women

For the purpose of this paper we have defined as "menopausal" those women who last menstruated less than a year before oophorectomy. A group of six patients who had been oophorectomized for metastatic breast cancer during

the menopause was investigated. Oestrogen studies after oophorectomy were made at a time when the disease had recurred, from 1 to 24 months after operation, in these patients. Table II shows the mean oestrogen levels based upon the analysis of 50 urine specimens from the six patients. The amounts and pattern of oestrogen excreted do not differ from that found in the pre-menopausal group (Table I).

TABLE II.—Oestrogen Levels 1 to 60 Months After Oophorectomy in Six Menopausal Women (50 Analyses)

	Oestrone	Oestradiol-17 β	Oestriol	Total
Arithmetical mean	1.8	0.4	3.9	6.1
Standard deviation	1.5	0.5	5.3	6.4

Results expressed in $\mu\text{g./24 hours}$.

More detailed studies were made on four menopausal patients with metastatic breast cancer.

Case 5 (Fig. 4).—This patient, aged 45, married, had a previous history of mastectomy, with the later appearance

FIG. 4.—Case 5. Excretion of oestrogen before and after bilateral oophorectomy.

FIG. 5.—Case 6. Excretion of oestrogen before and after bilateral oophorectomy.

of supraclavicular nodes. These and subsequent pelvic bone deposits were treated by deep x-ray therapy. Periods were regular until nine weeks prior to oophorectomy but had ceased at this time incidental to the deep x-ray therapy. Excretion of oestrogen was very low, but oophorectomy occasioned a transient though pronounced rise in excretion. An objective regression of five months' duration followed oophorectomy. No oestrogen could be detected three months after operation. The disease progressed from the sixth month until death, 13 months after operation. Oestrogen excretion during this period had returned to a mean value of $5.2 \mu\text{g./24 hours}$, above the pre-operative level of $1.9 \mu\text{g./24 hours}$.

Case 6 (Fig. 5).—This patient, aged 55, married, had a six-months history of a lump in the breast with involvement of the axilla. Treatment by deep x rays to the breast and axilla was started. Menstruation had been regular until six months before operation. Just before operation the

vaginal smear showed moderate to high oestrogen activity, but the total amount of oestrogen was low. The immediate effect of oophorectomy was difficult to evaluate, since deep x-ray treatment was continued. A very low level was found in the first month after operation. Clinically some subjective improvement was noted for the first post-operative month, but by the third month deep x-ray treatment to the breast and axilla was resumed. Subsequent progression of the disease, with the appearance of new lesions, was noted over a period from the fifth to the seventeenth month after operation. Oestrogen excretion had increased by the tenth month, and a further very marked rise was shown in the seventeenth month, a few days before death.

Case 7.—This patient was single, aged 42. Fifteen months after mastectomy and deep x-ray treatment for carcinoma of the right breast she developed a pleural effusion and metastases in the spine, ribs, and pelvis. Pre-operative oestrogen (2.6 μ g./24 hours) and 17-oxosteroid excretion (1 mg./24 hours) were low. At operation both ovaries contained secondary deposits. Both oestrogen and 17-oxosteroid excretion were raised above the pre-operative levels in the month after oophorectomy (7.6 μ g./24 hours and 5 mg./24 hours respectively). The progress of the disease was not affected by operation. Some palliation was obtained with deep x-ray treatment, but the patient died four months after oophorectomy with widespread pleural and pulmonary metastases and skeletal deposits. At post-mortem examination deposits were found in both adrenal glands.

Case 8.—This patient, aged 51, married, had a seven-months history, before oophorectomy, of an inoperable carcinoma of the left breast with gross skin and axillary node involvement. Improvement had been obtained by deep x-ray treatment and the disease appeared to be responding. Four months prior to operation vaginal smears showed high oestrogenic activity. At operation oestrogen excretion was not high (3.6 μ g./24 hours) and an atypical fall to zero was obtained up to the time of discharge, the 17-oxosteroid excretion being unchanged by operation. An objective regression lasting for three years followed oophorectomy, but as it has been impossible to carry out further investigations it is not known whether oestrogen secretion has returned or not.

Summary of Findings in the Menopausal Group

The oestrogen levels of the individual patients before and after operation do not differ from those found in the group of patients studied after operation (Table II). The pre-operative levels are low compared with those found in pre-menopausal women, and suggest that in the menopausal cases an ovarian contribution was absent before operation. The immediate effects of operation on oestrogen excretion in this small series show three variations: unchanged, increased, and decreased excretion.

The immediate effects of oophorectomy on oestrogen secretion would appear to be determined by the degree of operative stress and the individual reaction to this. In the two cases followed for some time after operation the immediate effects were not maintained. In Case 5 the excretion fell to zero over a period of remission, and rose with the progression of the disease; in Case 6 the oestrogen excretion, unchanged by operation, rose as the disease progressed.

The four cases show a clear association between the effects of oophorectomy on oestrogen excretion and the clinical state. The operation was not effective in two cases showing an increased or unchanged excretion, but objective regressions were produced in the two cases in which oestrogen excretion fell to zero. In one of the latter, oestrogen excretion returned when the patient relapsed.

3. Clinical Effects and Hormone Excretion After Oophorectomy in Post-menopausal Women

We have defined as "post-menopausal" those women who had not menstruated for at least one year before

TABLE III.—Oestrogen Levels 2 to 8 Years after the Menopause in 16 Post-menopausal Women (81 Analyses)

	Oestrone	Oestradiol-17 β	Oestriol	Total
Arithmetical mean	1.8	0.9	2.4	5.0
Standard deviation	1.3	1.3	2.1	2.6

Results expressed in μ g./24 hours.

TABLE IV.—Oestrogen Levels 2 to 36 Months After Oophorectomy in Six Post-menopausal Women (31 Analyses)

	Oestrone	Oestradiol-17 β	Oestriol	Total
Arithmetical mean	1.8	0.9	3.5	6.3
Standard deviation	1.0	0.6	1.9	2.7

Results expressed in μ g./24 hours.

Fig. 6.—Case 9. Excretion of oestrogen before and after bilateral oophorectomy.

oophorectomy. A comparison of the oestrogen excretion levels of a group of post-menopausal women with metastatic breast cancer with the readings from a similar group after oophorectomy shows that the results are the same in the two groups (Tables III and IV) and suggest that oophorectomy has no effect on oestrogen excretion.

Four cases studied before and after oophorectomy conform to this general pattern, and in these no regression of the disease was obtained. In addition, three of the four cases showed an increased excretion of oestrogen within the first weeks after operation. Case 9 illustrates the general findings in this group.

Case 9 (Fig. 6).—The patient, aged 52, married, had a one year's history of inoperable breast cancer treated by deep x rays, and subsequently by oophorectomy for skeletal metastases, with no effect. The disease slowly progressed, and by the ninth month after opera-

Fig. 7.—Case 10. Excretion of steroids before and after mastectomy. Each vertical column gives the mean of a duplicate determination for oestrogen, pregnanediol, 17-oxosteroid, and 17-oxogenic steroid on a 24-hours specimen of urine.

tion the breast had ulcerated and the bone metastases had spread. The patient died 11 months after operation. The immediate effects of operation are shown in Fig. 6. The mean pre-operative level was 9.2 μ g./24 hours, and in the first two weeks there was a marked adrenal reaction to operation, the mean level being 12.7 μ g./24 hours.

A more detailed study of operative stress is shown in Case 10.

Case 10 (Fig. 7).—The patient, aged 56, married, was post-menopausal, had an operable breast cancer, and was treated by mastectomy only. The rise in oestrogen excretion was not marked and took place from the first to the fourth day after operation before reaching pre-operative levels. The increase in 17-oxosteroid, 17-oxogenic steroid, and pregnanediol excretion was more marked, and occurred on the first and second days after operation.

Summary of Findings in the Post-menopausal Group

As with the group of menopausal women, the immediate effect of oophorectomy may be an increase in oestrogen excretion due to operative stress. The overall effect of oophorectomy in the post-menopausal women is that both the clinical course of the disease and the oestrogen levels remain unaltered.

Discussion

The levels of urinary oestrogen found after oophorectomy in pre-menopausal, menopausal, and post-menopausal women with metastatic breast cancer are similar in amount and pattern to those of normal menopausal and post-menopausal women. It is only in pre-menopausal women that a post-operative fall invariably takes place. In all three groups there are considerable variations in the total amount of oestrogen excreted after operation, and the quantity varies from one patient to another and in each patient at different times. In many instances the levels approach those found in normal menstruating women. On the other hand, oestrogen excretion is rarely recorded as being below 1 to 1.5 μ g./24 hours, the arbitrary limit imposed by the sensitivity of the chemical method used.

The failure of surgical castration to reduce oestrogen excretion in menopausal and post-menopausal women is probably related to variations in the relative amounts of oestrogen contributed by the ovary on the one hand and the adrenal on the other. No fall in oestrogen could be expected if the ovarian contribution were negligible, whilst a post-operative suppression of ovarian oestrogen production could be offset by an increase of adrenal oestrogen production, such adrenal overactivity being a possible result of operative stress. This interpretation of our clinical and biochemical observations in menopausal and post-menopausal women affords some justification for further endocrine ablation as the subsequent treatment of choice. Adrenalectomy would be expected to accomplish both a steep fall in oestrogen excretion and a reduction below a critical level, which in all probability varies from patient to patient.

The removal of the pre-menopausal ovaries, although reducing oestrogen excretion, is not always accompanied by regression of the disease. There are several possible explanations for this observation, but no definite conclusions can be drawn from the data presented in this paper. For example, the beneficial effects of oophorectomy in some pre-menopausal women may depend upon the extent of the post-operative fall in oestrogen production. This is unlikely to be constant in all patients submitted to oophorectomy, since it depends upon the relative contributions of the ovaries and adrenal glands pre-operatively, the stressing effect of the operation on adrenal secretion, and the "resting" level of adrenal oestrogen production. Each of these factors is known to vary widely from patient to patient (Brown, 1958; Pirke *et al.*, 1958; this paper), and this would

provide an adequate basis for the variation to be expected in the extent of the fall in oestrogen production after oophorectomy.

Alternatively, the clinical success of oophorectomy may depend upon the reduction of circulating oestrogen below a critical level irrespective of the pre-operative level. If this be attained regression might follow. On the other hand, such a period of growth remission could be interrupted by a period of progressive growth if adrenal oestrogen production were increased by a sustained episode of traumatic stress. The well-attested variation in the capacity of the adrenal glands to take over oestrogen production after surgical castration has already been emphasized and the absence of oestrogen in two cases in objective remission may well be significant examples of this phenomenon.

For this discussion we have used the simple example of oestrogen reduction. It must be appreciated that the effects of oophorectomy, like the effects from the natural menopause, are not those of simple oestrogen removal or reduction, but involve a complex of changes which result in a gross disturbance of both adrenal and pituitary function in addition. It is probable that tumour regression is not related to simple changes in oestrogen, but is related to the whole complex of changes by alteration in oestrogen, progesterone, and pituitary hormone variation.

Summary

The effects of bilateral oophorectomy upon the clinical state and oestrogen excretion have been studied in patients with metastatic breast cancer.

Objective remission in pre-menopausal women after oophorectomy was not invariable, despite a fall in oestrogen excretion. Possible reasons for this are presented.

Objective remission in menopausal and post-menopausal women appeared to be unlikely unless the ovarian contribution of oestrogen was significant and adrenal secretion of oestrogen unaffected by operation.

Oestrogen derived from the adrenal glands appears to be present in all patients after oophorectomy. The removal of this source of production by further endocrine surgery appears to be indicated when oophorectomy fails to arrest the progress of the disease.

We are grateful to the surgical staff and the staff of the radiotherapy department of St. Bartholomew's Hospital for allowing us to investigate patients under their care, and particularly to Professor Sir James Paterson Ross, who has also been most helpful with his advice and criticism.

ADRENALECTOMY IN BREAST CANCER

AN ATTEMPT TO CORRELATE CLINICAL RESULTS WITH OESTROGEN PRODUCTION

BY

London

Continued excretion of oestrogen produced by the adrenal cortex occurs after oophorectomy in the majority of women with breast cancer. In 1945 Huggins and Scott performed bilateral adrenalectomy in four cases of advanced breast and prostatic cancer in an attempt to remove the second source of oestrogen production from the body. One patient survived for 116 days in a hypo-adrenal state, with some objective improvement in skeletal metastases. When cortisone became available the operation was carried out in 18 cases (Huggins and Bergental, 1952). Seven were women suffering from cancer of the breast, and clinical improvement was induced in all of them. The results stimulated great interest in the subject, and since 1952 many series of cases have been reported. It seems that bilateral adrenalectomy can play a definite and sometimes valuable part in the palliative treatment of breast cancer.

When adrenalectomy fails to induce a growth regression in breast cancer, oestrogen independence is generally assumed to be the cause. A second possible explanation was suggested by the reports of Scowen (1955) and of Struthers (1956), who found that oestrogen secretion could continue after bilateral adrenalectomy, as judged by the appearance of the vaginal smear. This was an unexpected result at that time, but these findings have since been confirmed by urinary oestrogen estimations, using Brown's (1955) chemical method (Greenwood and Bulbrook, 1956; Bulbrook and Greenwood, 1957), and also by biological assay (Dao, 1957; Bulbrook *et al.*, 1958c).

We have been unable to find any published reports in which an attempt has been made to correlate oestrogen excretion with the patient's clinical state after adrenalectomy. This paper reports such a survey of 13 cases of metastatic breast cancer in women treated by bilateral adrenalectomy.

Methods

Chemical.—The chemical method of Brown (1955) for the determination of urinary oestrone, oestradiol-17 β , and oestriol was used initially. This technique gives an underestimate of the amount of oestradiol-17 β and oestriol when cortisone is administered to the patient. A minor modification removes this source of interference, but a variety of drugs and aperients can lead to an overestimate of the amount of oestrogen in the urine (Brown *et al.*, 1957). Oestrogen excretion is recorded as below the limit of sensitivity of the chemical

method. This is an arbitrary limit which can be lowered by the more sensitive biological assay (Bulbrook *et al.*, 1958c).

Clinical.—In this series regression is defined as objective improvement in either surface lesions or in deep metastatic lesions visualized by radiography. Clinical assessments were carried out without prior knowledge of the biochemical results. The patient's age quoted is that at the time of adrenalectomy. Thirteen patients with metastatic breast cancer were studied; in seven cases urinary oestrogen estimations were carried out before and after adrenalectomy and at intervals after operation; in the remaining six, only post-operative estimations were carried out.

The cases are divisible into two groups: those in objective remission, and those in relapse.

Oestrogen Excretion in Patients During Objective Remission

Of the 13 patients studied, only three were in remission at the time the oestrogen estimations were carried out. The detailed results are described below.

Case 1 (Fig. 1).—The patient, aged 48, was married. Ten years after left radical mastectomy the wound ulcerated. Seven years later, when she was 46 years old, she was treated by oophorectomy, with some benefit for six months, although the wound did not completely heal. Two years later there was gross ulceration of the chest wall spreading into the axilla; there was no evidence of distant metastases. Bilateral adrenalectomy was performed and induced

FIG. 1.—Case 1.—Excretion of oestrogen before and after bilateral adrenalectomy. In Figs. 1, 2, and 4 the day of operation is marked with a vertical arrow. In all Figs. the oestrogen excretion is shown as total oestrogen—the sum of the oestrone, oestradiol-17 β , and oestriol values. Each vertical column gives the mean of a duplicate determination on a 24-hour specimen of urine. Open circles on the abscissa indicate no detectable oestrogen.

regression of the growth, which has been maintained for eight months. Before adrenalectomy the mean total oestrogen level was 3.7 μ g./24 hours; after operation zero levels were frequent, with occasional small amounts of oestrogen found in some specimens of urine. At subsequent follow-up at intervals after operation, oestrogen was occasionally detected in the urine. Thus in this case regression of the tumour was associated with the virtual disappearance of oestrogen from the urine.

Case 2 (Fig. 2).—This patient, aged 42, married, underwent oophorectomy three and a half years after radical mastectomy because of the appearance of metastases in the left axilla and supraclavicular glands. There were no pulmonary or skeletal secondaries. The operation led to a short symptomatic regression, but skeletal secondaries ultimately developed. Two years and nine months after oophorectomy, bilateral adrenalectomy was carried out. An objective remission was induced. This lasted for four months, during which time a pathological fracture of the ulna healed and secondary deposits in the skull became smaller and calcified. During this period oestrogen excretion was reduced but not entirely abolished. Zero values were uncommon, and the mean total level of oestrogen over the first post-operative month was 1.9 μ g./24 hours.

At a subsequent examination, eight months later, the disease was progressive, metastases being present in the clavicles, spine, lung, and brain. At this time oestrogen excretion had risen to a relatively high level and was persistent (mean total=8.5 μ g./24 hours). Two months before death—which occurred 11 months after adrenalectomy—only one

FIG. 2.—Case 2. Excretion of oestrogen before and after bilateral adrenalectomy.

of three urine specimens contained detectable amounts of oestrogen. This case illustrates the transition from regression to relapse. During the short remission oestrogen excretion was persistent and rose considerably in relapse until just before death.

Case 3.—From this patient, a married woman aged 46, no pre-operative specimens were obtained. A radical mastectomy was performed at the age of 45. Ten months later skeletal metastases developed, and at oophorectomy, which had no effect, liver secondaries were found. Adrenalectomy was carried out three months later and led to an objective regression of both skeletal and hepatic metastases. During the period of regression oestrogen estimations were carried out 15 and 40 months after operation. No oestrogen was detected in any of the 11 specimens analysed. Four years after adrenalectomy there was evidence of progressive disease. Seven analyses were carried out, and in only one was there detectable oestrogen (approximately 1.5 μ g. of oestriol). Unlike Case 2, the transition from remission to relapse was not accompanied by a rise in oestrogen excretion.

In these three cases the period of remission was associated with either no detectable oestrogen (Case 3) or with a negligible and spasmodic excretion (Case 1). Case 2 shows that the continued excretion of oestrogen, admittedly small, is not incompatible with objective remission. Progression in this case was accompanied by a rise in oestrogen excretion but in Case 3 this did not occur.

Oestrogen Excretion Before and After Bilateral Adrenalectomy*

*The case numbers are those referred to in the text; the age of the patient at adrenalectomy is given in parentheses in the first column. O, D, and T refer to oestrone, oestradiol-17 β , and oestriol respectively, and the figures given are arithmetical means. Figures in parentheses in the columns headed "Total" refer to the number of estimations carried out. All results are expressed in μ g./24 hours.

All patients had been previously oophorectomized, with the exception of Cases 4, 11, and 13, who were subjected to bilateral oophorectomy and adrenalectomy at the same time.

months of objective remission followed and a pathological fracture of the humerus consolidated. Thereafter the disease progressed and adrenalectomy was carried out. No benefit was obtained, and the patient died of progressive disease 22 months after operation. It can be seen from Fig. 4 that bilateral adrenalectomy had virtually no effect on oestrogen excretion.

A further seven patients were studied in relapse. In four oestrogen was found in the urine, in one case in remarkably high amounts—up to 50 $\mu\text{g./24 hours}$. This abnormal level of excretion was followed by a period when the patient excreted over 9 $\mu\text{g./24 hours}$. This level, subsequently confirmed by quantitative biological assay, is greater than the mean amount of oestrogen produced by the adrenal glands and excreted in the urine of post-menopausal women.

In the 10 cases described in this section, five either derived no benefit from adrenalectomy or, when the oestrogen estimations were carried out, were in relapse and not excreting detectable amounts of oestrogen. The remaining five were excreting oestrogen whilst the disease was progressing. A summary of the findings for the 13 patients is presented in the Table, in which the mean total pre-operative oestrogen values are given and the mean levels found in relapse or in remission are also shown. It must be pointed out that the mean figures should be accepted with some reserve. Reference to Figs. 1 and 2 shows the intermittent nature of oestrogen excretion after adrenalectomy, and from this it can be concluded that the estimation of the oestrogen content of single 24-hour specimens of urine may be misleading. Short periods, during which oestrogen excretion is relatively high, may be followed by periods during which little oestrogen can be detected. This phenomenon therefore reduces the value of a mean figure. Nevertheless, the table illustrates the mean excretion before operation and the extent to which adrenalectomy causes a diminution in excretion. The mean pre-operative figure is within the range given for post-menopausal women or oophorectomized women with cancer of the breast given in a previous paper (Bulbrook *et al.*, 1958a). Average oestrogen levels in remission are less than 1 $\mu\text{g./24 hours}$ (total), with a considerable increase when the levels in relapse are considered.

Discussion

It must be emphasized that the series of patients described is small and that of a total of 13 cases six were studied only during relapse. Any conclusions based on the results must therefore be tentative.

It is clear that adrenalectomy reduces, even if it does not always abolish, oestrogen excretion. There is a significant difference between the mean pre-operative level and the mean post-operative level for the patients shown in the Table. This affords clear evidence that the post-oophorectomy or post-menopausal excretion of oestrogen described in a previous paper (Bulbrook *et al.*, 1958a) is of adrenal origin in the human (see Brown, 1958). Remission of the disease, however, does not always follow the reduction or abolition of oestrogen excretion.

It seems that continued oestrogen excretion is not necessarily exclusive of objective regression of the disease. The amounts excreted by Case 1 after operation were negligible and inconstant. But Case 2 showed a definite and persistent excretion. If this result can be confirmed by a wider study of more cases, the implication is that the cessation of secretion of hormones other than the oestrogenic steroids produced by the ovaries and adrenals may be decisive in causing the regression of human breast cancer. The complex nature of the dependence of normal breast growth on a group of hormones acting together is well established in experimental animals (see, for example, Lyons *et al.*, 1955; Hadfield, 1957), but such data are almost entirely lacking for the human. The participation of a pituitary factor is suggested by the finding that two patients (Cases 11 and 13) in relapse after adrenalectomy were without detectable oestrogen but obtained remission after subsequent hypophysectomy (Bulbrook *et al.*, 1958b).

Half the patients in relapse in this series showed continued excretion of oestrogen after adrenalectomy, compared with roughly one-third in a larger series studied without consideration of clinical state (Bulbrook and Greenwood, 1958). It seems unnecessary to postulate oestrogen independence of the tumour as the cause of the failure of treatment in these cases. In considering the six patients in relapse in whose urine no oestrogen could be detected, some caution must be used before continued tumour growth is ascribed to oestrogen independence or to dependence upon pituitary factors. With the use of the more sensitive biological assay (Bulbrook *et al.*, 1958c) it has been shown that oestrogen excretion may continue in some oophorectomized adrenalectomized patients, although in amounts not detectable by the chemical method.

The source of the continued oestrogen remains obscure. The literature describes the occurrence of microscopical ectopic adrenal tissue, but no macroscopic rests have been found after death in four of the patients in this series. One (Case 8) was excreting considerable amounts of oestrogen. Furthermore, Strong *et al.* (1956) could not elicit an increased oestrogen excretion by the administration of adrenocorticotrophin in adrenalectomized patients. On the other hand, Bulbrook and Greenwood (1958) have found that continued oestrogen excretion after adrenalectomy tends to be present with the continued excretion of androsterone and aetiocholanolone, compounds which are not considered to be derived from administered cortisone. This result therefore indicates that the probable source of the steroid hormone production is likely to be adrenal tissue; otherwise it is necessary to postulate an alternative source with adrenal-like properties.

It has also been suggested that the tumour itself may be responsible for the production of oestrogens. Chemically and biologically detectable amounts of oestrogens have been found in all cases in a series of adrenalectomized patients with diffuse carcinomatosis (Daniel and Mitchell, personal communication). This theory is supported to a certain extent by the results in this paper, which show that oestrogen excretion may be associated with progression of the disease. In a previous paper (Bulbrook *et al.*, 1958a) oestrogen excretion rose as the disease progressed in a patient following oophorectomy until, just before death, relatively enormous amounts of oestrogen were recorded (four times the mean post-oophorectomy level). These results could be interpreted as indicating tumour production of oestrogen. Similarly, in Case 8 (see Table) the mean oestrogen level after oophorectomy and adrenalectomy was almost twice that found for patients after oophorectomy alone. In this patient a careful search at post-mortem examination failed to reveal macroscopic adrenal rests. If the tumour itself produces oestrogen, this does not occur in all cases of progressive disease (see Cases 3, 4, 6, 11, 12, and 13 in the Table), where no oestrogens were detected by the chemical method.

Finally, oestrogen analyses of urine obtained from patients after adrenalectomy afford no reliable guide to the clinical state of individual patients. Every permutation may occur, remission or relapse being accompanied in some cases by oestrogen excretion, while in others no oestrogens were detectable. Only when the patients in this small series are considered as a group does it appear that there is a tendency for remission to be accompanied by low or zero excretion and for relapse to be associated with higher levels of excretion.

Summary

The effect of adrenalectomy on both the clinical state and oestrogen excretion has been studied in 13 women with metastatic breast cancer.

Bilateral adrenalectomy caused a marked reduction in the amount of oestrogen excreted, but complete abolition of excretion was not always achieved. However, continued oestrogen excretion did not exclude objective regression.

Conversely, progression of the disease might take place in spite of the fact that no oestrogen could be detected in the urine. In general, continued oestrogen excretion was found more often in cases in relapse than in remission.

We are grateful to the surgical staff and the staff of the radiotherapy department of St. Bartholomew's Hospital for allowing us to investigate patients under their care, and particularly to Professor Sir James Paterson Ross, who has also been most helpful with his advice and criticism.

HYPOPHYSECTOMY IN BREAST CANCER

AN ATTEMPT TO CORRELATE CLINICAL RESULTS WITH OESTROGEN PRODUCTION

BY

R. D. BULBROOK, M.Sc., Ph.D.

F. C. GREENWOOD, M.Sc., Ph.D.

E. F. SCOWEN, M.D., F.R.C.P.

Medical and Surgical Units, St. Bartholomew's Hospital, London

In 1953 Luft and Olivecrona reported that hypophysectomy was an effective means of palliation in a significant proportion of cases of metastatic breast cancer. Subsequent work has confirmed these results (Luft and Olivecrona, 1955; Pearson *et al.*, 1955). The beneficial effects of the operation were ascribed to the inhibition of ovarian and adrenal function due to the removal of the relevant pituitary trophic hormones, and to the removal of those pituitary hormones which might have a direct influence on human breast cancer.

The technical difficulties in totally removing the pituitary gland are formidable, and reports on post-mortem findings suggest that complete removal is infrequently achieved (Hortling *et al.*, 1957; Luft *et al.*, 1958). Post-operative investigations of the living patients are therefore of value in deciding if removal has been complete; and, whilst methods are available for the bio-assay of pituitary gonadotrophin and for measuring the functional capacity of the thyroid, adrenals, and ovaries, it is possible that repeated oestrogen measurements provide reliable information on pituitary function following attempted ablation

(Dodds *et al.*, 1956). It has been shown (Greenwood and Bulbrook, 1956, 1957) that many patients still excrete appreciable quantities of oestrogen in the urine after hypophysectomy, but no correlation of these or subsequent results with the clinical state and/or the post-mortem findings has been attempted.

The present paper reports an effort to correlate oestrogen excretion with the clinical state of 16 breast-cancer patients on whom hypophysectomy was performed.

Methods.—The clinical and chemical methods were exactly as described in previous papers (Bulbrook *et al.*, 1958a, 1958b).

In the 16 patients studied, oestrogen estimations were carried out before and after operation. The results have been divided into groups: the first showing oestrogen levels found in 11 patients who obtained regression at hypophysectomy, the second showing the oestrogen levels in the five patients who derived no benefit from surgical hypophysectomy. One in the latter group was a male. The ages given refer to age at hypophysectomy.

Oestrogen Excretion in Patients in Whom Objective Remission of Growth was Induced by Hypophysectomy

Of the 11 patients included in this group, five were post-menopausal, four had previously been treated by oophorectomy, and two by oophorectomy and adrenalectomy. All but two (Cases 1 and 11) had undergone radical mastectomy. Remission of the disease varied from 2 to 16 months after hypophysectomy, and in five patients remission has continued to the time of writing. Oestrogen studies were carried out before operation and at least one month after operation—with one exception, Case 4. The mean oestrogen levels were calculated from serial analyses of 24-hour specimens of urine. Table I summarizes the clinical and biochemical findings of the 11 patients studied in this section, and the salient features of the cases are considered in detail below.

Case 2 (Fig. 1).—This patient, aged 55, had a ten-years history of breast cancer treated in turn by mastectomy, deep x-ray therapy, and cortisone. At hypophysectomy, when

FIG. 1.—Case 2. Excretion of oestrogen before and after hypophysectomy. In Figs. 1–4 the day of operation is marked with a vertical arrow; oestrogen excretion is shown as total oestrogen—the sum of the oestrone, oestradiol-17 β , and oestriol values. Each vertical column gives the mean of a duplicate determination on a 24-hour specimen of urine. Open circles on the abscissa indicate no detectable oestrogen.

aged 55, she was three years post-menopausal. She had metastases in the lumbar spine, an ulcerated chest wall, and skin nodules in the neck. Oestrogen excretion was low compared with the mean level for post-menopausal women with breast cancer and was reduced in the first post-operative month to levels indistinguishable from zero. Growth regression followed hypophysectomy, and this has continued up to the time of writing, 15 months after operation. Follow-up specimens obtained 13 months after operation showed the continued absence of oestrogen in the urine. The

oestrogen excretion in this patient (Fig. 1) illustrates the expected effect of hypophysectomy in abolishing oestrogen excretion.

In five further cases (Nos. 1, 3, 4, 6, and 8) a similar unequivocal fall to zero in oestrogen excretion was found after the first post-operative month, accompanied by regression of the disease.

Case 4 (Fig. 2).—This patient, aged 65, was studied within two weeks of operation, and oestrogen was detectable in the urine in amounts greater than those found before

FIG. 2.—Case 4. Excretion of oestrogen before and after hypophysectomy.

FIG. 3.—Case 5. Excretion of oestrogen before and after hypophysectomy.

operation. This increase in oestrogen was confirmed by biological assay. No oestrogen was detected three weeks after operation, and follow-up specimens at nine weeks and 14 months suggest that the fall to zero continued. Skin and glandular metastases decreased after operation, and remission has been maintained up to the time of writing, 16 months after operation.

Case 5 (Fig. 3).—In this patient, aged 42, an initial fall of oestrogen excretion to zero was associated with regression of cutaneous and skeletal lesions. Although this marked regression continued, oestrogen was detected in the urine for a short period some three months after operation. Biochemical estimations of urinary oestrogens, confirmed by biological assay, showed that the predominant urinary steroid was oestriol with trace amounts of oestrone. The total amount of oestrogen was equivalent to that found in normal menstruating women, and eight times the mean pre-operative level. In this case it would seem that regression of the disease following hypophysectomy is not invariably accompanied by a persistent fall in oestrogen excretion to zero.

Case 7.—This patient, aged 44, showed little fall in total oestrogen after hypophysectomy with remission of the disease: oestrogen was detectable in three of six specimens collected after operation.

Case 9.—In this patient, aged 40, hypophysectomy was accompanied by a remission of skeletal metastases, and this has continued to the time of writing, 15 months after operation, in the absence of detectable oestrogen. Hypophysectomy in this patient reduced oestrogen excretion to levels indistinguishable from zero by the chemical method used, but oestrogen was detectable on one occasion, one month after operation, by the more sensitive biological assay.

Two patients were studied with progressive disease after a previous oophorectomy and adrenalectomy. Case 10 had not benefited from this treatment, while Case 11 had been in regression for two years before exacerbation of breast and skin symptoms occurred. Oestrogen was not detectable either before or after operation, which was followed by remission of symptoms for three months in both cases. The disease thereafter progressed in Case 10, death taking place four months after operation. In Case 11, however, mastectomy had not been performed and the patient was still in regression up to the time of death from an acute bacterial infection following post-operative necrosis in both the involved breasts.

Mastectomy had not been performed in Case 1 and a marked regression of growth of the breast tumour accompanied a fall in oestrogen excretion at hypophysectomy. This

regression continued up to the time of death three months after operation. As in Case 11, post-mortem examination showed gross necrosis of the mass in the involved breast, and it is not improbable that death was caused by the liberation of toxins from rapid autolysis of necrotic tumour tissue.

The anticipated effect of hypophysectomy is to reduce and abolish oestrogen excretion. The overall results in this section confirm that this is generally true for women after the menopause or those who are in remission after oophorectomy. In seven of the nine patients no oestrogen could be detected after the first post-operative month, and the effect appears to be persistent. In two cases no oestrogen could be detected before operation, and oestrogen analyses, although zero after operation, provided no evidence of the completeness of the removal of the pituitary in these cases. However, in 2 of the 11 patients oestrogen was detected although remission of the disease followed operation.

If the pre-operative levels of oestrogen are considered the mean total oestrogen for the nine patients is somewhat lower than the mean level found for 39 women with metastatic breast cancer after the natural menopause or bilateral oophorectomy.

Oestrogen Excretion in Patients not Benefited by Hypophysectomy

Four women were studied in this group (Table II). All had previously been treated by mastectomy; three had undergone subsequent oophorectomy; the fourth had not menstruated for a year following a course of testosterone treatment. At the time of operation all patients showed evidence of progressive skeletal metastases, and these were unaffected by hypophysectomy. The average survival time after operation was eight months. In no case was oestrogen excretion reduced or abolished by operation. A typical example of the variation in amount and pattern of excretion is shown in Fig. 4 (Case 12). The mean level of oestrogen

before operation of these four patients appears to be greater than the mean pre-operative level of the patients recorded in Table I obtaining benefit from hypophysectomy.

Of incidental interest is the fact that Case 16 was a male suffering from breast cancer with widespread metastases. Neither orchidectomy nor subsequent hypophysectomy altered the progress of the disease. The latter operation reduced but did not entirely abolish oestrogen excretion.

Discussion

The object of this study was to decide if the excretion of oestrogen was correlated with the pre- and post-operative clinical state of patients suffering from metastatic breast cancer and subjected to hypophysectomy. Although the series is small, a correlation seems clearly established, since oestrogen excretion was generally absent in urine from patients in regression after hypophysectomy and present when the operation failed to benefit the patient. In four cases in remission oestrogen was demonstrated in the urine, but this was a transitory phenomenon in three of these patients. For example, Case 4 (Table I) was excreting more oestrogen two weeks after operation than before. This patient was studied at an earlier stage after hypophysectomy than the remaining cases. The presence of oestrogen 12 to 18 days after operation, followed by a period of 14 months in which no oestrogen could be detected, suggests that it may take two weeks for the elimination of circulating pituitary and adrenal hormones.

The amounts of oestrogen detected only by biological assay in Case 9 suggest that the grouping of patients in regression showing no oestrogen excretion by the chemical method may be an arbitrary classification depending only upon the sensitivity of the chemical method. No oestrogen could be detected in the urine of Case 5 for a long period. Three months after operation relatively large amounts of oestrogens were excreted for two days; this was followed by a prolonged period when again no oestrogen could be found in the urine. In both instances the chemical results were confirmed quantitatively by biological assay. We have no satisfactory explanation for this result, but it is extremely unlikely that the oestrogen could have been derived from the diet, since a patient after adrenalectomy in the same ward and on an identical diet excreted no oestrogen during this period.

In only one patient (Case 7) did oestrogen excretion continue on the same level as before operation, and this patient had an objective regression. It may be significant that survival time and the period of regression were short. This finding is discussed later.

The first two sections in Table I show that the mean pre-operative levels for the post-menopausal and post-oophorectomy patients obtaining benefit from hypophysectomy tend to be below the mean level found for women with cancer of the breast in these categories (Bulbrook *et al.*, 1958a). The mean levels were 3.6 and 4.2 µg./24 hours (total oestrogen) respectively, compared with 5 to 6 µg./24 hours. On the other hand, the mean amount of

oestrogen excreted by the four patients who failed to benefit from operation (Table II) was 7 $\mu\text{g.}/24$ hours—a value slightly higher than the mean level for all patients in this category, and higher than the mean pre-operative level of patients obtaining remission at hypophysectomy (Table I). There are not enough patients in the series for these findings to have any statistical significance, but there may be a tendency for patients with a low pre-operative oestrogen level to benefit from hypophysectomy while those with a high level do not. Further work is needed to check the validity of this suggestion.

In two instances patients who had been previously treated by oophorectomy and adrenalectomy were subjected to hypophysectomy. In neither case was oestrogen detected in the urine either before or after hypophysectomy, yet in both patients their objective regressions were short. Unless they were excreting amounts of oestrogen not detectable by the chemical method, these results suggest a direct participation of pituitary hormones in the maintenance of human breast cancer, as opposed to an indirect trophic effect on target organs. Similarly, in the patient already referred to (Case 7) objective regression occurred in spite of continued oestrogen excretion. Again, this result is explicable on the assumption that the levels of growth hormone, prolactin, or both had been reduced below a critical level.

In the four patients referred to in Table II the most simple explanation for the failure of hypophysectomy to influence the growth of the breast cancer is the continued excretion of oestrogens due to incomplete hypophysectomy. We have, as yet, been unable to study the transition from remission to relapse in this series. However, Hortling *et al.* (1957), using the vaginal-smear technique, found that oestrogen secretion increased simultaneously with the deterioration of the patient's clinical condition.

The explanation of failure or success following endocrine ablation for breast cancer must be largely speculative until we are able to assess directly the functional capacity of the human hypophysis with a reasonable degree of precision. The results of the investigations on the small number of patients in the present series suggest that repeated biochemical estimation of oestrogens before hypophysectomy may prove to be of some value in forecasting the clinical outcome of this operation.

Continued post-operative excretion of oestrogen, by indicating incomplete removal, suggests that no significant clinical palliation is likely to occur, while cessation of oestrogen excretion would suggest the reverse. The exceptions to these generalizations provide cogent reasons for supposing that the growth of some human breast cancers is maintained by the direct action on the tumour cells of anterior pituitary hormones.

Summary

The effect of hypophysectomy on the clinical state and on oestrogen excretion has been studied in 15 women and one man with metastatic breast cancer.

Patients obtaining regression following hypophysectomy tended to have a low pre-operative level of urinary oestrogen, and in the majority oestrogen excretion virtually ceased after operation. On the other hand, continued oestrogen excretion was not always exclusive of objective regression.

Patients deriving no benefit from operation tended to have a high pre-operative oestrogen excretion and continued to excrete oestrogen after operation.

We are grateful to the surgical staff and the staff of the radiotherapy department of St. Bartholomew's Hospital for allowing us to investigate patients under their care. We would like particularly to thank Professor Sir James Paterson Ross and Dr. A. A. G. Flemming. All the operations for hypophysectomy were performed by Mr. J. E. A. O'Connell, and we are grateful to him for allowing us to continue the observations on these patients.

A BIOCHEMICAL CONCEPT OF TUMOUR GROWTH, INFILTRATION, AND CACHEXIA

BY

G. WISEMAN, Ph.D., M.B., B.S.

Lecturer in Physiology, the University, Sheffield

AND

F. N. GHADIALLY, M.D., Ph.D.

Lecturer in Pathology, the University, Sheffield

Among the many perplexing properties of a growing tumour is its ability to build up protein and increase in weight in a host (experimental animal or man) which is fast losing weight. This ability to obtain the precursors of its protein from the metabolic pool at the expense and to the detriment of the host has been investigated in some detail by Mider, Tesluk, and Morton (1948) (see Greenstein, 1954), and from the results they obtained with the transplantable Walker 256 tumour in growing rats they have been able to show three distinct phases in the growth history of the tumour and tumour-bearing animal. During the first stage (while the tumour is relatively small) both the tumour and the host gain weight. In the second stage the tumour alone continues to gain weight, and at an increasing rate. The host tissues in this second stage at first fail to gain weight and later may even lose weight. In the third and terminal stage (often very brief) the rate of growth of the tumour falls, and eventually the tumour itself may lose weight, although not as markedly as that of the rapidly wasting tissues of the host.

Such observations in the experimental animal, and the well-known clinical fact that tumours continue to grow even in cachectic subjects, suggest that the tumour is an autonomous entity capable of thriving irrespective of the metabolic status of the tissues of the host. It is obvious, however, that even the most autonomous neoplasm must have an adequate supply of metabolites for the purposes of growth, and if the essential metabolites are not forthcoming then the rate of growth must suffer.

The effect of dietary restriction on the incidence and rate of growth of spontaneous tumours has been the subject of much careful study. Tannenbaum and his colleagues (see review, Tannenbaum, 1947), in a series of brilliant experiments, have shown that dietetic restriction can greatly reduce the incidence of both naturally occurring and carcinogen-induced tumours in experimental animals. Indeed, some 14 different tumours have been shown to be affected in this manner, and the statistical evidence from insurance companies' records collected by L. T. Dublin in 1927 (quoted by Tannenbaum, 1947) shows that the incidence of various neo-

plasms is higher in overweight humans than in underweight ones. The growth of established tumours is not as dramatically affected by dietetic restriction as is tumour incidence, but nevertheless the rate of growth is dependent upon the nutritional status of the host (Rous, 1914; Tannenbaum, 1947; Ghadially and Wiseman, 1956).

From a consideration of these fundamental studies emerges the concept of a contest between the host and the tumour for the capture of metabolites circulating in the blood and in the extracellular fluid. Although such antagonistic behaviour between tissues in an animal has been suggested for a long time, and superior ability credited to the tumour cell, detailed experimental evidence has only recently become available to indicate an aspect of the nature of the metabolic mechanism which gives the tumour cell an advantage over normal host tissues.

It seems to us that, from a consideration of the work of many investigators, the metabolic superiority of the tumour cell is largely due to its enhanced amino-acid concentrating power. It is the purpose of this paper to evolve a hypothesis to show how infiltration of normal tissues by neoplastic cells, tumour anorexia, tumour cachexia, and the paradoxical growth of tumours in a wasting host can be explained on this simple biochemical basis.

Nature of the Metabolic Competition

Undoubtedly one of the most important factors in the successful synthesis of protein, and hence tissue growth, is the availability of the essential amino-acids for this purpose. Once the extracellular fluid in which the cells live becomes rich in these amino-acids (via the blood stream or autolysis of cells) then the next important step is the uptake of the amino-acids by the cells concerned. In any multicellular tissue we must picture the cells which share a common volume of extracellular fluid as competing with each other for the available metabolites. The cells which are better endowed in regard to the mechanisms concerned for metabolite uptake are in a better position for synthesis of new protein.

In 1913 Van Slyke was able to demonstrate that the intact cells of the animal body are able to accumulate amino-acids from the extracellular fluid and that they can concentrate the amino-acids until their content of these substances is about 10 times that of the animal's plasma. Since that time many tissues of the normal animals have been shown to concentrate amino-acids actively, and recently such work has been extended to neoplastic cells. In 1948 Christensen, Streicher, and Elbinger found that glycine, and probably alanine, serine, proline, methionine, and histidine, are actively taken up (that is, against a concentration gradient) by normal liver and muscle in the intact rat. Sassenrath and Greenberg (1954) and Greenberg and Sassenrath (1955) have published results of experiments in which they estimated, by specific microbiological means, 18 free amino-acids in the livers, muscles, and plasma of fed and fasting tumour-bearing rats, and they showed that the amino-acids were all present in higher concentration in the liver and muscle cells than in the plasma. It is a pity that these latter workers did not estimate the concentration of the free amino-acids in the tumours that their animals possessed.

Work with isolated normal diaphragm by Christensen and Streicher (1949) showed that the muscle could concentrate free glycine *in vitro*. In 1953 Wiseman found that the isolated small intestine of the rat was able to concentrate the L-forms ("naturally" occurring) of alanine, phenylalanine, histidine, methionine, and isoleucine. He showed (Wiseman, 1955, 1956) that isolated small intestine of the hamster was able to concentrate 13 different amino-acids and also that they competed with each other for the concentrating mechanism of the cell. While this work with normal tissue

was being done, work with neoplastic cells was being carried out. In 1952 Christensen and Riggs found that the Ehrlich mouse ascites tumour cells actively concentrated amino-acids, and Christensen and Henderson (1952) showed that in the intact animal glycine, and possibly alanine, are concentrated by the Ehrlich ascites cells to a greater extent than by the liver. In 1955 Wiseman and Ghadially showed that suspensions of RD₃ sarcoma cells *in vitro* could actively concentrate histidine, proline, ornithine, lysine, and methionine. The results of our experiments indicated a qualitative difference in the capture of amino-acids by the sarcoma cells and normal intestine, in so far as the neoplastic cells could actively concentrate the diamino-acids, lysine and ornithine, while the intestine could not.

We were also able to show that apart from this qualitative difference there were two quantitative differences. Under similar conditions the sarcoma cells not only concentrated the amino-acids to a greater extent but the effect of methionine as an inhibitor of amino-acid uptake by cells was less marked. In the case of isolated normal intestine it was found that when methionine was present with an accompanying amino-acid in equimolecular amounts the methionine completely prevented the accompanying amino-acid from being concentrated. The effect of methionine on the isolated sarcoma cells, however, was only to depress, but not to abolish, the concentrative uptake of the second amino-acid.

Various earlier workers (Pilsun and Berg, 1950; Graham, Hier, Waitkoff, Saper, Bibler, and Pentz, 1950; Wretling and Rose, 1950) have noted that excess dietary methionine retards the growth of young rats, and the results obtained by Wiseman (1955) show that this growth retardation is probably due to the powerful inhibitory effect of excess methionine on the uptake of other amino-acids by normal tissues. A consideration of the differences of the action of methionine on isolated intestine and sarcoma cells (Wiseman and Ghadially, 1955) led to the conclusion that excess dietary methionine should increase the rate of growth of a tumour in a tumour-bearing animal while at the same time causing the host tissues to waste. This, in fact, was shown to be the case (Ghadially and Wiseman, 1956) when 4% DL-methionine was added to the diet of rats bearing RD₃ sarcoma. The results of those experiments strongly suggested that the excess methionine decreased the ability of the normal tissues to take up other amino-acids and thereby provided a readier source of amino-acids for the growing tumour, whose amino-acid uptake was not so greatly affected by the excess methionine. Thus there was confirmation *in vivo* of the earlier *in vitro* findings.

Metabolic Superiority of the Neoplastic Cell

Numerous other experiments have also demonstrated this metabolic superiority of the neoplastic cell over its normal counterpart. Zamecnik, Frantz, Loftfield, and Stephenson (1948) found that slices of rat hepatomata (induced by the use of 4-dimethylaminoazobenzene) incorporated more radioactivity from labelled alanine and glycine than did slices of normal rat liver. Rutman, Cantarow, and Paschkis (1954) have shown that mitochondria from preneoplastic livers and from hepatomata of acetaminofluorine-treated mice showed an enhanced ability (20 to 50% increase) in incorporating L-lysine-1-¹⁴C into peptide linkages. Studies by Burke and Miller (1956) revealed that in the preneoplastic phase during 3'-methyl-4-dimethylaminoazobenzene carcinogenesis the livers of rats incorporated into proteins between two and three times the normal amounts of L-lysine. This was associated with a depression of katabolism of the amino-acid as evidenced by a yield of ¹⁴CO₂ from the labelled lysine lower than expected, and a decreased urea production. Tumours other than hepatomata show an increased uptake of radioactive amino-acids.

Zamecnik *et al.* (1948) and Winnick (1950) found that the rate of uptake of ¹⁴C-labelled glycine and alanine into mouse mammary tumour homogenate was several times as great as that of normal mouse liver homogenate. LePage (1953)

has been able to demonstrate that the Gardner lymphosarcoma cells and the Ehrlich carcinoma cells can incorporate up to 50 times as much glycine- ^{14}C into protein as can normal mouse liver cells. Mouse mammary tumour mitochondria show essentially the same phenomenon (Winnick, 1950). Roberts and Tishkoff (1949) have found that the preneoplastic epidermis of mice receiving applications of methylcholanthrene can concentrate free amino-acids to a greater extent than normal mouse epidermis. It would seem, therefore, that the ability to outdo normal tissues in the capture of amino-acids is an early acquisition of the neoplastic cell, and this we would expect if the neoplastic cell is to compete rapidly and successfully for these essential metabolites.

The rapid rate of incorporation of amino-acids into cellular protein in the neoplastic and preneoplastic cell, as compared with its normal counterpart, would keep the level of free intracellular amino-acid lower than it might otherwise be and thereby help the movement of more amino-acid into the cell from the extracellular fluid. Thus not only is the rate of production of neoplastic tissue kept high, but also the field is set for the continued deprivation of the local normal cells of adequate amounts of the precursors of their protein. An added advantage occurs in the event of the neoplastic cell being able to concentrate an essential amino-acid actively while the local normal cells are unable to do so. Under these conditions the local normal cells would be largely deprived of one or more essential amino-acids, and they would then virtually cease to produce their own intracellular protein, as all the precursors of a protein molecule must be present at the same time for protein synthesis. In the absence of one or more essential amino-acids, cells are unable to retain for any length of time those amino-acids which are available, and a negative nitrogen balance occurs (Cannon, 1948).

Activity of *in vitro* Preparations

We must point out at this stage that the enhanced activity of many of the *in vitro* preparations to incorporate labelled amino-acids into protein has not always been demonstrable *in vivo* (Griffin, Bloom, Cunningham, Teresi, and Luck, 1950; Kit and Greenberg, 1951; Tyner, Heidelberger, and LePage, 1952). It seems likely, however (Zamecnik, Loftfield, Stephenson, and Steele, 1951), that this is a result of inherent technical limitations, for it was observed that, although the avascular portions of the tumours were relatively inactive, the regions with a good blood supply showed high activity. From these observations we may conclude that the rate of uptake found in the *in vivo* experiments indicates only the average activity of the whole tumour and not the true activity of its most rapidly growing periphery. A similar view is put forward by Caspersson and Santesson (1942), and by Rutman *et al.* (1954).

It might be argued that the increased rate of incorporation of amino-acids into cellular and mitochondrial protein does not indicate that new and extra protein is being produced and that the results obtained by many of the above experiments might be the result of exchange of an amino-acid for another molecule of the same amino-acid without new protein synthesis occurring. However, the ability of the neoplastic cells to capture and concentrate free amino-acids at a rate higher than that of normal cells has been clearly demonstrated, and when that fact is added to the well-known observation that tumour tissues grow at a rate far greater than the host tissues it seems that the most likely explanation is that the tumour cells do in fact incorporate amino-acids into protein more rapidly than their normal counterparts.

An enhanced power to capture amino-acids is, of course, seen in fast-growing tissues other than malignant tumours—for example, placental tissue (Christensen and Streicher, 1948). The malignant tumour cannot, therefore, be looked upon as being unique in this respect; furthermore, it must be emphasized that an increased ability to capture amino-acids cannot be regarded as the hall-mark of malignancy

or the essential neoplastic change. However, once this fundamental metabolic superiority is possessed by a tissue it has a potentiality to grow at the expense of its neighbours and will in fact do so whenever other growth-restraining influences fail to act. The understanding of this metabolic superiority enables many of the perplexing paradoxes of tumour-host relationships to be explained. It is, of course, possible that other important biochemical factors are involved at various stages in the neoplastic disease. Among such possible factors are competition for metabolites other than amino-acids, the production of toxic materials by established tumours, and changes in energy requirements.

Infiltration

The capacity of malignant cells to infiltrate into and destroy normal tissues is well known. One of the most recent and intriguing accounts attempting to explain the essential malignant change and the ability of neoplastic cells to wander is Green's (1954) antigenic theory of cancer. According to this hypothesis the ability of the malignant cell to wander and infiltrate is due to the failure of the antigenic mechanism of the body to "recognize" the cell once it has lost certain marker antigens. The growth of cells in unusual places and their extension beyond normal planes will therefore go unnoticed by the controlling mechanisms of the body. Loss of a series of such marker antigens, one by one, will confer an increasing independence upon a cell, and eventually such a cell will have the potential to infiltrate local tissues and spread beyond the normal physiological boundaries without arousing an adequate defence reaction on the part of a host. The development by a cell of the attribute to wander, however, seems to be in itself insufficient to account for its continuous growth unless such potentiality were aided by some metabolic superiority. Exploitation of its newly acquired growth independence, however acquired, must ultimately depend on its ability to outdo the local cells in a contest for available metabolites.

Infiltration by neoplastic cells does not only imply their growing between normal cells or along paths of least physical resistance, but it is essentially and ultimately a cell-by-cell destruction of the normal at the interface of the tumour and the normal tissue. In cases of low malignancy—that is, without marked metabolic superiority—there may be merely compression of neighbouring tissues and little real infiltration, but with highly malignant growths with overwhelming metabolic superiority it is not long before the normal cells are replaced by tumour tissue. Over a fairly broad zone surrounding a tumour one can as a rule detect islands of cells in various stages of disintegration, atrophy, and necrosis. Pressure exerted by the increasing tumour mass is usually the explanation given to account for the death of the normal cells at the tumour's advancing edge, but cannot in fact be the explanation (as already pointed out by Ghadially and Wiseman, 1957). The growing edge of the tumour derives its blood supply from vessels at the tumour/normal tissue interface (Algire and Chalkley, 1945), and any appreciable rise in pressure at this region would destroy the tumour cells as well as the normal cells.

It seems to us that the phenomenon of infiltration by a cell which has lost its marker antigens can best be explained on the basis of a metabolic competition of the type described in the early part of this paper. The advancing columns of tumour cells are bathed in the same extracellular fluid and share the same local environment as the adjacent normal cells. Thus it is inevitable that a local competition for available amino-acids will arise. The more efficient power of concentration possessed by the tumour will have a two-fold action. Firstly, it provides the tumour with material necessary for protein synthesis and growth, and, secondly, it deprives the adjacent normal cells of their basic metabolic requirements and thereby induces atrophy, degenerative changes, and finally necrosis. It is for this reason, in our opinion, that the normal cells at the periphery of a growing tumour suffer most. The disintegrating normal cell no doubt provides further metabolites for the insatiable

demands of the flourishing tumour. Thus our hypothesis explains not only why malignant cells flourish and infiltrate but also why the normal cells are destroyed.

Anorexia and Cachexia

As previously mentioned, three phases have been identified in the growth history of the tumour and the tumour-bearing animal. In the first stage the volume of tumour tissue is small and the needs of both the normal and the neoplastic cells are easily met from the general metabolic pool. By the time that the second stage is reached, however, the volume of tumour tissue has increased, and it is at this stage that the severe competition for essential amino-acids must arise. The tumour, by virtue of its more powerful amino-acid concentrating mechanism, deviates large amounts of the available amino-acids for its own protein synthesis, and the normal tissues begin to suffer as the metabolic pool is heavily depleted. The catabolic processes in normal tissues continue (perhaps at an increased rate), but the amino-acids for the anabolic process are no longer freely available.

One of the tissues to suffer early on in this metabolic competition is the intestine, and as a result food intake is reduced. The intestine of a tumour-bearing host is found to suffer a severe weight loss in common with most other normal tissues (Bloor and Haven, 1955), and in rats bearing a Walker carcinoma 256 the intestinal weight may be reduced to about three-quarters of that in control animals. Herein probably lies a good deal of the explanation of the anorexia seen both in patients and in experimental animals suffering from neoplastic diseases. The rate of turnover of cells in the intestinal mucosa has been demonstrated to be very rapid indeed, and the entire mucosa is replaced every 14 days in the rat (Leblond and Stevens, 1948) and every 24 days in the cat (McMinn, 1954). This rate of tissue production entails much protein synthesis and calls for a constant supply of amino-acids from the general metabolic pool. Such a demand on the metabolic pool will tend to become more onerous in the later stages of neoplastic disease, and when scarcity of essential metabolites begins to make itself felt the tumour will continue to grow at the expense of the intestine as well as of other normal tissues.

Increasing anorexia and cachexia then herald the third and terminal stage of the disease, for not only is the metabolic pool being rapidly drained of amino-acids by the tumour, but in addition the intestine is no longer able to replenish that pool from the diet efficiently.

As well as obtaining amino-acids in large amounts from the extracellular fluids of the body, there is an actual translocation of amino-acids from normal to neoplastic cells. The work of White (1945) showed that mouse mammary carcinoma continued to grow even when the diet contained almost no nitrogenous substances. Much of the amino-acids necessary for the growth of the mammary tumour could have come from no other source except the normal tissues.

In contrast to other normal tissues, the effect of the growing tumour on the liver is more complex. Instead of the wasting as seen in most other normal tissues there is often an actual gain in liver weight during the earlier stages of the disease (Medigreanu, 1910; Cramer and Lochhead, 1913; McEwan and Haven, 1941; Yeakel, 1948), and Abels, Rekers, Binkley, Pack, and Rhoads (1942) found that there was liver hypertrophy in 42% of patients suffering from gastro-intestinal cancer. The increase in weight of the liver is due to an increase in liver nitrogen (Yeakel, 1948; Sherman, Morton, and Mider, 1950) as well as an increase in liver water content (McEwen and Haven, 1941). It has been suggested that some growth-promoting factor is produced by the growing tumour and acts specifically on the liver (Paschkis, Cantarow, Stasney, and Hobbs, 1955).

The liver hyperplasia may, on the other hand, be due to an increased liver activity concomitant with the increasing metabolism of the growing tumour, and may be similar to the liver enlargement seen in pregnancy (Cramer and Lochhead, 1913; Walter and Addis, 1939; Poo, Lew, Lee, and Addis, 1940). The stimulating effect on the liver of a

growing transplanted tumour has also been shown by Annau, Manginelli, and Roth (1951) and by Malmgren (1956). The latter was able to demonstrate an increase in the number of mitoses in the liver, and similar changes in liver mitosis were observed after the administration of saline extracts of tumours (Malmgren, 1956). But eventually, in the third stage of the disease, when most of the normal tissues are rapidly losing weight and even the rate of growth of the tumour is reduced, the liver suddenly shows a marked weight loss (McEwen and Haven, 1941). It appears that when the last usable sources of nitrogen from the normal tissues of the body have been utilized by the growing tumour mass the liver suddenly surrenders its own nitrogenous materials to keep the malignant cells supplied with metabolites. At this stage of the disease the derangement of the host's nitrogen metabolism has proceeded so far that death rapidly brings the whole process to an end.

Conclusion

The success of the neoplastic cell once it has appeared in the host seems to us to be in the superior ability of such cell to capture from the internal environment, and to concentrate intracellularly, the free amino-acids essential for its protein synthesis. In this activity the neoplastic cell is superior to the normal cell, and the degree of such superiority decides the eventual history of the tumour. Those tumours which are only slightly more active than the normal in their ability to concentrate amino-acids will grow slowly and produce only minor metabolic disturbances, while the more active ones will infiltrate faster, cause anorexia, and produce rapid cachexia and eventual death.

MONKEY-BITE ENCEPHALOMYELITIS

REPORT OF A CASE—WITH RECOVERY

BY

G. E. BREEN, M.D., D.P.H., D.O.M.S.

Physician-Superintendent

S. G. LAMB, M.B., Ch.B., D.P.H.

Assistant Physician

AND

A. T. OTAKI, M.B., B.S.

Registrar

The South Middlesex Hospital, Isleworth, Middlesex

Those who handle monkeys are frequently bitten, usually without untoward results. Exceptionally, however, disaster may follow. Sabin and Wright (1934) first recorded a case of acute encephalomyelitis in a doctor who had sustained such a bite. Within three days vesiculo-pustular lesions developed at the site of the bite followed by regional lymphangitis and adenitis. A week later signs of motor and sensory disturbances began in the legs and bladder, and these were followed by an acute ascending myelitis. Death in respiratory failure occurred in a few days. From lesions in the cord, brain, and spleen a strongly neurotropic filterable virus was isolated which they named "monkey B." Sabin (1949) also reported a second case with a somewhat similar history, course, and termination, though there had been no bite and infection had presumably resulted from contamination of a laceration on the right hand with infected monkey saliva. A similar virus was again recovered.

Olitsky and Casals (1952) referred to two similar cases following monkey-bites; but they were not reported, but were presumed to be virus B infection; both showed encephalitis; both were bitten by monkeys prior to the disease; both, however, were not studied for virus isolation (Olitsky, 1958, personal communication). Sabin (1958, personal communication) believes that he has now traced 10 additional cases retrospectively, one of which recovered with severe disability. We have knowledge of one fatal case in this country, while two other fatal cases have been reported from Canada (*The Times*, March 22, 1958). How many of these have been studied virologically is unknown and none has been published. The following is the first complete account of the natural history of the disease, as well as the first recovery to be recorded. This is the more pertinent, since it is now clear that monkey-bite encephalomyelitis is not only a lethal but an increasing hazard.

(Virus B appears to be closely related to the herpes simplex virus of man, of which, indeed, it may be regarded as the simian variant. Most commonly it causes shallow ulceration on the dorsum of the tongue, though ulceration may occur elsewhere in the mouth or pharynx. Rarely it excites a vesiculo-pustular eruption on the lips. An important point is that the animal appears quite well, although at post-mortem examination the tracts of the cranial nerves may show multiple infiltrations by microglia surrounding cells containing what appear to be inclusion bodies. In tissue culture, virus B causes typical ballooning of the cells, frequently resulting in the formation of giant cells.)

Case Report

A monkey-handler aged 31 had been immunized against poliomyelitis in midsummer, 1957. On September 24 he was bitten in turn by two apparently healthy monkeys, once on the terminal phalanx of the left index finger and once on the dorsum of the third left finger. Both lesions were made to bleed and washed under the running tap, following which tincture of iodine was applied. They healed uneventfully. On September 30 he was vaccinated against influenza. On October 7 he went to his doctor complaining of a pain between the shoulder-blades, which the following day developed into a left-sided girdle pain and later passed off. (This was attributed to the vaccination against influenza.) For the next few days, apart from a headache, he felt well, but on October 13 his left leg gave way at work and he was sent home as a case of influenza. On the following day he could scarcely walk and was unable to pass water. He was sent to hospital as a suspected case of poliomyelitis.

When seen by one of us (G. E. B.) at Maidenhead Isolation Hospital on October 16 he was febrile but conscious and co-operative. He had been vomiting frequently. He could not sit up, but could bend his head freely—there was no true meningism. Pupillary reactions were normal, but there was marked anisocoria, with twitching of the face and trembling of the tongue. The abdominal reflexes were present. The left arm was weak and the triceps-jerk absent. The right arm appeared normal, but the reflexes were grossly exaggerated; the muscles of the back, pelvis, and abdomen were also weak; the left leg was almost immobile, with absent jerks; the right was weak and the reflexes were reduced; the plantars were equivocal. In addition there was loss of touch, pain, and vibration sense over the left lower leg and ankle, and a patchy loss of sensation over the lower half of the body generally. A lumbar puncture showed a clear fluid containing 75 cells per c.mm.; protein, 80 mg. per 100 ml.; sugar, 68 mg. per 100 ml. His was clearly not a case of poliomyelitis, and, in view of the history, the possibility of virus B infection had to be considered.

Two days later (October 18), because of developing weakness of respiration, he was transferred to the South Middlesex Hospital. On admission paralysis was found to have progressed. In addition to the signs previously noted there was weakness of the intercostals and of the left leaf of the diaphragm, and the vital capacity was down to 2 litres. The abdominal reflexes too were now absent. Both lower limbs were extremely weak, with absent reflexes, and the reflexes were also reduced in the left arm. The right arm still seemed normal, with increased jerks. There was now some left facial weakness, and, though the anisocoria had disappeared, there was marked nystagmus on looking upwards and to the right. Sensory loss over the lower half of the body was widespread and retention of urine was absolute. In the hope that it might contain some relevant antibody, he was given 10 ml. of human gamma-globulin.

On the morning of October 19 his vital capacity had fallen to 800 ml. and respirations were rapid and shallow. He was placed in a tank respirator and at first settled down well. High pyrexia continued, however, and vomiting was frequent. His vital capacity continued to fall—to 460 ml. at 8 p.m. At the same time his voice became hoarse, and pooling of secretions in the pharynx necessitated frequent suction. He was therefore removed from the tank respirator and, under general anaesthesia, a tracheostomy was made, a cuffed endotracheal tube was inserted, and he was placed on intermittent positive-pressure respiration, using a Radcliffe respirator. As the nose was impassable to a catheter, an intravenous drip was set up in which cortisone, 100 mg., was incorporated. A further 10 ml. of gamma-globulin was also given.

As is common in such cases, progress during the following week was somewhat chequered, though eventually the patient settled down fairly well. During the week, cortisone,

200 mg. daily, was administered by intramuscular injection, antibiotic cover being maintained. The temperature fell by slow lysis. Limb paralysis was now almost complete, with absent reflexes all round; facial weakness was notable and nystagmus pronounced. Fortunately, some improvement in swallowing soon began, so that by October 26 fluids could be taken by mouth and by October 29 semi-solids could be taken as well; intravenous maintenance was therefore discontinued. Shortly thereafter some increase in motor power in the limbs generally was noted, but painful involuntary spasms appeared in the left leg. On November 7 the patient went for two minutes without assistance to respiration, and breathing power continued to improve until November 9, when it was interrupted by massive collapse of the left lung which was cleared only by vigorous physiotherapy. Thereafter respiratory capacity increased slowly but steadily, and it was possible to substitute a rocking-bed for positive-pressure respiration for short periods. General progress was much influenced by an intractable bladder infection, at first with *E. coli* and later with *Pseudomonas pyocyanea* requiring treatment with polymyxin B. The pressure points also gave trouble, and an intractable bed sore developed over the sacrum which demanded the use of a ripple mattress. Daily enemata were also necessary. On November 8, for the first time, he felt an injection into the right buttock.

The patient's psychology presented a curious parallel to his physical condition. At first he was well controlled if occasionally confused, and he was always an unsatisfactory witness for sensory evaluation. When placed in the tank respirator he was fairly calm, but a few days later he became increasingly irritable, excitable, and emotional, often weeping spontaneously. Subsequently he stated that he had no memory of events from the time he was placed in the respirator on October 19 until about November 15. After that date, though still highly emotional, irritability diminished markedly, but he continued very apprehensive, thereby delaying his weaning from the respirator considerably. About November 15 bladder control became re-established. Gradual improvement in breathing resulting in a vital capacity of 2 litres enabled artificial respiration to be discontinued on December 9. About this time reflexes and sensation also began to appear in the limbs, and by January 15, 1958, power was regained almost fully in the right arm and leg and to a considerable extent in the left arm. The left leg, however, remained sharply contracted and tremulous and apt to go into painful clonic spasms on the least stimulation. On passive extension it gave a sensation reminiscent of that encountered in cases of post-encephalitis lethargica. The plantar reflexes remained extensor. By now the left facial nerve had quite recovered and the pupils were normal, but there was still some fine residual nystagmus, especially on looking upwards.

On January 27 the patient was transferred to a long-stay hospital for further rehabilitation. The latest report (April 9) stated that he was quite fit, and with elbow crutches and a full-length calliper could walk 25 yards without aid. The power in his arms was back to normal. There was no sensory disturbance left and bladder control had entirely returned. The spasm in the left leg was progressively diminishing and there was every indication that he would be able to resume an active life and return to full work in due course.

Comment

The picture is consistent with a virus infection which ascended along the peripheral nerves to the cord, producing widespread foci of inflammation throughout the whole central nervous system. It is remarkable that signs were much more pronounced and lasting on the left (the bitten side) than on the right, which recovered much more rapidly. The lesions appeared to affect the long tracts mainly, the anterior horn cells escaping undamaged. Sensory changes, while at one time widespread, also proved transitory.

Psychological changes were also notable—irritability and gross emotional lability. There was amnesia for a period of about three weeks. The patient's intelligence seemed to be unimpaired.

The value of the gamma-globulin and of the cortisone given in treatment is difficult to assess. Even if the former contained significant quantities of herpes simplex antibody valid against virus B, it would appear (by analogy with other virus disease) to have been given much too late to exert any appreciable influence on the course of the condition. From the time that cortisone was administered, the march of the paralysis appeared to halt and the temperature returned to normal by a slow lysis, but there was no dramatic fall such as is commonly seen in other conditions where it has proved effective.

A NOTE ON VIROLOGY

By W. Wood, O.B.E., M.B., B.S.

Attempts to isolate the causal agent from faecal and serum samples and determinations of virus B neutralizing antibody on acute and convalescent sera were carried out. All tests were run in monolayer tissue cultures of monkey-kidney tissue, employing a method outlined previously (Tyrrell, Keeble, and Wood, 1956). Samples of faeces were prepared for inoculation by making a 10% suspension in normal saline and clarifying by centrifugation at 2,500 r.p.m. Serum samples were titrated against two strains of virus B—one isolated at Sefton Park, the other isolated in Canada in 1953 (Wood and Shimada, 1954).

Specimens.—Faecal samples were obtained on October 16 and 28, 3 and 15 days respectively after onset of illness. Serum samples were obtained on October 16 and 21, November 8, and January 21; 3, 8, 26, and 100 days respectively after onset.

Results.—Tests for virus isolation on both faecal samples and the first three serum samples were negative. The final serum sample was not tested for presence of virus.

The virus B antibody titres in the four serum samples were as follows: day 3, 1:16; day 8, 1:25; day 26, 1:48; day 100, 1:32.

Conclusions.—Failure to isolate virus B from faecal samples is considered of no significance in that the route of infection via a wound would not necessarily involve alimentary infection. The results of the antibody tests are difficult to interpret, as we are ignorant of the degree to which neutralizing antibody develops in humans recovering from a virus B infection. It is also possible that the administration of cortisone in this patient depressed the antibody response in convalescence. However, a moderate rise in antibody did occur between the third and 20th days which, if considered in conjunction with the clinical data, suggests virus B encephalomyelitis as a probable diagnosis. It should be remembered, however, that monkeys may harbour many different viruses whose potentialities for causing disease in man are not yet fully known, so that it is not impossible that a virus of monkey origin other than virus B may have been responsible for this patient's disease.

Summary

A case of encephalomyelitis following monkey-bites is described. After a very stormy illness necessitating tracheotomy and intermittent positive-pressure respiration the patient made a good recovery and should be able to return to an active life.

NEUROLOGICAL COMPLICATIONS OF PERTUSSIS IMMUNIZATION

BY

J. M. BERG, M.B., B.Ch., M.Sc.

From the Fountain Hospital, London

Since Madsen (1933) first drew attention to the possibility of serious consequences following active immunization against whooping-cough, reports of neurological sequelae of such immunization have come from various parts of the world. These sequelae (post-inoculation poliomyelitis is not being considered here) have ranged from transient convulsions with complete recovery to gross crippling, mental retardation, and death.

A survey of the literature, greatly facilitated by Köng's (1953) review of cases reported up to 1951, revealed records of 107 cases. A further case is now reported (the seventh from Great Britain), together with a review of the literature.

Case Report

A male child was born at full term on September 28, 1954, weighing 5 lb. 13 oz. (2.635 kg.) following an uneventful pregnancy (apart from an attack of acute salpingitis at 11 weeks, associated with a negative Wassermann reaction and gonococcal complement-fixation test, which responded rapidly to chloramphenicol) and an uncomplicated labour. His parents and two elder brothers were normal, physically and mentally, and there was no family history of allergy, mental disorder, convulsions, or other neurological ailments.

No abnormalities were found in the neonatal period, apart from a minor degree of hypospadias not considered worth treating, and the child thrived from the outset.

Until May 25, 1955 (aged 8 months), progress was normal and he had had no illnesses. The mother, an intelligent woman, considered him more advanced than his normal brothers had been at the same stage, and the milestones of development were well in keeping with the criteria of normality enumerated by Illingworth (1953).

On May 25 he was given a first inoculation of 1 ml. of combined diphtheria-pertussis vaccine (containing a plain suspension of 20,000 million *Haemophilus pertussis* and 25 Lf of fluid diphtheria formol toxoid). That night he was whimpering and unsettled, an unusual feature for him. Early next morning he was drowsy, hypotonic, and pyrexial, and the following morning—that is, within 48 hours of the injection—convulsive episodes began, described by a doctor then attending him as “involving a preliminary cry which is not his usual sound, clutching at the chest, queer breathing, and spasms of all four limbs.” Rolling of the eyes was also noted. The pyrexia settled that day, but the fits persisted (one to four daily) despite bromides. That day, too, the child was no longer sitting up, could not support his head, and was indifferent to his environment.

Because the fits and associated features persisted, he was admitted to hospital three weeks after the inoculation. Observation revealed a child without interest in anything, who, if placed in a sitting position, could remain thus unsupported for only a few seconds, and who was having bouts of fits, each lasting a few seconds and each bout a few minutes. Apart from these findings, physical examination revealed no abnormalities, and the blood count, cerebrospinal fluid, and urine examinations were normal. The Wassermann reaction and Mantoux (1/100) were negative. Several weeks later skull x-ray films and lumbar encephalography showed no abnormality apart from the left lateral ventricle appearing slightly larger than the right.

At 11 months of age the child was severely retarded mentally, and phenobarbitone, $\frac{1}{4}$ gr. (16 mg.) twice daily, was needed to control his fits.

At 15 months grand-mal episodes became associated with the original convulsive pattern, and it was found necessary to increase the dose of phenobarbitone to 1 gr. (65 mg.) daily, and introduce phenytoin sodium, $\frac{1}{4}$ gr. (50 mg.) thrice daily.

Electroencephalography on May 16, 1956 (aged 19 months), was considered diagnostic of epilepsy with the epileptic activity generalized and no focus. The main activity was in the delta range and of high frequency.

At 2 years of age no significant progress had been made mentally; fits were controlled with phenobarbitone, 1 gr. (65 mg.) twice daily, and primidone, 250 mg. twice daily; and there were no focal neurological signs.

At 3 years the child remained grossly retarded mentally, with no speech or understanding of speech, inability to do anything for himself, and an I.Q. of 23 on the Griffiths mental development scale. Fits were less severe and were controlled with primidone, 250 mg. twice daily, alone. Localizing neurological signs were absent, as were signs of disease elsewhere.

In the accompanying review of the literature, the 107 case reports from 25 sources mentioned in Table I were examined.

General Data

Sex of Affected Children.—Byers and Moll (1948) thought that the difference in sex incidence in their cases was similar to that encountered in relation to other substances causing gross injury to the developing nervous system. In the 22 other instances where the sex of affected children is stated a similar, though less striking, difference is present (Table II).

TABLE II

	Males	Females	Total
Byers and Moll	12	3	15
Others	14	8	22

Age When Inoculated.—This varied from 4 days to 3 years, most inoculations being done between 6 and 15 months. These figures simply reflect the ages when immunization is usually carried out, and the only conclusion to be drawn from them is that neurological sequelae may occur at any age in which immunizations are done.

Vaccines Used.—The vaccine used is recorded in 68 instances: in 28 a pertussis vaccine was used alone; in 12 a combined diphtheria-pertussis vaccine; and in 28 a combined diphtheria-tetanus-pertussis vaccine. The vaccines were prepared in a variety of ways by different manufacturers, and included fluid, alum-precipitated, aluminium hydroxide adsorbed, and detoxified formalized preparations. In Byers and Moll's (1948) study of 15 cases alone, the products of eight different manufacturers were identified, and in

Toomey's (1949) series of 38 cases at least six different pharmaceutical laboratories were concerned.

No significance can be attached to the number of times when pertussis vaccines alone or combined vaccines were used. These merely reflect the trends in immunization practice and the nature of the material under review. Thus, in the 10 cases reported up to 1945, pertussis vaccine was used alone in all, and thereafter combined vaccines became implicated too because of their increasing use. Further, in the report of Halpern and Halpern (1955), for instance, a triple vaccine was implicated in all 15 cases simply because their questionnaire was concerned only with triple vaccine immunization.

It is generally agreed that the pertussis antigen in all these vaccines is responsible for the reported neurological sequelae. There are good grounds for this view. Thus, the clinical manifestations of neurological complications following injections of pertussis antigen alone and of combined antigens containing pertussis are so strikingly similar that a common factor in all these vaccines is very probable. That this factor is pertussis antigen is suggested by the observations of Miller and Stanton (1954) that neurological complications of pertussis vaccination “are different from those encountered in other prophylactic inoculations in that the illness is always cerebral” and that “the neurological sequelae of a particular prophylactic inoculation appear to be similar in distribution to the neurological complications of the infective disease concerned.” Complications of whooping-cough include convulsions and upper-motor-neurone type paralyses (Banks, 1949), and Cockburn (1951) points out that the convulsions may be the precursors of mental deficiency in a small number of cases. This is precisely the sort of pattern observed in the cases under review, irrespective of whether pertussis antigen alone or combined vaccines containing pertussis antigen were used.

Dose of *H. pertussis* in Vaccines Used.—In 28 instances the number of *H. pertussis* organisms in the injection followed by neurological complications is recorded. This ranged from 1.5 to 45 thousand millions with no particular tendency for reactions to be associated with larger doses (Table III).

TABLE III

Dose (in 1,000 millions of organisms)	1-15	16-30	31-45
No. of cases	8	12	8

Injection Associated with Reaction.—In 61 instances where the injection order is given, neurological sequelae occurred for the first time, as shown in Table IV. These figures indicate that a reaction may occur with any injection, and, possibly, a decreasing likelihood for subsequent injections to provoke reactions the more previous ones there have been that have not done so. In seven cases neurological sequelae followed more than one of the injections (the first

TABLE IV

Injection order	1st	2nd	3rd	4th
No. of cases with neurological sequelae	26	20	12	3

of these injections producing sequelae is recorded in Table IV). It is notable that only one of these seven children recovered rapidly and completely (a case of Grace's, 1950). Of the remaining six children, two died 24 hours (Low, 1955) and 7 weeks (Brody, 1947) respectively after the last inoculation, and four were left with sequelae ranging from recurrent convulsions to gross physical and mental deterioration (Brody, 1947; Byers and Moll, 1948)—this despite the fact that earlier inoculations had not been thought to have had consequences serious enough to contraindicate subsequent ones.

Past Personal and Family Histories

An analysis of these data is difficult to interpret because in many instances no information is given, and when it is given the amount varies greatly from author to author.

TABLE V

	Personal History No. of Cases	Family History No. of Cases
Neurological abnormalities	7	6
Allergic manifestations	1	5
Normal	48	16
Not stated	51	80

Such an analysis is shown in Table V. It may be presumed that considerably more of the personal and family backgrounds were normal than is indicated by these figures, and this is often implied. Table V records only the instances where this was actually stated.

Clinical Features of Acute Illness

Time Interval Till Onset of Symptoms.—The early onset of neurological symptoms was characteristic, though not invariable. Table VI shows the time interval from inoculation to the onset of symptoms in the 63 instances in which it was recorded.

TABLE VI

Time interval in hours	Up to 12	13-24	25-36	37-48	49-72	Over 72
No. of cases	39	9	4	3	2	6

State of Consciousness.—In all instances where this is mentioned changes varying from listlessness to deep coma occurred.

Convulsions.—These, ranging from mild localized episodes to severe generalized ones, were an almost invariable and striking feature. There were, however, several notable exceptions: In one case reported by Brody (1947), four different inoculations (the last an intradermal one) between the ages of 6 and 41 months were associated with severe neurological sequelae at progressively shorter intervals, culminating in complete paralysis and death, apparently without associated convulsions; in Sutherland's (1953) case, listlessness and weakness of the limbs appeared some five to seven days after a third inoculation, with evidence of bilateral pyramidal-tract dysfunction about one month later, and apparent complete recovery within seven months, with no mention of convulsions; and in one of Miller and Stanton's (1954) cases neurological signs (drowsiness and right hemiplegia) were delayed for about a week after a third inoculation, with right hemiparesis still present two years later—here, too, convulsions are not mentioned.

Pareses or Paralyses.—These were specifically stated to have occurred in 19 cases.

Other Features.—Besides the above neurological signs, occasional cases presented additional features such as cyanosis, hiccups, diarrhoea, and vomiting. In 39 cases where the temperature is mentioned, it was elevated in 35. Pyrexia is, however, a not infrequent transient concomitant of immunization in which no question of neurological sequelae arises.

Mortality.—In 8 cases death was reported within 48 hours of inoculation, 7 of them within 24 hours.

Progress

Complete Recovery.—This was specifically reported in 41 cases, including 23 of Toomey's (1949) 38, and 11 of Halpern and Halpern's (1955) 15, and presumably occurred in at least nine other instances.

Persisting Morbidity.—Follow-up of the affected children for varying periods revealed evidence of persisting abnormality (Table VII). So far as could be determined from the case reports, in a number of cases in which absence of details makes a fuller analysis of the above signs somewhat hazardous, these signs were distributed as follows: A only, 9 cases; B only, 8; C only, 1; A+B, 2; A+C, 2; B+C, 3; A+B+C, 6. Thus a total of 31 children were specifically

TABLE VII

Major Signs	Follow-up Period	No. of Cases in Which Actually Reported

C=Mental retardation	2 months—5½ years	12

* Varying from slight hemiparesis to gross crippling.

reported as having physical and/or mental signs of cerebral involvement one month to five and a half years after immunization.

Mortality.—Fifteen deaths (seven of them within 24 hours) were reported at varying time intervals since inoculation (Table VIII). Thus, an analysis of the available data indicates a recovery rate of about 50%, a persisting

TABLE VIII

Time interval since inoculation	1-48 Hours	1-2 Months	6 Months	20 Months	Unspecified
No. of deaths	8	2	1	1	3

morbidity rate of about 30%, and a mortality rate of about 15%. The small percentage of cases unaccounted for because of lack of information in the reports would not significantly alter these figures.

Aetiological Considerations

Various hypotheses to account for the complications discussed have been advanced from time to time, but each is open to objection and there is still no unanimity of opinion. Among the suggested causes are the following.

1. **A Sensitization Phenomenon.**—Miller and Stanton (1954) considered that "most neurological illnesses which follow prophylactic inoculation are manifestations of hypersensitivity," and Brody (1947) favoured a sensitization phenomenon as an explanation in the two cases reported by him, pointing out that both had a family history of allergic disturbances. However, allergy was recorded in only two other instances in the reviewed cases: the father of twins reported by Werne and Garrow (1946) as having died within 20 hours of a second diphtheria-pertussis inoculation had had two episodes of angioneurotic oedema of the lip; and one of Köng's (1953) cases had a personal and family history of asthma and eczema. An antigen-antibody response to previous specific sensitization has been suggested as a possible cause, but this is difficult to reconcile with the relatively large number of children who developed neurological sequelae following a first inoculation. It could well account, however, for some of the other cases—for instance, those of Werne and Garrow (1946), where necropsies "disclosed lesions consistent with death in anaphylactic shock."

2. **A Specific Toxin or Toxins Produced by *H. Pertussis*.**—Toxins have been isolated from *H. pertussis* cultures (Byers and Moll, 1948); and Miller (1951), who favours this view of the aetiology, points out that they are known to be neurotropic in experimental animals. However, Byers and Moll (1948) have raised the serious objection that as these toxins are unstable they can hardly survive in properly aged vaccines.

3. **Some Constitutional Predisposition in Affected Children.**—The sex ratio in Byers and Moll's series has been thought to suggest this possibility (*British Medical Journal*, 1950), but it is difficult to know what is meant by the term "constitutional predisposition." Certainly a large proportion of the patients reviewed were regarded as normal in all respects prior to their inoculations.

4. **Pyrogens Contaminating Vaccines.**—While this hypothesis has sometimes been postulated, there appears to be no definite evidence in favour of it.

5. **Accidental Intravenous Injection of Vaccine.**—As Faber and Miller (1948) have pointed out, this could be a

factor only in reactions occurring almost immediately after injection. In the reviewed cases, reactions within half an hour were reported only six times.

Contraindications to Immunization

Though complications following pertussis immunization may be serious and even fatal, they are extremely rare, and it is generally conceded that such immunization is undoubtedly worth while. It is well known that whooping-cough itself may produce serious complications, neurological and others, and the opinion of Brody and Sorley (1947) that "the risks of not immunizing against whooping-cough are vastly greater than the risks of immunizing" probably reflects the general view. Byers and Moll (1948) found that, in the same 10-year period during which their 15 cases of pertussis vaccine encephalopathy were admitted to the Boston Children's Hospital, 26 children suffering from the effects of encephalopathy complicating pertussis itself were admitted to the same hospital. Of these 26 children seven died during their acute illness, six had mental retardation, three had chronic convulsions, and one had cerebral palsy.

Opinions differ, however, on what constitute the contraindications to immunization. Some have regarded a personal or family history of convulsions or other neurological disorders as a definite contraindication (for instance, Cockburn, 1951; Tudor, 1951; Escardo and Vazquez, 1950; Köng, 1953; Sutherland, 1953). Others, while tending towards this viewpoint, have been less emphatic. Both Toomey (1949) and Grace (1950), for example, suggest a decreased dosage in these circumstances. As analysis of the reviewed data does not indicate any tendency for reactions to be associated particularly with larger doses, decreased dosage would not seem helpful, besides creating the problem of possible inadequate immunity. On the other hand, Melin (1953), basing his views on experience with epileptic children in Stockholm, actually recommends pertussis vaccination for children with convulsive disorders because he considers that "the risk of a seized child contracting pertussis and eventually developing complications is more pronounced than the risk involved in the immunization procedure itself." Peterman (1953), Livingston (1953), and Byers (1953) have agreed with Melin.

The small number of reported suspect nervous systems, based on personal and family histories, in the cases reviewed would seem to bear out Livingston's (1953) doubt about children with convulsive disorders or tendencies being more likely to develop cerebral complications from pertussis immunizations than other children. The whole question depends on whether a child, in any given circumstances, both personal and environmental, is more likely to contract pertussis with serious complications therefrom than he is to develop serious sequelae from pertussis inoculation, and this is a matter not easily settled. On one point, however, there appears to be no room for controversy, and this is that any suggestion of a neurological reaction to a pertussis inoculation should be an *absolute* contraindication to further inoculation. This is forcefully illustrated by the fact that of the seven patients who had neurological sequelae after more than one injection two died and four were left with grave complications.

Allergy is sometimes considered a contraindication to inoculation. Köng (1953) lists allergic diseases among his contraindications, and Miller (1951) considers fractional doses advisable in asthmatic children. Halpern and Halpern (1955) feel that it may be advisable to administer smaller doses more frequently in older, highly allergic children. The few cases among those reviewed where a personal or family history of allergy was reported suggest that it is perhaps over-cautious to consider this as a contraindication.

Some authors, amongst them Miller (1951), Cockburn (1953), and Sutherland (1953), have recommended that inoculations should not be undertaken while a child is unfit or suffering from acute illness of any sort. While there appears to be no direct evidence that reactions are more likely under such circumstances, it seems a reasonable

precaution to avoid provoking a possible reaction at a time when resistance is likely to be relatively low.

Summary

A case is reported of an 8-months-old normal child who, within 24 hours of a combined diphtheria-pertussis inoculation, became pyrexial, drowsy, and hypotonic. Convulsions and evidence of mental deterioration followed rapidly. At 3 years of age convulsions still persisted and mental retardation was gross (I.Q.=23).

Review is made of 107 cases of neurological complications of pertussis inoculation reported in the literature. Males predominated; reactions occurred in all age groups in which immunizations were done, irrespective of the dosage used, and followed first or subsequent inoculations. A wide variety of vaccines, single and combined, were implicated. Past personal and family histories indicated relatively few instances of neurological or allergic abnormalities. The early onset of neurological symptoms was characteristic, with changes of consciousness and convulsions as the most striking features. Pareses or paralyses were not infrequent, and eight children died within 48 hours of inoculation. Follow-up revealed a recovery rate of about 50%, a persisting morbidity rate (physical and/or mental) of about 30%, and a mortality rate of about 15%.

The question of aetiology is considered and contraindications are discussed. The value of pertussis immunization is emphasized, as is the grave danger of further inoculations when a previous one has produced any suggestion of a neurological reaction.

My thanks are due to Dr. L. T. Hilliard, physician-superintendent of the Fountain Hospital, for his comments and permission to publish. Also to Drs. B. H. Kirman, L. Crome, P. Sylvester, and J. Stern for reading the manuscript and offering helpful criticism, and to Miss M. Craib for so expeditiously arranging various interviews. I also thank Dr. A. A. Cunningham, of the Kingston Hospital, for making available many of the data about the case reported, and Dr. W. C. Cockburn, of the Public Health Laboratory Service, Colindale, for his kind interest and comments.

THE NEUROLOGICAL COMPLICATIONS OF MUMPS

BY

R. ROSS RUSSELL, M.D., M.R.C.P.

Formerly Captain, R.A.M.C., B.M.H., Taiping, Malaya

AND

J. C. DONALD, M.B.

Formerly Captain, R.A.M.C., R.M.O. Gurkha Depot, Sungei Patani, Malaya

The neurological complications of mumps have been recognized since the eighteenth century, and a number of reports have appeared in the European and American literature describing various forms and the frequency with which they occur. Thus in 1911 Doptor reviewed 1,700 cases of mumps and estimated that 9.8% showed meningeal symptoms. Laurence and McGavin (1948) found 60 cases in an epidemic involving 208 New Zealand Service men; and Frankland (1941), in discussing an outbreak of 234 cases, put the incidence of meningitis as high as 30%. On the other hand, Paddock (1932) and Coe (1945) found neurological involvement in only 0.15–0.5% of their series, which were less selective and covered a wider age range.

It has been suggested that differences in frequency of meningitis in various epidemics are due to variations in resistance to infection, perhaps due to racial factors or to an altered virulence of the mumps virus leading to an increased affinity for nervous tissue. It is partly accounted for by the different criteria which have been used in the diagnosis of meningitis, some authors relying on symptoms, others on symptoms and physical signs, and some on the alterations in cerebrospinal fluid. To add to the confusion, it has been repeatedly confirmed, since Lavergne's observation in 1938, that cerebrospinal pleocytosis may occur in uncomplicated cases of mumps (Finkelstein, 1938) or even in contacts showing no signs of mumps (Frankland, 1941), and that meningeal symptoms may precede parotitis by as much as ten days (Bedingfield, 1927; Frankland, 1941).

These facts led Doptor and others to the view that the mumps virus is primarily neurotropic and that involvement of the parotid glands occurs as a secondary and not invariable complication. The existence of a separate neurotropic strain of the virus has not received much support (Macrae and Campbell, 1949), and Gordon (1927) was able to produce a fatal meningo-encephalitis in a monkey by intracerebral inoculation of material from throat-washings of uncomplicated cases. No correlation has been found between the occurrence of nervous complications and the severity of parotid disease or of epididymo-orchitis (Holden, Eagles, and Stevens, 1946).

Mumps meningitis is a remarkably benign condition usually appearing within a few days of the parotid enlargement and recovering without complications in three to four days; occasionally it may precede parotitis or occur alone. The cerebrospinal fluid contains a variable number of lymphocytes (10–1,000 per c.mm.) with slight increase in protein and normal values for chloride and glucose. Mumps virus has been isolated from the spinal fluid (Henle and McDougall, 1947).

The major neurological complications are much less common (approximately 1 in 6,000) and have been

reviewed by Miller, Stanton, and Gibbons (1956). They may occur at the time of parotitis or up to 23 days afterwards, the average latent period being 7.2 days. Encephalitis cases are less rare than the other varieties—myelitis, polyradiculitis, and polyneuritis. Mental symptoms are prominent in encephalitis, and clinical features include drowsiness, convulsions, headache, psychoses, ataxia, and hemiplegia. Neck stiffness, involuntary movements, increased reflexes, and extensor plantar responses may be found. Deep coma may occur, and is an unfavourable prognostic sign. The cerebrospinal fluid often shows a lymphocytosis, but may be normal. Death occurs in approximately 20% of cases, and 33% of those who recover may show major sequelae consisting of hemiplegia, ataxia, and involuntary movements.

Fatal cases show a patchy perivenular demyelination similar to that seen following other post-infective encephalitides (Donohue, Playfair, and Whitaker, 1955).

Cranial nerve palsies involving the optic, facial, trigeminal, or oculomotor nerves may occur (Laurence and McGavin, 1948; Macrae and Campbell, 1949), and the important complication of labyrinthitis may be permanent and unassociated with signs of neurological damage. Local weakness of the limbs with transient loss of tendon reflexes and subjective sensory disturbance has been described (Lightwood, 1946; Laurence and McGavin, 1948).

In the following report 18 cases of meningitis and one of encephalitis occurring in the course of a mumps epidemic are described.

Incidence

During February–October, 1956, there was an epidemic of mumps in Gurkha troops stationed at Sungai Patani, Malaya. A total of 287 cases occurred, and 84% of the patients came from "Recruit Company" and "Boys' Company," aged 14–17. A number of those infected had arrived from widely scattered areas in Nepal two months previously.

The infection reached a peak in June, when there were 58 cases.

In the great majority the disease ran a benign course over a few days, but in the latter part of the epidemic meningitis began to appear, reaching a maximum in July, when there were 12 cases, one in every five being affected.

Thirteen cases had salivary glandular enlargement and meningitis; one had parotitis, orchitis, and meningitis; one had orchitis and meningitis; and three had meningitis alone.

TABLE I.—Onset of Meningitis Related to Appearance of Parotitis

	Days Before		Appearance of Parotitis	Days After									
	2	1	0	1	2	3	4	5	6	7	8	9	10
Cases of meningitis	1			1	1	2	4	1	1		2		1

The occurrence of these events is shown in Table I; it will be seen that in one case the meningitis preceded the parotitis by two days.

In the three cases presenting with meningitis alone there was no opportunity of confirming the diagnosis by serological means as described by Kilham, Levens, and Enders (1949), but, in view of their similar benign course and the presence of an epidemic, it was assumed that they were variants of the same malady.

The incidence of all complications is set out in Table II, and it will be noted that, in contrast to meningitis, orchitis occurred in sporadic fashion evenly distributed throughout the epidemic.

TABLE II.—Incidence of Complications

	Feb.	Mar.	Apr.	May	June	July	Aug.	Sept.	Total
Cases admitted	13	39	29	41	58	51	35	21	287

Meningitis					2	12	1	1	18
Encephalitis									1
Percentage incidence of meningitis					3.4	23.5	8.6	5.0	6.3

Clinical Features

Meningitis (18 cases)

The patients reached hospital on the first or second day following the appearance of parotitis. They were usually pyrexial, but in good general condition and reluctant to be confined to bed.

The pyrexia settled in 48 hours, but with the onset of meningitis it recurred (see Chart), and the cheerful swollen

Case 14. Boy aged 15. Temperature and pulse rate during illness.

faces were transformed overnight by expressions of extreme misery. The patients lay curled up in bed, complaining of severe headache and photophobia and refusing food and drink with such persistence that some had to be given fluids by tube. Vomiting occurred frequently and some had pain in the muscles of the legs.

On examination the most prominent finding was rigidity of the spine, which moved "in one piece" if an attempt was made to flex the neck. Kernig's sign was positive and there was slight muscle tenderness in the calves but no other objective neurological signs. Nystagmus, which had been reported in this condition, was not seen, and tendon reflexes were unaltered.

All the patients were irritable when disturbed and resented examination, but when induced to talk they seemed rational. They tended to spend a large part of the day asleep, but there was no nocturnal restlessness. The headache responded to aspirin in large doses, and appeared to be somewhat relieved by lumbar puncture.

The urine often contained ketone bodies but no albumin, and white-cell estimations showed values of 8,000–12,000 per c.mm., with a normal differential count. Recovery was rapid and complete in two to three days, and neurological examination four months later was negative. Two boys were thought by their instructors to be slower mentally after the illness, but apart from this equivocal finding there were no sequelae.

Cerebrospinal fluid was examined in all cases, and was usually repeated after 10 days. The results are summarized in Table III.

The cellular reaction was predominantly lymphocytic, although up to 60% of polymorphs was not unusual in the early stages. Estimations done later in the disease invariably

showed a preponderance of lymphocytes. Total counts in the acute stage varied between 200 and 800 cells per c.mm., falling rapidly in a few days, but in some cases being still significantly raised at the end of two weeks, when patients were asymptomatic and seemed fit for discharge. The protein was raised in proportion, with a usual reading at 60–100 mg. per 100 ml., and chloride and sugar estimations showed no significant abnormality. Six uncomplicated cases of mumps from the same epidemic and at the same time were subjected to lumbar puncture. Results were normal in every respect.

Encephalitis (1 case)

A previously healthy boy aged 14 with no past or family history of psychiatric disturbance was admitted with swelling of parotid and submandibular glands present for two days. He was slightly pyrexial on admission—temperature 99.4° F. (37.4° C.).

The swelling subsided over the first week, but on the ninth day he began to vomit and refused all nourishment. Over the course of 24 hours he became speechless and extremely drowsy, with episodes of mania when disturbed. In these he struggled violently with the attendants, grinding his teeth and biting anyone within reach, although never speaking a word. Headache was not prominent, but he appeared to have some abdominal pain. Temperature and pulse were normal. He was restless at night and slept fitfully during the day. He developed retention of urine, requiring catheterization.

Satisfactory examination of the nervous system was well-nigh impossible, but there was no gross disturbance of

D

cranial nerves or limbs; there were no signs of meningeal irritation. The tendon reflexes were present and equal and the plantar responses were flexor. Lumbar puncture yielded normal cerebrospinal fluid under increased pressure. The urine contained no albumin or sugar and the urinary diastase was normal. Blood-sugar and blood-urea estimations gave no additional information.

After three days of mutism and grossly abnormal behaviour he began to improve; speech returned after a further 24 hours, and within a week he was completely recovered, having an amnesia extending over the encephalitis episode. Examination at this time and again three months later revealed no neurological or psychiatric abnormality and his subsequent mental state is reported as unchanged.

Comment.—There are many resemblances to previously reported cases, notably the acute onset nine days after the appearance of parotitis, and the predominance of mental over physical features. The absence of meningeal symptoms and of cerebrospinal fluid changes is well recognized. Unusual features are retention of urine unaccompanied by any signs of spinal-cord involvement, and the occurrence of mutism.

Discussion

The cases reported above conform to the description given by previous authors. They emphasize the important clinical distinction to be made between meningitis, a common and relatively trivial complication, and encephalitis, a serious condition with high mortality. The reason why the nervous system reacts in these two ways to infection with the mumps virus is not fully understood, although it has been the subject of much recent research.

The clinical syndrome of meningeal irritation, combined with the finding of cerebrospinal pleocytosis and the fact that the virus can be isolated from the spinal fluid, makes it likely that the changes of mumps meningitis are due to the direct action of the virus. In the present epidemic, an unusual one in that it occurred in an adolescent community only recently exposed to mumps, the overall incidence of meningitis (6.3%) is not unduly high, but it is significant that all the meningitic cases occurred in the course of a few weeks in the latter part of the epidemic. This suggests that the virus acquired an unusual degree of neurotropism during the epidemic, reaching a peak in July, when the incidence of meningitis was 23%. There was no increase in the frequency of orchitis or other visceral complication at this time.

If separate strains of virus with increased affinity for nervous tissue do arise in this way the incidence of meningitis in an epidemic of mumps is related more to the properties of the virus than to the state of immunity of the patients. This may help to explain the widely differing estimates of the frequency of meningitis as reported by various authors. It is, of course, also possible that the meningitic cases were due to a superadded infection with an unrelated virus, but this seems unlikely, and has received no support from serological studies (Kilham, Levens, and Enders, 1949).

The occurrence in the present series of two cases of meningitis without other features of mumps serves as a reminder that mumps should be included in the differential diagnosis of benign lymphocytic meningitis. The identity of the infection may be obvious during an epidemic, but isolated cases may give rise to difficulty, which is only solved by routine serological testing. In a recent series (Adair, Gauld, and Smadel, 1953) mumps was found to account for 12% of 854 cases of aseptic meningitis in America, and serological studies have been confirmed by the isolation of the virus from the spinal fluid (Kilham, Levens, and Enders, 1949).

Although most authorities agree in attributing meningitis to the direct action of the virus, there are conflicting views on the aetiology of encephalitis. This has been attributed to a further extension of the virus from the subarachnoid space into the neuraxis, possibly as a result of a high degree of neurotropism or a low resistance on the part of the patient

(Donohue, Playfair, and Whitaker, 1955). However, the latent period before the appearance of encephalitis and the occasional absence of meningeal symptoms and of cerebrospinal pleocytosis (as shown by the case reported here) do not support this view, and favour a primarily encephalitic process rather than a spread from the meninges.

The clinical resemblance between mumps encephalitis and the encephalitis which may follow measles, varicella, and rubella, and the fact that the histological appearances of perivascular demyelination are common to them all, suggest that they arise from the same pathological process (Miller, Stanton, and Gibbons, 1956). The nature of this process is unknown, but it may be a non-specific allergic reaction to virus protein (Miller and Evans, 1953), and similar lesions have been produced experimentally by the injection of brain material with adjuvants (Lumsden, 1949).

Summary

Previous reports on the neurological complications of mumps are reviewed. Lymphocytic meningitis is not uncommon, and recovery is full in a few days. Encephalitis is extremely rare, and has a mortality of 20%.

Eighteen cases of meningitis and one of encephalitis arising in an epidemic of 287 cases are described. The meningitic cases occurred only during the latter part of the epidemic.

The aetiology of the neurological sequelae is briefly discussed. Meningitis may well be due to the emergence of strains of viruses of increased neurotropism during an epidemic.

We wish to thank the Director of Medical Services, R.A.M.C., for permission to publish.

Medical Memorandum

Advantages of "Polythene" Ring Pessaries

The advances achieved in surgical technique and, more particularly, in the art of anaesthesia in the past twenty years have made the surgical repair of genital prolapse the ideal method of treating this common disability. However, in spite of these advances there are some women whom it would be too great a risk to subject to an operative cure. We find this group to constitute less than 3% of the total number of patients with symptoms caused by a genital prolapse. A second group of patients complaining of genital prolapse, on whom a surgical repair is not immediately desirable, are the women of child-bearing years who have either been recently delivered or are about to embark on another pregnancy. A third group of patients refuse to undergo a surgical repair. These three groups can have their symptoms relieved by the fitting of a ring pessary into the vagina.

The ideal ring pessary should possess the following properties. (1) It should be made of a substance that is inert and produces no tissue reaction that will lead to a malignant change in the vaginal walls and no offensive vaginal discharge. (2) It should be sufficiently compressible to introduce through a small vaginal introitus, yet possess enough elasticity to regain its shape when introduced into the vagina, and it should not alter in shape or in its physical properties with prolonged use. (3) It should be technically easy to manufacture and cheap to produce.

The many varieties of material from which ring pessaries have been constructed can be divided into those of the pre-plastic era and those of the plastic era. The former group are the rubber watchspring pessary and the vulcanite pessary. The watchspring pessary is compressible, but it produces an offensive vaginal discharge. The vulcanite pessary has both the disadvantage of incompressibility and the property of producing leucorrhoea. Pessaries made from the many varieties of plastics can be constructed of compressible material or a plastic that is for practical purposes incompressible.

The flexibility of plastics such as P.V.C. depends on the presence of a plasticizer. The majority of plasticizers are toxic to tissues when in contact with them for any length of time and may induce a malignant tissue response. A plasticizer with a low vapour pressure, such as dioctylphthalate, does not produce a tissue reaction. It has, however, the disadvantage of escaping from the material with which it has been mixed, and brittleness and loss of flexibility follow.

Pure polythene, however, is chemically almost inert and has been buried in living human tissues for long periods of time without producing any toxic reaction. It is, furthermore, sufficiently flexible and compressible to use as a pessary and firm enough to support the vaginal walls and uterus in a genital prolapse. The material does not lose its flexibility whilst in the vagina. We have had experience of using the pessaries for three years in the vagina without any apparent physical change occurring in the material. The management of the cases treated with polythene pessaries does not vary from pessaries of other materials.

Patients are examined every three months, the vaginal walls are inspected for evidence of ulceration, and the pessary is washed and replaced.

Polythene is made in a number of different grades which, chemically speaking, differ only in their molecular weight. There is very little variation in the physical properties between different grades except at temperatures up to 100° or below 0° C. In particular the modulus of elasticity which determines the flexibility of the product is much the same for all grades at normal temperatures. The only advantage of using a grade of higher molecular weight is that it can be boiled without danger of deformation. From the manufacturer's point of view, however, the light molecular weights are easier to mould. For these reasons the choice of grade is not very important. A $\frac{1}{4}$ in. (0.6 cm.) diameter cross-section provides the necessary flexibility and at the same time is thick enough to support the vaginal walls yet will not cause ulceration.

Cost.—The polythene pessary is cheaper to manufacture than the rubber-ring pessary and its life is infinitely longer; while a rubber ring has a life of only six months at the most, a polythene pessary retains its shape, smooth surface, and flexibility for years.

We are indebted to Mr. D. Annat, M.P.S., chief pharmacist, Stoke Mandeville Hospital, for negotiating the original samples of plastic and polythene and organizing the supplies of the polythene pessaries from the manufacturers, Portland Plastics Ltd., Hythe, Kent.

Reviews

LAW AND ETHICS FOR DOCTORS

Law and Ethics for Doctors. With a Section on General Practice in the National Health Service. By Stephen J. Hadfield, M.A., M.B., B.Chir.(Cantab.). With contributed sections on Negligence, by W. G. Hawkins and the late W. Mair; Superannuation, by L. S. Potter, M.B., Ch.B.; and Income Tax, by W. Donald, C.A. (Pp. 399+xvi. 42s.) London: Eyre and Spottiswoode. 1958.

This excellent book treats with accuracy and judgment the many practical problems which may nowadays confront a doctor outside the purely clinical field. Some of these problems are happily rare in their incidence, but a doctor's career may nevertheless be a good deal influenced by the way in which he handles, for example, a complaint by a colleague of unethical conduct on his part, an allegation of negligence, or an appearance in a court of law. Other difficulties, such as those raised by cases of mental disorder, by questions of certification, or by dangerous drugs and poisons, may be less acute in themselves but are apt to recur more frequently. In his book, which rests on a comprehensive plan, Dr. Hadfield sets out the legal, ethical, and practical considerations which should guide a doctor when he encounters these and many other problems. While offering balanced and realistic advice, in which he has been able to draw on his experience as an Assistant Secretary of the British Medical Association, Dr. Hadfield does not omit to stress the need for seeking early advice in some cases—for example, from a defence organization—before any "home-composed reply" is posted or other irremediable action is taken.

Much of the latter part of the book deals more particularly with general practice in the National Health Service. Apart from supplementary information given in appendices, the aim has been to summarize and throw light upon the lengthy regulations, as distinct from reproducing their terms in full.

A foreword to the book has been contributed by Dr. Solomon Wand.

WALTER PYKE-LEES.

SURGERY AND THE LABORATORY

An Introduction to Experimental Surgical Studies. By W. J. Dempster, F.R.C.S. (Pp. 463; illustrated. 50s.) Oxford: Blackwell Scientific Publications. 1957.

The experimental laboratory has made notable contributions to the progress of modern surgery—sometimes in respect of technical problems that are purely surgical, but often in respect of fundamental physiological, biophysical, and biochemical problems that are equally the concern of all the disciplines of medicine in its widest sense. In fact, it is the almost automatic reference of clinical difficulties to the laboratory—the complete if tardy permeation of medicine by the experimental outlook and method of Harvey and by the experimental and Lister—that has transformed medicine from an art to a science. Unfortunately the fruits of much research are scattered widely in a now voluminous literature; the tyro has difficulty in finding out what has or has not been submitted to critical experimental scrutiny; and the ageing clinician has certainly not the time, even if he has the inclination, to plough through so many original papers. An introduction—or a guide—to what has been accomplished or is at present under investigation is therefore a welcome and important addition to medical literature. Nevertheless—and possibly because one had hoped for more—the present book is a little disappointing. The author is widely recognized as a distinguished and versatile and original research worker, and in those sections of his text that deal with his own interests—the regeneration of tissues, wound healing, and transplantation and tissue and organ grafting—his account is, on the whole, judicious and critical and

comprehensive, though he makes some surprising and incorrect pronouncements—for example, that surgeons have abandoned arterial grafts. He is on less sure ground in his review and criticism of research in such special fields as the gastro-intestinal tract and the liver; here there are some surprising omissions, some obviously personal—and unsupported—opinions, and a bibliography that is less comprehensive than elsewhere. This may be due to a desire to keep the book within reasonable compass; equally it may reflect the impossibility, as on the clinical side, of a single individual's being able to master all facets of surgery.

These friendly criticisms do not detract from the value of a book which I have vastly enjoyed, and greatly admired for its erudition. Indeed, it could form the basis for a longer and more comprehensive book—possibly collaborative—that would enhance the reputation of both the author and his school. If this should happen, or when a second edition of the present work is called for, perhaps Mr. Dempster would delete the somewhat pontifical injunction on page 203 to the effect that "the reader is well advised to take cognizance of the contributions being made to medicine by the basic sciences." There are disadvantages in long residence in any "ivory tower."

JOHN BRUCE.

FAMILY LIFE OF THE AGED

The Family Life of Old People: An Inquiry in East London. By Peter Townsend. Foreword by J. H. Sheldon. (Pp. 284+xvi. 30s.) London: Routledge and Kegan Paul. 1957.

Mr. Townsend has carried out an interesting and important inquiry into the lives of a random sample of 200 old people living in the borough of Bethnal Green. This survey, and the conclusions to be drawn from it, make an important contribution to our knowledge of how the old, and in particular the needy old, live. Mr. Townsend is careful to point out that his inquiries were confined to one only of the metropolitan boroughs, and that his conclusions cannot therefore be universally applied. But there is little, if anything, in his conclusions which differs from those arrived at in comparable, if not precisely similar, surveys that have been carried out in other parts of the country.

Although a large number of the old persons interviewed lived alone, it was interesting to read how few were really isolated: most had relatives living in the borough who were in regular touch with them, and it is heartening to read of the important part still played by the grandmothers in what may be called the "three tier" family. They help to prepare meals, to take care of the grandchildren, and in many other ways continue to play their full part in the life of the family. Retirement of men, particularly if it is enforced on healthy persons of 65, is a real tragedy. The fall in income and in status leads to a loss of friends and diminution of social activities. Jobs for the retired are not easy to find, and are only too often of a character which is uninteresting and humiliating. Yet occupation can be of considerable value in maintaining health, both mental and physical. It is interesting to note the increased proportion of the unmarried or childless who enter the wards of the local geriatric hospital; this further emphasizes the ill effects that loneliness and friendlessness have upon the aged. Boredom, due to lack of suitable occupation, is one of the terrors of old age: one has only to examine any of the well-organized schemes for the employment of the elderly to realize their value. Mr. Townsend's book will provide much valuable information for those who have the welfare and the well-being of the aged at heart.

AMULREE.

THE HINDU PERSONALITY

The Twice-Born: A Study of a Community of High-caste Hindus. By G. Morris Carstairs. Preface by Margaret Mead. (Pp. 343. 30s.) London: The Hogarth Press. 1957.

This is a strangely old-fashioned book for a young author to write. It is perhaps the last of attempts begun in the 1930's to apply psychological theories and psycho-analytical

methods elaborated in the cultures of the West to people and to groups in alien societies. Apart from the epistemological objections, such works (associated notably with the name of Margaret Mead, who provides a brief preface to the present book) have been criticized for their lack of the prerequisite analysis of the social forms within which personalities emerge, loose handling of the evidence, and an over-reliance upon the popularity of the topic. Dr. Carstairs, more sober and modest in style, does not entirely avoid the failings of his predecessors.

The material offered is drawn from a village in Rajputana where the author compiled 45 case histories derived from four castes. The argument attempts to show that there are recognizable personality types corresponding to each of the first three castes (the fourth is marginal), that there is a more basic personality type common to all three, and that finally this basic personality is not without relevance to an understanding of the Hindu personality as such. Dr. Carstairs by no means makes it clear at which level of abstraction his generalizations are to apply. I am surprised to find him ready to comment, from his village data, upon the behaviour of politicians in Delhi.

The most satisfactory sections of the book are the case histories of three informants together with the Rorschach tests analysed by Dr. Rosemary Gordon. There are only three objections to be made here. First, on methodological grounds one may wonder whether Dr. Carstairs is correct in taking as his examples his English-speaking informants. It seems probable that "the distorting influence of translation" which he seeks to avoid is a lesser hindrance to understanding than the imperfect English of villagers. Secondly, the paranoid and suppressed homosexual tendencies which are stressed as elements in the basic Hindu personality do not emerge in the first two examples, and there is only a possible element of homosexuality in the emotional friendship of the third, who is not in fact a member of the local community studied. Thirdly, a query by Dr. Gordon raises serious epistemological doubts. She suggests (p. 325) that differences in cultural life, religious symbolism, and so on make it difficult for a European analyst to score confidently upon the Hindu responses to Rorschach tests. One cannot prevent this doubt extending itself to the range of technical vocabulary derived from psychopathology in the West. Terms like "paranoia" have significance and value only in relation to their opposites—that is, to states of mind regarded as normal in a given society. If paranoia characterizes a whole society and is consequently normal in that society, we have either to redefine our terms completely or else be a good deal more circumspect in our dealings with any of our friends who happen to be Hindus.

The over-all criticism rests finally not upon the relation of evidence offered to conclusion drawn, unsatisfactory as it is. More fundamental are doubts concerning the kind of knowledge sought and the logical premises of the attempt.

D. F. POCOCK.

ALDOSTERONE

An International Symposium on Aldosterone. Edited by Alex F. Muller, M.D., and Cecilia M. O'Connor, B.Sc. (Pp. 232+x; illustrated. 40s.) London: J. and A. Churchill, Ltd. 1958.

This book is a detailed report of contributions by recognized authorities to specialized fields of research on aldosterone. It is based on 13 papers of high standard, followed by detailed discussions, which as usual contain a mass of useful information. The organizers of the symposium, held in Geneva last year—Professor R. Mach and his Swiss colleagues—are to be congratulated, and the editors too have done their work well. I feel that the technical production of the book itself does not give the ease of reading characteristic of earlier volumes by the same publisher; in particular, some of the diagrams are a little obscure and some are accompanied by liberal amounts of excessively small print.

It would be invidious to draw distinction between the various contributions, but chapters that might be expected

to have the most general appeal include those on the site of aldosterone secretion by Giroud and colleagues, its metabolism by Tait and colleagues, and oedema by Wolff and colleagues. Those by Garrod and colleagues and Stanbury and colleagues contain useful review material on so-called primary aldosteronism and renal abnormalities in relation to aldosterone respectively.

F. T. G. PRUNTY.

MEDICINE FOR DENTISTS

Oral Medicine: Diagnosis and Treatment. By Lester W. Burket, A.B., D.D.S., M.D., Sc.D. With a Chapter on Oral Cancer by S. Gordon Castiglano, B.A., B.S., M.D., F.A.C.S. Third edition. (Pp. 558+xxi; illustrated. £5.) London: Pitman Medical Publishing Co., Ltd. 1957.

This is a further edition of an already well-known book. Many chapters have been rewritten and therapy has been brought up to date. A special colour atlas of common oral lesions is now included with a chapter on oral cancer. The attempt to bridge the gap between general medical conditions with specific signs and symptoms in the oral cavity, and purely local conditions, is difficult to achieve. It might perhaps at times have been better to have left these conditions as something of which the dental surgeon should have some knowledge, rather than try to link them, often on very tenuous grounds, with some oral manifestations—for example, urogenital conditions, appendicitis, etc. On the whole, however, this is a very useful book, but I hesitate to think what would happen in this country if the over-worked dental hospitals and practitioners were asked to use the questionnaire as given to all patients at the University of Pennsylvania School of Dentistry, where 80 questions have to be answered by the patient before treatment is started, including ones such as No. 78, "Do you wish that you always had someone at your side to advise you?" and No. 80, "Do you feel you mix well with people?" The instructions are "to answer all questions and if you are not sure—guess."

A. B. MACGREGOR.

REGIONAL BLOCK

Regional Block: A Handbook for Use in the Clinical Practice of Medicine and Surgery. By Daniel C. Moore, M.D. Second edition. (Pp. 393+xvi; illustrated. 80s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1957.

The first edition of this excellent manual achieved the success which was predicted for it. The second edition will be as eagerly sought after as its predecessor. On every page it bears the hallmark of long personal experience by the author. The illustrations and text, as before, are particularly clear, and enable anyone who takes sufficient care to attain success with these methods of local analgesia. The production is once again of a high standard, paper, printing, and binding being excellent.

W. W. MUSHIN.

A small handbook on *Respiratory Disease and the General Practitioner*, by C. H. C. Toussaint, has been published by the National Association for the Prevention of Tuberculosis (28 pages, illustrated; 7s. 6d.). It contains practical advice on the diagnosis of respiratory tuberculosis and bronchial carcinoma and on the management of bronchitis. Special emphasis is laid on the value of diagnostic radiography.

Modern Drug Treatment in Tuberculosis, by J. D. Ross (National Association for the Prevention of Tuberculosis, 47 pages; 5s.), is intended primarily for nurses. It describes the use of streptomycin, P.A.S., isoniazid, viomycin, pyrazinamide, oxytetracycline, cycloserine, and thiosemicarbazones. A chapter on drug resistance is included.

The National Library of Medicine Catalog for 1957 provides an author and subject catalogue of the additions to that library during the period January-October, 1957. Besides new works the catalogue records titles of older material recatalogued during the period. It is obtainable from the Card Division, Library of Congress, Washington, 25, D.C., U.S.A., price \$17.50.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JULY 5 1958

TEN YEARS

Ten years ago, as both of the plebiscites of 1948 showed, a majority of the profession was opposed to entering the National Health Service. A plebiscite to-day, exactly ten years later, would undoubtedly show a majority to be highly critical of the Service and in favour of reform. Our correspondence columns have shown that the desire for reform is widespread. At Birmingham next week the Representative Body will hear from the Chairman of Council, Dr. S. Wand, that the Royal Colleges in England, to be joined soon, it is hoped, by the Royal Scottish Corporations, the Society of Medical Officers of Health, and the College of General Practitioners, will co-operate with the B.M.A. in a review of the health services of Great Britain. A committee widely representative of the whole profession will thus set out to discover just what general practitioners, consultants and specialists, professors and teachers, and medical officers of health think of the N.H.S. The intention behind this exercise is to bring together the facts, to sort them out and to classify them, to make comparisons with similar facts in other countries, and to make recommendations which may lead to a service in which doctors can work more happily and efficiently than they do at present. The end of the first decade of a social revolution finds the profession in no mood for jubilation. The politicians must inwardly regret their enormous errors of calculation. Whatever benefits it has received the public is beginning uneasily to wonder whether the price has not been too high in this free-for-all scramble for medical attention. It is at least good that the doctors of this country are entering the second decade with a determination to put aside their internal differences in order to find out just what the past ten years of experiment have added up to, and to decide what direction the medical profession shall take in the coming ten years.

In the *Supplement* this week is a symposium of articles written to mark the end of the first decade of the N.H.S. In it we have also brought together the principal resolutions on various aspects of the N.H.S. passed by the Representative Body: here-for

ready reference is a summary of the official policy of the Association. The two principal protagonists in the medical arena ten and more years ago were Dr. H. Guy Dain as Chairman of the Council of the B.M.A. and Lord Moran as President of the Royal College of Physicians. We have invited them to put down some of their reflections on the past decade. What they say has behind it the weight and authority of two men who more than any other were, ten and fifteen years ago, intimately involved in the intricacies of medical politics—the one predominantly concerned with the Association and the interests of the general practitioner, and the other with the problems of the hospital and consultant world. What is of special interest is that both these experienced Elder Statesmen of the profession throw out more than a hint that some form of direct charge should be made at least for some services. This is not exclusively a political issue. Doctors are, of course, concerned to see the N.H.S. solvent, to make sure that money that should be available for hospital development, for instance, is not thrown away on household remedies everyone used to buy for himself but now gets out of the Health Service. The politician averts his gaze from this and pretends it is the expensive proprietaries that send the drug bill soaring. The doctor wants to ensure that there is no barrier between the patient and the life-saving or disease-preventing remedy. He also wants to ensure that the public uses the Service in a responsible way. He casts an envious glance at Australia, where, as Dr. Ronald R. Winton puts it in his article in the *Supplement*, "the view has prevailed that the benevolent but bureaucratic grandfather who presides over the Welfare State is not for us. Various social services provide for those with genuine needs, but a premium is still put on self-reliance and independence of spirit." This is well said, and many doctors in Britain would echo his words. Quite apart, therefore, from any question of financial solvency, many doctors now would like to see the patient taking a greater share of direct responsibility for his own physical welfare, and it is interesting to note the views of Dr. Dain and Lord Moran on this.

We should, Dr. Dain says, have a look at health services in other countries, and in this connexion he refers to the fee-per-service system: "Both doctors and patients would seem to set a better value on a service if some payment was made at the time." The articles in this week's *Supplement* show that our colleagues in Australia, Canada, and New Zealand are firmly opposed to the capitation method. What seems to be behind this opposition is a dislike of a uniform levelling of reward for work done which

takes little regard of the diversity of human ability. The great virtue of the merit awards for consultants was—and is—that they take this diversity into account. We have criticized certain aspects of this system in the past, but at the end of ten years it is true to say that consultants as a whole accept merit awards as a valuable stimulus to effort and a practical recognition of the results of that effort and ability. Lord Moran's name has been closely linked with this novel experiment, and at the end of a decade of operation he can with justifiable satisfaction record that he has converted the Treasury to his view as well as his fellow consultants. But he has his fears for the future of medicine. Does medicine offer a challenge to achievement to those seeking to enter its portals? Or is it just one more port of security for the safe but mediocre minds for whom the Welfare State has such a dreary appeal? There is reason to fear that medicine may be attracting less of the available top talent than it used to do: and if this can be laid at the door of the N.H.S. then the aims of the Spens Reports have not been fulfilled—which is not surprising, as their terms have not been carried out.

Most people would agree with Dr. Dain that from the point of view of the public the Health Service has been a success. Many barriers that existed before have been removed, especially for those of moderate means. There has been a more even distribution of consultants throughout the country and a general increase of hospital facilities. But many of the benefits laid at the door of the N.H.S. more properly could be credited to the advances of modern medicine. One of the most remarkable of these has been in the field of medicinal therapeutics: yet we already hear the State managers growling at the pharmaceutical industry, whose participation in this phenomenal progress has been indispensable. British medicine to-day is at a high peak of achievement. In research, in ingenious experiment, in speculative energy, we can hold a candle to any other country in the world. But those who are paramount in these fields came into medicine before 1948. Will British medicine stand so high ten years hence? Unless we can be sure that it will, or at least create the conditions that make for excellence, then the N.H.S. may a decade from now be a perfect machine manned by an army of uniformed conductors but without a driver.

Among the articles in this week's *Supplement* appears one by Professor Paul F. Gemmill, who is a professor of economics in the University of Pennsylvania. He conducted a survey of his own in this country in 1956. It would be fair to judge that his conclusions were favourable to the N.H.S., and he has

certainly tried to bring some kind of measurement into the matter. Yet his figures are disquieting. Nearly 40% of the general practitioners in his survey found the "paper work" burdensome. Nearly 50% of the doctors questioned said their time was often taken up with "very minor ailments." Only 11% said that these complaints of "very minor ailments" led to the prevention or detection of something more serious. But what will surprise many is the reply to the question put to patients by Professor Gemmill about a comparison of the medical services under N.H.S. with those before 1948: only 37% said the N.H.S. was better than what went before; 50% said the medical service to-day was about the same as it used to be; and 13% said conditions were actually worse. It is to be hoped that the implications of this result will be understood by the Conservative M.P. whose stupid and ill-informed observation is reported at the end of Professor Gemmill's interesting paper.

In this week's special *Supplement* we have not attempted to review the Act and its deficiencies, the numerous reports issued since 1948 such as the Goodenough, the Guillebaud, the Bradbeer, and so on. We have chosen, instead, to bring together by selection or by invitation contributions from men who are first and foremost individuals with minds of their own, and in particular from the two opening contributors, whose views have a historical interest in that they were the first actors on the stage set by Sir William Beveridge (as he then was) in 1942. No one—not even Professor Gemmill's slightly absurd politician—would repeat in all its detail the experiment of 1948 if given the chance to do so. It is no good crying over the milk that was spilled then by the pailful. The urgent task is to look into the future, to repair, to reconstruct, to liberate the spirit of medicine from the inept embrace of the bureaucrat.

The most promising sign is the coming together of the Royal Colleges with the B.M.A. and others to examine the immediate past ten years in order to plan more wisely for the next ten. It will be no easy task—there are bound to be setbacks and disappointments. But the leaders of the profession to-day recognize there is far more at stake than the prerogatives of this or that organization or institution. If July 5, 1968, is to witness a more happy kind of celebration than is possible to-day it will be the result, as much as anything else, of the co-operative movement towards reform being undertaken by the committee now moving into action as a result of the initiative of the B.M.A. and of its Chairman of Council, Dr. S. Wand.

CANCER RESEARCH

Under the auspices of the Union Internationale contre le Cancer, the Seventh International Cancer Congress will be held in London from July 6 to 12, with Sir Stanford Cade as president. It is now thirty years since the last international cancer congress took place in London, sponsored by the British Empire Cancer Campaign. In the interval congresses have been held in Madrid (1933), Brussels (1936), Atlantic City (1939), St. Louis (1947), Paris (1950), and Sao Paulo (1954), under the aegis of the Union Internationale. The proceedings of this series of meetings naturally provide a useful record of the development of cancer research over a period sufficiently long to show its main trends; and much will be learned from comparison of the London meeting of 1928 with that about to take place. The earlier meeting had Sir John Bland-Sutton as president, and its membership embraced a host of famous names. Its official report (edited by the late Professor Archibald Leitch, then director of the Research Institute of the Cancer Hospital) contained many useful papers on aetiology, the causative role of viruses, occupational cancer, the relative values of surgery and radiation, chemotherapy with heavy metals, early diagnosis, the biological effects of radium and x rays, and cancer of the lung—with a contribution by Sir Robert Hutchison on the increased frequency of this disease, which was then beginning to be suspected and defined, though very far from attaining its present spectacular dimensions. The expansion of cancer research in the intervening years is to some extent exemplified by the numbers who will attend the forthcoming Congress: in place of two or three hundred there will be nearly 2,000 from 63 different countries, including some 500 from the United States and 50 from the Soviet Union.

What is the present situation of cancer research and what are the prospects for the future? The two major aspects, clinical and experimental, are reflected in the programme of the Seventh Congress. The beginnings of cancer research in the earlier part of the nineteenth century—coincident with the rise of the cell theory—were followed by a long period of description and classification. This period certainly laid the foundations of our modern knowledge, but it was followed, inevitably, by a phase in which doubts arose about how much further progress could be expected from study of the disease in man alone. In turn this led to wider application of the experimental method—in this country through the establishment in 1902 of the laboratories of the Imperial Cancer Research Fund under the auspices of the Royal College of Surgeons of England and of the Royal

College of Physicians of London, and in 1909 of the Research Institute of the Cancer Hospital. The clinical and pathological approach on the one hand, and the experimental approach on the other, are of course complementary, and must remain so. In spite of the difficulty in extracting fresh knowledge from study of the human disease alone, advances are still being made along this path, notably in the fields of statistics, demography, geographical pathology, and endocrine control, which is the subject of three papers in this issue by R. D. Bulbrook, F. C. Greenwood, G. J. Hadfield, and E. F. Scowen. We must not forget that the first essential clues to cancer causation came from clinical and occupational medicine alone. Yet there is equally no doubt of the power and flexibility of the experimental method. Employing it, the great E. F. Bashford, first director of the Imperial Cancer Research Fund, was able, in the ten years prior to the first world war and with the aid of a small but brilliant staff, to elucidate the basic characteristics of the cancer cell. Starting with a demonstration of the almost universal zoological distribution of the disease in nature, he was soon able to define, in terms of tissue immunology, the capacity of the cancer cell to propagate itself in serial transplantation. His genius is shown in a statement which he left us, forecasting in prophetic fashion the needs and development of cancer research. He realized, as did others, that the next great step forward must depend on the artificial production of the disease under experimental conditions at will. This is not the place to recount the many failures of such attempts. Eventually success came to the Japanese Yamagiwa and Ichikawa in 1915, when they were able to induce undoubted cancer by long-continued application of coal-tar—already incriminated in the causation of many forms of cancer occurring as an industrial hazard—to the skin of rabbits. The new Japanese discovery provided the means of tracing and identifying the agent responsible, and from the work of the late Sir Ernest Kennaway and his school at the Cancer Hospital in the nineteen-twenties and thirties the cancer-producing agent in pitch and coal-tar was ultimately defined as the polycyclic aromatic hydrocarbon 3:4-benzpyrene. Since that time many other types of chemical substance have been discovered, equally capable of producing cancer, and ranging from azo-dyestuffs and aromatic amines to polymers, plastics, and metals. In the past ten years fundamental information of great importance has been derived from study of the so-called alkylating carcinogens—nitrogen mustards, epoxides, ethyleneimines, and dimesyl compounds—the reactive side-chains of which may conceivably exert their chief effects against the integrity of the

nucleic acid structure. In addition, the same cancer-producing property is to be found in many kinds of radiation—infra-red, ultra-violet, x and gamma rays, alpha and beta radiation, and protons and neutrons.

Early in the history of cancer research two main conclusions were quickly reached: first, that the cancer cell and the normal embryonic cell are in many ways remarkably similar; and, secondly, that malignant change involves a reversion to a more primitive state and less specialized function. Modern research not only supports these conclusions but has added to them. Far from the cancer cell having acquired any new property, it appears to have lost something present in normal cells which is required for controlling their growth, so liberating permanently the suppressed growth potential that they had all along possessed. In the past ten years interest has extended from carcinogenic agents in their own right towards the means by which so many agents, chemically and physically diverse, can bring about malignant change. As to the production of cancer by chemical carcinogens, it appears that these may combine with substances responsible for cellular heredity and growth control, thus leading to elimination of the forces which ordinarily restrain the change to malignancy. Although the evidence is not yet conclusive this supports the view already suggested that the cancer cell is biochemically deficient, either in its growth-regulatory systems or in the hereditary material responsible for their synthesis. Apart from this as it were chemical interpretation, research workers, particularly in the U.S.A., have made notable advances in the past few years in the field of tumour viruses—advances in many cases proceeding directly from the discoveries of Ludwik Gross, whose paper on the viral aetiology of mouse leukaemia is printed in the opening pages of this issue. Discussion of these viruses will certainly have a prominent place in the proceedings of the Congress.

Complete knowledge of the attributes of the cancer cell, when this is obtained, will perhaps suggest, on a rational basis, the means of control. Meantime the chemotherapy of cancer has been making good progress, and it has been gratifying to see how the results of experimentation in animal species—in many instances, although not, of course, in all—have proved capable of clinical application in man. But cancer chemotherapy is still in its merest infancy, and the few advances that have been made do not as yet affect the treatment of cancer as a whole. Almost certainly the present chemical remedies will be superseded by far more specific molecules, which will possibly restore the control of cell division and growth which the cancer cell appears to lack. When the suppression

of the disease is achieved, the success will have been made possible by one thing alone—that international co-operation in science and medicine which will be the underlying theme of the Seventh International Congress.

CAUSATION OF CANCER

A special number of the *British Medical Bulletin* has been issued by the British Council devoted exclusively to the causation of cancer.¹ It includes 27 contributions from sixteen different cancer research centres. A similar special number of the *B.M.B.* appeared in 1947, and was concerned chiefly with chemical carcinogenesis. Professor A. Haddow, F.R.S., in his introduction compares these two cancer surveys and points out that the period 1947 to 1958 has witnessed a revival of interest in tumour immunology, with considerable and unexpected advances in our understanding of transplantation immunity and immunogenetics. The nature of the autonomy of tumours and their hormonal dependence has also been much clarified during the last few years and much more is now known about endocrine carcinogenesis.

The advent of the nuclear age has not only brought startling scientific advances, but has also created innumerable problems of hazard and control, many of which have a direct bearing on the incidence of cancer. These secondary consequences of scientific research are referred to more than once, but considered most fully by Dr. W. M. Court-Brown. After discussing the incidence of leukaemia among survivors of atomic explosions, and among radiologists and patients irradiated for diagnostic or therapeutic purposes, the author summarizes his conclusions as follows:

"The findings of the Atomic Bomb Casualty Commission, the results of surveys on the incidence of leukaemia in irradiated patients, and the increased leukaemia mortality recorded among radiologists, all suggest that ionizing radiations can cause leukaemia in man. Difficulties in interpretation have arisen in some of these investigations, but if all are taken together the data provide convincing evidence of man's susceptibility to the induction of leukaemia by irradiation. It now seems established that radiations do not increase the incidence of chronic lymphatic leukaemia but that they increase the incidence of the acute leukaemias and of chronic myeloid leukaemia. There is some conflict of evidence, in regard to the average length of the latent period, between the Japanese data and the findings of both the spondylitic and Danish surveys. It seems reasonable, however, to conclude that in Western Europe the latent period before the appearance of the acute types of leukaemia is usually from three to five years, but that it may well be longer in some cases of chronic myeloid leukaemia."

The carcinogenic effect of radiation and the manner of its operation are discussed also in papers contributed by Dr. R. H. Mole and Dr. A. Glücksmann, but most of the articles in this special number of the *Bulletin* are concerned with chemical carcinogenesis, and of them the most comprehensive is Professor Haddow's. His masterly survey of a very complex subject ends by pointing

¹ *Brit. med. Bull.*, 1958, 14, No. 2.
² Green, H. N., *Brit. med. J.*, 1954, 2, 1374.

out that, whatever the precise chemical mechanism of the action of carcinogens, there can be little doubt of the importance of their combination with genetical material or its precursors. It seems at present as if the primary step in carcinogenesis may be the inhibition of certain fundamental processes of genetical or enzyme synthesis.

The papers of chief clinical interest are those on cancer of the bladder contributed by Dr. Georgiana Bonser and her co-workers at Leeds and by Professor E. Boyland, of the Chester Beatty Research Institute. Occupational cancer is discussed by Dr. M. W. Goldblatt, and aromatic amines by Drs. A. L. Walpole and M. H. C. Williams. Both these papers condense much new and valuable information into a few pages.

The article by Professor J. W. Orr which is listed on the cover under the rather misleading title of "Irreversible Changes in Chemical Carcinogenesis" is really a plea for the renewed study of a much neglected subject—namely, the effect of a carcinogenic agent on the nutrient stroma by which a tumour is supported. It is more than twenty years since Orr pointed out that in the case of epidermal tumours there is a progressive alteration of collagen and elastic fibres throughout the latent period which follows the application of a carcinogenic agent, and that the rate at which this change advances is correlated with the potency of the carcinogen used. His subsequent series of grafting experiments has certainly given support to the view that the effects of a carcinogen on the supporting tissues are of first importance.

Many cancer research workers will be glad to have the opportunity of rereading Professor H. N. Green's article on the immunological basis of carcinogenesis, because the theory on which it is based has been considerably expanded and to some extent modified since first published in this *Journal* four years ago.² Dr. F. Bielschowsky, of Otago University Medical School, New Zealand, and Professor E. S. Horning, of the Chester Beatty Research Institute, have collaborated in a general review of the influence of endocrines in the development and control of tumours; this is a carefully documented paper with a long list of references.

The "Causation of Cancer" is a subject which looms large in the programme of the International Congress being held in London next week (see leading article at p. 35), though, understandably, no opening speaker has dared to choose it as the title for a communication. From the programme of the Congress it seems most likely that the general subject of the causation of cancer will be a central theme in the discussion of the Biology Sections on Monday and Tuesday afternoon, at the Congress Plenary Session on Thursday afternoon, and in the Biochemistry Section on Friday afternoon, but in one form or another the general aetiology of cancer will form part of the programme of the Experimental Group at each of the morning sessions also.

HEALTH SERVICE EXPERIMENTS

Of all the criticisms of the administration of the National Health Service lack of co-ordination is the one most regularly repeated. Time and time again "the

various branches of the Service have been urged to work more closely together, yet glaring instances of failure to co-operate are always in evidence. Often these are not the fault of individuals but rather of the system, and it has been one of the important functions of the Nuffield Provincial Hospitals Trust to diagnose organizational defects in the N.H.S. and to see how they can be put right. The Trust's most recent report,¹ published this week, mentions with particular satisfaction the development in the new town of Harlow of comprehensive medical services on which the Trust is spending over £250,000. Co-ordination of services has always been the principal aim of the Trust, and at Harlow "the administration of the various medical and dental services is a divided responsibility, but the whole appears as one service to the patient, because the (group practice and clinic) centres are properly planned and equipped to this end and encourage those working there to co-operate naturally."

One of the most useful services which the Trust, as an unofficial body, can perform is to take unproved but promising ideas and base practical experiments upon them. The report is full of accounts of such experimental studies in all branches of the N.H.S., clinical and administrative. For instance, many patients leave hospital still needing help, and the effect of bringing all the available social services to their aid is being studied; the whole problem of bringing a new hospital (the Princess Margaret Hospital at Swindon) into use is being investigated; the incidence of leukaemia in adults is to be surveyed; the rehabilitation of elderly invalids has been successfully carried out in their own homes instead of in hospital; and a general practitioner is collecting sociological and medical data about his patients with a view to correlating morbidity with as many of the known environmental and hereditary factors as can be obtained.

Some of the most rewarding of the Trust's activities are in the field of mental health. The taking over by a regional hospital board of a home established by the Trust for deaf children with emotional difficulties is yet another example of a successful social experiment by a voluntary body being adopted officially by the State. Another regional hospital board, with the help of a grant from the Trust, has established a "day hospital service" in an ordinary hospital for mental defectives. The patients are brought to the hospital for the day and "absorbed into the hospital routine." The relief to the relatives of the patients is great, and the scheme also helps to avoid the blocking of much-needed beds, by long-stay cases. A plan to ease pressure on mental hospitals is being tried out in Worthing, where a district mental health service has been set up. The object of this experiment is to see if a comprehensive psychiatric out-patient service can materially affect the steady annual increase of patients admitted to mental hospitals. Another way of relieving pressure on the hospitals is to see whether some of the long-stay psychotic patients can be improved to the point where life outside the hospital becomes a possibility. The report of the Trust suggests

¹ The Nuffield Provincial Hospitals Trust. *A Record of the Progress of Schemes and Descriptions of New Projects, 1955-1958: Fourth Report*, 1958. Oxford.

that "under certain conditions the mentally ill patient will react to such accepted stimuli from the outside world as incentives." A grant has therefore been made towards the establishment of a work-therapy unit in the grounds of a mental hospital. Here patients will work side by side with normal people in a simple series of manufacturing processes, and they will have the same incentives as are offered to other workers. This is an experiment which will be watched with special interest.

HAZARDS FROM COSMETICS

The incidence of reactions to cosmetics is probably very low, but cannot be accurately assessed. Most women experiencing some irritation or discomfort after using a particular product will change to another without consulting a doctor. Only if the symptoms are severe or prolonged or appear to be provoked by the products of more than one manufacturer is medical advice likely to be sought. Most reactions to modern cosmetics result from the development of a simple allergic sensitivity or from the action of certain ingredients as photosensitizers. Accumulated experience and controlled trials enable manufacturers to avoid incorporating in their products chemicals which are known to be potential sensitizers.

Advances in cosmetic science are often followed by the introduction of new chemicals into cosmetic products. Despite the manufacturers' precautions, untoward reactions, sometimes of bizarre or unexpected pattern, may occasionally be provoked. Recent examples are granulomatous papules in the axillae after the use of deodorant sticks containing sodium zirconium lactate,¹ and dermatitis of the hands apparently caused by the synergistic action of household detergents and triethanolamine in a hand lotion.² Such special hazards are rare and can be eliminated once their existence and cause have been satisfactorily established. It may fairly be claimed that cosmetics employed for the purpose for which they are intended provoke reactions in only a very small proportion of users, and that these reactions seldom cause more than temporary discomfort and inconvenience, though they may present the dermatologist with intricate problems in differential diagnosis.

A recent report to the Committee on Cosmetics of the American Medical Association³ discusses the dangers arising from the misuse of cosmetics. Review of over 15,000 reports of poisoning due to the accidental ingestion of chemicals showed that cosmetics were involved in 3% of cases. Nail lacquers and polish removers, shampoos, permanent-waving solutions and neutralizers, scents, and various lotions were most frequently implicated. Whether cosmetics are responsible for a similar percentage of cases of accidental poisoning in Great Britain is unknown. Deaths from accidental poisoning in England and Wales are classified according to the toxic agent involved and not according to the substance in which the agent was present. However, the Registrar-

General has been able to trace since 1950 records of two fatal cases of poisoning in girls under 5 in which a hair lotion was specifically mentioned. The American report draws attention to the increasing use of pharmacologically active substances in cosmetics; even the more conventional ingredients include petroleum distillates, metallic salts, and a multitude of organic chemicals. That manufacturers of cosmetics are aware of the need to consider the consequences of possible misuse is certain; potassium bromate was widely employed to neutralize cold-waving solutions (salts of thioglycolic acid). Since fatal cases of poisoning⁴ have been reported less toxic substances have largely replaced bromates.

CONGENITAL DISLOCATION OF THE HIP

From the time of Hippocrates, who associated congenital dislocation of the hip with uterine pressure or birth trauma, various opinions have been advanced to account for the abnormality. The emphasis on environmental factors at the beginning of the present century later gave way to genetical hypotheses; to-day it is thought that both factors play a part and that actual dislocation and subluxation are generally secondary to the more common condition of flat socket associated with genetic dysplasia of the hip.¹ The average age at which the dislocation becomes complete is not known, but usually the femoral head is only partly dislocated during infancy and before weight bearing.² Most cases in this country are diagnosed at the age of 1 or 2 years; the earlier the diagnosis is made the better are the results of treatment. A recent paper by R. G. Record and J. H. Edwards,³ of the department of social medicine at Birmingham University, provides a useful objective analysis of some environmental factors which, they suggest, may be associated with the 186 cases of the abnormality studied in that city. The incidence (0.65 per thousand live births) is low compared with other estimates, but the sex ratio (85% female), the preponderance of left-sided dislocation (64%), and the association with breech deliveries is in conformity with previous reports. The birth weight of affected babies was found to be below the expected figures, and the incidence in the winter was double that in the summer months. The risk of the condition occurring in subsequent pregnancies was about 5%, but this figure naturally depended on the sex and season of birth. Record and Edwards suggest that the seasonal incidence may be associated with the heavier clothing and wrappings used during the cold winter months with a consequent restriction of limb movements, and that similar mechanical factors may be associated with the high incidence of the abnormality among some Lapp and Red Indian communities. This is a controversial hypothesis, but any possible aetiological factor which may be subject to control requires careful study. The Birmingham report as a whole underlines the opportunities for further research into environmental factors associated with congenital abnormalities.

ENUMERATION OF THE "CRAVINGS" OF SOME PREGNANT WOMEN

BY

J. M. HARRIES AND T. F. HUGHES

Scientific Adviser's Division (Food), Ministry of Agriculture, Fisheries, and Food, London

The strong desires experienced by pregnant women for various items of food, and even for inedible substances, seem to be a matter of common knowledge, but there is considerable disagreement about the reasons for, and the significance of, these "cravings." It is sometimes stated—for example, by Drummond and Wilbraham (1939)—that a pregnant woman's increased requirement of vitamin C and calcium leads her to crave foods which are rich in these substances; but it is also thought that her desires may be purely psychological in origin. Thus Yudkin (1956) suggests that "the pregnant woman may well demand not oranges but peaches out of season." A search of the literature has revealed only meagre factual information on the subject, and the object of this paper is to describe a collection of such "cravings"—an inadequate record from many points of view, but one which may serve as a stimulus to a more systematic inquiry.

The Records

Early in 1956, during one of a series of broadcasts under the title "Is There a Doctor in the House?" given in the Light Programme of the B.B.C., pregnancy was discussed briefly, and the phenomenon of strong desires for, and aversions from, certain items of food was mentioned. Listeners were invited to write to the B.B.C. on this subject, and the letters received in response to this request have been made available through the kindness of Miss I. D. Benzie, who produced the series.

The nature of the records is such that they do not provide a statistically adequate sample. In the first place, it seems likely to be biased on the side of the unusual, since correspondents to the B.B.C. may tend to write only when there is something remarkable to write about. Secondly, the sample cannot be assumed to be random or representative, since it might be biased both geographically and by the broadcast which gave rise to the letters. Conclusions may therefore be drawn only with caution, and cannot be applied to pregnant women in general; but where a number of women, however unrepresentative they may be, agree in "craving" the same substances to the exclusion of others, some explanation is necessary, though it may of course be psychological rather than physiological.

Results

There were 514 letters, of which 509, reporting 820 pregnancies, have been used in the present report. The remaining five described likes and dislikes for colours, types of music, etc. Most of the letters came from the Home Counties, 102 of the cases reported being in London. There were 36 from Yorkshire, 36 from Lancashire, 23 from Scotland, 20 from Wales, and 1 from Northern Ireland. Most of the reported cases were in 1955 and 1956, but there were many recollected from earlier years, the earliest being in 1894.

The 991 cases of "cravings" have been classified in Table I, which shows the frequency with which various groups of substances were desired. The grouping of substances was decided on as convenient, and it was also considered advisable to separate the records of demands for vegetables and cereal products, according to whether they

TABLE I.—Reported Frequency of Cravings Among 991 Cases

Fruit (see Table II)	261	Alcoholic drinks	17
Vegetables (raw 72, cooked 33)	105	Ice-cream and iced lollies	17
Confectionery	79	Spices and condiments (eaten neat)	17
Pickled foods	66	Milk and milk products	15
Cereal products (prepared 17, dry raw 48)	65	Sugar and preserves	12
Fish (including shellfish)	49	Eggs	10
Nuts	35	Other food products*	17
Mineral waters	20	Non-food substances (see Table III)	187
Meat and meat products	19		

*Coffee grounds (5); fat (unspecified) (3); tea leaves (2); aspirin, coconut milk, custard powder, dog biscuits, "health salts," jelly, and "stomach powder" (one each).

were eaten raw or cooked, because of the high frequency of the former. By cooked (prepared) cereal products is meant bread, biscuits, cakes, and breakfast foods, whereas a considerable number of the demands were specifically for such foods as macaroni, Indian corn, rice, oatmeal, and maize, eaten dry and raw.

In view of the large number of cases of cravings for fruit, these are shown in greater detail in Table II. It is noteworthy that most of those craving apples wanted green sour ones.

TABLE II.—Details of 261 Cravings for Fruit

Apples	76	Tomatoes	31	Pineapples	4
Oranges	68	Soft fruit	25	Bananas	3
Other citrus fruits	24	Stone fruit	16	Dates	3
		Pears	5	Other fruit*	6

*Melon (2), plantains, pomegranates, raisins, and rhubarb.

The frequency of desires for substances normally considered inedible is shown in Table III, and the 193 reports of substances normally liked, but disliked during pregnancy, are detailed in Table IV.

TABLE III.—Details of 187 Cravings for Substances Other Than Food

Coal	35	Petrol	10	Soil	7
Soap	17	Polish (metal)	10	Chalk	4
Disinfectant	15	Tar	10	Charcoal	4
Toothpaste	14	Paraffin	9	Cinders	4
Mothballs	10	Wood	8	Others	30

TABLE IV.—Details of 193 Reports of Substances Normally Liked, But Disliked During Pregnancy

Tea	78	Bacon	7	Beer	4
Tobacco (smoking)	24	Chocolate	6	Fish	4
Coffee	22	Eggs	5	Oranges	4
Marmalade	8	Sweet foods	5	Others	26

There are also certain features common to a sufficient number of the letters to make them worthy of note, though in each case the writer volunteered the information, so that their number is no indication of incidence.

Many correspondents stated that, though they were able to joke about a "craving" after the baby was born, at the time it was overpowering. There are many statements of the specificity of the desire, and there are several descriptions of the temptation to steal in order to satisfy a particular appetite. Though the tone of many letters is amused as well as amusing, written after the event, there is general agreement about the seriousness of these "cravings" during pregnancy.

Also mentioned on numerous occasions is the sense of secrecy which surrounds the phenomenon. Many women state that they went to great lengths to keep their "cravings" secret even from their husbands. Several experienced a sense of shame.

There is no mention in any of the letters of a "craving" not being satisfied. Though there are many descriptions of how the required substance was obtained there are no reports of failure to obtain it. A few state that the satisfaction of their particular demands was capable of unbalancing the family budget.

The stage of pregnancy at which the "craving" was experienced is mentioned in 135 of the letters. Only six state that it was experienced for the full term; 59 report that it was experienced from the first to the fourth month of pregnancy; and generally it seems that the desire is usually felt fairly early.

"Cravings" for two or more substances during the same pregnancy are mentioned in 76 of the reported instances. These have been examined separately for the food items but exhibit no pattern, either of similar or of contrasted substances being craved at the same time. Apart from following the general pattern of Table I they are fairly randomly distributed.

There are 57 cases of the same substance being craved in each of several pregnancies by the same person. Of these, 15 are for fruit and 11 for inedible substances, the others being scattered amongst various foods in too random a fashion to exhibit a pattern or to be reported in detail.

Discussion

The word "craving" commonly applied to this phenomenon may be an unfortunate one. It indicates desire of the strongest possible intensity, and it can be argued that ordinary preferences or likings for various foodstuffs have been called "cravings" in retrospect, the phenomenon being dismissed as due largely to this effect. On the evidence of the present letters there can, however, be little doubt that these desires are real, though it is possible that on occasion they are complicated by the intrusion of ordinary likes and dislikes.

Dietary surveys of groups of pregnant women—for example, People's League of Health (1942) and Burke *et al.* (1943)—make no mention of such large quantities of certain items of food as must have been consumed if these letters are any guide. Whether this is because of infrequent occurrence it is hard to say, but the impression left by the letters is that the women themselves surround their desires with such an aura of secrecy that they may well be more common than the evidence from ordinary dietary surveys would lead one to expect. Also relevant in this connexion, though by no means conclusive, is the total number of letters received. It is, of course, impossible to estimate the proportion of pregnant women who experience these "cravings," but we understand from the B.B.C. that the response rate was striking in view of the casual nature of the request for information, made at a time when the Light Programme is faced with the massive competition of Children's Hour.

In assessing the results of the present inquiry the large number of "cravings" for inedible substances must be largely discounted because of the possibility of bias in favour of the unusual, though many of the items shown in Table III lend support to psychopathic explanations. The preponderance of coal may be due to its having been mentioned by one of the speakers in the broadcast that gave rise to the letters. It was also apparent in many cases that it was the smell of such substances as disinfectant and petrol that appealed during pregnancy; but so many letters were vague on this point that separate results for eating and smelling have not been quoted.

So far as food items are concerned there is no doubt about the preponderance of fruit. Further, some 70% of the recorded cases are for varieties of fruit available virtually all the year round—apples, oranges, tomatoes, and lemons. Availability seems to be a more reasonable explanation of the order of popularity shown in Table II than vitamin C content, though with the exception of apples the more popular fruits are reasonably good sources of this vitamin. Such substances as wall-plaster and chalk are also said to be common objects of "cravings" during pregnancy because of increased requirements of calcium, but the number of such cases recorded in this series is very small.

A more probable explanation is that the expectant mother takes light refreshing snacks of those substances which "go down well" in order to counter the sickness and nausea which often accompany pregnancy, and fruit may be an ideal substance from this point of view. Another is that the snacks may be occasioned by the need for more calories during pregnancy—a general hunger which would hardly justify the use of the term "craving." But why in this case are the "cravings" so specific?

A theory advanced by one correspondent who had gathered considerable information on her own account was that the desire is for something to crunch. The texture of the food, she states, is more important than the flavour. This theory, which was also mentioned in the original broadcast, certainly finds some support in the present data in the high frequency of pickled foods, confectionery, nuts, such unusual foods as dry raw cereals, and the preference for uncooked vegetables.

Clearly, the data are inadequate to prove or disprove any of these hypotheses. They indicate, however, that these "cravings" are real, that they are kept secret so far as is possible, and that there seems to be a preponderance of "cravings" for fruit. Few solutions have been obtained to the many problems which arise in this connexion, but these results may help to pose them in such a way that they could be unravelled by a more systematic inquiry.

Summary

A series of 991 cases of "cravings," and 193 cases of aversions during pregnancy is reported from a collection of letters received by the B.B.C.

A preponderance of the "cravings" for food items was for available fruit, with a relatively high incidence of desires for raw vegetables, confectionery, pickles, and raw cereals. In addition, 187 cases of desires for inedible substances are detailed, the most popular item being coal.

It was clear from the letters that genuine cases of serious "cravings" did occur, and that there was a compulsion on the part of the women themselves to keep their desires secret, which may explain the lack of evidence in published reports of dietary surveys among pregnant women.

ADDENDUM.—Since these findings were reported to the Nutrition Society in May, 1957, our attention has been drawn to a paper by L. B. Posner, C. M. McCottry, and A. C. Posner (*Obstet. and Gynec.*, 1957, 9, 270) which describes a more systematic inquiry carried out at the Harlem Hospital, New York, where 600 patients in the third trimester of pregnancy were asked, "Is there some special food you crave during this pregnancy?" 394 answered "Yes," 196 answered "No," and 10 admitted "pica." The most common of the 30 items craved were Argo starch (106 cases), sweets (68 cases), and fruit (47 cases). Also noticed were a desire for secrecy and a preponderance of "foods commonly found in the average home kitchen." The paper also gives further references.

WORLD CONGRESS OF GASTRO-ENTEROLOGY

[FROM A SPECIAL CORRESPONDENT]

A World Congress of Gastroenterology was held in Washington during the last week of May. It represented the third international congress of gastroenterology, the first having been held in Brussels in 1935, the second in Paris in 1937, while the third was to have been held in London in 1940 but was prevented by other international events. This first World Congress amply demonstrated the growth of gastroenterology as a special field in medicine, for it was attended by more than 1,100 delegates from fifty different countries. The American Gastroenterological Association was the official host organization.

The programme was a busy one, comprising five main symposia and a very large number of individual communications. The proceedings will fill a large book (to be published in about six months), and even a brief conspectus of the congress cannot be expected from a single pen. I shall confine myself to some of the more interesting points which emerged in the symposia.

Peptic Ulcers

Dr. REINHOLD BOLLER (Vienna) described the medical treatment of duodenal ulcer in his hospital, emphasizing the rapid rehabilitation now being achieved chiefly through the education of the patient in diet, nutrition, and regular habits of living. For gastric ulcers he used a special milk, consisting of "yoghourt" made poor and acid by the use of liquorice, but enriched with fat, and which was known in Austria as "lakhurt." Both duodenal and gastric ulcers were increasing in incidence in Austria, but the loss of work due to them was diminishing with these treatments.

Dr. J. M. DE LA VEGA (Mexico) described sharp differences in the clinical behaviour of peptic ulcer in Mexico compared with the United States. Dr. F. AVERY JONES (London) described studies which had shown duodenal ulcer to be common in all social classes in Great Britain, although those holding responsible positions were somewhat more likely to suffer from it than others. By contrast, gastric ulcer was more prone to affect labouring classes than professional workers. A controlled study had shown that patients advised to give up smoking showed improved healing of a gastric ulcer compared with those who were not so advised; the best results were obtained in those who followed the advice and actually ceased to smoke. Dr. SARA M. JORDAN (Boston, Massachusetts) stated that 10% of the population of the United States suffered from a peptic ulcer at some time in their lives, there being 3.5 men for every woman affected. She estimated the mortality of the disease as 4%, but remarked that the morbidity was great and was very detrimental to the economic life of the nation, especially as the condition was particularly prone to affect men in responsible and executive positions.

Dr. A. LAMBLING and his colleagues (Paris, France) reported interesting features of peptic ulcer in France. At the beginning of this century gastric ulcer in women was the prevalent type of peptic ulcer. Up to 1939 the disease then steadily became more and more represented by duodenal ulcer in men. During the war the disease reverted to the characteristics of a half-century earlier, while since the end of the war it had gradually swung back to the features shown in 1939. The wartime shift was attributed to the emotional shock of the Occupation, coupled with a sudden change in nutritional habits, but not to under-nutrition of itself. Alcoholism did not appear to play any significant role in France. Drs. G. GARRIDO-KLINGE and LUIS R. PENA (Lima, Peru) described the high incidence of gastro-duodenal ulcer among miners working in the Peruvian Andes at an altitude of more than 12,000 ft. (3,660 m.). Among these miners, gastric ulcer was many times more common than duodenal ulcer and haemorrhage was a frequent complication. They concluded that vascular changes played an important role in this liability to gastric ulcer at high altitudes. Other speakers dealt with peptic ulcer in Venezuela, India, and Brazil. The discussion was notable for an excellent summing up by Dr. MORTON GROSSMAN (Los Angeles).

Malabsorption Syndromes

Special interest attached to the symposium on this subject, because it is a field of gastroenterology which has shown great progress during the past decade, and especially since the announcement in 1950 by Dicke, of Holland, that removal of the gluten from the diet of children with coeliac disease would bring about normal growth and development. In addition, quantitative methods of studying intestinal absorption have been greatly developed and widely

used, while recently biopsy of the small intestine by means of tubes introduced through the mouth has enlightened us on pathology.

Dr. E. E. WOLLAEGER (Rochester, Minnesota) described the behaviour of non-tropical sprue in the United States, emphasizing the fact that impairment of absorption was not confined to fats but applied to all nutrients, including proteins, carbohydrates, vitamins, minerals, and even water. Its diagnosis rested on the demonstration of defective absorption coupled with the exclusion of diseases which might give rise to a secondary steatorrhoea.

Dr. H. A. WEIJERS (Utrecht, Netherlands) described work done in collaboration with Dr. J. H. VAN DE KAMER on coeliac disease and wheat sensitivity, a communication of great interest, as they were pioneers in this field following Dicke's original clinical observations. As well as the generally accepted criteria for making the diagnosis, the establishment of wheat sensitivity must also be shown before idiopathic coeliac disease could be regarded as proved. The existence of such sensitivity could be established by measuring the amount of fat in the faeces after introducing wheat into the diet, but could be established more rapidly by determining the rise of blood glutamine following ingestion of gliadin. In normal people there was little rise in blood glutamine levels, whereas patients with coeliac disease showed a rise of more than 40% with a peak two hours after ingestion. The abnormal increase in blood glutamine suggested that there was defective proteolysis in the intestinal cells.

Dr. MARGOT SHINER (London) described the histological findings in non-tropical sprue as judged from small biopsy specimens obtained by peroral intubation (of which she was the pioneer). There was atrophy of the intestinal villi together with partial atrophy of the crypts of Lieberkühn. The post-gastrectomy and pancreatic types of steatorrhoea did not show any abnormality of the mucosa. In tropical sprue changes resembling those of non-tropical sprue might be found, but they were reversible with treatment with folic acid and antibiotics. By contrast, in patients with non-tropical sprue (idiopathic steatorrhoea) there was no improvement in the histological picture even though the patient had shown complete symptomatic recovery with appropriate treatment. Later in the symposium, Drs. C. E. BUTTERWORTH and E. PEREZ-SANTIAGO (Washington, D.C.) reported somewhat similar histological changes in tropical sprue to those observed by Dr. Shiner. They based their remarks on specimens obtained by means of a very ingenious instrument devised by Dr. W. H. CROSBY (Washington) consisting of a capsule at the end of a fine polythene tube, the capsule being swallowed by the subject. (This instrument seems likely to become a standard research tool, and possibly even a routine diagnostic one. When the capsule has reached a suitable place in the small intestine, suction applied to the free end of the polythene tube causes a knuckle of mucosa to enter a hole in the side of the capsule; this is followed by the creation of negative pressure, which in turn causes the release of a spring-loaded knife which cuts off the knuckle of mucosa. The polythene tube is then used to withdraw the capsule.)

Dr. J. M. FRENCH (Birmingham, England) described the successful results obtained from treating adult cases of non-tropical sprue (idiopathic steatorrhoea) with a gluten-free diet. "Almost all patients respond if appropriate measures are taken." The most important point to realize was the very slow nature of the response in some patients, so that it was necessary to persist with the gluten-free diet for three to six months before abandoning it as useless.

Professor A. C. FRAZER (Birmingham, England) discussed the pathogenesis of the malabsorption syndrome. He recognized two main classes of patient. There were those without intestinal disease who were chiefly examples of lack of pancreatic enzymes, with consequent failure to digest food efficiently. The others had intestinal disease and could be divided into examples of gluten-induced enteropathy (coeliac disease or non-tropical sprue), folic acid deficiency (which dominated some cases of tropical sprue),

altered bacterial flora (which applied in some of the other patients with tropical sprue), enteropathy due to dietary factors such as the ingestion of rancid fats, or one of the diseases in which the bowel wall was grossly abnormal, such as regional ileitis, Whipple's disease, gastro-colic fistula, and "blind-loop" syndromes.

Tropical sprue was dealt with by Dr. F. HERNANDEZ MORALES (Santurce, Puerto Rico), who described both florid and larval forms of the condition, the former being less common now than formerly because of the use of liver extracts and, later, of folic acid and vitamin B₁₂.

Amoebiasis

Amoebiasis remains one of the most important diseases in the world, and the session at the Congress showed how many problems of its epidemiology and treatment remain to be solved. Thus Dr. R. ARMAS CRUZ reported work from Santiago, Chile, based on the study of 700 cases of intestinal amoebiasis in which the diagnosis was supported by both clinical and parasitological findings. Therapeutic trials had been carried out which gave the astonishing result that a placebo had been found to give a 70% cure rate, whereas some drugs widely used in treating amoebiasis gave results which were no better or even worse.

Dr. ELSDON-DEW (Durban, South Africa) discussed the factors influencing the pathogenicity of *Entamoeba histolytica*, and showed that the mere presence of the organism was not sufficient to cause the disease. The accessory factors were probably complex, and several might need to operate simultaneously to evoke the disease.

In the subsequent discussion Dr. Armas Cruz's results evoked a good deal of critical comment, especially in view of the fact that a majority of his patients carried "small-strain" amoebae, which some parasitologists consider to be non-pathogenic.

Cancer of the Stomach

Cancer of the stomach remains common in almost all countries of the world, although varying greatly in incidence from one to another, with Japan holding the doubtful distinction of having the highest level. The results of treatment are still disappointing, and there is great need to improve early diagnosis as well as to learn the reasons for the geographical variations in its incidence, which presumably reflect important environmental factors concerned with the aetiology of the condition.

Dr. JOHANNES CLEMMESSEN (Copenhagen, Denmark) gave the results obtained by the Danish Cancer Registry for the period 1943-53 and compared the findings with those of other countries. In Denmark, gastric carcinoma accounted for 30% of all cases of cancer, which was somewhat higher than in England, but lower than in the other Scandinavian countries. Gastric cancer was particularly prone to affect the lowest-income groups in Denmark, as was also true for England. On the other hand, the condition was scarce in Africa, so specific carcinogens might be involved.

Dr. LEO RIGLER (Los Angeles, California) considered that detection of gastric cancer was best achieved by x-ray examination. It was essential to diagnose the condition early, which could sometimes be done before the stage of symptoms. Routine radiological surveys of the entire population were not practicable, but they were feasible in subjects who were known to be unduly likely to develop gastric cancer. These were patients aged 50 and more with pernicious anaemia, gastric ulcer, gastric symptoms, achlorhydria, or occult blood in the stools. In 3,150 patients with either pernicious anaemia or simple achlorhydria he had found 36 examples of cancer and 80 of gastric polyps, which were known to be pre-malignant lesions. By contrast, not a single example of either cancer or polyp was found in a control group of 1,098 patients with normal gastric acidity.

Dr. I. S. RAVDIN (Philadelphia, Pennsylvania) dealt with the factors affecting the outcome after surgery for gastric cancer. The essential was to diagnose cases while the disease was still limited to the gastric wall. All patients with a gastric ulcer which did not heal in 3-5 weeks with medical treatment should be treated by partial gastrectomy, and it should be appreciated that x-ray evidence of healing could not be taken as absolute evidence that the lesion was a benign one.

Nutrition and the Liver

The generally accepted view that nutritional deficiency is of great importance in causing chronic liver disease received some setbacks from some of the information presented. Dr. J. CAROLI and his colleagues (Paris, France) described the close relationship they had found between the average daily consumption of alcohol and the development of cirrhosis. Below 72 grammes of alcohol a day (equivalent to 1 litre of wine) no evidence of cirrhosis occurred. Above 144 grammes, almost all subjects developed hepatic cirrhosis. In between these two limits about 40% of patients were cirrhotic, and it was in this group alone that protein intake appeared to have any influence on liability to cirrhosis. Dr. CHARLES S. DAVIDSON (Boston, Massachusetts), also dealing with alcoholic cirrhosis, considered that the development of this type of cirrhosis was chiefly due to the replacement of normal components of a good diet by alcohol, but he judged that this explanation did not entirely account for the facts.

Drs. BERNARDO SEPULVEDA and SALVADOR ZUBIRON (Mexico City) described their findings in patients with chronic primary malnutrition in whom the total caloric intake had been less than 50% of that usually recommended for health and with low protein and vitamin components. Fatty infiltration was the only hepatic lesion commonly found and cirrhosis occurred only as a rare event.

A Special Social Occasion

One evening of the congress was designated "Embassy Night," to permit foreign delegates and their ladies to attend the embassies of their respective countries. The British contingent was warmly received by HER MAJESTY'S AMBASSADOR and LADY CACCIA, and it may not be amiss to put on record our thanks for the pleasant hospitality they afforded us.

"IN ARDUIS FIDELIS"

SIR GORDON GORDON-TAYLOR'S ORATION

A fine moment in the celebrations attending the Royal Army Medical Corps's diamond jubilee last week was the commemorative oration* Sir GORDON GORDON-TAYLOR delivered in the Great Hall of B.M.A. House on June 25. It was a noble and moving address, not least remarkable for being given without benefit of a single note, orator was imbued with the spirit of his subject and complete master of his words.

Mr. WELDON WATTS, President of the Association, welcomed the distinguished and representative audience, and introduced the orator. Mr. Watts recalled that officers of the B.M.A. had headed the deputation to Lord Lansdowne in 1898 to urge the formation of the Corps. "The R.A.M.C.," said Mr. Watts, "since its formation it has proceeded from strength to strength."

A Time to Take Stock

"Like Proteus of old, I have assumed many guises," began Sir Gordon Gordon-Taylor. He might even, he said, be

*The oration will be published in full in the *Journal of the Royal Army Medical Corps*.

arraigned for divided Service loyalties. From the well-ironed silk hat and morning coat of the first decade of the century, he had donned the khaki of the Corps, subsequently transferring to the blue and gold of the Senior Service in the second armageddon, and thereafter to the drab and sombre *tenue de ville* of the modern civilian surgeon. "1898-1958: sixty years on!" continued Sir Gordon. "The chariot wheels of time roll relentlessly onward: *omnia fert aetas, animus quoque*—time carries everything away, even the memories. Yet would I dare to challenge the last fragment of this sad Virgilian line. Although we are assured by Sir Thomas Browne that 'diuturnity is a dream and folly of expression,' that is surely but a long-term reflection. Look closer! With each revolution of time's wheels 'who runs may read' on flying felly the impress, perhaps faint, of some event or happening from the past in the life of individual, cohort, corps, nation, or the very world itself. It is fitting that from time to time we should look back and take stock of ourselves: for 'people will not look forward to posterity, who never look backward to their ancestors.'"

It might not to-day be wise to dwell too much on the birth-pangs attending the inauguration of the Corps, the struggle with the War Office and governmental circles. Nevertheless there was one aspect which must be emphasized—the important part played by the British Medical Association, which finally, on January 20, 1898, sent a powerful deputation to wait on Lord Lansdowne, then Secretary of State for War. The deputation was introduced by Dr. Robert Farquharson, himself a former Army medical officer and at that time M.P. for West Aberdeenshire; it included the president-elect of the B.M.A., Sir Thomas Grainger Stewart, who also represented his own University of Edinburgh, and others, as well as the most important officers of the Association. In just two months' time the *British Medical Journal* was able to report "some very satisfactory announcements" from a parliamentary debate. There followed Lord Lansdowne's speech at the mayoral banquet in the City of London on May 4, in which he stated that there would be a new Army Medical Corps and that Queen Victoria had been pleased to signify her intention of bestowing upon it the title "Royal."

Ancestors of the R.A.M.C.

Thirty-six years ago, in his rectorial address to the "red gowns" of St. Andrews University, Sir James Barrie had asked how some old graduate returning to his *alma mater* would spend his time if this were restricted to a single hour, or, better still, with whom would he choose to have a few minutes' conversation. "Many of your Army medical ancestors are far beyond our ken this afternoon," continued Sir Gordon. "John of Arderne, who accompanied Edward III at Crécy in 1346; Thomas Morstede with Henry V at Agincourt in 1415; Gale and Clowes; Woodall and Wiseman." He would like to meet Sir Stuart Threipland, who was Prince Charles's chief medical adviser in "the forty-five," but he would rather talk to Sir John Pringle, one of the founders of modern military medicine. "I should find it difficult to break off conversation with those great surgeons of the Peninsula and Waterloo—Sir James McGrigor, Guthrie, or Hennen." If statuary, obelisks, or eponymous buildings were a talisman to ensure immortality, McGrigor stood secure for all time. A hundred years had passed since his death: sired by an Aberdeen father, he was born at his mother's paternal home in Inverness-shire in 1771. Much of his education took place in Aberdeen, but he also studied medicine in Edinburgh, walking the hundred-odd miles to the Scottish capital and visiting St. Andrews on the way. While deputy inspector of hospitals in the Southern Command, he had to make arrangements for the battered remnants of Sir John Moore's forces from Corunna; finally in January, 1812, at the request of Wellington he arrived in Lisbon to undertake the medical care of the troops. McGrigor wrote of his officers: "Great experience and reflection had at this time created a body of operators never

excelled or before equalled in the British Army." He was Director-General from 1815 until 1851.

Hennen died at a relatively early age at Gibraltar of an epidemic fever he was endeavouring to control. George James Guthrie had always been one of Sir Gordon's heroes. He was posted to the 29th Regiment when only 16 years of age, serving with it in North America and the Peninsula. Later, after Waterloo, he successfully amputated at the hip-joint—on a French soldier. This was only the second occasion on which success had attended a British surgeon performing such an operation, the other being by another Army surgeon, Mr. Brownrigg, in 1812. For 30 years Guthrie lectured and gave demonstrations to officers of the Army, Navy, and East India Company without price, as a mark of the esteem in which he held them. He was president of the College in 1833, 1841, and 1854; and he refused a knighthood—"a great little man."

High up on the façade of the London School of Hygiene and Tropical Medicine were carved in stone the names, among others, of Edmund Alexander Parkes (1819-76), an Army surgeon who founded the science of hygiene; David Bruce and William Leishman, both members of the Corps; and Ronald Ross from an allied service. At another place one might see the names of two others who had worked in the Corps—Sir Almroth Wright and Sir Alexander Fleming.

"If services to humanity are the standard of a man's greatness, Whitby stands high among the great benefactors of mankind." One need only reflect on that great Army Blood Transfusion Organization of the 1939-45 war years, which he inaugurated, developed, administered, and commanded, an organization for which more than three-quarters of a million donations of blood were collected; which not only supplied our own armies but also some of the armies of our allies; which created and trained almost a corps of expert transfusion and resuscitation officers. Since some 10% of all wounded men required transfusion fluids, Sir Lionel's contribution to victory was very considerable.

Many would remember Cuthbert Wallace and what he did to advance the surgery of abdominal wounds of war. He saw the importance of early surgery and used to take up Spencer Wells forceps surreptitiously in his pockets. In Mesopotamia George Grey Turner was consulting surgeon at Amara; one of the greatest surgeons of the century, he was an early worker in thoracic surgery. The two surgeons who contributed most to promoting the surgery of thoracic wounds in the 1914-18 war were George Gask and Pierre Duval, of France. More brilliant but only just spreading his wings for his upward flight in chest surgery was Tudor Edwards. And Sir Gordon mentioned many others by name.

Laurel and Rosemary

"The cavalcade has passed," continued Sir Gordon. "The stage is blacked out. We are translated from the past to the fierce light of the present, with eyes firmly fixed on the future with all its incertitude." Remembrance was the greatest incentive and inspiration that history could offer to those who laboured in similar causes to-day. It was unnecessary to go back to Pericles and the Athenian dead; there were memorials nearer at hand, in the R.A.M.C.'s own historical museum at Crookham. "*In arduis fidelis*"—fidelity, next to courage, was the loveliest virtue which God handed down to his children. "I offer to the Corps laurel for tribute on this its diamond jubilee, and rosemary for remembrance of those who have preceded us on the way," concluded Sir Gordon. "*Surgat gloria usque astra*."

The vote of thanks to Sir Gordon was proposed by the Chairman of Council of the B.M.A., Dr. S. WAND. Sir ALEXANDER DRUMMOND, Director-General, Army Medical Services, then ended the proceedings by reading a message of congratulations to the Corps from Queen Elizabeth the Queen Mother, its Colonel-in-Chief. Before the lecture the R.A.M.C. band was playing in the forecourt of B.M.A. House as the guests assembled.

BRITISH EMPIRE CANCER CAMPAIGN THIRTY-FIFTH ANNUAL REPORT

The British Empire Cancer Campaign held its annual meeting at the House of Lords on July 1, under the chairmanship of the DUKE OF DEVONSHIRE. Last year the Campaign achieved the record income of £762,972, a rise of nearly £200,000 over the previous year. Of this large sum it spent £620,722 on what are termed "the main objects of the Campaign"—for instance, grants to research centres (£403,000) and individuals (£99,000), fellowships (nearly £29,000), and the installation of a theratron at the Westminster Hospital (£60,000); nearly £60,000 on publicity and appeals; and just over £10,000 on management and administration. The Campaign's income was derived as follows: from donations, collections, etc., £532,000; from legacies, £187,000; from interest on investments, about £44,000.

The *Annual Report* this year is issued in three parts: Part I—"The Chairman's Statement and the Accounts" (pp. i-xi); Part II—"The Scientific Report" (pp. xliii-lxiii and 1-528); and Supplement to Part II—Report by Dr. Percy Stocks on "Cancer in North Wales and Liverpool Region" (pp. 1-156). The *Annual Report* may be obtained from the Campaign's Offices, 11, Grosvenor Crescent, Hyde Park Corner, London, S.W.1.

Progress of Research

The scientific volume opens with this cautiously optimistic appraisal of current research:

"In the field of chemical and physical carcinogenesis, it is not perhaps surprising that the already long list of carcinogens continues to expand. What is more important is that this is matched by a gradual increase in our knowledge of the underlying mechanisms of cancer production, and of the essential differences (especially in biochemical and biophysical terms) between cancer cells and normal cells. Of much current interest are reports of differences in the chemical and physical structure of the cell surfaces, and in the resultant biological behaviour. The newer ideas and methods in immunology also continue to be applied to good purpose. These are among the more rational approaches. Yet there are many other avenues of attack, some of them much more empirical, which cannot be neglected. In the field of experimental chemotherapy, some work is of negative value in serving to define the limitations of individual agents. Equally obvious, however, is that the potentialities in this direction have scarcely been revealed, let alone exhausted."

Here it is possible to note only a selection of the researches reported.

Further work has been done on the identification of polycyclic hydrocarbons in cigarette smoke tar, some of which are known to be carcinogenic. On the other hand, experiments in which animals of many different species have inhaled tobacco smoke for long periods have yielded no tumours. Likewise attempts to produce tumours in animals by skin painting or oral administration of carcinogens from cigarette tar have met with little success. In view of the possibility that 3:4-benzpyrene discharged into the air from motors of various kinds is an additional factor in the causation of lung cancer in cigarette smokers, the effect of combinations of this carcinogen and tobacco condensate on the lung cultures is also being studied.

Besides biochemical and enzymological studies of nucleoproteins, much work is being done on the surface properties of normal and tumour cells.

Endocrinological and Immunological Studies

At several centres work has continued on the elucidation of the endocrine changes in breast cancer patients variously treated by oophorectomy, adrenalectomy, and some form of pituitary ablation. Particular attention has been given to determinations of the oestrogens excreted in the urine, though, states the *Report*, there seems to be little correlation between the results of these and the clinical progress of the patients. An extensive survey of a large series of patients who had in the past been treated with oestrogen has shown that only two out of 530 traced subsequently developed carcinoma, one of the uterus, the other of the breast. Of 120 patients with carcinoma of the body of

the uterus, only five were found to have been taking oestrogens for longer than one year some time previously. Other clinical and biochemical studies of the endocrine aspects of breast cancer have included a comparison of the effects of pituitary yttrium implantation with adrenalectomy. Oestrogens continue to be excreted in the urine even where the endocrine ablation is complete.

A judicious, intermittent use of prednisone and prednisolone has been shown to provide a means of controlling adrenal activity in post-pubertal adrenal hyperplasia.

Further studies on cancer immunology are reported. The main lines followed at one centre include the detection of antibodies in tumour-bearing animals and of immunological changes during chemical carcinogenesis. At another centre the immunological structure of normal and carcinogen-treated tissues is being examined to determine whether abnormal tissue antigens are formed during carcinogenesis. Attempts to inhibit carcinogenesis by producing immunological tolerance to cancer tissue formed *in vivo* have been unsuccessful. Studies have also been carried out on the phenomenon of tissue transplantation immunity and on the immunological consequences of inducing tolerance of skin homografts in mice by inoculating them at birth with living adult homologous spleen cells.

Experimental Chemotherapy

A new series of cyto-active amino-acids is being studied, and of special interest is a mannitol-busulphan—the first of a new series of busulphan-like derivatives—of low toxicity yet with powerful tumour-inhibitory properties. In studies of the mechanism of action of alkylating agents, a new lead has arisen from the observation that deoxyguanic acid can be alkylated *in vitro* at the 7-position of the guanine moiety. This and related work is stated to be of great potential interest as suggesting the possible importance of alkylation of the purine moieties of nucleic acid in the production of biological effects.

Twenty-one new nitrogen-mustards have been synthesized, designed to act selectively on tumours by enzymic action at the site or by selective transport.

Clinical Studies

With increasing experience of exfoliative cytology in the diagnosis of malignant disease of the uterus it is being found at most centres that three or four women out of every 1,000 attending gynaecological clinics have unexpected cancer of the cervix, usually carcinoma *in situ*. At one centre, however, the incidence of pelvic malignancy revealed by cytology when no clinical suspicion attaches to either the history or the clinical findings is put as high as 2%.

Two investigations bearing on the surgery of carcinoma of the bronchus are reported, one designed to discover for how long the blood supply of the lungs can be interrupted without permanent loss of lung function, the other to establish the precise routes of direct spread of these tumours. Fourteen pregnant patients treated with radium for cancer of the cervix have been reviewed to determine the influence of pregnancy on the clinical course of the disease after treatment.

The incidence of structural damage in the chromosomes of tumour cells of experimental animals has also been studied, more especially in relation to the influence of oxygen tension on the effectiveness of a given x-ray exposure. An extensive investigation into the important question of the reduction in life span and the acceleration of ageing by ionizing radiation has been started at one centre, and the effects of radiation and radiomimetic chemicals on ageing have been compared at another centre. The effects of radiation on many different aspects of iron metabolism in experimental animals are also being investigated.

Natural Radioactivity

The measurement of the low levels of radioactivity which occur in our natural environment continues to occupy an important place in the study of factors which may influence cancer incidence. On the physical side such measurements

To-day's Drugs

In this column we publish from time to time authoritative notes on a selection of drugs in current use.

Dindevan (Evans Medical Supplies Ltd.)—This is phenindione, an anticoagulant which exerts its effect by interfering with the hepatic synthesis of prothrombin. Its chemical formula is related to that of dicoumarol (or bishydroxycoumarin). It is more rapidly absorbed than dicoumarol and exerts its full effect clinically 24 to 36 hours after treatment is started. Its duration of action is shorter, and prothrombin activity returns to normal within 48 to 72 hours after treatment is stopped. In addition its effects on blood coagulation are believed to be more constant, and hence the dose is more uniform. It is supplied in tablets containing 10 mg. and 50 mg. The tablets are given orally, 200 mg. on the first day, followed by 50 mg. twice daily, the exact dose for the individual patient being carefully controlled by daily prothrombin estimations. Treatment is aimed at increasing the blood prothrombin time to two to three times normal. When given for long periods, smaller doses are prescribed and prothrombin estimations are less frequent.

Phenindione is given for the treatment of coronary thrombosis, phlebothrombosis, and pulmonary or peripheral embolism. The use of this or similar anticoagulants has helped to reduce the incidence of serious post-operative thrombo-embolic complications. Its place in the treatment of coronary thrombosis is still a matter of controversy, though clinical evidence is mounting to show that it helps to prevent the spread of thrombosis locally in the coronary vessels and to prevent the development of thrombosis elsewhere, especially in the calf veins with consequent pulmonary emboli. The possibility of serious complications in the form of severe haemorrhage must be set against this, and some clinicians feel that the dangers outweigh the therapeutic advantages. It is generally thought, however, that phenindione is indicated in the more severe cases of coronary thrombosis, though it is doubtful whether it need be given in the milder cases. The drug is contraindicated in severe hepatic or renal disease and also in peptic ulcer or haemorrhagic disease on account of the danger of serious haemorrhage. Vitamin K₁ should always be available to combat the complication of haemorrhage; 10 to 20 mg. intravenously or 20 to 25 mg. orally will reverse its action and produce a rapid fall in prothrombin time in 6 to 8 hours.

N.H.S. basic price: 100 10-mg. tabs., 15s.; 100 50-mg. tabs., 21s. 8d.

Rondase (Evans Medical Supplies Ltd.)—This preparation of the enzyme hyaluronidase is supplied in ampoules containing 1,500 international units in freeze-dried powder. Water or normal saline must be added to it before use. The solution is compatible with most fluids given by subcutaneous injection. In a dose of 1,500 units the drug has no side-effects.

The essential action of rondase, as of other preparations of hyaluronidase, is to aid the dispersal of fluids injected into the tissues. By this means it aids the penetration of local anaesthetics, but at the same time it hastens their absorption and thus tends to increase their toxicity. Hyaluronidase may also be added to solutions used for hypodermoclysis, but the need for this procedure is limited. Hyaluronidase has a reputation for dispersing irritant substances injected accidentally paravenously. Thus it can be employed to diminish the likelihood of local reactions to thiopentone or the contrast media used in radiology when they escape outside a vein.

It has been suggested that hyaluronidase may be injected into areas of oedema with a local cause, but this measure, though rational therapeutically, is not firmly established.

N.H.S. basic price: 6 ampoules, 14s.

New Appliances

A PESSARY RECOGNITION BOX

Mr. C. H. DE BOER, assistant gynaecological surgeon, United Liverpool Hospitals, writes: Patients complaining of recurrent vaginal discharge frequently give a history of past treatment by drugs in the form of pessaries. Often an

identification by shape and colour can be made by the patient. Through the courtesy of Messrs. Ward Blenkinsop & Co. I have obtained a demonstration case for the pessaries commonly used in this area and have found it most helpful. By its use the repetition of ineffective treatments can be avoided.

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Alcohol and Driving

SIR,—I was interested in the article by Professor John Cohen, Mr. E. J. Dearnaley, and Mr. C. E. M. Hansel, "The Risk Taken in Driving Under the Influence of Alcohol" (*Journal*, June 21, p. 1438). However, I wish to suggest that the authors have drawn a very false conclusion in their penultimate paragraph, when they write "either a large number of people are wrongly convicted by the magistrates or wrongly acquitted by the jury." Electing trial by jury usually involves a counsel's brief and is a costly affair. It would appear fairly logical that people with a good defence should resort to such a tactic and those without a reasonable answer to the charge should content themselves with a magistrates' court, which in the event of conviction tends to be more lenient.—I am, etc.,

Chirk, North Wales.

R. P. W. KUP.

SIR,—The publicity that the article by Professor John Cohen, Mr. E. J. Dearnaley, and Mr. C. E. M. Hansel on "The Risk Taken in Driving Under the Influence of Alcohol" (*Journal*, June 21, p. 1438) has received in the press, and the legal implications of such articles, invites enlargement and comment.

The ability to drive after the consumption of alcohol must be related to the initial level of competence of the driver, and it would be only reasonable to test the offender's ability to drive the vehicle concerned whilst sober before deciding that his incompetence was due to the effects of alcohol. Many of us have been granted licences to drive vehicles whose dimensions may be similar to that of a Manchester Corporation bus after having passed a test on a vehicle three feet (0.9 m.) narrower and a tenth the weight. It would have been interesting to have included a control group of, for example, university staff who hold licences to drive heavy vehicles but who have not actually passed a driving test on such a vehicle and who do not drive one regularly.

The gap through which the drivers who had taken 6 fl. oz. (170 ml.) of whisky could drive was only 0.6 in. (1.5 cm.) less than that through which the control group could drive, a difference of 0.6% of the total width of the gap. This is a figure which would hardly seem significant, even statistically, and the number of drivers who took part in the tests is not stated.

It is a pity that the convivial atmosphere which is said to have been present when the tests were commenced was not extended to those who undertook the test sober, and they were not subsequently invited to take the test after the consumption of alcohol. It is possible, as the method of selection of the controls is not stated, that those who cautiously avoided taking the test after the consumption of alcohol were by nature also the more cautious drivers, so that the results of the experiment might have been reversed if they had been given the alcohol and those who were audacious enough to consume 6 fl. oz. (170 ml.) of whisky before driving a bus had been persuaded to take the test sober. They might then have been able to show off their natural audacity by even greater overestimation of their ability to drive a bus through a narrow opening. It would have been more enlightening if each driver had acted as his own control, and half had been tested before alcohol and the other half had been tested whilst under the influence.—I am, etc.,

Altrincham, Cheshire.

Prevention of Lung Cancer

SIR,—The letter from Dr. Lennox Johnston (*Journal*, June 21, p. 1483) raises issues that are even more important than his main theme, serious as the problems of lung cancer and excessive smoking may be. Since I do not

smoke, Dr. Johnston will perhaps exonerate my remarks of the hypocrisy that he associates with those who do.

Dr. Johnston will surely not expect his unrealistic scheme for curing the nation's smoking almost overnight to be taken very seriously. I hope, also, that he does not really mean what he writes about the propriety of deliberately frightening people. There are extremely cogent objections to the practice of frightening children about the effects of fire or anything else. It is essential to protect young children from fire and other dangers by external means over which, like Legge's workmen, they have no control. This must continue until they are mature enough either to assess the dangers realistically for themselves or to be reliably obedient to parents with whom they have a sufficiently trusting relationship (which is the more likely if, *inter alia*, the parents have not deliberately frightened them). Guiding a child into habits of safety, and explaining the reasons for these, is of course quite a different matter from frightening the child (or the smoker) as Dr. Johnston advocates.

Foolhardy behaviour of either children or adults, in common with many other psychological difficulties, is ultimately a result of some kind of fear, and it often appears to be caused by fear of the consequences of the very activity in question. Perhaps, therefore, the resistance of some smokers to repeated warnings is due, not to a hypothetical process of immunization, but to a compulsive need for reassurance that the danger is not after all as serious as the warnings assert. If this be so, a campaign to induce greater fear seems rather futile. The motives of smokers (and also the motives of those who are anxious to prevent smoking) are undoubtedly complex, and clearly the problem can have no such simple solution as that proposed by Dr. Johnston. In general medicine it has long been recognized that rational therapy demands an understanding of underlying processes and is not achieved by merely trying to abolish symptoms. It is also generally agreed that the adequate physical care of children is a much better way to produce healthy adults than trying to correct maldevelopments in later years. Unfortunately there is still considerable resistance against accepting that these principles are just as true for psychological problems—amongst which smoking must surely be considered one of the less important.—I am, etc.,

St. Albans, Herts.

A. C. WOODMANSEY.

Cancer Education

SIR,—The efforts of Mr. Malcolm Donaldson to promote wider dissemination of what we know to be the true picture of cancer have aroused the gratitude and admiration of many of us, so that his letter in the *Journal* of May 31 (p. 1302) deserves support. The reluctance in this country especially to accept information about cancer, or even to acknowledge its very existence, is more reminiscent of the ostrich than of beings endowed with perception and judgment. Surely it is time for the psychologist to enter this field as he has done so effectively in other spheres of public relations where irrational factors seem to be operating.

Many people regard a malignant growth as something with an independent life which is devouring them and which cannot possibly be brought under control, so that a diagnosis of cancer is necessarily a sentence of inevitable mutilation, pain, and eventual destruction. It is no use telling them either collectively or individually that they are wrong and that it is better to diagnose cancer at an early stage when it can be treated with a very good chance of palliation, if not cure, as they simply do not believe it. It is surely significant that in almost any lay discussion about cancer frequent reference is made to the large number of sufferers who die apparently uninfluenced by treatment, while in a similar discussion about, say, hypertension or heart disease reference is rather made to the increasing number of sufferers living happy and useful lives as a result of treatment.

In some countries, such as France, there is wide publicity of the early signs of cancer, coupled with assurances that treatment gives great hope of cure, but there has not been any significant improvement in the overall survival figures after some years of this propaganda. In this country there is the impression, possibly due to the news value of large benefactions and of large and

impressive machinery, that cancer can only be helped at all by treatment in one of the large centres with "something atomic," as a recent patient has put it, so again there is a denial of the confidence placed in the ordinary facilities provided for medical treatment at provincial level. It seems that the word "cancer" conveys much of the despondency, and just as the gradual substitution of "T.B." for "consumption," with its sinister connotation, has accompanied the change in outlook about this disease, so should we hope to find some new general term to cover the neoplastic diseases.

But, until such time as we can fully control new growth, it can be shown that we have much to offer, and that it is just as possible to live with a tumour as with arthritis.—I am, etc.,

Hove.

E. MILLINGTON.

Asphyxia by the Cord

SIR,—I should like to comment on Dr. H. E. Reiss's scholarly and well-documented article on "Foetal Asphyxia Associated with Umbilical Cord Around the Neck" (*Journal*, June 14, p. 1394). I assume that the foetal distress was caused by tension during labour on a relatively short cord and not solely by the number of coils.

At first sight it seems strange that, while cord round the neck is common, foetal distress is rare, but Nature has provided two compensating mechanisms. First, if the length of cord from placenta to neck is very short, the breech presents and will not turn spontaneously. Secondly, Nature provides a push on the fundus by means of the voluntary contractions of the diaphragm and abdominal muscles during the second stage of labour. This helps to relieve tension. It follows that, if the child can survive the squeeze of the uterus, which increases the length of the uterine cavity during the first stage, it ought to be able to survive the push and squeeze of the second stage. Dr. Reiss's case illustrates very clearly that foetal distress appeared during the second stage. When the os is fully dilated it is undoubtedly proper to correct any malposition and deliver with forceps so long as firm fundal pressure is maintained during delivery. Push, and tension is released; pull, and tension is increased. If the cord is intact when the head is delivered, it is always possible to deliver the body by fundal pressure without dividing the cord.

It is a pity that British textbooks accept the findings of Gardiner,¹ as they are demonstrably false. It is untrue to say that a cord of nearly 13 in. (32 cm.) is necessary for spontaneous delivery. Gardiner forgot that the fundus can follow the foetus and be pushed down nearly to the symphysis pubis either by the mother's own efforts or by the obstetrician. Nature provides the human foetus with a very long cord, usually 20 in. (50 cm.) or more, not because it is necessary for delivery—indeed, the longer the cord the more likely it is to become coiled round the foetus and so be relatively short—but because it was necessary for many hundreds of thousands of years for the mother to be able to pick up her child immediately after delivery without tension on the placenta during the hazardous third stage. But that, Sir, is another story.—I am, etc.,

Cambridge.

C. W. WALKER.

REFERENCE

¹ Gardiner, J. P., *Surg. Gynec. Obstet.*, 1922, 34, 252.

SIR,—Cord round the neck is a common condition at birth, and Dr. H. E. Reiss (*Journal*, June 14, p. 1394) rightly points out that it may cause serious foetal asphyxia and even foetal death. Whether or not the foetus shows signs of distress from compression of the umbilical vessels depends, firstly, on the tightness of the cord round the neck, and, secondly, on its thickness. The amount of Wharton's jelly in cords is variable, and, when it is reduced, the umbilical vessels, deprived of its cushioning effect, are more easily compressed.

During an investigation of 100 cases of foetal distress at St. Helier Hospital, Carshalton, several years ago, I attributed 24 of them to cord round the neck. What impressed

me most was that signs of distress appeared late in labour. In 20 cases it occurred in the second stage and in the remaining 4 at three-quarters dilatation. I believe that the reason for this is that the cord is liable to be nipped by the foetal chin during flexion and rotation of the head on the pelvic floor. Since delivery can usually be readily effected when the danger signs appear, the baby is saved in most cases and stillbirths from cord round the neck are relatively rare.—I am, etc.,

Birmingham, 16.

D. B. WHITEHOUSE.

SIR,—I read with interest the article by Dr. H. E. Reiss (*Journal*, June 14, p. 1394), not so much on account of the coiling of the umbilical cord around the foetal neck five times, but because general inhalation anaesthesia was used when it was known foetal distress had been present for some time. It is not surprising there was delay in establishing regular respiration in a baby when, in addition to the distress, a second dose of pethidine, 125 mg., was given two and a half hours before the administration of cyclopropane, gas, oxygen, and ether. Caudal analgesia by the single-dose technique would have been well worth attempting. In the majority of patients it is simple to administer, effective, and always safe to mother and baby. Moreover, it takes little time and one knows well within fifteen minutes if one has been successful. The time to have given it would have been just prior to full dilatation. This would not have delayed, but probably hastened, labour. That the method is a practical one I have proved to myself, and now it is my method of choice in all vertex presentations requiring forceps unless the head is very low, in which case local analgesia is used. In the last 225 cases there have been 25 failures and not all these have failed completely. General inhalation anaesthesia is not only dangerous to the mother but also to the baby, particularly to the latter when there has been evidence of foetal distress.—I am, etc.,

Haywards Heath, Sussex

C. J. FARR.

Out-patient Anaesthesia

SIR,—Professor William W. Mushin and Dr. Peter W. Thompson's favourable report (*Journal*, June 14, p. 1376) on cyclopropane in out-patient anaesthesia may help to persuade manufacturers in this country to make the necessary apparatus. More than two and a half years ago I

Apparatus for administering cyclopropane in dentistry.

developed in conjunction with Sparklets Ltd. the apparatus shown in the photograph; but it was not put into production because the value and safety of this method of anaesthesia did not seem to have gained wide acceptance by

anaesthetists. Cyclopropane continued to be regarded as too powerful and dangerous to be placed in the hands of the "occasional" anaesthetist.

Ever since 1951, when I first described the use in out-patients of 50% cyclopropane given from a six-litre bag,¹ I have urged the safety of the method. The following year I reviewed 1,000 administrations and suggested that it might, with advantage, replace the nitrous oxide method²; and in 1954, the year in which Hingson³ began to use it, I reported nearly 2,000 administrations and repeated my suggestion.⁴ Nevertheless, contrary to the statement of Mushin and Thompson, cyclopropane has never been widely tried in out-patient work. Moreover, apart from Hingson and myself, the few who have made reports have used it in low concentrations which give longer and therefore less satisfactory induction and recovery. None of them suggested its general adoption in place of N₂O; only Hingson supported me in this.

In the apparatus shown here, the Sparklet bulbs, which are sealed together, charge the bag through a non-return valve with 50% cyclopropane, and oxygen and nitrogen in equal parts, after which the gun is detached. The mixture is non-ignitable, but, as with Hingson's mixture, if it is discharged from the bag into a flame the cyclopropane will catch fire, since on leaving the bag the gas becomes diluted with air and enters its ignitable range. Warning should also be given that nitrous oxide and oxygen given nasally to dental patients after induction with the cyclopropane mixture, as Mushin and Thompson recommend, may reintroduce the risk of igniting the patient's breath with sparks from teeth and dental forceps.

A soda-lime canister has not been incorporated in the apparatus, because it was designed for use by "occasional" anaesthetists, whom I recommended not to prolong the administration for more than a minute. This gives satisfactory anaesthesia lasting about a minute and a half, which is sufficient in most of the dental-extraction cases that need general anaesthesia, which number more than 2,000,000 a year in England and Wales. The soda-lime canister in Hingson's apparatus gives it a distinct advantage in other kinds of operation, for which more prolonged administrations may be needed. If either type of apparatus were made available, the method might be given the extended trial I have long thought it deserved.

—I am, etc.,

London, S.E.1.

Tubeless Gastric Analysis

SIR,—I read with interest the articles on tubeless gastric analysis by Drs. M. A. Denborough and F. P. Retief and Professor L. J. Witte (*Journal*, May 24, p. 1213). During an investigation of 23 cases with "diagnex," using the azure-A method, I had five false negatives. I had no false positives. This is in agreement with all the other workers quoted in the article, who do not find false positives to be a problem. The authors of the article, however, in 36 cases negative to the augmented histamine test screened by azure-A test had two false positives showing an excretion of azure-A greater than 0.6 mg. I wonder was this after cooling—a measure which I did not use or find desirable. Another possibility is that these were true positives and that the test meal was at fault probably owing to passing into the duodenum. In the one positive I had that did not correlate with the test meal, when I repeated the latter, I found that in fact the meal was at fault. I would suggest that apparent false positives should have their test meal repeated.

To overcome the false negatives I evolved a technique which was tried on 27 further patients and the results have now been published.¹ Briefly, the test was carried out as usual and the urine was tested immediately. If it was negative a gastric tube was passed at once and the gastric contents aspirated. The tube was therefore passed about 2½ hours after the granules had been swallowed. The aspirated juice showed one of three things: (1) The gastric contents

were normal in appearance—i.e., the dye had passed through the stomach and it was therefore a true negative. (2) There was a large or small amount of undissolved granules, showing that there was some gastric hold-up with achlorhydria. (3) There was a large amount of partially undissolved granules, this being evidence of gastric hold-up with free hydrochloric acid present.

Using this modification I was able to eliminate the problem of false negatives. It will be evident that in about 70% of cases it is not necessary to pass a gastric tube. Further, an unsuspected delay in gastric emptying may be revealed. I have found the azure-A test, with this modification, to be an excellent one, although it cannot always be strictly called "tubeless."—I am, etc.,

Dublin.

Treatment of Leg Ulcers

SIR,—The following quotation from a letter written in 1781 will interest those doctors who have taken part in the correspondence on the treatment of leg ulcers by compression:

Dear Sir, . . . A gentleman whose leg had been ill for several years and had several running sores on it, was advised by an old Clergyman to discard his physicians and surgeons and to follow this simple prescription: "Take a fillet of soft Welsh flannel four inches broad and four yards long, let it be rolled as tight as you can bear it over your leg from the knee to the sole of the foot, and keep it on day and night without any alteration." He wore this for a month and has been perfectly well ever since. If she is not well already, I have little doubt but that the same method would cure Mrs. Brackenbury. I trust that you and she are both pressing on to the mark and strengthening each other's hands in God.

I am, dear sir,

Your affectionate friend and brother,
JOHN WESLEY.

This letter is interesting as showing that wisdom is not confined to us. It was written by the Rev. John Wesley¹ to Robert Carr Brackenbury from Towcester on November 19, 1781.—I am, etc.,

Hong Kong.

D. VAUGHAN REES.

Chain-store Glasses

SIR,—I missed Mr. J. Primrose's letter (*Journal*, April 19, p. 943), but with Mr. A. C. Shuttleworth's (*Journal*, June 14, p. 1419) no medical practitioner, one might think, could disagree. I expressed the same views three years ago (*Journal*, July 23, 1955, p. 267). Yet from time to time I learn from patients that they have been sent by their doctors direct to opticians for examination of their eyes with the object of getting glasses if thought desirable, rather than to medical practitioners at hospitals or in the competent Supplementary Ophthalmic Service provided by the State. (To their honour, I have known opticians to resist the temptation to correct the small errors of refraction which are almost invariably present.) If the Ministry is aware of this undesirable practice, it may feel justified in taking appropriate action, and the profession has partly itself to blame for an unwise decision.

But buying glasses over the counter is another matter. Every day I use professionally a pair—the last survivor of half a dozen pairs, the others being war casualties—of multiple-store glasses bought 25 years ago at a shilling a pair. One more breakage, and, if the Opticians Bill is passed, replacement will cost £1 for the lenses and a considerable sum for the frame. Well, that won't break me financially, but it will be a hardship to many poor people who can see just as well with self-chosen 3s. 6d. spectacles (I think that is now the store price) as with the £2 plus ones. Why, then, interfere with a harmless and necessary trade

which has never been known to damage eyes, and has had the implicit support of such specialists as Sir George Berry and Mr. D. Priestley Smith (*Journal*, August 6, 1955, p. 382). Mr. Shuttleworth does well to appeal for clear thinking and unprejudiced judgment.—I am, etc.,

Portsmouth.

W. S. INMAN.

Case of Exomphalos

SIR,—I feel it is worth while reporting a case of exomphalos which survived operation but died on the twenty-third post-operative day with volvulus of the mid-gut.

H. A., a baby boy, was admitted to the Evangelical Hospital on January 1, 1958, at the age of 1 hour, with a congenital umbilical hernia. The liver and parts of the gut were felt in the hernial sac. The baby weighed 2.375 kg.

The baby was prepared for operation when it was 2 hours old, but it was noticed that the colour of the face, hands, and feet was becoming blue and the operation had to be postponed until the baby recovered good colour. It was taken to the theatre at the age of 5 hours. At operation the contents were found to be the liver, many loops of small intestine, caecum, and appendix, together with a part of the transverse colon. The coverings were intimately adherent to the antero-superior aspect of the liver over more than two-thirds of its extent. These were patiently freed, although I had to leave a good deal of the extra-embryonic coelom adherent to the liver, which had to be returned with it to the abdominal cavity. The gall-bladder was peeping through a circular hole on the anterior surface of the liver; it could not be seen on the inferior surface nor was it adherent to the liver substance; it was covered with peritoneum all round. A Meckel's diverticulum was found lying along the small intestines and stuck to its wall with fine adhesions near the terminal ileum; it was about 2 cm. long and 5 mm. wide.

The defect in the abdominal wall measured 7 by 10 cm. This was too small for the reduction of the liver and I had to enlarge the opening upwards to achieve this stage of the operation. Reduction could not be completed without aspirating most of the gas in the intestines at three different points. The wound was closed satisfactorily with difficulty and the baby was sent to its cot on hourly feeds of 10 ml. glucose-water for six hours and then three-hourly feeds of 30 ml. for the rest of the first 24 hours. It was given its mother's breast next morning. It sucked vigorously and thrived well, gaining weight after an initial loss of 250 g.

On the evening of the twenty-third post-operative day the baby suddenly collapsed and became cold and pale. It was screaming all the time, pulled its knees to its abdomen, and vomited repeatedly. The abdomen was slightly distended at first, but it became excessively so in less than three hours. Its condition deteriorated very quickly and the baby died eight hours after the start of symptoms. No post-mortem examination could be done, and the diagnosis of volvulus of the mid-gut is based on the clinical findings alone.—I am, etc.,

Nablus, Jordan.

E. HANDAL.

Azacyclonol in Schizophrenia

SIR,—The general conclusion of Dr. S. Gray and Dr. A. D. Forrest (*Journal*, February 15, p. 374) that azacyclonol is "unlikely to be a very useful drug in the treatment of chronic schizophrenia" agrees with my own experience with this drug¹ in the dosage employed. I also agree that further trials using higher dosage are indicated. May I, however, question the means by which their conclusions were reached?

In the course of their "controlled trial," 17 out of 40 patients received reserpine, and another 6 chlorpromazine, together with the drug being tested. This means that, in fact, only 17 patients could be expected to demonstrate change attributable to azacyclonol, any alteration in the mental function of the remainder being possibly due to the effect of a combination of drugs. That this point is of importance can be demonstrated by the effects of other drugs given in combination. Examples easily come to mind from clinical experience—e.g., potentiation of barbiturate activity seen commonly with some phenothiazine derivatives.

It would seem appropriate to recommend the greatest caution in interpreting the effects of medication on mental

function. Research design should attempt to eliminate, so far as possible, any artifact. The objections to attempting to reach conclusions about the activity of any drug when it has been administered in conjunction with another also apply to the administration of psychotherapy during a drug trial or indeed to any change, physical or psychological, in the patient's environment.—I am, etc.,

Out-patient Gynaecology

SIR,—Dr. Max B. Clyne (*Journal*, June 7, p. 1353) says, "And yet out of 60 women 42 . . . were referred to the wrong agency . . ."; and earlier, "This is a very serious challenge to us general practitioners." Certainly. Think again. A gynaecological (or any other) department is a consultant department even before it is a specialist treatment department, under the charge of a consultant.

The general practitioner, when in doubt and difficulty, will not institute psychological treatment until he has excluded organic causes for the symptoms. All these 60 women were rightly sent to a consultant, who was able to reply in 42 cases, "There is no gynaecological organic lesion; you may institute your psychological treatment with a clear conscience."—I am, etc.,

Crowthorne, Berks.

H. D. FORBES FRASER.

Induction of Labour

SIR,—As a general practitioner who does a fair amount of midwifery, I was very interested in the paper by Mr. Ian Cope and Mr. Morton Pearson (*Journal*, May 24, p. 1211) and in the letter by Professor G. Gordon Lennan and Mr. E. M. Edwards (*Journal*, June 14, p. 1413). I do not wish to enter into the discussion about the thorny question whether such a high induction rate is justified, especially as you dealt with this problem so excellently in your leading article (*Journal*, May 24, p. 1226). However, I wish to express my surprise that neither of the two reports mentions the possibility of medical induction.

For several years now I have made it my rule to induce labour if the patient goes two weeks beyond her expected date, and earlier if there are signs of toxæmia. Lacking facilities of an operating-theatre, I naturally turned to medical induction, and, since an intravenous drip is also difficult to arrange under domiciliary conditions, I adopted the following method.

1. The patient is given 15 mg. stilboestrol every waking hour. This apparently heroic dosage is surprisingly well tolerated by most patients.

2. If labour has not started after about 48 hours, the patient is given a course of oxytocic injections. She is asked to come to the surgery, and is warned that she may have to stay there for 2½ hours, and that she may have to take a taxi to get home. Oxytocin injections are then given at half-hourly intervals, up to six injections if necessary, starting with 0.3 ml., then 0.4 ml., and then for four times 0.5 ml.

3. If after the sixth injection the patient has only slight and indefinite contractions, she is given six 2 gr. (130 mg.) tablets of quinine sulphate, and asked to take one tablet every half-hour, but to stop it if she starts labour, or if she notices any ill effects like palpitations or deafness or buzzing in her ears.

Unfortunately I am unable to give the exact number of cases in which this method of induction was tried, but I can trace the records of 13 cases, and I remember only three failures. Although I realize that these figures are too small to draw any valid conclusions, they do show that it is worth while to try medical induction before one turns to surgical methods.

The advantage of medical induction becomes obvious if one considers that surgical induction is not without dangers and disadvantages. Cope and Pearson mention the increased caesarean-section rate with its increased morbidity rate, and the psychological shock to the patient. They do not mention the (although rare) cases of ruptured uterus in succeeding pregnancies. They mention that the morbidity rate in

the induced cases could be kept low only by the routine use of antibiotics—with all its well-known disadvantages and dangers. Neither of the two reports mentions whether there was an increased forceps rate with its additional risks (anesthetic) and its psychological shock, and neither of the reports mentions whether owing to the difficulties and complications of dry labour (with or without forceps) there was an increased number of spastic, epileptic, and mentally defective children.

To avoid misunderstanding, I wish to make it clear that I found medical induction ineffective if used to induce labour before term.—I am, etc.,

Leicester.

BELA GALANDAUER.

Food Conversion in Babies

SIR,—Dr. Ian G. Wickes's letter (*Journal*, June 14, p. 1415) makes the suggestion that the ratio weight of food consumed/increase in infant body weight may produce an index figure useful in diagnosing certain diseases of infancy, a high index suggesting poor food utilization.

It seems probable that a group of healthy infants would be found to have widely varying indices and that any given infant would have a variable index from period to period. The range acceptable as indices within normal limits would therefore have to be broad, and the wider the acceptable normal range the less the value of the index as a diagnostic pointer. However, within the range of normal conversion ratios, the difference in index obtained for a number of healthy infants (healthy, that is, on general clinical grounds) might be attributed to a difference in metabolism, providing the broadest of pointers to the future nature of the individual. A high figure clearly suggests that the baby will become active-minded and highly strung rather than placid and easygoing.

If, in this respect, time showed the ratio to be in any sense reliable, it might be of help to those subsequently endeavouring to assess the child's temperament against a background of data supplied and perhaps coloured unduly by parents or others. The ratio would be comparable with an E.S.R. in being free from external influences but in requiring judicious appraisal of its meaning and worth in the individual case.

Such philosophical studies do not of course interest the farmer in studying the meaning of his pig conversion ratios. To him, high ratios mean only more fodder to provide without financial return, but, since high-ratio infants may produce some of the more talented of our species, we need not take the same gloomy view of them.—I am, etc.,

Nottingham.

GORDON CURRIE.

Mortality and Morbidity of Steroid Therapy

SIR,—In a leading article last year¹ you warned us about the mortality and morbidity which follow treatment of arthritis with steroids. Bunim was mentioned as having reported six deaths in 39 patients after prednisone. Of 50 patients of mine who started prednisone treatment more than two years ago,² four have died. Others who have reported fatal arthritic cases are Nelson,³ four; Stolzer *et al.*,⁴ three; Hart *et al.*,⁵ two; Medical Research Council and Nuffield Foundation,⁶ one. Three times as common were non-fatal gastro-intestinal disasters, severe infections, thrombo-embolic episodes, heart failure or arrhythmia, and mental disease.

Previously the mortality and morbidity after cortisone and corticotrophin were equally high. The Americal Rheumatism Association reported 26 deaths in 446 rheumatic patients in one year.⁷ Howell and Ragan⁸ reported 11 deaths in 68 patients; West⁹ 6 deaths in 52 patients, and Savage¹⁰ 6 deaths in 90 patients. The mortality rate for Levin *et al.*¹¹ was five in 50 patients; for Toone and Irby¹² five in 35; for Bunim *et al.*¹³ five in 78; for the Medical Research Council and Nuffield Foundation⁶ 2 deaths in 33 patients in one year. Similar death rates were seen in controlled trials on non-fatal disorders such as skin diseases¹⁴ and asthma.¹⁵ Baldwin *et al.*¹⁶ had 7 deaths in 60 steroid treated asthmatic patients. There is a steadily increasing

roll of death and disease from this therapy, for which I can see no compensating advantage.—I am, etc.,

East Melbourne, Australia.

Full-term Extrauterine Pregnancy

SIR,—Professor Coralie Rendle Short reports a case of a full-term extrauterine pregnancy with a living child, followed two years later by a full-term normal delivery (*Journal*, May 10, p. 1123), and, not having heard of a similar case, she was interested to learn that such a patient could conceive again so easily. The following case provides further evidence that this can happen.

A coloured woman, aged 22, primigravida, was admitted as an emergency to the Provincial Hospital, Port Elizabeth, on April 4, 1951, as a case of "obstructed labour." She was 37 weeks pregnant and had complained of abdominal pains for three days. The pains had increased in severity and she was very distressed on admission. She was small and thin, and her pulse rate was 128 per minute. The abdomen was distended, and the foetus, which was lying obliquely, was easily palpable under the thin abdominal wall. No foetal parts were palpable in the pelvis and the cervix was closed. A provisional diagnosis of an extrauterine pregnancy was made and was confirmed at laparotomy, when a healthy female infant weighing 5 lb. 2 oz. (2.6 kg.) was delivered from the sac. The placenta was firmly attached to the left broad ligament, the small bowel, the mesentery, the transverse colon and mesocolon. The tubes were not identified, as they were obscured by the numerous adhesions. The umbilical cord was cut short and ligated; the sac was closed and the placenta left *in situ*. The mother made a normal recovery and left hospital with the baby on the tenth day.

On August 23, 1953, the patient was again admitted in labour and had a normal vertex delivery of a healthy male infant, weighing 7 lb. 4 oz. (3.6 kg.). The duration of labour was 13 hours. The first child had died at 9 months from bronchopneumonia.

If a patient who has had an extrauterine pregnancy does not return to hospital for her subsequent confinements, the case will almost certainly be lost sight of. I feel sure that somewhere in Africa and Asia there are several of these unrecorded cases which have had subsequent normal deliveries at home.—I am, etc.,

Port Elizabeth,
South Africa.

G. MAIZELS.

Do Sebaceous Cysts Exist?

SIR,—Would Dr. J. L. Edwards (*Journal*, June 21, p. 1480) then leave us with no difference between our old "seb. cysts" and implantation dermoids except that in the latter condition the causative factor is believed known?—I am, etc.,

Leicester.

B. J. FOWLER.

Monkeys for Polio Vaccine

SIR,—I still enjoy a good steak even though I find slaughterhouses revolting. Likewise my whole family have been given poliomyelitis vaccine even though its production depends on the death of many monkeys. However, I could not help feeling that if the word "slave" had been substituted for "monkey" your annotation on monkeys for polio

myelitis vaccine (*Journal*, May 17, p. 1168) might have appeared in a moderately enlightened early nineteenth-century medical journal.

"Slaves are trapped by professional trappers—Some—will have to be destroyed or released because they are unfit for export.—a load of healthy slaves will tolerate a journey of many days, with little or no loss in transit. Indeed the slaves' health may improve on the journey owing to their receiving better food than in the wild state.—The worst of the slaves' hardships occur before they reach the (ship) and this is a matter for the exporting countries to control.—only large operators can supply the slaves in the numbers in which they are required.—the supply might be less liable to interruption from political or religious motives.—The African species are different but would probably serve well enough—"

There seem to be other reasons than mere shortage of supply for hoping that technical methods will be evolved which will obviate the use of monkeys.—I am, etc.,

Fort William, Ontario.

P. C. MACGILLIVRAY.

Medical War Crimes

SIR,—I should like to add to the comments made by Dr. Wilhelmina C. Maguire (*Journal*, June 14, p. 1420). The fact that notorious German doctors, tried, found guilty, and heavily sentenced for crimes of unbelievable horror, are now restored to full rights of medical practice in Germany—their sentences reduced, and discharged because of good behaviour—seems beyond belief.

One overwhelming surprise has been the damage still existing among the victims of these experiments. The wounds and results of operation can heal and stay healed apparently, but psychological trauma remains. To see a victim professionally to-day—15 years after—reduced to tears and trembling by the simplest and kindest examination produces an urge to see simple justice done and their needs given careful and practical consideration. Surely Germany must stand by her promises to the United Nations and fulfil her promise to help and compensate such cases. Some victims have been given compensation on a truly absurd financial basis; many have not even had this.

Surely the revelations of a doctor's wife, who herself was an eye-witness, will stir medical men and women to express in no uncertain terms what we in England feel on this subject. To Mrs. Salvesen,¹ wife of the medical adviser to the Norwegian Royal Household, we owe a debt for her book, *Forgive—But Do Not Forget*, for throwing into the lime-light the misdeeds of the German medical profession in charge of prison camps in Germany.—I am, etc.,

London, N.W.8.

E. T. WRIGHT.

REFERENCE

- ¹ Salvesen, S., *Forgive—But Do Not Forget*. Translated by E. Ramsden. 1958. Hutchinson, London.

SIR,—We are asked by Dr. Wilhelmina C. Maguire (*Journal*, June 14, p. 1420) to join her in taking action to prevent war-criminal Dr. Herta Oberheuser from continuing to practise medicine on the grounds of her past behaviour. I wonder if it would not be more adult for Dr. Maguire to present us with the facts as they are now. We might find that this person is now a dedicated practitioner, doing good work. It is possible. If it were so and Dr. Maguire knew it, I wonder if she would be so determined to finish what she wishes to start.—I am, etc.,

Derbyshire.

A. P. TAIT.

Tetanus Immunization

SIR,—It is heartening to read the letter (*Journal*, May 17, p. 1176) from the honorary secretary of the Medical Officers of Schools Association deploring the indiscriminate use of anti-tetanus serum in casualty departments and stressing the desirability of boosting active immunization wherever possible. Your leading article on this subject¹ admirably summarizes the strong grounds on which this plea is made.

One must agree, however, with Mr. Maurice Ellis (*Journal*, May 31, p. 1299) that it is usually extremely difficult to obtain information regarding previous active immunizations. In previous reviews on the matter^{2,3} I have stressed the need for providing the sort of record that Dr. A. H. Morley issues at Mill Hill School (*Journal*, May 31, p. 1299), and Dr. H. J. Parish's authoritative book⁴ makes this necessity quite clear. It has been suggested, so far without avail, that the Medical Directorates of the Armed Services should issue each Service man returning to civilian life with a small card giving a record of his Service immunizations so that the growing pool of actively immunized civilians does not drain away. It would not be impossible to find a space on the National Health Medical Card (Form F.C.4) for this purpose. The Wellcome Foundation have, in fact, issued for some years past a neat and comprehensive record card of protective inoculations, supplied on request, and one would like to see this used in all cases of such prophylaxis.

It is only by means of such a record-card system that the increasing build-up of actively immunized members of the civilian population can be utilized to supersede the less effective and more hazardous method of passive immunization. Dr. Morley's remarks that, in spite of the production by his boys of record-cards, serum has been given to them in casualty departments support my previous contention that the teaching on tetanus immunization in medical schools still leaves very much to be desired.—I am, etc.,

London, S.W.3.

Guildford Cathedral

SIR,—May I be allowed very warmly to support the appeal by Dr. J. O. M. Rees and others (*Journal*, June 14, p. 1419) on the matter of a window in the name of the new Guildford Cathedral to be given by the doctors? I hope this appeal will be met with a brisk response. As I am a Guildford diocesan lay reader and an honorary guide the issue is one which is very near to my heart. This beautiful cathedral will be undoubtedly one of the twentieth century's most remarkable buildings. When the Queen saw it a year ago she very aptly described it as being so serene and beautiful.

In connexion with the proposed window I feel it would be a splendid idea if a doctor with an artistic gift could design it. As readers of the *Journal* may know, the nurses' window has been designed by a qualified nurse. It might be possible, as with the nurses' window, to hold a competition for the best design. Medical men have a great variety of hobbies and skills apart from their own vocation.—I am, etc.,

Redhill, Surrey.

J. B. GURNEY SMITH.

Occupational Diseases of Musicians

SIR,—I am at the moment completing a paper on occupational diseases of musicians. There is very little in either medical or musical literature about this, and the material at my disposal has been obtained partly from my own limited clinical experience in this field and from information volunteered by musician friends. I am anxious to obtain further case histories from doctors who have had experience in treating musicians, and would very much appreciate it if any of your readers who are interested would care to share their experiences with me. The source of this information would of course be acknowledged.—I am, etc.,

Ingham Infirmary,
Westoe Road, South Shields.

M. ANDERSON.

Obituary

SIR RUDOLPH HAMPDEN SMITH, Bt., C.B.E.
M.B., B.Ch., F.R.C.S.

Sir Rudolph Hampden Smith, honorary consulting surgeon to the Torbay Hospital, died at Hindhead on June 25, aged 89.

Thomas Rudolph Hampden Smith was born on January 24, 1869, the eldest son of Sir Thomas Smith, first baronet, who was consulting surgeon to St. Bartholomew's Hospital, Surgeon Extraordinary to Queen Victoria, and Honorary Sergeant-surgeon to Edward VII. Rudolph Smith was educated at Winchester, Trinity College, Cambridge, and St. Bartholomew's Hospital, qualifying in 1892 and graduating M.B., Ch.B. two years later. He took the F.R.C.S. in 1895. After holding resident appointments at St. Bartholomew's he became a consulting surgeon at Stockton-on-Tees, where he was on the staff of the local hospital. During these early years he wrote a number of papers on surgical subjects, including one published in this *Journal* on "Chloroform Syncope and Direct Manipulation of the Heart." In 1909 he succeeded his father as second baronet, and a few years later he moved to Torquay, where he was appointed to the consulting staff of several hospitals in the locality. During the first world war he directed a hospital for the wounded and was appointed C.B.E. in 1920.

Sir Rudolph married Ann Ellen Sharp in 1897 and she died in 1928. The heir to the title is his nephew, Mr. Thomas Turner Smith, of New Zealand.

Mr. H. K. GRIFFITH writes: During the first world war Sir Rudolph showed that he was an able organizer as commandant of the Torquay Hospital for the wounded, and in 1922 he was appointed honorary secretary of the committee responsible for building the new Torbay Hospital. In this he spared neither time nor energy in working with his colleagues to produce the best possible hospital for the district. The Torbay area owes him a great debt for the work he did so efficiently. An excellent clinician, he was deservedly popular with his colleagues, whom he was always ready to help in any way. With his patients he was sympathetic and inspired complete confidence. He did not suffer fools gladly, and if a house-surgeon did something foolish he was unlikely ever to repeat it. In committee he was a good chairman, and would enliven the proceedings with an occasional witty remark. Like his father he was an excellent raconteur and after-dinner speaker. Among his professional brethren he set a high ethical standard.

OSCAR PARKES, O.B.E., M.B., Ch.B.

Dr. Oscar Parkes, who practised in London and in Ringwood, Hampshire, died suddenly at his home in Co. Down on June 24, aged 72. A well-known naval historian, he was editor of *Jane's Fighting Ships* from 1918 to 1935.

Oscar Parkes was born at Handsworth, Birmingham, on October 18, 1885, the son of Dr. W. E. Parkes. He was educated at Rydal Mount, Colwyn Bay, Berkhamsted, and Birmingham University, where he graduated M.B., Ch.B. in 1914. He played both rugby football and cricket for his university. After holding resident appointments at the General Hospital, Birmingham, he joined the Royal Navy, and towards the end of the first world war served in the Naval Intelligence Division at the Admiralty. In 1919 he became official naval artist and director of the naval photographic section at the Imperial War Museum. Before he left the Service in 1920 he had already been appointed editor of *Jane's Fighting Ships*, an annual publication founded in 1897. Between the wars he practised in Knightsbridge and was for a time an adviser in neurology to the Ministry of Pensions. He moved to Ringwood in 1943

and continued to practise there, being for a time on the staff of Fordingbridge Hospital. Six months ago he retired from medical practice and went to live in Northern Ireland, having been appointed a director of a publishing company there.

Besides his work as editor of *Jane's Fighting Ships*, Dr. Parkes contributed many articles on naval history and other matters to the *Navy League Magazine* and other journals. He was a very capable marine artist and had exhibited at the Royal Academy. His major work, *British Battleships from 1860 to 1950*, was published at the end of last year.

R. H. L. writes: Oscar Parkes came to Ringwood about 1943, when he took over a small general practice. He had previously been in specialist practice in London, and was always ready to admit that general practice was not his *métier*. He continued to follow his previous work in his general practice, and this consisted of electrical treatment of various kinds, in which he had a fanatical faith. He always strongly resented the fact that the National Health Service did not include payment for such services. He was indeed a real "character" in the true sense of the word, always full of fun, kindness, and energy. But his two chief interests in his leisure hours were his "ships" and his garden. There must be many more capable to tell of his vast knowledge of the Royal Navy, as shown in the fact that for about 17 years he was editor of *Jane's Fighting Ships*. He was a fine artist and very ready to use this gift to entertain others. A founder member of Rotary in Ringwood, he could, with a blackboard and chalk, be always relied on for a most entertaining evening. He retired to Ireland last year when his wife became seriously ill, and she predeceased him by only a very few months. We would like to extend our sympathy to their only child, a daughter, now living in Ireland.

H. M. PEREIRA, L.R.C.P., L.R.C.S.Ed.
L.R.F.P.S., D.P.H.

Dr. H. M. Pereira, formerly smallpox consultant to the Ministry of Health and medical superintendent of the Eastern Hospital, London, died at his home at Bexley, Kent, on June 11. He was 87 years of age.

After qualifying in Scotland in 1895 Henry Manning Pereira held posts in the fever-hospital service in London and then took the certificate of the London School of Tropical Medicine and the D.P.H. of Cambridge University in 1901. Going out to India, he worked first at St. Martha's Hospital, Bangalore, and then became medical officer to tea plantations in Mysore. Coming back to London, he rejoined the fever-hospital service, and after many years in various posts in and around London he was appointed medical superintendent of the Eastern Hospital in 1930.

Dr. J. PICKFORD MARSDEN writes: H. M. Pereira was one of that famous medical team who worked under T. F. Ricketts in the Hospital Ships and River Ambulance Service during the smallpox epidemic of 1900-2. Thereafter he never ceased to practise, and to preach, that great master's teaching on the diagnosis and the hospital management of smallpox. Because of his characteristic modesty, to the medical world at large Pereira was probably the least well known member of that team; but those of us who worked under him learned more about smallpox from him than from any other source. And his value, especially to medical officers of health, as a consultant—a real smallpox expert of the Ricketts school—was, of course, outstanding and almost unique. In addition to his smallpox experience Pereira possessed an exceptional knowledge of diphtheria, enteric fever, and the old type of scarlet fever gained from years of work in the fever hospitals of the Metropolitan Asylums Board; and when the London County Council took over those hospitals in 1930 he was appointed medical superintendent of the Eastern Hospital at Homerton, where he remained until his retirement. Pereira was a most lovable man, supremely happy in his family life. There are many of us who will treasure the memory of his friendship.

EUNICE M. HATCH, M.R.C.S., L.R.C.P.

Dr. Eunice M. Hatch died suddenly at her home at Palmers Green, London, on May 9. She was 64 years of age.

Eunice Mary Hatch was born in Highgate and studied medicine at the London School of Medicine for Women and at St. Mary's Hospital, where she was one of the first women students. Qualifying in 1927, for some years she was in general practice at Ilford, and later became an assistant in a country practice at Lavington, Wilts. In 1940 she returned to London, where she practised in Wood Green until her death. She will be greatly missed by her patients, who appreciated her unfailing kindness and sympathy and her special gift for allaying their anxieties with her humour and cheerfulness. During the second world war Dr. Hatch gave much valuable help to the Red Cross, in addition to bearing the strain of working during the numerous air raids.—G. P. S.

G. J. WILLIAMS, M.D.

Dr. G. J. Williams, who was a general practitioner in London, died peacefully at his home in Paddington, aged 95.

Dr. E. O. LEWIS writes: Much has been written about the "country" doctor, but comparatively little about the "town" and especially the "metropolitan" doctor. Dr. Griffith Jones Williams may be aptly described as a "country" doctor in a metropolis. At all times, and especially when dealing with patients, Dr. Williams had, and induced in others, that feeling of leisure we associate with rural life. His slow, quiet, and dignified entrance to the sick-room gave the patient a sense of calm and assurance. He always gave the impression that he had plenty of time to listen to his patient, and he was most indulgent towards those who were garrulous and hysterical. Dr. Williams's professional approach to his patients was a great contrast to the hustling visit that the overworked general practitioner these days often finds compelled to do.

The family to which Dr. Williams belonged has rendered great services, more particularly in medicine, to Londoners during this last century. His father, Elias Williams, was a chemist in Poultry, E.C., in the middle years of the nineteenth century—a strong personality who was a pioneer in establishing Welsh Presbyterian churches in the metropolis. Three of Elias Williams's sons became doctors and had separate practices in Paddington. Dr. Isaac Williams, the eldest, after about twenty years in practice died in 1896. The second son, Dr. John Cadwaladr Williams, was nearly fifty years in practice before he retired to North Wales, where he died in 1950; his daughter, Dr. Mabel Rolant Thomas, is a dental surgeon in Caernarvon, and his son, Sir John Cecil-Williams, is the honorary secretary of the Honourable Society of Cymmrodorion. Dr. Griffith Williams was the youngest son of Elias Williams, and he spent the whole of his professional life, with the exception of a few years when he was in Kroonstaad and East Rand, in London. His eldest son, Dr. Howell Griffith Williams, was in practice with him for a few years, but died in 1950 when in the prime of life. This is surely a unique record of medical service in one metropolitan area by one family.

Dr. Griffith Williams received his medical training in Edinburgh, where he graduated M.B., C.M. in 1892, and in 1915 he proceeded to the M.D. All-round efficiency and thoroughness were Dr. Williams's chief features as a clinician. Although he was in practice when past his 90th birthday he kept abreast with modern methods of treatment; but he was critical of the indiscriminate empiricism in the use of some of the synthetic proprietary drugs practised by the younger generation of doctors. During the first world war Dr. Williams gave valuable services as a physician at military hospitals; and during the last war he continued with his general practice in Paddington. He was not absent from London a single night during these six

years. The "courteous old doctor" was a familiar figure to the residents and war workers in Paddington, and he was highly respected by them for the great service he rendered in the terrible conditions in London at that period. One night heavy bombs razed to the ground all the houses opposite his surgery and several others on both sides. When the doctor was in one of the top rooms above the surgery an incendiary bomb burst through the ceiling and fell on the bed on which he was resting; he calmly rendered the bomb harmless, removed it to a safe place, and then continued with his rest. Dr. Williams had a most lovable disposition; he was a better saint from his first birth than most Christians are after their "second birth." Even those who lived daily with him never remember Dr. Williams ruffled, annoyed, or irritable. Whilst he had in himself all the resources for contentment, he was very sociable. His geniality, courtesy, and delicate humour made him a most acceptable and congenial member of any home circle, club, or society.

The infirmities of old age which he suffered without complaint compelled Dr. Williams to retire soon after he was 90 years of age. His last years were made as happy and as comfortable as possible by the devoted and excellent nursing care of Mrs. Williams, and the companionship of his only surviving son, Mr. John Trevor Williams. Both have the solace of many happy memories of a most charming personality.

T. R. WILSON, L.R.C.P., L.R.C.S.Ed.
L.R.F.P.S.

Dr. T. R. Wilson, who practised for many years at Wainfleet, Lincs, died at Skegness on June 10.

Thomas Robert Wilson studied medicine at Anderson's and St. Mungo's Colleges, Glasgow, and qualified in 1917. After a period of active service in the R.A.M.C. he settled in practice at Wainfleet and became a well-known figure in the medical life of the district.

R. N. K. writes: Dr. Thomas Robert Wilson came to Wainfleet in 1921, bringing with him a pawky sense of humour which was to be enjoyed by his patients and colleagues. He served this community for 33 years and quickly earned the respect and esteem of its members. A firm favourite with children, there were many now grown up who inquired anxiously for their well-remembered "Dr. Thomas" during his last illness. He had seen service with the R.A.M.C. during the first world war in Egypt and Palestine, and was a member of the British Legion. He was a familiar and popular figure at B.M.A. functions and was chairman of the Holland Division in 1950. It was a bitter blow when the illness which overtook him in his last years of practice curtailed his activities. The many who miss him extend their deepest sympathy to his wife and son.

JOHN LAMBERT, O.B.E., M.D., D.P.H.

Dr. John Lambert, who was medical officer to Wellington College for 27 years, died suddenly at Crowthorne, Berkshire, on June 16. He was 78.

John Lambert was born at Sheffield on January 2, 1880. From the Perse School, Cambridge, he won a scholarship to Downing College, and took first-class honours in the Natural Sciences Tripos. Going on to the London Hospital, he graduated M.B., B.Ch. in 1904, proceeding to the M.D. in 1908 and taking the D.P.H. in 1909. After holding the posts of house-surgeon and house-physician at the London Hospital, he became a clinical assistant at the Hospital for Sick Children, Great Ormond Street, thus stimulating his interest in paediatrics. Thereafter he became senior medical officer to the Brighton education committee, and then, for two years, medical officer to Lancing College. Joining the Royal Navy at the beginning of the first world war, he served mainly in hospital ships, and was appointed O.B.E. in 1919.

Leaving the Navy with the rank of surgeon commander in 1919, he went to Wellington College, where he spent the greater part of his life before retiring in 1946. In his work

there as resident medical officer and as doctor to neighbouring preparatory schools he built up a reputation for accurate diagnosis and sound advice on all matters of school health. He acquired a wide experience of the ailments and epidemics of schoolboys, and, though he wrote little for publication, he kept the most careful records of all medical events at Wellington and his other schools. Though retirement brought him relief from the clinical routine of school doctoring, his interest in all things medical was as lively as ever. He sat on committees—one of them being the Medical Officers of Public Schools Subcommittee of the B.M.A.—and in debate made gently expressed but extremely sane contributions. He was indefatigable in attending medical meetings right up to the time of his death, and was ready to add some well-informed remarks to discussions on almost any medical topic. Before retirement he held office for a time as president of the Medical Officers of Schools Association.

For some boys he stood in a rather special position, since in his early days at Wellington he combined the job of school doctor with that of housemaster in charge of a waiting house. Many generations of Wellingtonians will remember him with affection.

H. R. TIGHE, M.D., F.R.C.S.I., D.P.H.

Dr. H. R. Tighe, a former medical officer of health and school medical officer of Swansea, died suddenly at Morriston Hospital on June 20, after a short illness. He retired in June, 1949, having been in office since 1939, after serving as deputy to the late Dr. Thomas Evans from 1920.

Harman Richard Tighe was a native of Southern Ireland and qualified in 1910, obtaining the F.R.C.S.I. in the following year. In 1914 he took the D.P.H. at Liverpool and held his first public health post as assistant school medical officer in that city. In 1920 he came to Swansea, and 12 years later he took the degree of M.D. at the University of Durham. A man of distinction and of the highest integrity, during the whole of his time in Swansea he was looked upon as an authority on preventive medicine, which he did much to promote. He took an active part in the medical life of Swansea, serving for some years as honorary secretary of the Swansea Division of the B.M.A., and being chairman of the Division from 1936 to 1937. He had also been president of the Welsh Branch of the Society of Medical Officers of Health. Those who served under Dr. Tighe have the happiest memories of his charm and kind personality and mourn his passing. He is survived by his wife, his son, Dr. J. R. Tighe, and two daughters, one of whom is medically qualified.

B. W. ARMSTRONG, O.B.E., M.C., M.B.

The obituary of Dr. B. W. Armstrong was printed in the *Journal* of June 14 (p. 1422).

Dr. P. SZUMOWSKI writes: For 31 years the Royal Sea Bathing Hospital had been Dr. Armstrong's home, his work, his life. Even after his retirement from the post of medical superintendent in 1954 he never completely lost contact with the hospital, continuing to serve as honorary consultant surgeon and president of the League of Friends of the hospital. He told me he was always extremely happy here. Although I knew him only for a short time, I formed the impression that his medical work was for him not merely a profession—it was something much more. He lived for his work and for his personal contact with the sick. He was first of all a friend of his patients. He lived with them through their sufferings, great and small, and he found with them the way to a happy recovery. They always remained his personal friends. No wonder I have seen a patient coming to "her Dr. Armstrong" for routine check-up all the way from New Zealand. Apart from his being one of the leading authorities in his specialty, surgical tuberculosis, Dr. Armstrong had always

been a pioneer and artisan in his work. For him his work was an art and a constructive one. He was a perfectionist in everything he said or did, be it something big and important or some small and seemingly unimportant detail, and this art he taught to his staff and in fact to everybody working in the hospital. Under Dr. Armstrong there prevailed in the hospital the spirit of professional pride and perfection. I am sure that many technical achievements of the highest standard in the treatment and nursing of long-standing surgical tuberculosis illnesses in the Royal Sea Bathing Hospital were entirely due to his inspiration and scrupulous work. The plaster and splint departments are second to none in the country. He certainly made the Royal Sea Bathing Hospital what it has been during the last three decades—well known in this country and abroad. He knew where and how to find the "proper people" for the proper place in the hospital, and during this time he succeeded in forming a team of most devoted and inspired workers in all departments. It was his personality which was the secret of his success and achievement. He was full of charm, deep culture, with wide cosmopolitan interests, and with special consideration for everyone, thereby enabling him to be respected and admired by his staff and his patients. He was the last medical superintendent of the Royal Sea Bathing Hospital, and with his retirement closed a chapter in its history. It was a pity that he had so little time after his retirement, and his activities were further curtailed by a progressively debilitating disease.

LORD WEBB-JOHNSON, G.C.V.O., C.B.E., D.S.O.
Hon.L.L.D., M.B., Ch.B., F.R.C.S.

The memorial service for Lord Webb-Johnson was held at St. Margaret's, Westminster, on June 26. The church was filled by a very large gathering of relatives, private and professional friends, and representatives of the many institutions with which Lord Webb-Johnson was connected. The Queen was represented by Lord Evans. The Rev. C. L. Creswell and Canon Michael Stancliffe conducted the service, and Sir Gordon Gordon-Taylor read a passage from *Proverbs* beginning: "Happy is the man that findeth wisdom, and the man that getteth understanding."

Medico-Legal

AN UNEXPECTED BABY

[FROM AN OBSTETRIC CORRESPONDENT]

On March 17 the Birmingham Coroner's Court investigated an unusual neonatal death (*The Times*, March 18). The mother of the baby said that she did not realize she was pregnant and in labour until after the waters broke. Four years previously she had had a normal pregnancy and labour. In her evidence she stated that she had spent a year in the Far East with her husband prior to sailing for England on May 12, 1957. While abroad she discovered that her husband wanted to marry someone else, but she had shared a bedroom with him shortly before her departure for England. She had no idea that she was pregnant, because she had no symptoms. Her periods had continued regularly and she had felt no movements. On getting up on February 27, 1958 (i.e., 291 days after embarkation), she had started to have some vaginal bleeding which she took for the start of her normal period. Later in the morning she had very severe pain, but still did not realize what was happening and sat on the toilet, where the waters broke. The baby had been born very suddenly while her mother, to whom she had called out, was getting help. She stated, "If I'd realized I was pregnant, I'd have seen my doctor and have prepared for the child—even if I had divorced my husband I'd still have wanted it." The woman's mother, mother-in-law, and next-door neighbour all affirmed that they had not suspected that she was pregnant.

The pathologist who carried out a necropsy on the baby the day after its birth said that the child had been born alive and had breathed. No water was found in the air passages. In his opinion the death of the baby, which weighed 6 lb. 15 oz. (3.3 kg.), was due to shock from immersion in water. He stated that he had known of about half a dozen cases where the mother had not known she was pregnant, including a woman who had previously had 10 children.

The coroner recorded a verdict of death from lack of care and attention at birth.

Comment

One of the most interesting features of this case was the affirmation by a parous woman that she did not know she was pregnant until the baby was actually being born. Most obstetricians of experience have encountered cases where a woman found to be advanced in pregnancy, or even in labour, denies awareness of being pregnant, and sometimes, as in the case cited, there is no history of amenorrhoea. Usually, however, the patient is primigravid and unmarried, and it is tempting therefore to draw an analogy between these cases and those of pseudocyesis. Fried *et al.*¹ remarked that spurious pregnancy commonly followed a situational stress which would best be resolved by the presence of pregnancy. The patient's basic mental conflict made it desirable that she should be pregnant, and therefore she developed all the symptoms and some of the signs of pregnancy, even to the point of her doctor being deceived. Presumably, by a similar mechanism, the symptoms of a true pregnancy might be suppressed or denied conscious recognition because the pregnancy was not in the particular circumstances welcome. But if this can happen it is surprising that pregnancy unsuspected by the mother is not encountered more often.

DROWNED IN NINE INCHES OF WATER

[FROM AN EXPERT IN FORENSIC MEDICINE]

At 2 p.m. on February 1 a boy of nearly 13 finished his midday meal and went out to play. A quarter of an hour later he was found lying face down in a brook in the playing fields behind his home in Sutton Coldfield. The water was nowhere more than 9 in. (23 cm.) deep, and indeed did not cover his head. Artificial respiration was carried out without response until 2.50 p.m., when a doctor arrived and pronounced the boy dead. Post-mortem examination showed no marks of violence, no congenital defects, and no organic disease. The stomach contained a large undigested meal. Petechial haemorrhages were noted upon the heart and lungs—a rather unusual finding in death from drowning—but gravel as well as froth was found in the ballooned lungs, leaving little doubt that the immediate cause of death was, in fact, drowning. A police sergeant is reported to have said that a cigarette was found on the bank of the brook, and that the boy had a packet of the same brand in his pocket.

Another recent fatality from drowning occurred in a pool on Tooting Bec Common. On April 11 at 12.39 p.m. a small boy ran up to the Common keeper and told him that another small boy had fallen into a pool. The keeper ran to the pool and saw the body of a child of 2½ lying on the bottom in 3 to 4 ft. (about 1 metre) of water. The body was recovered, immediate first-aid given, and an ambulance was summoned. The boy reached the casualty department of St. James's Hospital at 12.55 p.m. Here further resuscitative measures were instituted, including cardiac massage, and at 1.25 p.m. the heart began to beat. Spontaneous respirations returned and the child made remarkable progress until at 9 p.m. that evening what were thought to be purposive movements were observed. A tracheotomy was performed but the child died about 20 minutes later. Post-mortem

examination showed partial collapse of the lungs with a great excess of mucus throughout the air passages.

Comment

Theories on the mechanism of death in drowning have been rationalized in the last few years. The work of Swann and Brucer^{1,2} suggests that the interval between immersion and cardiac arrest is almost 3½ minutes in fresh water and 10 minutes in sea water; and, further, that the cause of death in fresh-water drowning is haemodilution and overloading of the heart, while in salt-water drowning fluid is sucked by osmosis from the circulation into the lungs so that acute pulmonary oedema develops.

The two cases noted here present a strange contrast: the elder boy falls into a shallow stream in conditions of apparently minimal danger, while the small boy falls into a pool where every circumstance would seem to be against him—and yet is kept alive for six hours. This contrast makes one wonder whether there was not some extraneous circumstance in the case of the elder boy, one which would not be obvious to the pathologist. Among such could be epilepsy, some form of vagal shock followed by drowning, or the very remote possibility that he had been held under water. There was of course speculation at the inquest and in the press as to why this healthy boy should have drowned in such shallow water, especially as he had ready access to the brook and had often played around and in it. Epilepsy might be an explanation, though there was no history of fits. Nor was there anything in the post-mortem findings to suggest epilepsy—e.g., a bitten tongue or empty bladder—though these findings would not necessarily be present after a fit. A cigarette was picked up near the boy, and smoking one at that early age could undoubtedly cause giddiness and might result in a fall into the brook. But one would have thought that giddiness from smoking or an ordinary faint would have been as effectively relieved by falling into water as by most stimulants.

At the inquest on the younger boy doubts were expressed whether after such a prolonged period of anoxia full cerebral recovery could have been expected. However, the partial recovery in this case does underline the value of modern resuscitative measures, including cardiac massage, in cases of drowning and electrocution.

Medical Notes in Parliament

ANSWERS TO QUESTIONS

Student Grants

Mr. G. LONGDEN (South-west Hertfordshire, Con.) asked the Minister of Education on June 25 whether he would make a further statement about the arrangements for financial awards to university students. Mr. GEOFFREY LLOYD said that with the Secretary of State for Scotland he had decided to set up a committee with the following terms of reference:

"To consider the present system of awards from public funds to students attending first degree courses at universities and comparable courses at other institutions and to make recommendations."

The committee would therefore consider the kinds of awards to be made from public funds, the method of selecting students for such awards, and the principle of the hardship test required by the law as it now stands. Sir Colin Anderson had accepted the Government's invitation to act as chairman, and the other members of the committee were: Mrs. Gladys Buxton (chairman, Derbyshire County Council), Mrs. Margaret Cooke (Birmingham City councillor), Mr.

The figure consists of two vertically stacked line graphs. Both graphs have 'WEEKS' on the x-axis, ranging from 0 to 52 with major ticks every 4 weeks. The y-axis for both is 'NUMBER OF CASES'.

The top graph is titled 'ENTERIC FEVER'. The y-axis scale ranges from 0 to 140 in increments of 20. It shows two data series: a dashed line representing the period 1949-57 and a solid line representing 1958. The 1949-57 series has several peaks, with the highest reaching approximately 135 cases around week 32. The 1958 series shows a single prominent peak of about 40 cases around week 10. Labels include 'Highest, 1949-57' pointing to the peak at week 32, 'Lowest, 1949-57' pointing to a low point around week 28, and '1958' pointing to the peak at week 10.

The bottom graph is titled 'DYSENTERY'. The y-axis scale ranges from 0 to 2600 in increments of 200. It also shows two data series: a dashed line for 1949-57 and a solid line for 1958. The 1949-57 series shows multiple peaks, with the highest reaching nearly 2400 cases around week 12. The 1958 series shows a steady increase from week 4, peaking at about 1550 cases around week 10, and then fluctuating between 800 and 1100 cases. Labels include 'Highest 1949-57' pointing to the peak at week 12, 'Lowest 1949-57' pointing to a low point around week 20, and '1958' pointing to the peak at week 10.

Week Ending June 21

The largest fluctuations in the notifications of infectious diseases in England and Wales during the week ending June 21 were increases of 514 for measles, from 5,594 to 6,108; 53 for whooping-cough, from 747 to 800; and decreases of 53 for dysentery, from 891 to 838; and 33 for acute pneumonia, from 247 to 214. The largest rises in the notifications of measles were 165 in Lancashire, from 672 to 837 (Liverpool C.B. 237, Blackburn C.B. 214); 112 in Devonshire, from 144 to 256 (Exeter C.B. 129); 84 in Somersetshire, from 121 to 205 (Bath C.B. 145); 66 in Nottinghamshire, from 219 to 285 (Nottingham C.B. 145). The notifications of scarlet fever numbered 657, 9 fewer than in the preceding week, and there were no large fluctuations in the local returns. The largest increase in the incidence of whooping-cough was 20 in Somersetshire, from 8 to 28. For the second consecutive week no case of diphtheria was notified.

The notifications of acute poliomyelitis numbered 36, and these were 2 more for paralytic and 5 more for non-paralytic cases than in the preceding week. The largest returns were Yorkshire West Riding 9 (Halifax C.B. 3, Morley M.B. 2) and Lancashire 5.

The areas returning the largest number of cases of dysentery were Yorkshire West Riding 195 (Barnsley C.B. 42, Huddersfield C.B. 27, Sheffield C.B. 26, Leeds C.B. 13, Rotherham C.B. 12, York C.B. 12), Lancashire 154 (Liverpool C.B. 48, Manchester C.B. 16, Rawtenstall M.B. 14, Oldham C.B. 10), London 60 (Islington 11, Stepney 10), Surrey 58 (Banstead U.D. 42, Carshalton U.D. 11), Essex 50 (Walthamstow M.B. 27, Chigwell U.D. 17), Staffordshire 39 (Newcastle-under-Lyme M.B. 25), Durham 35 (Hartlepool M.B. 17), Middlesex 33, Hampshire 26 (Droxford R.D. 17), Yorkshire North Riding 26 (Middlesbrough C.B. 24), Warwickshire 25 (Bedworth U.D. 14), and Cambridgeshire 25 (Cambridge M.B. 25). 75 of the 279 cases of food-poisoning were notified in London (Stepney 57).

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending June 14 (No. 24) and corresponding week 1957.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the whole of England and Wales (London included). London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

‡ Includes puerperal pyrexia.

Medical News

N.A.P.T. Commonwealth Chest Conference.—The Commonwealth Conference, which incorporates the British Tuberculosis Association's annual conference, opened in London on July 1. The DUCHESS OF KENT, president of the National Association for the Prevention of Tuberculosis, performed the opening ceremony. Besides problems concerned directly with tuberculosis, the Conference's wider interests are shown by the inclusion in its programme of discussions on leprosy and tuberculosis, environmental factors in respiratory disease, the management of the heart in chronic respiratory disease, and the problem of lung cancer. After the four days of scientific sessions, there were tours and visits for the delegates.

Poliomyelitis Centre.—On June 25 the EARL OF LIMERICK, chairman of the Medical Research Council, opened a poliomyelitis research centre at Hendon Isolation Hospital, London, N.W.9. The centre is under the direction of Dr. A. B. KINNIE WILSON, and the Institute of Orthopaedics (London University) will administer it. Dr. Kinnier Wilson is specially interested in artificial respirators and rehabilitation. The centre is the outcome of a recommendation in 1951 by a committee of the Royal College of Physicians of London for a unit to carry out research on the clinical aspects of poliomyelitis, and the proximity of the centre to the Public Health Laboratory Service's virus reference laboratory at Colindale will be useful in investigations of other viral diseases of the central nervous system. The Royal National Orthopaedic Hospital, Stanmore, is assisting in staffing the unit.

Ciba Foundation.—The names of the nine winners of the Foundation's 1958 awards for research relevant to the problems of ageing have now been announced. The two winners of £300 prizes are Dr. R. J. BOUCEK, of Miami, and Dr. D. S. McLAREN, of Mwanza, Tanganyika, the latter for a report entitled "Age and Nutrition in the Aetiology of Cataract." Dr. A. COMFORT (University College, London) is one of the four winners of £200. These awards are being offered for the last time next year, the closing date being January 10, 1959. The Ciba Foundation issued its annual report for 1957 recently. During that year over 800 scientific visitors from 35 countries were provided with rooms. Among its other activities the Foundation held six international conferences, and, as a new venture, five study groups. The conferences were on hormones in the blood, the mechanisms of drug resistance, the mucopolysaccharides, the C.S.F., hormone-producing tumours, and the neurological basis of behaviour. The Foundation's address is 41, Portland Place, London, W.1.

Speeding Medical News.—The Institute for Advancement of Medical Communication, New York, announces its establishment as a non-profit organization to study and develop ways of facilitating the exchange of information between medical scientists, medical educators, and practising physicians. The Institute intends to do this by devising and testing methods of disseminating medical information which promise advantages over those in present use and by serving as an information centre for medical organizations wanting help with communication problems. The Institute will be financed by general and research grants from private foundations and from agencies, private and Federal, which support medical research. The charter members of the Institute's board are Professor CHAUNCEY D. LEAKE, Ph.D., professor of pharmacology, Ohio State University; Professor HOMER W. SMITH, professor of physiology, New York University; Professor IRVING S. WRIGHT, professor of clinical medicine, Cornell University. Dr. RICHARD H. ORR, assistant editor of *Metabolism* and formerly medical director of Messrs. Grune and Stratton, Inc., is executive director. From whom further details may be obtained at the Institute's temporary headquarters, 37, East 67th Street, New York, 21.

F.R.C.S.—The following were successful in the recent examination for the Fellowship of the Royal College of Surgeons of England:

G. B. Northcroft, V. M. Thompson, W. B. Ashby, R. S. Sneath, F. R. Coffin, A. E. Buckle, P. L. C. Diggory, A. Gillespie, F. J. Moynihan, J. M. Powley, W. J. Pryn, D. M. Millar, K. R. S. Pool, R. Y. Calne, A. R. Bearn, R. James, P. S. Boulter, G. Hayes, J. Mutch, I. K. Mikhail, A. K. Chowdhury, W. Lees, K. A. McCluskey, K. A. Menon, J. Y. Fowler-Wright, H. Harrop-Griffiths, N. H. Harris, R. H. Lewis, A. H. Petty, K. Bloor, H. C. Brown, T. I. El-Gailani, J. Magri, G. A. W. Milner (Otolaryngology), R. F. Rohan (Otolaryngology), D. S. Sardana (Otolaryngology), C. B. Walker (Ophthalmology), K. R. Alimchandani, D. S. Dharmage, J. L. A. Dowse, J. G. Gray, G. L. Grigg, A. C. Jain, K. N. Khanna, M. L. Rajakaruna, V. Rasanayakam, G. E. Rousseaux (Otolaryngology), E. J. Williams, J. A. Adams, S. D. Chatterjee (Ophthalmology), M. H. Cox, J. C. M. Currie, E. J. England, A. P. Fuller (Otolaryngology), B. E. Hagan, A. H. T. Hodgkinson, R. A. Howett, I. Kaplan, B. H. Kelham (Otolaryngology), H. M. Learoyd, C. V. Mann, J. A. P. Marston, V. G. Mavalankar, J. Moran, D. C. Patel, G. C. Robin, I. B. Tait, L. J. Walker, J. H. Williams, R. Attard, D. Churchill-Davidson, J. A. Girling, P. B. Humphris, S. R. Mitra, S. K. Nair, B. T. O'Connor, K. C. Perry, W. D. Proudman, G. R. A. Raad (Ophthalmology), M. P. Robinson, J. F. Sander, L. Souvlis, H. H. Srinivasan, P. Virmani, N. K. Yong, L. Das, I. D. A. Johnston, M. Y. D. Koawavwala, M. G. Maguire, B. A. Maurice, D. C. O'Sullivan, C. G. Paul, J. G. Ross, S. B. Singh, J. R. Solomon, D. E. Cam, R. D. P. Craig, A. R. Desai, K. H. Langford, M. B. Menelaus, R. P. Silverton, R. G. Smith, J. L. Dawson, H. F. Jeejeebhoy.

Faculty of Anaesthetists.—Dr. G. S. W. ORGANE, of the Westminster Hospital, has been elected dean, and Professor E. A. PASK, of King's College Medical School, Durham University, vice-dean of the Faculty for the coming year.

British Association of Urological Surgeons.—The 14th annual meeting, held in London from June 19 to 21, under the presidency of Mr. ARTHUR JACOBS, was attended by about 170 members. There was a full scientific programme, the main discussion being on carcinoma of the prostate. The papers will be published in the *British Journal of Urology*. The following were elected officers and members of council for 1958-9:

President, Mr. Arthur Jacobs; immediate past president, Mr. R. H. O. B. Robinson; vice-president, Mr. Hugh Donovan; hon. treasurer, Professor Victor W. Dix; hon. secretary, Mr. J. D. Ferguson; hon. editorial secretary, Mr. N. M. Matheson; members of council, Mr. F. R. Kilpatrick, Mr. W. S. Mack, Mr. T. J. Millin, Mr. R. A. Mogg, Mr. D. S. Poole-Wilson, Mr. N. L. Shepperd, Mr. J. Swinney, Mr. D. Innes Williams, and (ex officio) the president of the Section of Urology of the Royal Society of Medicine and the chairman of the editorial committee of the *British Journal of Urology*.

Liverpool University.—Dr. K. MCCARTHY and Dr. K. R. DUMBELL have been appointed senior lecturers in bacteriology; Dr. J. L. BRAITHWAITE and Dr. E. W. MACMILLAN senior lecturers in anatomy; and Dr. J. GLOVER, Ph.D., and Dr. H. K. KING, Ph.D., senior lecturers in biochemistry. These appointments take effect from next October.

Parapsychiatry and Human Development.—Messrs. S. Karger, of Basle, announce the publication of two new journals. *Confinia Psychiatrica*, whose editors are Drs. H. HEIMANN and T. SPOERRI, of Berne, is intended for papers on borderland subjects to psychiatry—psychology, behaviour research, endocrinology, pharmacology, sociology, medical history, etc. *Vita Humana*, edited by Professor H. THOMAE, of Erlangen, will be concerned with the science of human development and will cover such fields as anthropology, psychology, physiology, paediatrics, geriatrics, social hygiene, etc. Both journals are international in scope and will publish papers in English, French, or German, with summaries in all three languages; both are to appear quarterly, at an annual subscription in each case of 38.50 Swiss francs.

Health Service Supplement.—Next Monday (July 7) *The Times* will contain a 16-page supplement on the

National Health Service. The opening articles will discuss the general practitioner, the consultant service, local authority administration, and the cost of the Service. Other subjects include the future of private practice, hospital insurance, and the pharmaceutical industry.

"Family Doctor."—The July issue includes articles on suicide (Dr. E. H. HARE), Parkinsonism (Dr. DOREEN MOORHOUSE), and weight-lifting and "body-building" (by Mr. I. MACQUEEN, F.R.C.S.), as well as regular features such as "Family Doctor answers," the question-and-answer section for the layman.

COMING EVENTS

British Association of Paediatric Surgeons.—Annual meeting, July 23-25, in London. Details from Mr. R. ZACHARY, hon. secretary of the association, Children's Hospital, Sheffield, 10.

Prophylactic Medicine and Social Hygiene.—World congress at Gmunden, Austria, September 8-13. Details from the general secretariat, 41, Pianistengasse, Vienna, 8.

International Congress of Balneology.—Arranged by the Czechoslovak Society of Physiotherapy, September 8-13 at Marienbad. Details from the secretary of the congress, 5, Reznicka, Prague, 2.

International Collegium for Neuro-Psychopharmacology.—First international symposium, September 9-12, in Rome. Details from Dr. P. B. BRADLEY, Department of Experimental Psychiatry, the Medical School, Birmingham, 15.

International Scientific Film Association.—Twelfth congress in Moscow, September 10-20. Details about the British delegation and entries for the congress may be obtained from the Scientific Film Association, 164, Shaftesbury Avenue, London, W.C.2.

Institute of Medical Laboratory Technology.—Triennial conference, September 13-20 at Bristol University. Further details from the institute, 9, Harley Street, London, W.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Sunday, July 6

UNIVERSITY COLLEGE HOSPITAL, London.—10.15 a.m., clinical demonstration by Dr. H. A. Burt: Backache, its Prevention and Treatment. Open to all general practitioners.

Monday, July 7

LONDON UNIVERSITY.—At Wright-Fleming Institute Lecture Theatre, St. Mary's Hospital Medical School, 5 p.m., special university lecture in medicine by Professor Gerrit Bras (West Indies): Veno-occlusive Disease of the Liver.

Tuesday, July 8

INSTITUTE OF CHILD HEALTH.—5 p.m., Dr. David Gitlin (Harvard Medical School): Plasma Protein Metabolism in the Nephrotic Syndrome.
INSTITUTE OF PSYCHIATRY.—5 p.m., public lecture by Professor George Rosen (Columbia University): Social Stress and Mental Diseases in the 18th, 19th, and 20th Centuries.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Bertram Louis Abrahams Lecture by Sir Lindor Brown, F.R.S.: The Mode of Action of Sympathetic Nerves.

Wednesday, July 9

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. G. Belyavin: Serology of the Influenza Viruses.

Thursday, July 10

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., F. E. Williams Lecture by Professor P. B. Medawar, F.R.S.: The Biology of Ageing.
ROYAL SOCIETY OF HEALTH.—At Town Hall, Lancaster, 10.15 a.m., Dr. R. W. Farquhar: Care of the Aged—Some Socio-medical Problems; Mr. F. Shaw: Public Control of Housing—A Broad Survey.

Friday, July 11

NUTRITION SOCIETY.—At Queen Elizabeth College, Campden Hill Road, London, W.1. Symposium on Applied Nutrition: The Human Factor in Group Feeding. Speakers, Mr. F. Le Gros Clark, Alexis Soyer (1809-1858) Historical Note on His Contributions in Applied Nutrition; Sir Zachary Ope, The Medical Aspect of Soyer's Illness and His Culinary Experiences; Miss B. R. Stanton, The Human Factor in Hospital Feeding; Dr. J. J. O'Dwyer, Some Experiences in Group Nutrition; Brigadier Roscoe, The Problems of Feeding Women in Industry; Miss P. Morkam, The Human Factor in School Dinners; Mrs. D. W. Newman, Appetites in Retirement: The Organized Feeding of Old People.

Saturday, July 12

NORTH OF ENGLAND OTOLARYNGOLOGICAL SOCIETY.—At Royal Manchester Sick Children's Hospital, 2 p.m., meeting.

APPOINTMENTS

CLYNICK, F. E., M.B., Ch.B., F.F.A.R.C.S., D.A., Part-time Consultant Anaesthetist, St. Peter's, St. Paul's, and St. Philip's Hospitals, London.
FLOOD, CHARLES, M.D., M.R.C.O.G., Honorary Assistant Obstetrician and Gynaecologist, Hospital of St. John and St. Elizabeth, 60, Grove End Road, London, N.W.

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, London, W.C.—Thérèse M. Vanier, M.B., B.Chir., House-physician; K. J. Brown, M.S., F.R.A.C.S., House-surgeon to Orthopaedic and Plastic Departments; P. J. Koblenzer, M.B., B.S., Assistant Medical Registrar; C. G. H. Newman, M.B., B.S., M.R.C.P., D.C.H., House-physician; R. H. R. White, M.B., B.Chir., M.R.C.P., D.C.H., Medical Registrar and Pathologist; Rosalie E. B. Eastwood, M.B., Ch.B., Resident Officer to Department of Neurology and Neurosurgery; Dinah C. M. Henderson, M.B., Ch.B., D.M.R.D., Senior Registrar in Radiology (to be shared with Royal Free Hospital); D. Barltrop, M.B., B.S., and G. W. Hatcher, M.B., B.S., D.Obst.R.C.O.G., House-physicians; J. M. Kingsmill Moore, M.B., B.Ch., and J. Abrahamson, M.B., Ch.B., House-surgeons; D. A. Larnder, M.B., Ch.B., F.R.C.S., and C. J. Stevenson, M.D., M.R.C.P., Senior Registrars to Department of Dermatology; R. M. Innam, B.M., B.Ch., Senior Registrar to Ophthalmic Department; D. G. Mackie, M.B., B.S., Resident Ear, Nose, and Throat Registrar; June E. Brett, M.B., B.Chir., F.F.A.R.C.S., D.A., Junior Anaesthetic Registrar.

LONDON COUNTY COUNCIL.—The following have been appointed whole-time medical officers in the Council's Public Health Department: T. J. Mahon, M.B., B.Ch., L.M., D.P.H., D.C.H., C.P.H., R. W. Watton, M.B., B.S., D.P.H., W. T. Orton, M.B., B.Ch., D.P.H., and M. L. Graeme, M.B., B.Chir., D.P.H.

MANCHESTER REGIONAL HOSPITAL BOARD.—N. S. Gordon, M.D., M.R.C.P., M.R.C.P.Ed., Consultant Neurologist, Booth Hall Hospital, Manchester, Royal Manchester Children's Hospital, with additional duties at David Lewis Epileptic Colony, Cheshire, and in Preston Hospital Centre; E. Sherrah-Davies, M.B., B.Chir., F.R.C.S., D.M.R.T., Consultant Radiotherapist, and K. E. Hainan, M.D., F.R.C., D.M.R.T., Assistant Radiotherapist (S.H.M.O.), Christie Hospital and Holt Radium Institute, Manchester; G. R. Carr, M.D., Ch.M., F.R.C.S., Consultant Surgeon, Stockport and Buxton Group of Hospitals; D. L. Chadwick, M.D., F.R.C.S., D.L.O., Consultant Ear, Nose, and Throat Surgeon, Crumpsall, Ancoats, and Manchester Ear Hospitals.

NORTH-WEST METROPOLITAN REGIONAL HOSPITAL BOARD.—Ella Preiskel, M.B., B.S., D.M.R.T., Consultant Radiologist, Wilkeson General Hospital; S. A. James, M.R.C.S., L.R.C.P., D.Phys.Med., Assistant Physician in Physical Medicine (S.H.M.O.), West Herts Group; Susan Gordford, M.D., Assistant Pathologist (S.H.M.O.), Clare Hall Hospital; F. J. Fowler, M.B., Ch.B., Senior Administrative Medical Officer, as from August 1, 1958; D. Preiskel, M.D., M.R.C.P., Consultant Physician in Physical Medicine, Acton Hospital; J. L. Anderson, M.B., B.S., C. Robinson, F.R.C.S.Ed., Consultant Orthopaedic Surgeon, and T. Faulkner, F.R.C.S., Consultant Plastic Surgeon, St. Charles' Hospital; O. F. Swann, M.B., B.S., M.R.C.P., D.M.R.D., Consultant Radiologist, West End Hospital for Neurology and Neurosurgery; K. E. Schmidt, M.D., D.P.M., Assistant Psychiatrist (S.H.M.O.), Hill End Hospital; G. Stroh, M.B., B.S., D.P.M., Consultant Psychiatrist in Charge, High Wick, Tyttenhanger, St. Albans; Edwina R. Goodall, M.B., B.S., D.M.R.D., Consultant Radiologist, Ashford and Hounslow Hospitals; J. G. Roberts, M.B., Ch.B., F.R.C.S., Consultant Assistant Neurosurgeon, Central Middlesex Hospital; G. E. Steln, M.B., B.Chir., F.R.C.S., Consultant Ear, Nose, and Throat Surgeon, Acton Hospital; Mary I. Wray, M.B., B.S., D.M.R.D., Consultant Radiologist, Barnet General Hospital; J. R. E. Richardson, M.R.C.S., L.R.C.P., Assistant Pathologist (S.H.M.O.), King Edward Memorial Hospital, Ealing.

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—P. F. Boreham, M.Chir., F.R.C.S., Consultant General Surgeon in North Gloucestershire Clinical Area; P. A. Skinner, M.B., B.S., F.F.A.R.C.S., Senior Anaesthetic Registrar at Frenchay Hospital, Bristol; J. L. James, M.B., Ch.B., Medical Registrar in Bath Group of Hospitals; H. A. McClelland, M.B., B.S., D.Obst.R.C.O.G., D.C.H., Medical Registrar at Cheltenham General Hospital.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Champion.—On June 21, 1958, at "Lawnwood," Ventnor, Isle of Wight, to Valerie, wife of Dr. Alan Champion, a daughter—Rosemary Ann Dixey.—On June 22, 1958, at Newmarket General Hospital, to Christie (formerly Humphrey), wife of Dr. John Dixey, of Isicham, Cambs, a son and a daughter.

Harman.—On June 2, 1958, at Grey's Hospital, Pietermaritzburg, South Africa, to Dr. and Mrs. M. J. Harman, twin sons.

Merrileather.—On June 19, 1958, at Lobatuli Hospital, Bechuanaland, to Dr. and Mrs. A. M. Merrileather, a daughter—Winifred Joy.

Reynolds.—On June 25, 1958, at Brighton General Hospital, to Patricia (formerly Aldridge), wife of Patrick C. Reynolds, a daughter—Christine Anne.

DEATHS

Ashton.—On June 10, 1958, Joseph Ashton, M.B., of Colwyn Bay, Denb., formerly of Wandsworth, London, S.W., aged 88.

Bryson.—On June 7, 1958, at St. Leonard-on-Sea, Sussex, Alexander Carruthers Bryson, M.B., B.S., formerly of Shanghai, China.

Cosgrave.—On June 20, 1958, Alexander Kirkpatrick Cosgrave, M.C., V.D., M.B., B.Ch., D.P.H., D.T.M.&H., of Westleigh, Beaconsfield, Bucks, late of Malaya.

Garlick.—On June 6, 1958, at Lucerne, Switzerland, George Herbert Garlick, M.R.C.S., L.R.C.P., of Singapore.

Innes.—On May 27, 1958, at Menton, France, Arthur Innes, M.B., Ch.B., F.R.E.P.S., of Greenways, South Lynn Drive, Eastbourne, Sussex, late of Glasgow.

Melvin.—On June 20, 1958, at Sherwood, Lofthouse, near Wakefield, Yorks, Moray Melvin, M.D., aged 62.

Perreira.—On June 11, 1958, at his home, Bexley, Kent, Henry Manning Perreira, L.R.C.P.&S.Ed., L.R.F.P.S., D.P.H., late of Homerton, London, E., aged 87.

Wilson.—On June 10, 1958, Thomas Robert Wilson, L.R.C.P.&S.Ed., L.R.F.P.S., of Skeaness, Lincs, formerly of Wainfleet, Lincs.

Yates.—On April 17, 1958, Robert Burton Melkie Yates, M.B., Ch.B., of Market Drayton, Salop.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Origin and Spread of Influenza

Q.—Does the natural history of influenza epidemics and pandemics give any indication of their usual place of origin and rate of travel?

A.—The short answer to this question is no. The precise origin of the recent Asian epidemic is unknown, though it is said to have appeared first in a relatively small area of south-west China. The 1949 European epidemic broke out among shepherds in Sardinia. The first cases of the 1918 pandemic are said to have occurred in Army camps in the U.S.A., and the outbreak in Europe occurred after the arrival of American troops in Sardinia. The 1889 pandemic has been traced to north-central Asia. Thus it cannot be said that there is any usual place of origin for influenza epidemics nor that the first sufferers are people with an exceptional susceptibility to the virus. But the age-specific attack rate of the recent epidemic was highest in children. Adults who were in close contact with children probably suffered more severely than those with less intimate contact. This was shown by a change in the age-distribution of deaths as the epidemic progressed. There was a shift in the distribution towards the older age-groups of the population in successive weeks of the epidemic, thus suggesting a gradual involvement of the more resistant members of the population. The rate of travel of the Asian epidemic appears to have been no greater than that of the epidemics of 1890 or 1918. It was noteworthy that local outbreaks followed the arrival of ships rather than aircraft, and this suggests that a sufficient quantum of infection must be imported before spread takes place.

Potassium Bicarbonate and Chlorothiazide

Q.—Is it possible to give potassium bicarbonate instead of potassium chloride to counteract hypokalaemia in chlorothiazide therapy?

A.—One of the practical reasons against giving potassium bicarbonate is that it is not possible to make it into tablets. There is, however, 1 g. of potassium bicarbonate in 14 ml. of mist. pot. cit. et hyoscyami, so it would theoretically be possible to give enough, although this is a most unpleasant mixture to take. The main disadvantage is that it is an alkali. Chlorothiazide acts chiefly on chloride excretion, and therefore potassium chloride might be expected to be beneficial in this respect. Potassium bicarbonate, on the other hand, will enhance the alkalaemia which chlorothiazide tends to produce by virtue of its action as a carbonic-anhydrase inhibitor.

Recurrent Sprains

Q.—What can be done to prevent recurrent sprains of the ankle in a woman which occur on the slightest provocation since an original sprain 25 years ago?

A.—When a woman suffers recurrent sprains of the ankle after an original "sprain" 25 years ago it may well be that the original injury was in fact something more serious than a simple sprain. She may possibly have sustained a complete rupture of the lateral or deltoid ligaments of the ankle. She may even have fractured or avulsed the tip of the medial or lateral malleolus. Such lesions could have been overlooked at the time and the injured ankle treated as an uncomplicated sprain by strapping only.

Often these more serious injuries can be detected with certainty only by radiography with the foot passively held in forced full inversion and eversion. Disruption of the ankle-

joint on its lateral or medial aspect will then be shown by the opening up of the talo-tibio-fibular mortise on the respective side.¹ This kind of lesion usually demands more radical surgical measures than simple strapping support. Failure correctly to diagnose the full extent of the injury and to give proper initial treatment results in a permanently unstable ankle-joint. In view of this possibility in the patient in question, she should be referred to a consultant orthopaedic surgeon for any surgical treatment that might be necessary.

Apart from the more serious causes suggested, recurrent ankle sprains in women are frequently due to a combination of obesity, unsuitable footwear, and weak calf muscles. The treatment of these is diet, low-heeled, lace-up shoes, and supervised ankle exercises in a physiotherapy department.

Nasal Haemolytic Streptococci

Q.—Why is it that when haemolytic streptococci are found in a throat swab they are not usually found in a nasal swab taken at the same time?

A.—The area sampled by an anterior nasal swab is remote from the fauces and has a different flora. The direction of flow of secretion produced by the action of the nasal ciliated epithelium is from before backwards, and this is an obstacle to the migration of throat bacteria even into the posterior part of the nasal cavity.

Haemolytic streptococci are cultivated from throat swabs in patients who have an acute streptococcal tonsillitis or a more diffuse form of angina, or from those who are tonsillar carriers of this organism. Unless there is an accompanying rhinitis, which is sometimes seen in both the acute and the chronic infection, there is no reason why the organism should also be found in the nose.

Infection from Books

Q.—Can library books convey infection? What measures are suitable for disinfecting them?

A.—Pathogenic organisms such as haemolytic streptococci can certainly be recovered from books, but it is difficult to prove that infection has been caused by them. It is highly likely that when the organism is very resistant to light and drying, as in smallpox, books could be dangerously infectious. Infection with various diseases has often occurred when human contact with another case could be excluded. Laundry articles are then the commonest vehicles of infection, but, allowing for the difference in the amount of contact and handling, books could act in the same way. It is important to remember that it is an offence under the Public Health Act to allow a book from a public or circulating library to be used by a person suffering from a notifiable disease: if it has been so used, the local authority must disinfect or destroy the book. Unless the book is valuable, the safest measure is to burn it. For disinfection, books should be exposed in a special chamber to a maximum concentration of formaldehyde for at least 24 hours. The gas has limited powers of penetration, so that the books should be hung on wires in such a way that the pages are kept as open as possible.

Fats and Coronary Disease

Q.—What is the strength of the evidence of a relationship between dietary saturated fatty acids and coronary artery disease?

A.—Epidemiological studies indicate that in countries and communities where the total fat consumption is high the incidence of coronary artery disease is also high. Unfortunately very little is known about the contribution of saturated or of unsaturated fatty acids to the total fat intake in various countries, and so it is impossible at present to relate the incidence of coronary disease to excess or lack of any particular type of fatty acid. Most of us in this country

eat more or less the same amount of fat, but fortunately most of us do not develop myocardial infarction or even advanced coronary atherosclerosis. It is obvious, therefore, that the total intake of fat is only one part of the aetiological picture of coronary disease.

All that can be said at present is that saturated fatty acids elevate the serum cholesterol and that the serum cholesterol is often elevated in patients with coronary disease. These two observations may not be very closely related, and so far there is no evidence that there are more saturated or less unsaturated fatty acids in the serum of patients with coronary disease than in healthy controls. Thus, the evidence for a relationship between saturated fatty acids and coronary artery disease is no more than circumstantial.

Hard Beds for Small Children

Q.—Is a hard bed without pillows satisfactory for small children?

A.—Sleeping on a hard bed without pillows is a perfectly satisfactory orthopaedic state for normal young children. It is important that the bed should not sag in the middle. A bed or mattress may be hard yet still sag because the bedstead springing is of poor design. In this respect a fine wire mesh over vertically placed coiled springs is a better base than a wire mesh with no supporting vertical springs.

On top of a sprung base should be a firm mattress, not a spring interior or foam rubber one. An interior sprung or foam rubber mattress on a sprung base is an unhealthy combination, as it is too soft, sags too easily, and predisposes to low back pain. It can be improved by placing wooden boards or a large sheet of thick plywood between the mattress and the bedstead. A very satisfactory, and inexpensive, bed for two young children is to make wooden bunks in which are placed 4-in.-thick (10-cm.) foam rubber mattresses resting on a plain wooden board base. As there is only board and no springing under the mattresses the latter are compressed evenly by the body weight and do not sag.

Pillows are not essential for normal children provided they sleep well without them. Pillows assume more importance if a child has some deformity like torticollis or scoliosis. For the normal child a single pillow is best. If there is any allergic tendency a pillow filled with soft latex rubber foam (in one piece or foam rubber chips) should be chosen in preference to a feather or kapok pillow.

NOTES AND COMMENTS

Thin and Greasy Hair.—Dr. E. J. MOYNAHAN (London, S.E.1) writes: It is a popular belief, evidently shared by your expert ("Any Questions?" June 7, p. 1365), that massage of the scalp will "delay the progress of hair loss" in a young man with premature baldness. This is a condition which is determined genetically and invariably inherited as a dominant character. The gene responsible for it, like the gene (or genes) which give rise to a number of other traits affecting the skin, such as hirsutism in the female, acne vulgaris, psoriasis, and loss of the so-called juvenile hair-line on the forehead during adolescence, is much more frequent in white populations than in those of other races. There is little evidence which supports the view that any form of treatment, other than castration (which is rather a high price to pay to preserve one's locks), will arrest or slow up the process of hair loss in common baldness, whether premature or not. There is evidence, however, that scalp massage may, in fact, make the baldness worse. It is not surprising that this is so, since it is a common experience to find that many of the follicles which are ultimately destined to lose the power of producing hair first show this by producing thinner and shorter hairs before giving up hair-production altogether. These hairs, which are more fragile than the normal terminal scalp hair, are apt to break off when the scalp is massaged, thus making matters worse for the balding individual. The evidence that any improvement in the local circulation consequent on massage of the scalp will help such an individual to retain his hair is even more slender, and must be regarded as pure speculation for as long as we remain as ignorant as we do of the factors which are responsible

for the progressive atrophy and/or disappearance of the hair follicles. A great deal remains to be done, by way of investigation of the normal cycle of hair growth in the human scalp, before any useful suggestions can be made to help those who are so genetically endowed to postpone or avoid their fate.

OUR EXPERT replies: The fact that premature baldness depends partly upon genetic factors does not in itself mean that it cannot be influenced by treatment. The same argument could apply to psoriasis and acne, which Dr. Moynahan also mentions. The value of massage or of any kind of treatment is extremely difficult to assess in a disorder, such as this, which runs a variable and unpredictable course. It is, however, a widely held belief among doctors as well as the lay public that massage has some beneficial effect in these cases. It is for this reason that I said no more than that it may be possible to delay hair loss. Most patients certainly prefer to do something rather than wait for the inevitable progress of their baldness. The harmful effect of massage on the hair results from friction between the fingers, the hair, and the scalp. This point has been well brought out by the observations of Bowers.¹ Massage with the flat of the hand is recommended as free from this risk.² As Dr. Moynahan points out, a great deal remains to be known about the mechanism of hair growth, but until knowledge is more precise we should not be too ready to condemn empirical treatment.

Senna and Colic.—Mr. E. W. GODDING (Westminster Laboratories Ltd., London, N.W.1) writes: Your expert ("Any Questions?" May 31, p. 1313), in quoting Professor Duncan's¹ findings of a 17% incidence of griping in puerperal women following relatively large doses of standardized senna, omitted reference to a much more practical aspect of Professor Duncan's data. Thus, in the same article he states: "The fact that a higher proportion of the 'senokot' series had gripes is thought to be due to overdosage, because for the purpose of the trial it was necessary to give the same dose to all patients. Further experience with senokot has shown that an occasional patient experiences severe gripes in spite of smaller dosage, but this has been so infrequent [my italics] that it has not detracted from the advantages of the drug." The clinical reports which have reached us during the past five years leave little doubt as to the correctness of the statement²: "The great advantage of prescribing a standardized preparation of constant laxative action is that, once the dose for each patient is decided, there should be no griping, since this seems to be a symptom of overdosage."

Correction.—In the answer to the question on diuretics ("Any Questions?" May 31, p. 1313), mercaptopurine was listed as a mercurial diuretic. The name of the drug should have been mercaptopimerin.

SITTING, STANDING, AND WALKING*

BY

MICHAEL KREMER, M.D., B.Sc., F.R.C.P.

Physician, Department for Nervous Diseases, the Middlesex Hospital, London; Physician, National Hospital, Queen Square, London

In the terms of the original bequest the Oliver Sharpey Lectures are required to have some physiological leaning, and physiology in the widest sense is the basis of medicine. A clinician, particularly a clinical neurologist, is conscious, all the time he is practising his art, that he is using the work of the physiologists and anatomists who preceded him, whether these were labelled as such or were in fact clinicians. There is now perhaps a tendency to swing away from the technique of meticulous clinical observation as a basis for determination of function, whether in the nervous system or elsewhere. Instead there is often the substitution of the results of investigations carried out by technical experts who may see only a part of the patient. The former is said to result only in the description of disease; the latter to fundamental observations on the nature of disease. In spite of this, whatever may be the fate of descriptive neurology, which must surely be the same as that of descriptive clinical medicine of any kind, there is still room for the elucidation of physiological mechanisms by the careful clinical study of disease processes aided, wherever necessary, by planned laboratory investigation. This was true of the past and it is still true to-day. One has only to watch a Symonds, Critchley, or Carmichael at work elucidating a clinical problem and then (perhaps this is what the critics fail to realize) applying these results to the interpretation of normal function and its breakdown to see that the clinical techniques still have much to offer to physiology.

It is with a little hope of following this well-established principle that I am offering the following clinical studies, and as a support for what may appear to be a narrow presentation of a few clinical phenomena as the basis for the analysis of function I will quote Karl Pearson (1911). "To decry specialization in education is to misinterpret the purpose of education. The true aim of the teacher must be to impart an appreciation of method and not a knowledge of facts. This is far more readily achieved by concentrating the student's attention on a small range of phenomena than by leading him in rapid and superficial survey over wide fields of knowledge."

Posture

The apparently simple physiological procedures of adopting and maintaining a posture can be regarded as simple only until an analysis is made of the various mechanisms which must be brought into play to initiate, continue, and close the underlying motor activity. The

*The first of two Oliver Sharpey Lectures delivered before the Royal College of Physicians of London on February 11 and 13, 1958.

first or original action, as every parent knows, is always an uncertain one—needing constant repetition before a pattern is established; beginning as so many learning processes do by a series of attempts which gradually achieve success, until firstly sitting, then standing, and finally walking become fixed patterns which are followed with consummate ease, no longer requiring more conscious thought than is necessary to set the pattern in action. It is a commonplace of daily observation that complicated performances can be carried out while walking. One has only to see a messenger boy walking down the street, biting an apple held in one hand while reading with apparent complete concentration some book held in the other, avoiding oncomers, stepping on or off kerbs without pause, to realize that the youth is walking without the least effort of body or of mind and that all the co-ordination of muscles under sensory guidance is taking place with no apparent correction, intervention, or supervision.

It is not my intention in this lecture to make any analysis of the peripheral or spinal physiological phenomena of posture or of the partial contraction which enables a muscle to remain active indefinitely. This has been so well covered by Sherrington and his followers that it is now standard teaching, though I hope in the next lecture to discuss modifications of these views. What I will attempt is to show, by consideration of some patients with dissolution of powers of sitting and standing, some of the phenomena other than those of spinal cord activity that are necessary to the efficient performances of these motor functions.

Some Elementary Principles

First, however, as many of my patients have suffered brain damage, it is necessary to restate certain elementary principles which are sometimes overlooked in the desire to localize a lesion or, what is so much worse, a "function" of the brain. When a part of the brain is damaged a disorder of function may be produced. What we observe is the result of the rest of the brain making an effort to adjust for the deficiency, with greater or less success. It is never a simple arithmetical state of affairs. The situation is further complicated by the fact that men are not born equal. One brain is better than another in many ways, not the least of which is the power of adjusting for loss of part of the structure. Further, a poor original equipment may appear to suffer out of proportion to the rest. As a simple example one can take the individual who has normally the greatest difficulty in knowing his right from his left—the recruit

5088

who breaks the drill instructor's heart because he will turn the wrong way as often as not. Let such a person sustain a closed head injury of only moderate severity and as a result lose some brain activity as an overall deficit; then the lowering of his ability to recognize his right from his left will appear now to be great, perhaps even glaringly obvious, and may well give the impression of an apparent focal disorder.

In his most comprehensive account of the parietal lobes, Macdonald Critchley (1953) takes great pains to stress the impossibility of precise anatomical localization of the multitudinous fractions of disordered functions evident in brain damage. He makes clear that it would be wrong to attempt more than the most general distribution of higher functions—perhaps not more than lateralization, perhaps not as much as that in many cases. No one will deny that permanent damage to certain fibre tracts will produce permanent defects of function. Damage to the visual pathway will produce permanent defects in the visual field which are so clear because no adjustment is possible—a final path has been affected. It is true that occasionally the defect is disregarded or filled with images that do not exist, but no adjustment can be made to produce actual vision in the defective part of the field. In higher functions, however, constant and varying adjustments are being made which must account for the fluctuations in the results of examinations from day to day as pointed out by Head and Holmes (1912).

It is true, then, that the study of brain damage gives results which are difficult of interpretation and which may be valueless for anatomical localization. They must, however, be useful for pointing to the functional organization of the individual.

An infant usually sits up at about 6 months old, unless it has profound muscular hypotonia, or disease of the central nervous system, or mental defect, when it may take much longer. When it sits up at first it sways readily, and unless propped it falls in any direction very easily. Once it succeeds in sitting steadily it makes efforts to pull itself up or if held will take its weight on its legs for increasing periods. When it has succeeded in standing it sits down anywhere by letting go and ending sharply in the sitting position. Once it has reached independence in standing, then it gradually tries to achieve a more gentle translation into the sitting position. But when it can get around the room and needs to sit on something, whether a stool or even its pot, one may find in the early stages that it does not manage very easily to seat itself in exactly the position it wants, and has to manoeuvre itself round to get to the desired relationship *vis-à-vis* the outside world.

Trunk Apraxia

A similar situation can be found in the so-called rumpe apraxie or trunk apraxia, first described by Sittig (1929, 1931) in his monograph on apraxia, and further commented upon by Lange (1936). In this condition the sufferer is unable to sit up, lie down, sit down, or roll over on command, though he may do so spontaneously. Only one case is described, though in considerable and most revealing detail; but, as the underlying pathology was a vascular degeneration, there were numerous other defects which complicate and confuse the picture.

Nielsen (1946) briefly describes three cases of trunk apraxia. In the first a man of 40 was unable to rise from his bed or lie down upon it. He raised his arms and legs in the air in an effort to rise, but never succeeded in the attempt. Permission for a necropsy was not obtained.

The second patient could not read but could understand when spoken to. He could not undress himself; he tried to unbutton his clothes, but never succeeded in getting anything done. He acted like a child who had not learned how to do it. When on the examination couch, he turned and rolled like an infant and had to be carefully watched. When asked to sit down he walked across the room to the chair as though uncertain whether he was acting properly. When he finally reached the chair he turned round and regarded it from all angles. He tried to get himself into the chair but bent his knees while facing it. When this was not successful he turned half-way round, decided that was wrong, turned all the way round to the proper position, bent his knees a little—again decided that was wrong, and never succeeded in sitting down. At necropsy a diffuse glioma was found almost filling the left hemisphere, stretching from the tip of the frontal horn of the lateral ventricle to the occipital pole. It is remarkable that his defects were so few.

The third patient had difficulty in sitting up or lying down, yet he had no paralysis. He could not slide down the bed, but raised his pelvis in all sorts of clumsy ways, and finally put it down where it had started from. Necropsy was not performed, but the patient was regarded as suffering from diffuse cerebrovascular degeneration.

I have quoted almost all the details given in Nielsen's book. They are relatively few, but do indicate a difficulty with orientation of the body. Unfortunately it is all too clear that these patients had massive cerebral disease with great dysfunction of many parts of the brain, and it is impossible to use this sort of material to analyse the nature of the particular disturbances I wish to discuss.

To get a clearer view of the disorder I will describe two patients who showed this difficulty but who recovered, who were able to talk about their disorders, and whose general intellectual level was high. They were the best sort of subjects to help in working out the disorder, and, though it will be seen that this was not the only defect from which they suffered as a result of brain damage, it dominated the situation.

Case 1

A tank commander aged 28, while fighting in the battle of El Alamein, was struck in the back of the head by a shell fragment. He sustained a penetrating wound of the occiput from which brain was protruding when he was first seen. The first notes available to me were made 18 hours after the wounding, at a field surgical unit. Here he was found to be responding to questions but confused. His only complaint was of blindness. The evidence given for confusion was that when asked to move his right or left leg he moved either arm indifferently and insisted that he was moving his legs. A primary operation was performed with removal of some bone fragments and necrotic brain, and he was evacuated to the head centre, where I saw him 60 hours after wounding. He was then moderately confused, and his amnesia, both retrograde and post-traumatic, could not yet be estimated. He could now see, though he was very hazy in the lower half of each visual field. The only other abnormality was that he would not or could not move the correct limb on command, and this was out of proportion to the degree of confusion. X-ray examination of the skull showed a midline high occipital bone defect a little more to the left than right with radiating fissures and in-driven bone fragments to a depth of 4 cm. Two weeks later a small abscess was evacuated through the wound, after which he progressed uneventfully, and a month later his wound was soundly healed. He was rational and his amnesia was now clearly about half an hour retrograde and 18 days post-traumatic. There were, however, numerous islands in these 18 days. It is interesting, and perhaps of a patient's amnesia, that late in this intelligent young man gave his own views on the estimated time of loss of memory. He said that, lying in bed in hospital with few visitors, one day is so like another it may be quite impossible to be

certain when consecutive memory begins. In his case he marked it by the ward sister appearing one day wearing a Flanders poppy on her uniform as something different that he could hang on to in his mind.

Once he emerged from his confusion he showed a difficulty with visual imagery or visual recall. He would picture a uniform and try to attach the rank badges without finding the proper place for them. As he said himself a little later, "I knew I had two pips, but I couldn't see where I could wear them—wherever I pictured them seemed odd and absurd. It all came back to me quite suddenly, and I felt how stupid I had been ever to be uncertain." By the end of that first month his visual fields had improved and he then had only a homonymous defect of the right inferior quadrants which did not approach the fixation point nearer than 10 degrees. This remained as a permanent defect.

He was then allowed up and at once became aware of a queer inability to place himself correctly when getting into bed or trying to sit down. On his second day up he went into the lavatory and found he could not work out which way he must face in order to end up in the conventional position. He began by bending his knees and found them on the seat. He knew this was wrong, but no matter what he did he could not combine a knees bend with his posterior to the seat. This went on until he anchored himself by placing his hands on one of the side walls and keeping them there while bending the knees. This enabled him to sit sideways, which was a satisfactory compromise to begin with, though he soon shuffled round to the front. As this happened on several days he could not dismiss it, and tentatively mentioned it during a ward visit. Like so many patients with these bizarre disorders he was afraid that it meant insanity. When reassured he talked freely about this and applied himself to overcoming the defect. He soon worked out a technique of holding on to the lavatory door handle, instead of the side wall, before bending his knees.

At this time careful testing showed no visual agnosia, no visual disorientation; he could read, though he might miss a line now and again. He had no difficulty with his own right and left nor any finger agnosia, but he could be confused about the examiner's right and left by rotating through 180 degrees.

Two months after the wounding he discussed his difficulty in getting into bed. If he was sitting on the side of the bed and was told to get in, as often as not he would end up with his feet on the pillows and his head at the foot. He would get out to rectify this and often repeat the error. The same thing would happen if he told himself to get into bed, whereas if while undressing he started talking to another patient, then he would get into bed without thinking about it and find himself the right way up. He noticed that the action was also much easier if he was thinking with concentration about something such as the next day's activities. One day I asked him to get into bed to be examined; he was obviously in great difficulty, and helped himself by head and tongue movements such as may be seen in a child trying to solve a difficult problem. When asked what the difficulty was he said, "Once I take my eyes off the bed I'm lost, because I can't picture myself and the bed at the same time." It was certainly true that if he faced the bed and climbed in he achieved the correct ending more often than when sitting on the side. No defect of visual imagery for pictures, objects, or topography could be found at this time.

The following episode disturbed him greatly because it illustrated his difficulty in bodily orientation.

Because of the scar on his occiput he had become sensitive about the appearance of the back of his head. In places where he took off his hat he liked to sit with his back to the wall. In a favourite restaurant frequented by his regiment there were only round tables with as many as a dozen chairs. He could never decide which chair to

sit on in order to have the back of his head towards the wall. As a rule he gave up trying to work this out, but sat on any chair and moved round until he got into the right place.

Another interesting defect this patient showed was a difficulty in rapid visual interpretation. He had no visual agnosia as ordinarily interested, but in the cinema he found that he could follow only slowly paced action. Any rapidly changing scene or much activity on the screen was completely beyond him. After a short time he would abandon the effort of following visually and hope the accompanying sound would keep him in touch until he could once more see what was happening. Like other patients with this disorder he preferred the theatre, where as a rule most of the action is static, to the cinema.

This patient was seen again a year later and improvement had continued. The visual fields were unchanged. Now he could usually put himself into a desired chair, though on important occasions, or where fear of failure or ridicule was present, he would resort to trial and error. He had no trouble with lavatory seats, though occasionally his knees would begin to bend too soon, but this he could control. He could now manage the cinema. He had no apraxia, constructional or otherwise, and no defect of the body scheme as applied to himself or the examiner. Formal intelligence testing gave an I.Q. of 120 on the Wechsler battery of tests.

Case 2

A sergeant was struck on the head by a shell fragment during the invasion of Europe. He sustained a penetrating wound of the skull a little posterior to the vertex from which brain protruded. He had a retrograde amnesia of a few seconds and a post-traumatic amnesia of an hour or two. He was at once aware of a loss of power in both lower limbs, because when stood up by a stretcher-bearer he at once fell to the ground. He was seen by a neurologist 36 hours after his wounding, when he had a partial right homonymous hemianopia with some diminution in power and sensation in both legs. It was then noted that he had a curious difficulty with the initiation of movements of the legs, though power was reasonable once the movement was under way. Unfortunately no pre-operative x-ray films exist, but an operation note is available. A bone defect was present just anterior to the apex of the lambdoid suture extending 2-3 cm. to the left of the midline and just to the right of it. The superior wall of the sagittal sinus was missing for 2.5 cm. under the bone defect, and bleeding could be stopped only by a large muscle graft. The dura was tense on the left side of the sinus, and from below it some subdural clot and lacerated brain was removed, leaving a cavity just to the left of the falx and extending down for about 3 cm.

He recovered quickly and was transferred to the Hospital for Head Injuries at Oxford four days after being wounded. On arrival he was alert and rational but noticed difficulty in judging distances, in that he would put things down short of his locker. He complained also that he didn't know where his legs were in bed or how to start them moving. Either or neither might move, and he could not be certain what would happen.

At this time he showed a right homonymous inferior quadrantanopia to 10 degrees short of the fixation point. The upper limbs were normal, but the lower limbs showed a moderate increase of tone with marked weakness of dorsi and plantar flexion of the feet and toes, more so on the right; the ankle-jerks were exaggerated, ankle clonus was well sustained, and the plantar responses were extensor. Sensation was normal except over the feet. Here he had a gross loss of all forms of sensation, both cutaneous and kinaesthetic, over the toes and almost to the ankle-joint. He had no dysphasia or visual agnosia. He had a confusion between right and left in himself and the examiner. He had no finger agnosia so long as lateralization was not required, and could copy finger postures, though he produced a mirror image of the examiner's fingers. He could sit up on

command, but on being asked to roll over he had difficulty, and, after trying and failing, wanted to know whether he had to roll to the right or left. Whatever the reply, or if told it didn't matter, he still couldn't manage until given a shove, when he continued quite smoothly.

He improved steadily and was allowed up some three weeks after the wounding. The visual field defect had cleared, but he still had marked sensory loss in the feet. He then noticed, as did the first patient, difficulty in getting into bed—ending up across the bed or with feet on the pillow. He also said, "The more trouble I take the worse I seem to be." In spite of saying this he attributed his trouble to absentmindedness. As a further example of "absentmindedness" he said that the first time he went to the up-patients' dining-hall he stood with a plate in each hand and his knife and fork and spoon in his pocket. He had no idea what to do next, whether to put a plate down or to get the cutlery out of his pocket first. This inability to carry out a complicated movement pattern persisted for another two weeks, yet from the first he had no evidence of dyspraxia in carrying out simple actions or pretending so to do.

From the time he was allowed out of bed he had difficulty in sitting in a chair. If he started facing the chair then he would turn a complete circle and end up facing the chair. If he turned only 180 degrees, he usually sat down by the side of the chair and landed on the floor. This difficulty persisted for six weeks longer than any of the other difficulties and awkwardness. He was quite certain it had nothing to do with the loss of sensation in his feet, because he said, "It isn't the numbness; that only affects me in the dark, and it's quite a different feeling." At a later stage he said, "My legs are queer creatures and I am often confused about them. I've mixed them up with someone else's. I sat in front of another patient to help him off with his boots, and it wasn't until I had unlaced and almost got one off that I realized I was handling one of my own." I must emphasize that at this time he had no defect of his visual field and that the sensory defects had receded and were confined to the toes and distal parts of the feet, but here they were dense.

This man was intelligent, giving an I.Q. of 130 on the Wechsler series. He had some memory disturbance in that he could not remember more than 50% of the details of a short story. He did poorly with Koh's block patterns and also in visualizing tests. For instance, he gave 16 and 8 respectively for the number of corners and surfaces of a cube. This was not due to any impairment of reasoning, as he did well in the standard tests for abstract thinking. Six months later his body orientation was normal, while the sensory defects in the feet were unchanged.

Comment on Cases 1 and 2

Both these patients showed a disorder of movement which can be summed up as an inability to achieve a desired relationship between the body and the external world. This was most dramatically shown when they tried to sit down, but it is also clear in other actions. These movements were at their worst when commanded voluntarily, at their best when automatic. In this they resemble the classical case of Hughlings Jackson's (1931-2) of apraxia of the tongue and lips in which it was impossible to protrude the tongue on command but where it went out quite smoothly and dexterously to lick a crumb off the lips. It is clear, therefore, that, whatever the disorder, it is not one which has disorganized completely the orientation of the body, but one in which the voluntary drive has been blocked so far as this function is concerned.

Sittig (1931), in the analysis of his own case, felt that it was usually associated with apraxia for other parts of the body and that the order of development of the apraxia was face, upper limbs, lower limbs, and trunk. This he advanced as an example of Hughlings Jackson's (1931-2) law that the more highly differentiated functions show the first

evidence of dissolution in a large or general cerebral lesion. Sittig regards all forms of apraxia as really being bilateral, but that the hemiplegic weakness usually present covers up one side of the apraxia. In his view apraxia is primarily a disorder of movement and actually a form of paralysis. This he calls a paralysis of "higher potentiality."

A superficial view of the two cases here presented might class them as examples of ideational apraxia. This would mean that the disorder was due to a faulty conception of the movement as a whole; but this must be incorrect, for even the brief analysis here given makes it obvious that we are dealing with perceptual as well as movement disturbances.

"Body Image"

It is usual to attempt to explain these orientation defects in terms of disturbances of the body image, or schema, and this view has so many implications for my argument that I would like briefly to outline the major points of the hypothesis and its development. The term "body image," or schema, was introduced as such by Head (1920), though some of his views had been foreshadowed by Bouier, about 20 years earlier. This development was probably due to the failure in Head's (1920) view of the theories on sensation and its relation to motor activity propounded by Munk (1890). The latter argued that the parietal lobe is directly concerned with appreciation of touch, pressure, temperature, and muscle sensation. Apart from muscle sense, these sensations can be reactivated centrally in the form of images, and though muscle sense could not be revived by imagination it could in spite of this combine with the contact or pressure images. These provide definite and distinct images of the actual position of the parts of the body and of their changes, and served as the initiator of movements. By extirpation experiments he produced a mosaic of function, each fragment having sharply defined capabilities.

I cannot go further into this view, which was severely dealt with by Head both directly and by implication. Head suggested that three schemas existed. The first is a visual model and the second a surface or tactile model on which localization took place. Both of these can readily be brought into awareness. The third is a postural model, usually not part of our awareness or conscious introspection, the means of ascertaining the position of the body or of movement of its parts. Which of these body images or schemas, if they exist, is the most important is still being argued. Head is clearly in favour of the postural model, whereas Lhermitte (1939) and Schilder (1935) favour the visual model.

Head says: "The image, whether it be visual or motor, is not the fundamental standard against which all postural changes are measured. Every recognizable change enters into consciousness charged with its relation to something that has gone before, just as in the taximeter the distance or time is presented to us already transformed into shillings and pence. So the final product of the test for the appreciation of posture or passive movement rises into consciousness as a measured postural change. For this combined standard against which all subsequent changes of posture are measured before they enter consciousness we propose the word schema. By means of perpetual alterations in position we are always building up a postural model of ourselves which constantly changes. Every new posture or movement is recorded on this plastic schema, and the activity of the cortex brings every fresh group of sensations evoked by altered posture into relation with it. Immediate postural recognition follows as soon as the relation is complete."

It is clear that this must be (if we may continue the same terminology for a time) a dynamic model, for no single element in the past is sufficient as the basis of the recognition of posture. The standard must be a continuously variable one involving all that has gone before.

It is by means of this mechanism that we are able to make the adjustments of position that enable one movement to follow smoothly on another. It is difficult, however, if we follow this view in its entirety, to see how the breakdown

of the schema can result in the breakdown of the long-standing well-reinforced fully established patterns such as sitting in a desired place.

Lhermitte (1939) sees these orientation difficulties as "a change in spatial thought, particularly in the representation of external space, the objects in it, the relations of the body to external space, and the individual's concept of his physical personality."

This is, of course, expressing the results in the most general terms of the breakdown of the whole orientation mechanism, but the mechanism itself remains obscure.

To elucidate this a little further I should like to describe some further cases which, while not directly related to the mechanics of sitting, may help to clarify this obscure problem.

Case 3

A driver was wounded in March, 1945, sustaining a penetration in the right occipital region. He was operated upon within 12 hours, and a track went forward to the falx, which was bruised but not torn. Debridement was carried out to 6 cm., but a later x-ray film showed that a small piece of metal had entered the posterior end of the frontal lobe. Two days later it was noted that the left limb movements, particularly of the arm and hand, were slow and clumsy, and that he often used the right limbs instead. I first saw him on the fifth day, and then he had signs of damage to the supranuclear pathway of the oculomotor nerves, particularly no visual field defect. There was no loss of power in the limbs, but he never used the left arm if he could avoid it. A week later he was still reluctant to use the left arm, but it was possible to demonstrate that he had no difficulty with recognition of right or left, nor was there any sensory defect at all.

Three weeks later power was full in formal testing, yet there was falling away of the outstretched arm and hand. There was no ideational apraxia, because he could comb his hair, salute, and lather his face with his left hand. There was no finger agnosia. Yet when asked to find his nose with the left hand he groped for it. He could not put the left arm into the same position as the right arm with his eyes shut. With eyes open he had less difficulty, but he had to make constant visual references to the position of the two limbs. Three weeks later he could imitate right-arm postures with the left even with his eyes shut, but he still groped for his nose and chin. Particularly impressive was the test for visual disorientation. In either visual field he could locate an object with his right hand with the greatest precision even though his eye remained fixed on the centre of the field. With the left hand, however, under the same conditions, he was inaccurate by many inches until the object was close to the fixation point. He eventually made an almost complete recovery.

Comment on Case 3

In this patient we see that, during the acute phase of his injury before adjustment had set in, he was unable to maintain so simple a posture as the outstretched arm; yet his postural sense as ordinarily estimated by tiny movements of fingers, his tactile sense tested in every way, and his visual functions were all normal. With more complicated postures where movement must be imitated or initiated, the disorder becomes even more obvious. This shows that there is a dissociation between sense of passive movement and sense of position in space, that it is possible to have damage to one function without damage to the other. Head, in his studies of sensation, recognized that these could be distinguished, but believed it to be unlikely that anything more than minor differences in degree of disturbance could occur. That this is not so is shown not only by this patient but also by a similar case described by Lhermitte and Trelles (1933) of a man of 68 who also could not copy the position of one limb with that of the other in spite of apparently intact sensorium. We must accept, therefore, that more than

an intact sense of passive movement or position as ordinarily determined is necessary to achieve and maintain a posture. Can we find an example in which the converse is present—that is, an ability to maintain position when the sense of passive movement is absent?

Head says categorically that in order to maintain so simple a position as that of the outstretched hand and fingers one must be aware of the position of the hand in space either by kinaesthetic sensation or by vision, and in the absence of these the digits and then the hand would droop by gravity and remain uncorrected. This is standard teaching now, and we have all used the test to show the sensory defect. I have no doubt that this is true for the peripheral sensory pathways and their continuation up to the cortex, and even here it is usually true—but not invariably so.

Case 4

A Commando officer was struck on the head by the butt of a tommy-gun during a raid on the coast of France. He was rendered unconscious, and during this time he was captured. He had a post-traumatic amnesia of 14 days and on recovery he was hemiplegic on the right and aphasic. He gradually recovered power and speech, but after a few months he developed Jacksonian epilepsy. I saw him just over a year later, when he was repatriated. He then had a mild spastic hemiparesis on the right. He moved hand and fingers clumsily. He had a mild increase of tone with increased deep reflexes and an extensor plantar response on the right. Sensory testing showed a minor loss to pinprick and cotton-wool touch over the right digits extending into the palm. All appreciation of passive movement was lost in the fingers and thumb. Movement but not direction could be perceived at the wrist and direction could be perceived at between 20 and 30 degrees at the elbow. Two-point discrimination was lost over the fingers but localization was fair. Stereognosis was absent. In the toes there was no appreciation of movement, but direction could be felt only at the knee. In spite of this gross postural loss this man could maintain his hand and fingers outstretched without any droop. I may say that this surprised me to such an extent that only after I had tried this out on several different days using blindfolds did I dare show the phenomenon to colleagues.

Comment on Case 4

If we accept this as a valid case then it is clear that the maintenance of position without use of the eyes and without the conscious appreciation of sense of position is possible. A very similar case is described by Head, and therefore we must abandon his own postulate that one must always be aware of the position of a limb to maintain that position.

This case, and also Case 3, lead me to the same conclusion, though from opposite directions—that the ability to achieve and maintain a posture is not dependent only on that part of the postural mechanism which can enter our awareness. There must be another mechanism, outside our awareness, which plays an important part, and this mechanism must receive activation in some way from the periphery. It may explain the pseudo-athetotic movements in those patients with severe tabes or sensory polyneuritis which persist even with the eyes open. There may be also in the failure of this mechanism the explanation for those tabetics who cannot be trained by re-education to use their eyes to walk with some ease. But this may be dependent on intelligence rather than anything else.

The part played by different regions of the brain in these phenomena is still very uncertain, and for reasons already given it would be difficult to attempt any formal localization and probably valueless, certainly leading to false conclusions. It is useful, however, to add some negative evidence about localization.

Phantom limbs in amputees are an example of retention within memory of previous experience—a limb continues its existence within the mind where no limb is present. It

is generally accepted that if kinaesthetic sensation is lost owing to a parietal lobe lesion, then this phantom limb will disappear. Such a case is quoted by Head (1920), and I will describe another in the second lecture, though for a different purpose. On the other hand, phantom limbs can exist without loss of the limb if the sensory pathway from the limb is destroyed. Cases of this sort have been described at every level of the sensory pathway. Whether such a phantom would disappear in a parietal lesion is probable, but I am not familiar with any such case in the literature. The suggestion, however, that such phantom limbs disappear because the post-central region is no longer functioning is rendered invalid by the evidence of the "third phantom." Such cases have been briefly mentioned by Macdonald Critchley (1953), and I would like to offer another such.

Case 5

A young man received a left parietal wound which resulted in a right hemiplegia with complete loss of postural sensation in the right limbs. After recovery from the initial dysphasia he felt that the paralysed hand was making piano-playing movements (he was a pianist), and only by looking at it could he convince himself that it was lying immobile across his chest or under his bedclothes. When sitting up in a chair and wanting to reach a glass of water or to turn a door-knob he often apparently put out his paralysed arm, and the feeling of movement was complete until nothing happened and he looked down at the limb with the immediate disappearance of the phantom. The tendency to try to use the paralysed limb was increased because he was definitely dyspraxic with the good left arm. He could never work out why he couldn't do things with the left hand such as use a comb, blow a kiss, or use a pair of scissors. He always tried to excuse the failure by saying it was because he was very right-handed and this was the cause of the clumsy left hand. He also said that if he shut his eyes he could easily feel his right arm doing all the things at which the left was bad. He never said I can see the right arm doing all these things. With the partial recovery of postural sensation the phantom third limb disappeared permanently.

Comment.—Cases such as this would suggest that a parietal lobe lesion causing the disappearance of a phantom limb is massive and includes more than the post-central cortex and subcortex. It would suggest that the mechanism for the third phantom, the maintenance of posture, and the orientation of the body not only can take place outside consciousness but can remain efficient even when the conscious appreciation of movement is lost; further, that orientation of the body as a whole when sitting or standing can fail even though normal sensation is present.

Mechanism of Body Image

The concept of the body schema as put forward by Head indicates that it is conveniently on the edge of consciousness—usually outside it, but capable of being drawn into it and thus reaching our awareness. This use of words is unfortunate, for it creates a curiously solid picture of a body-image mechanism which may, even on this hypothesis, have a definite localization. Perhaps such a view is superficially useful to explain how one loses awareness of parts of the body in terms of disappearance or damage to the body image. Yet this concretization cannot but impede progress in determining the real mechanism.

From his studies of memory and its breakdown, Ritchie Russell (1957) suggests that the memory of movement patterns is due to constant activity within the cerebrum of neuronal circuits. These are established by constant repetition and reinforced by activity. With non-physical memory, reinforcement can take place even during sleep, indicating that a voluntary drive need play no part. The circuits producing postural tone control must be widespread, including cerebellum and brain stem, and must be capable of modification by the afferent information the body can

provide. It is clear from our personal experience that this mechanism exists outside our awareness once the neuronal circuits have been well established, but it must never be accepted as fixed but rather as a dynamic state. This is capable of constant change, as will be shown in the next lecture for the much simpler spinal circuits.

If the body-image mechanism is considered as a series of neuronal circuits, then at points where these circuits are narrowly confined, as in the reticular substance in the brain stem, physical change will produce the widest alterations in the pre-existing state of the individual. This may account for the ascendancy the brain stem has acquired in the neurophysiology of to-day.

This concept of neuronal circuits which are constantly active makes the difficulties of anatomical localization clear and must mean the abandoning of mosaics of function in the hemispheres. It will account also for the widespread area in which lesions may occur with the production of similar alteration in function.

The body image therefore must be regarded as a series of long-standing well-established neuronal circuits or loops which are constantly reinforced because the circuit is self-propagating. Superimposed are the modifying influences produced by streams of afferent impulses from eyes, muscles, and joints. Spreading from this are the impulses which will affect posture and movement, both of which will be considered in more detail in the second lecture.

[The second lecture, with a list of references, will appear in our next issue.]

SEROLOGICAL RESPONSE OF INFANTS TO POLIOMYELITIS VACCINE

BY

F. T. PERKINS, M.Sc., Ph.D.

RISHA YETTS, B.Sc.

From the Biological Standards Control Laboratory, Medical Research Council Laboratories, London, N.W.3

AND

WILFRID GAISFORD, M.D., M.Sc., F.R.C.P.

Director of the Department of Child Health, University of Manchester

It is now recognized that satisfactory serological response to poliomyelitis vaccine occurs in children after the age of 1 year (Medical Research Council, 1957), but as yet little is known of the response of infants to this vaccine. However, as it has been shown that even newborn infants can be adequately immunized against tuberculosis (Gaisford and Griffiths, 1951), diphtheria (Butler, Barr, and Glenny, 1954), and—with a suitable triple antigen—diphtheria, pertussis, and tetanus together (Feldman, 1954), it seemed logical to try to ascertain how early in infancy immunization against poliomyelitis could be successfully undertaken. This was the purpose of the study here described.

An additional reason for this investigation was the incidence of precipitated paralytic poliomyelitis after the injection of diphtheria and other prophylactic antigens, particularly when combined (Medical Research Council, 1956), because it was felt that if successful immunization against poliomyelitis were possible in early infancy this could precede all the other protective inoculations and might thereby eliminate the risk of provoked paralysis.

In this study, 88 mothers and their infants have been investigated in respect of the relationship between maternal serum and umbilical cord levels of polio-

myelitis neutralizing antibodies, the rate of loss of maternally transmitted antibodies in the infants, and the response of the infants immunized at different ages with poliomyelitis vaccine.

Procedures

Immunization.—The 88 infants were divided into three groups, A, B, and C, containing 34, 29, and 25 subjects respectively. The first dose of 1 ml. of vaccine was given to the infants in group A when they were 1 week old, to those in group B when they were 6 weeks, and to those in group C at 10 weeks. The second dose, also of 1 ml., was given to all the infants four weeks after their first dose. The injections were given intramuscularly into the left and right buttock alternately. Two batches of Glaxo vaccine were used, Nos. 7 and 10, and each was distributed equally throughout the three groups. These batches had been used in other field studies with older age groups and been shown to have satisfactory antigenic activity (Medical Research Council, 1958).

Collection of Sera.—Serum was collected from the cord blood of all the infants and from the mothers within three days of delivery. Pre-immunization samples of sera were taken from the infants in groups B and C on the day the first dose of vaccine was given; in the case of group A the cord serum served as the pre-immunization sample. Post-immunization sera were taken from all infants between 14 and 21 days after the second dose of vaccine.

Titration of Sera.—The sera were titrated for poliomyelitis neutralizing antibodies to each of the three virus types by the method previously described (Biological Standards Control Laboratory, 1957) which has been shown to give reproducible results (Perkins, Sousa, and Tobin, 1958). Fourfold serial dilutions of sera were made and the test dose of virus consisted of approximately 100 TCID₅₀. Each serum-dilution/virus mixture was inoculated into two monkey-kidney-cell culture tubes.

The sera from the mother, umbilical cord, and infant were titrated strictly in parallel in the same test in order that a valid comparison of antibody levels could be made. All titres are given as the dilution of serum in the serum-virus mixture before the addition to cell cultures.

Antibody Levels in Mothers, and Umbilical Cord Blood

Table I gives the distribution of antibodies in the cord sera of the 88 infants. A relatively large number (55) had antibodies to all three types and only four were "triple negative," having no antibodies to any of the types. There

TABLE I.—Distribution of Poliomyelitis Antibodies in the Cord Sera of 88 Infants

No. of Sera	No. of Sera with Antibodies to:			
	No Type	One Type Only	Two Types Only	Three Types
88	4 (5%)	9 (10%)	20 (23%)	55 (62%)

was considerable variation in the antibody levels, which ranged from less than 8 to 16,000 for types 1 and 2 and from less than 8 to 4,000 for type 3. The numbers of infants with no detectable antibody to one particular type were similar, being 21 for type 1, 19 for type 2, and 17 for type 3.

A comparison of the antibody levels of the cord sera with those of the mothers' sera is given for each subject in Fig. 1. With all three types the titres of the cord and mothers' sera were similar—in a high proportion the titres were the same—and where differences occurred they were mostly either twofold or fourfold, although in the case of two subjects the

difference was as great as 32-fold. The geometric mean titres of the cord sera and mothers' sera were also similar for all three types.

FIG. 1.—Poliomyelitis neutralizing antibody levels in mothers' and cord sera.

Loss of Maternal Antibodies in Infants

The loss of maternal antibodies in the 6-weeks-old and the 10-weeks-old infants is shown in Table II, where, for each type, the mean titres of the sera obtained at the time

TABLE II.—Loss of Maternal Antibody in Infants at 6 and 10 Weeks

Age of Group (Weeks)	No. of Sera	Virus Type	Geometric Mean Antibody Titre of Sera of		Loss of Antibody
			Cord	Infant	
6	29	1	125	42	66%
		2	271	73	73%
		3	62	21	66%
10	25	1	411	37	91%
		2	667	52	87%
		3	271	25	89%

of giving the first dose of vaccine are compared with those of the cord sera. In each age group the loss of maternal antibodies was similar for each type, being approximately 70% in the 6-weeks-old and 90% in the 10-weeks-old infants. Such a decline would suggest that the maternal antibody level was halved every 21 days.

Effects of Maternal Antibody on the Response to Immunization

The antibody response to immunization of the 1-, 6-, and 10-weeks-old infants is shown for each type in Fig. 2, which gives the titres both before and after immunization for each infant. Considering all three groups together, it is seen that

only a small proportion of infants responded to the vaccine; 12.5% responded to type 1, 47% to type 2, and 36% to type 3. It is also evident from Fig. 2 that, for each type, the lower the maternal antibody level the greater the proportion

TABLE III.—Response to Immunization of Infants with no Maternal Antibody at the Time of Giving the First Dose

Virus Type	No. with No Maternal Antibody before Immunization	No. Responding	Geometric Mean Titre of Sera after Immunization
1	24	6 (25%)	3
2	22	21 (95%)	329
3	20	15 (75%)	47

TABLE IV.—Proportion of Infants (a) With Maternal Antibody Titres of 64 or Less at the Time of Immunization, and (b) Responding to Immunization

Virus Type	Age of Group (Weeks)	Total No. of Infants	No. with Antibody Titres of 64 or Less	No. Responding to Immunization
1	1	34	8 (23%)	1 (3%)
	6	29	14 (48%)	3 (10%)
	10	25	19 (76%)	7 (28%)
2	1	32	10 (31%)	11 (35%)
	6	28	13 (47%)	14 (50%)
	10	25	20 (80%)	15 (60%)
3	1	34	15 (44%)	5 (15%)
	6	29	22 (76%)	14 (48%)
	10	25	20 (80%)	13 (52%)

of infants who responded. The effect of maternal antibody, however, differed with the three types. With type 1 no infant with a maternal antibody titre of greater than 16 responded, whereas a response was given by 10 out of the 32 who had titres of 16 or less. With type 2 no infant with a titre of greater than 512 responded, but a response was

TABLE V.—Effect of Age on Response to Vaccine

Virus Type	Age of Group (Weeks)	No. of Infants with Antibody Titre of 16 or Less	No. of Infants Responding to Immunization
1	1	5	1 (20%)
	6	11	3 (27%)
	10	16	7 (44%)
2	1	8	8 (100%)
	6	6	6 (100%)
	10	12	11 (92%)
3	1	9	5 (56%)
	6	11	9 (82%)
	10	12	9 (75%)

obtained in one infant with a titre of 512, in three with titres of 256, and in 36 of the 45 with titres of 128 or less. With type 3 no infant with a titre of greater than 64 responded, but 32 of the 58 responded when the titre was 64 or less.

The results clearly indicate that, with the vaccines used, the type 2 antigen was the most effective in overcoming the inhibiting effect of the homologous maternal antibody, that the type 3 was not quite so effective, and that the type 1 was the least effective. The relative activities of the three antigens are also shown in Table III, which gives the responses obtained in those infants who had no detectable homologous maternal antibody at the time of inoculation. It is evident that the type 2 antigen was the most active, that the type 3 was less active, and that the type 1 was poor. A similar result was also reflected in the responses obtained with the four triple-negative infants. Although the number was small, it is of interest to note that all four responded to type 2, two to type 3, and one to type 1.

Antibody Response in Relation to Age

When the results in the three different age groups are considered separately it is seen that for all three virus types the older the infant the greater the number with lower maternal antibody levels at the time of vaccination. This increase is evident from the analysis in Table IV, which gives for each type and for each group the proportion of infants with maternal antibody titres of 64 or less. It is also seen from Table IV that as the proportion of infants with low maternal antibody levels increased there was a corresponding increase in the proportion responding to immunization. However, the increase in the proportion of those responding was not entirely due to the decline in maternal antibody but appeared to be dependent, to a small extent, on the age of the infant. This is

evident from Table V, where the results are given for those infants with maternal antibody levels of 16 or less—levels which produced little or no interference with antibody response. Although the numbers are small, it appears that, in the case of types 1 and 3, the older the infant the better the response to vaccination, although in the older groups there was still a high proportion who did not respond, especially to type 1. With type 2, however, the age of the infant had no effect on the response, because in all groups all the infants except one responded well to this type.

Discussion

The chief points which emerge from this study are that the titres of maternal and cord blood neutralizing antibodies are strikingly similar for all three virus types; that the loss of placentally transmitted antibodies in the infant is of the same order for all three types, the level being halved approximately every 21 days; that the response of the infants to the vaccine varies with the level of transmitted antibodies, which interfere with the response to the homologous type; that this inhibiting effect is most easily overcome by the type 2 antigen; and that the age of the infant also plays a part in determining the ability to respond to types 1 and 3.

It is clear, therefore, that the earliest age at which infants can be successfully immunized against poliomyelitis depends on a number of different factors, but if, for practical purposes, it is assumed that the majority of infants are born with antibody levels of the order of those observed in the present investigation, it is unlikely that these will have disappeared, or fallen to non-inhibitory levels, until the infants are between 6 and 9 months old. This unfortunately precludes the use of poliomyelitis immunization as the first protection to be offered routinely to infants and leaves the problem of overcoming the risk of provoked paralysis still unsolved.

Early protection against pertussis is particularly desirable and can most conveniently and efficiently be combined with diphtheria and tetanus prophylaxis. To be effective in earliest infancy, this demands an alum-containing antigen (Feldman, 1957), which experience has shown to be the most dangerous in producing provoked paralysis. Some method must therefore be evolved whereby this triple antigen may be given with safety. One solution would be to boost the levels of placentally transmitted poliomyelitis antibodies by immunizing all pregnant women. This would ensure that the infant would have sufficiently high titres against poliomyelitis to last at least for the first four months of life and—under cover of this protection—immunization could be started as soon as possible after birth with three doses of triple antigen and thereafter followed with poliomyelitis vaccine. A study of such a procedure is already in progress, and will be the subject of a further communication.

Considered solely from the point of view of the protection of infants against poliomyelitis, the earliest age for successful immunization is still undetermined; for, although our evidence suggests that all infants would respond adequately to type 2 by the age of 6 to 9 months, it is not yet known whether this would hold true for type 3 and, more particularly, for type 1. This is at present being investigated, as also is the effect of a third inoculation given a month after the primary course, the usual practice for diphtheria, pertussis, and tetanus prophylaxis. It is possible that those infants who have shown no obvious response to their two primary injections of poliomyelitis vaccine may nevertheless have developed a sufficient degree of basal immunity to enable them to respond to the third injection.

Summary

The levels of poliomyelitis neutralizing antibodies in sera from the mother and from the umbilical cord are similar. The loss of maternal antibody in the infant is similar for all three types, the level being halved approximately every 21 days.

The response of infants to poliomyelitis vaccine depends partly on the age of the infant, but chiefly on the level of maternal antibodies, which inhibit the response to the homologous type. This inhibiting effect is overcome most easily by the type 2 antigen, not quite so easily by the type 3, and hardly at all by the type 1.

In order to avoid the inhibiting effect of the placentally transmitted antibody, immunization should at present be delayed until six to nine months after birth, although even at this age it is not yet known whether the responses to types 1 and 3 will be adequate. Studies are proceeding to determine the earliest age at which the response to all types will prove satisfactory.

Investigations are also in progress of alternative methods of immunization in early infancy.

Our thanks are due to Dr. G. V. Feldman, Dr. R. F. Jennison, and the nursing and laboratory staff at St. Mary's Maternity Hospital, Manchester, for their assistance, and to Miss K. South and Miss P. Tumber, of the Biological Standards Control Laboratory, London, for their help in titrating the sera. We also thank the Ministry of Health for the supply of poliomyelitis vaccine. This work was supported in part by a grant from the National Fund for Poliomyelitis Research to one of us (W.G.), for which we are most grateful.

ORAL TREATMENT OF DIABETES TRIAL OF PHENETHYLDIGUANIDE (D.B.I.)

BY

G. H. HALL, M.B., B.Sc., M.R.C.P.

Medical Registrar, Whittington Hospital, London

MARY F. CROWLEY, B.Sc.

Principal Biochemist, Whittington Hospital, London

AND

ARNOLD BLOOM, M.D., M.R.C.P.

Physician in Charge of Diabetic Unit, Whittington Hospital, London

In the treatment of diabetes insulin is irreplaceable: no satisfactory substitute has yet been discovered. However, the need for parenteral administration of insulin has stimulated the search for substances which will lower the blood sugar when given by mouth. Recently, certain sulphonylureas (notably carbutamide and tolbutamide) have been shown to do this. Unfortunately, sulphonylureas are effective only in mild diabetes, and this is in accord with the experimental finding that some functioning pancreatic islet tissue is necessary for them to exert full action (Levine, 1958).

Ungar *et al.* (1957) have investigated a series of compounds of different structure belonging to the diguanide group, and found that one of them, phenethyldiguanide, or N-beta-phenethylformamidinyl iminourea (D.B.I.), was able to produce hypoglycaemia even in eviscerated or alloxan-diabetic animals. Later workers have confirmed that this substance can lower the blood sugar in the absence of insulin (Nielsen *et al.*, 1958). Clinical trials of D.B.I. have been carried out by Pomeranze

Fig. 2.—Serological response of 1-, 6-, and 10-week-old infants to poliomyelitis vaccine.

(1957), and the results were held to be promising enough to warrant further investigation.

This paper records an attempt to assess the effectiveness of D.B.I. as a hypoglycaemic agent in diabetes of all grades of severity, to gauge its side-effects, and to compare its mode of action with that of insulin and tolbutamide.

Material and Methods

Forty diabetic patients were admitted to the ward for treatment with D.B.I. Their ages ranged from 18 to 78 years, average 57. The weights of 36 of them lay in the 5 to 95 centile range (Kemsley, 1952). Two males and two females were heavier than 95% of their peers. Fourteen of the diabetics were newly diagnosed and had received no treatment; one was relapsing on dietary control, never having had insulin; and the remaining 25 had all at some time had insulin, in varying amounts, for periods ranging from 3 months to 21 years. Diabetics of all degrees of severity were included; five of them developed thirst, poly-

uria, and acidosis if insulin was withheld for more than 24 hours. Where feasible, the patients were managed for a week by dietary control alone before D.B.I. was administered. This enabled the exclusion from the trial of the mildest diabetics who became normoglycaemic after simple food restriction, and permitted estimation of control figures for the blood and urine sugar contents. The calorie value of the diets was arrived at by consideration of the patients' age, height, weight, sex, and activity, and was kept constant through the trial. Patients were also weighed before and during treatment with D.B.I.

On the first day of treatment 150 mg. of D.B.I. was given by mouth half an hour before breakfast, while on the second and subsequent days 50 mg. of D.B.I. was given orally three times daily before the main meals. The full course of treatment with D.B.I. lasted for six weeks. The total 24-hour urine output of glucose (method of Benedict (King, 1951)) was measured daily and venous blood sugars (method of Hagedorn and Jensen (1923)) were estimated each day at 12 noon before lunch. In addition, on the day before D.B.I. was given and on the first day of treatment with D.B.I. blood samples were taken at two-hourly intervals: at 6 a.m., 8 a.m., 10 a.m., 12 noon, 2 p.m., and 4 p.m. These samples were analysed for sugar, plasma inorganic phosphorus (method of Fiske and Subbarow, 1925), and plasma amino-acid nitrogen—method of Folin as modified by Danielson (1933) and Frame *et al.* (1943). From all patients, before and during treatment with D.B.I., blood was also collected for a haemoglobin estimation, for white cell count and blood-film examination, and for liver-function tests.

Results

Effect of Single Dose of 150 mg. of D.B.I. on Blood Sugar.—Fig. 1 shows the mean percentage falls in the blood sugars produced by a single 150-mg. dose in 24 diabetic patients, some of whom showed no hypoglycaemic response to D.B.I. The individual blood-sugar values on the first day of treatment are expressed as a percentage of the value obtained at the same time on the previous day. A hypoglycaemic response to D.B.I. begins to be apparent in four hours, is maximal at six hours, and ceases to be noticeable ten hours after the administration of D.B.I.

Effect of Protracted Treatment on Noon Blood Sugars.—Fig. 2 shows the percentage fall in blood sugars produced by several days' administration of D.B.I., 50 mg. t.d.s. For each patient the mean pre-treatment noon blood sugar was calculated, and each value before and after treatment was expressed as a percentage of this. There was no significant change in the blood sugars during the period of dietary restriction alone. Administration of D.B.I. led to a progressive fall in the mean blood sugars, the lowest level being attained by the sixth day of treatment. Two-hourly serial blood sugars measured a week after treatment in a few diabetic patients were all lower than those observed on the first day of treatment.

Effect of D.B.I. on Glycosuria.—The urinary output of sugar reflected the blood-sugar levels and there was no evidence of an altered renal threshold.

Effect of D.B.I. on Ketosis.—The five patients whose life depended on insulin developed ketosis very rapidly when the insulin was discontinued. Administration of D.B.I. in these cases produced a small fall in the blood sugar, but the ketosis increased in severity. Of the remaining 35 cases, only occasional positive "acetests" were recorded before treatment. After D.B.I. was given, 11 of the 35 cases showed intermittent acetoneuria, of greater frequency and concentration than before treatment, although normoglycaemia and aglycosuria had been produced. The acetoneuria was

Fig. 1.—Effect of a single dose of D.B.I. on the blood-sugar level of 24 diabetics. Blood-sugar levels are expressed as a percentage of the value obtained at the same time the previous day. Each point on the graph is the mean of the figures obtained from the number of diabetics shown above each point. The horizontal lines bracketing each point represent the standard error of each mean.

Fig. 2.—Effect of protracted treatment with D.B.I. on noon blood-sugar levels. Blood-sugar levels are expressed as a percentage of the average pre-treatment level for each case. Each point is the mean value obtained from the number of diabetics shown above each point. Horizontal lines bracketing each point represent the standard error of each mean.

not due to starvation, as these patients had eaten well throughout. Acetonuria also developed in most patients who became nauseated, or who vomited while receiving D.B.I. In one case the paradoxical coexistence of ketonuria and aglycosuria was particularly marked.

An underweight male diabetic, aged 51, newly diagnosed, presented with thirst and polyuria. Heavy glycosuria and acetoneuria were observed. The initial noon blood sugar was 391 mg./100 ml. D.B.I. was given after two days' observation, and the noon blood sugars fell to 80 mg./100 ml. after a week's treatment. Although no sugar was passed in the urine, the daily output of acetone exceeded 1 g. and the blood acetone was 10 mg./100 ml. The D.B.I. was discontinued, with immediate reappearance of glycosuria. After two days without the drug, acetone disappeared from the urine, although the sugar content exceeded 2%, and the blood sugar rose to 300 mg./100 ml. D.B.I. was again given and the blood sugar fell again to normal levels. Glycosuria disappeared, but acetone bodies reappeared in the urine, the acetone being positive at a dilution of 1:32. It was thought unwise to continue with D.B.I., and insulin was given. Although the blood-sugar levels were normal, two days elapsed before the ketonuria was eliminated. The patient, although making no spontaneous complaint while receiving D.B.I., immediately commented on a sense of improved health when insulin was given.

Effect of D.B.I. on Plasma Inorganic Phosphorus and Amino-acid Nitrogen.—Although 150 mg. of D.B.I. administered on the first day of treatment produced some reduction in the blood sugar in all the 11 patients studied, there was no increase in the postprandial fall of serum inorganic phosphorus (5.4% at 10 a.m. compared with 10% on the previous day at the same time). Similarly, no effect of D.B.I. on the plasma amino-acid nitrogen could be demonstrated.

Relation of Severity of Diabetes to Response to D.B.I.—Five patients had a severe, brittle type of diabetes and required more than 30 units of insulin daily. D.B.I. was substituted for insulin in dosage varying from 150 to 250 mg. per 24 hours, but failed to prevent severe ketosis, hyperglycaemia, thirst, and polyuria. Insulin had to be reintroduced in these cases. The remainder of the patients had a mild or moderately severe diabetes, and most of them showed a fall in the blood sugar in response to D.B.I. In 18 cases the noon blood sugar was reduced to below 180 mg./100 ml., and in seven of these to below 140 mg./100 ml.

Relation of Response to Duration of Diabetes.—Of the 14 newly diagnosed diabetics, 12 showed a good hypoglycaemic response to D.B.I., and five of these did not relapse when the D.B.I. was withdrawn. Of the cases with diabetes of long standing, 17 showed some hypoglycaemic response, but none could subsequently be managed by diet alone. The impression was obtained that the drug was more effective in cases of diabetes of recent onset.

Pejorative Effects of D.B.I.—No fewer than 26 out of the 40 patients developed gastro-intestinal disturbances while on the drug. Nausea, anorexia, abdominal discomfort, vomiting, and diarrhoea were variable in severity, but in most cases were persistent enough to necessitate cessation of treatment with the drug. Symptoms usually appeared three or four days after the beginning of therapy and were not related to hypoglycaemia. Discontinuation of the drug caused the symptoms to abate, usually within two or three days.

Effect of D.B.I. Compared with that of Tolbutamide.—In two patients in this series in whom tolbutamide had previously been employed with unsatisfactory fall in the blood sugar, D.B.I. was effective in lowering the blood sugar. Unfortunately, in each case nausea and vomiting precluded continuous use of D.B.I. In three other patients in whom D.B.I. had produced normoglycaemia and in whom treatment with the drug was stopped because of nausea and vomiting, tolbutamide was introduced, but was much slower and less effective in reducing blood sugar.

Clinical Effects.—It was originally intended to administer D.B.I. for six weeks in all cases. In 25 out of the 40 patients this was not possible because of unpleasant side-effects or because an adequate fall of blood sugar had not been obtained. 20 of these cases now receiving insulin and five

tolbutamide. Of the remaining 15, six are still receiving D.B.I. (50 mg. t.d.s.) and are satisfactorily controlled. When the drug was discontinued in the rest after six weeks' treatment, in four the diabetes relapsed, necessitating treatment with insulin in two and with tolbutamide in two. In five dietary control seemed adequate to control the diabetes. Where D.B.I. was effective in lowering the blood sugar without causing gastro-intestinal symptoms, adequate relief of diabetic symptoms such as thirst or polyuria was afforded. Of the 15 patients who received a prolonged course of D.B.I., five complained of a sensation of lassitude and epigastric fullness after meals. One patient to whom a second course of D.B.I. was given after relapse of her diabetes mentioned that she felt much better "in herself" while receiving the tablets.

No skin rashes, blood dyscrasia, or toxic effects on the liver were observed in this series.

Discussion

D.B.I. has been demonstrated to be an effective hypoglycaemic agent in mild and moderate diabetes. At a dosage of 50 mg. three times a day it has been shown to reduce the blood sugar to normal levels, in some cases even in the presence of ketonuria and in some patients who have failed to respond to tolbutamide. Unfortunately, its administration was accompanied by gastro-intestinal disorders in no less than two-thirds of the diabetics in whom it was used. Nausea, abdominal discomfort, vomiting, and diarrhoea were severe enough to necessitate withdrawal of the drug in these patients. Symptoms usually quickly subsided on cessation of treatment, but vomiting is a particularly unwelcome symptom in diabetics. No toxic effects were observed in the blood or in the liver of patients so far treated, but the period of observation has not extended for more than a few months. While this paper was in preparation, Williams *et al.* (1958) recorded their experiences with the drug. They found a similar proportion of gastro-intestinal disturbances in patients on diguanides, but observed no permanent ill effect of any type. Pomeranze (1957) has stated that labile diabetics can be better controlled with supplementary use of the drug, but we have not investigated this aspect of its use.

Experimental evidence (Williams *et al.*, 1957) suggests that the drug has two main modes of action; firstly, it decreases the output of glucose from the liver by depressing gluconeogenesis, and, secondly, it increases glucose utilization by the tissues. Lundbæk *et al.* (1958) have also shown that D.B.I. has a strong effect on the uptake of glucose by the tissues. As, however, the amount of glycogen in muscle was decreased by D.B.I. (Williams *et al.*, 1957; Rafalsen, 1958) the effect of D.B.I. on the carbohydrate metabolism of muscle differs from that of insulin, and Williams *et al.* (1957) have suggested that the increased glucose uptake is due to increased anaerobic glycolysis. Our results support the view that D.B.I. does not act like insulin. In contrast to insulin, D.B.I. was quite unable to relieve acidosis in severe diabetics, and normoglycaemia could be attained in only about a third of diabetics to whom the drug was given.

Further, the appearance of ketone bodies *pari passu* with the development of normoglycaemia in certain cases makes it likely that carbohydrate oxidation is not completely rectified even when the drug has returned the blood sugar level to normal. The lack of a fall in a plasma inorganic phosphate may be due to the milder effect of D.B.I. on glucose uptake. Lotspeich (1949) found that insulin promoted the synthesis of proteins from amino-acids. The resultant lowering of the plasma amino-acid nitrogen could be seen in normal individuals (Luck *et al.*, 1928) as well as in diabetic patients. The lack of effect of D.B.I. on the amino-acid nitrogen levels in the present trial indicates again that D.B.I. does not act like insulin. On the other hand, the impression was obtained that D.B.I. was more potent as a hypoglycaemic agent than the sulphonylureas. As with tolbutamide, however, several days of treatment must elapse before maximal effect is demonstrated, and

D.B.I., like the sulphonylureas, proves more effective in patients whose diabetes is of short duration.

The ultimate value of maintaining normoglycaemia in diabetics by substances whose mode of action differs from that of insulin remains undecided. There is evidence that hyperglycaemia *per se* is harmful if allowed to persist and can be responsible for the degenerative changes that occur in diabetics (Duncan *et al.*, 1958). The search for an effective non-toxic hypoglycaemic agent is justifiable on these grounds. D.B.I., although its range of action is probably wider than that of tolbutamide, is unsuitable for general use because of the high incidence of unwanted side-effects.

Summary

A new oral hypoglycaemic substance, phenethyl-diguamide (D.B.I.), was administered to 40 diabetic patients, of all grades of severity.

A significant fall of blood sugar occurred in about two-thirds of cases.

Ketosis was not rectified, and occasionally developed, in patients on D.B.I.

In five cases in which tolbutamide proved ineffective, D.B.I. produced a fall in blood sugar.

Ill effects (usually nausea, vomiting, or diarrhoea) appeared in 25 of the 40 cases, precluding the general use of D.B.I. in diabetes.

We thank the Medical Research Committee of the North-west Metropolitan Regional Hospital Board for a grant to pursue these studies, and also Dr. Simpson, of Duncan Flockhart and Co., for supplies of D.B.I. We are grateful to Dr. J. McSorley for haematological investigations, to Miss J. Savage for laboratory assistance, to Mrs. Collins for diet supervision, and to the ward sisters and nursing staff for their most helpful co-operation.

The annual meeting of the Medical Sickness Annuity and Life Assurance Society, Ltd., was held in London on June 24, under the chairmanship of Mr. R. J. McNEILL LOVE, F.R.C.S. There had been an unprecedented increase in both sickness and life business, he said, arising from the excellent results of the 1956 valuation and the reduction in premiums for sickness and accident insurance. The sickness insurance fund now stood at over £2,700,000, the annual premium income exceeding £360,000, while the life assurance and annuity fund exceeded £5m., with a premium income of over £500,000. The net new life business at practically £2½m. was nearly 40% better than the previous year. New business under the scheme to cover the risk of death under the Medical Sickness Finance Corporation's hire purchase agreements amounted to £661,000. This subsidiary, which financed the hire purchase of cars and medical and dental equipment, charged rates little more than half those current among the ordinary finance companies. The society had formed a new subsidiary company, the Permanent Sickness Insurance Co., Ltd., whose non-cancellable sickness and accident policies would be issued to those in other than the medical and dental professions and, it was hoped, also to nurses, physiotherapists, and others in the ancillary medical services.

A NEW ORALLY EFFECTIVE LONG-ACTING GANGLION-BLOCKING AGENT FOR HYPERTENSION (189c56)

BY

S. LOCKET, M.B., B.S., M.R.C.P.

Senior Physician, Oldchurch Hospital, Romford, Essex

The substance 189c56, as can be seen from the formula, is a derivative of the group of ganglion-blocking sub-

stances originally described by Adamson, Billingham, Green, and Locket (1956). Careful and prolonged clinico-pharmacological investigation of these agents over a period of years has shown that systematic variations in certain chemical groupings could produce corresponding systematic and progressive alterations in pharmacological properties (Locket, 1956b; Green, 1956; Billingham, 1956). 189c56 is one of the compounds developed as a result of this investigation. Chemically it is related to pentacynium methylsulphate ("presidal"), a ganglion-blocking agent used in the treatment of hypertension (Locket, 1956a; McKendrick and Jones, 1958).

Clinico-pharmacological Studies of 189c56

Compared with pentacynium methylsulphate, about twice the dose of the active cation of 189c56 by subcutaneous or intravenous injection produced the same fall in blood pressure. Initial studies demonstrated that 189c56 produced hydrodynamic changes and effects on renal function comparable to those of pentacynium.

It was possible to identify 189c56 in human urine many days after the last therapeutic dose had been injected. For this identification special biological techniques using mice were developed (A. F. Green and N. B. Ward, 1957, personal communication). Prolonged excretion could mean prolonged action with appropriate dosage, and this might be of great advantage because of longer control of the hypertension.

The hypotensive effect of 189c56 begins about two minutes after intravenous injection, but may require up to three hours before reaching its lowest level. The subcutaneous dose is two to four times larger than that necessary to produce a comparable fall in blood pressure by intravenous injection. A local reaction due to the cation may occur at the site of the subcutaneous injection, and this may be immediately apparent. The fall in blood pressure begins half an hour after subcutaneous injection, but on occasion this interval may be two hours.

Administration by Mouth

The observations of the action of the drug by mouth extend over a period of more than a year and are based on many more patients than the few "long-term" cases here reported. The small supply of drug necessitated as wide a coverage as was practicable, on a short-term basis, of severely ill hypertensive patients.

The clinical results are better than with any other member of this series so far used therapeutically, and in many ways better than those obtained in comparative trials with the other ganglion-blocking agents available for clinical use by oral administration (see Cases 2, 4, 5, 7, and 9). Within the dose range of 200* to 1,250 mg. daily by

*All dosages in this communication refer to the salt bis-methylsulphate trihydrate unless specifically stated otherwise.

mouth of the salt 189c56 bis-methylsulphate trihydrate—that is, within the range of 114 to 713 mg. of active cation—given as a single dose, we are able with ease to produce prolonged and marked hypotension in every patient. The hypotension usually begins about 25 to 45 minutes (range 20 to 150 minutes) after the oral dose, reaches its maximal effect on an average about 4 hours (range 1½ to 8 hours) later, and lasts from 10 to 40 hours for a single dose.

Our current procedure is as follows. In any individual patient we start with a small oral dose, usually 200 mg. This is increased by 50 mg. each day until an appreciable hypotensive effect is obtained. This dose is then given daily. In a few days the patient becomes accommodated to the hypotension and it is now less marked. The dose is then increased by 25–50 mg. every few days. During these initial stages it will be necessary to stop on occasion in order to give the patient time to adjust, before proceeding to the desired degree and duration of hypotension. The degree and duration of hypotension achieved show little daily variation once a satisfactory drug level is obtained. After several weeks of daily administration of this constant dose it may occasionally be necessary to reduce it because of increased severity and duration of the fall in blood pressure. We presume this is because of a cumulative effect, as anticipated in our earlier studies.

The daily oral hypotensive dose most suitable for any individual patient is highly critical. Where the maintenance dose lies in the range 300 to 1,250 mg. a reduction of 25 to 50 mg. cuts the clinical effect quite appreciably, and an increase of 25 to 50 mg. converts a moderately severe hypotensive effect into a marked and prolonged hypotension.

Side-effects

Dryness of the mouth is noticeable with the larger doses, as with all other commercially available ganglion-blocking agents. Gastric emptying is hardly affected.

Disturbance of bowel motility is of little importance in this small series. As a rule, passage through the small intestine does not appear to be delayed, but when delay does occur it seems to be due to slowing down in the passage of gut content through the colon. Constipation is seldom complained of, and our information on this disturbance is elicited in most cases by leading questions. When present it is controlled by any mild aperient. Ileus does not occur.

No disturbance of bladder function occurred, nor was it complained of by any patient; yet with mecamlamine and little effective hypotension two of our small "long-term" group (Cases 5 and 9) developed severe retention of urine.

Disturbance of the vision occurs, as with other ganglion-blocking agents. This visual disturbance is in many cases of little significance, and the patient rapidly adjusts to it. On other occasions the use of 0.25–0.5% pilocarpine or physostigmine eye-drops will control the visual disturbance for several hours.

Effect of Renal Damage on Clinical Response

Using this drug, given only by mouth, we are able to control hypertension in malignant hypertensive patients. The severity of the hypertension at all ages, as judged purely by the height of the diastolic pressure, did not affect dosage in the small but severe group reported in this paper. We find that the larger doses, both per kilogram of body weight and per patient, are required by the younger patients. The presence of renal insufficiency may necessitate larger doses. Four patients in this group showed evidence of renal insufficiency, and in two cases this was severe. One patient (Case 2), who when first seen had a very considerable degree of renal impairment, showed a marked improvement in his condition, and his renal function as shown by renal-function tests rapidly improved. He has returned to work. The second patient (Case 9), though his blood pressure was adequately controlled and the retinal changes regressed, died of uraemia. Of the other two cases (Nos. 8 and 10) with

moderate impairment of renal function at the onset, one (Case 8) has shown a progressive deterioration in renal function in spite of an initial marked improvement in general condition and regression of ocular changes, and the other (Case 10) has improved, the blood urea falling steadily from 80 to less than 30 mg. per 100 ml.

It is a curious observation that with an effective reduction in blood pressure these cases and others have shown a reversal of retinal changes to normal, alterations in the electrocardiogram to a more normal picture, reduction in heart size, and amelioration of many disturbing symptoms (paroxysmal nocturnal dyspnoea and angina of effort); and these improvements seem to occur independently of and without necessarily any improvement in renal function. Nevertheless adequate control by the same drugs of the most severe hypertension, which, when treatment begins, is without apparent renal damage, is not followed by the occurrence of renal damage or progressive renal functional impairment.

Effect of Diet on Severity and Duration of Hypotension

No significant effect was elicited upon the duration of action of the orally administered drug, the size of dose, the time of onset of symptoms, or the hypotension, by a very considerable variation in the constitution of the diet. It was found, however, that to produce any specific length of effect the dose of drug necessary in any patient is smaller when given by mouth before breakfast than when given at night before going to bed, even if followed by a meal. For most patients giving the drug before breakfast is the recommended procedure. In some cases, by giving the drug at night and following it with a meal, it is possible to obtain prolonged hypotension, with the maximum hypotensive action whilst the patient is in bed. The less-disturbing later hypotensive effect (amplified by posture and activity) is present when the patient is up and about the next day. In other cases, and particularly when large doses are necessary, a more satisfactory scheme seems to be to give a large dose at night and a small "topping up" dose before breakfast.

Effect of Posture and Activity

Physical activity, when any degree of drug effect is demonstrable, is found to produce a fall in blood pressure. Posture has an appreciable hypotensive effect, the erect position invariably producing a far greater fall in blood pressure than the supine. The drug 189c56, however, produces an easily demonstrable hypotension in the patient reclining in bed during the first 5 to 10 hours of its action.

Action in Combination with Other Drugs

In view of the statement that chlorothiazide will augment the hypotensive effect of many hypotensive agents (including mecamlamine, pentolinium tartrate, chlorisondamine chloride, and reserpine) (Freis and Wilson, 1957; Hollander and Wilkins, 1957; Tapia *et al.*, 1957), some of our patients were given chlorothiazide additionally. We were unable in this brief trial to demonstrate any significant hypotensive action attributable to the combined use of chlorothiazide and 189c56 which in any way differed in intensity or duration from that given by the same dose of 189c56 without chlorothiazide. Nevertheless chlorothiazide produced its diuresis when the blood pressure had fallen in response to administration of 189c56.

After the initial pharmacological investigations all our patients given 189c56 for long-term control of their hypertension receive in addition 2 mg. of "rauwilloid" (a preparation of total active rauwolfia alkaloids) nightly.

Case 1

A girl aged 18½ (weight, 50 kg.) had malignant hypertension. She was a known hypertensive of nine months' duration when she first came under our care more than a year ago. There were visual disturbances, recurrent severe headaches, and vomiting. Nephrectomy for a unilateral

fibrotic kidney had no effect on her blood pressure. Her mother died of malignant hypertension, aged 52.

On examination her B.P. was 260+/170-180; blood urea 30 mg. per 100 ml.; renal function normal; urine normal; fundi—papilloedema, numerous haemorrhages, some very large, hard and soft exudates; x-ray examination of chest showed moderate cardiomegaly; E.C.G.—left axis deviation and left ventricular strain patterns.

Treatment with daily subcutaneous injections of 189c56 resulted in a complete relief of symptoms and a return of her fundi to normal. One year ago she was transferred to oral 189c56. Originally she required 1,250 mg. daily; but later was adequately controlled by 750 mg. nightly—this produced hypotension for 16+ hours. She has been back at work for six months and is more comfortably controlled by 650 mg. at night and 150 mg. before breakfast. In addition she receives 2 mg. of rauwiloid nightly. Chlorothiazide, 1 g. daily for four days each week, had no effect on hypotensive response. No gastro-intestinal disturbance. Some dryness of mouth and occasional blurring of vision. Postural symptoms not incapacitating.

Case 2

A youth of 17½ (weight, 60 kg.) had malignant hypertension superimposed on a long-standing renal lesion. He attended the medical out-patient department for six years with albuminuria and low clearance, but no hypertension until 1½ years ago, when his B.P. was 160/100. He was admitted to hospital in September, 1957, with a six-weeks history of vomiting and incapacitating headache.

Examination showed B.P. 260+/170, blood urea 180 mg. per 100 ml., albuminuria, bilateral papilloedema with exudates and haemorrhages.

Treatment was started with oral 189c56. The result was dramatic. 800 mg. daily before breakfast produced hypotension lasting 20+ hours. Headaches and vomiting ceased, papilloedema receded, and blood urea fell steadily to 40 mg. per 100 ml. Albuminuria diminished but persisted. In this patient the later trial of mecamlamine, 15 mg. daily before breakfast, produced little effect on blood pressure, which after three hours was 240/150, but vomiting, constipation, abdominal discomfort, and malaise were present; 17.5 mg. of mecamlamine produced moderate hypotension lasting six to eight hours, persistent vomiting, severe abdominal pain, ileus, and intractable constipation. With oral 189c56 this lad was able to return to work as a hospital orderly, but when put on to mecamlamine he became so ill that he was unable to work. No constipation with 189c56. The pre-breakfast dose was changed to 1,200 mg. at night with nearly as good a hypotensive effect (16+ hours), but more comfortable control is given by 1,000 mg. at night (9 p.m.) and 300 mg. before breakfast. He also receives rauwiloid, 2 mg. nightly. Chlorothiazide, 1 g. for four days each week, had no detectable effect on the hypotension.

Case 3

A man aged 56 (weight, 80 kg.) had severe essential hypertension with gross arteriosclerosis.

Examination revealed long-standing hypertension and marked vascular arteriosclerosis. Hemiplegia from stroke 14 months ago; gross retinal arteriosclerotic changes; no papilloedema. Uncontrolled B.P. 260-290/150-170; 450 mg. 189c56 daily before breakfast produced hypotension to 147-170/70-95 for 8-16 hours. No undue side-effects, according to this patient.

Case 4

A man aged 62 (weight, 64 kg.), with severe hypertension with papilloedema and gross arteriosclerosis, was admitted to hospital 10 months ago after a stroke; B.P. 260+/150; gross vascular arteriosclerosis; papilloedema, haemorrhages, and exudates. B.P. below 150/100 for 14 hours on 450 mg. 189c56; objectively, physical condition remained unchanged and in general poor; fundi now showed no papilloedema, only occasional haemorrhages and hard exudates; on

mecamlamine 10 mg. twice daily deteriorating mentally and physically, with aphasia and constipation, but no demonstrable effect on blood pressure. All hypotensive treatment with ganglion-blocking agents stopped; rauwiloid, 2 mg. nightly, continued—present condition unchanged. B.P. fairly static at 220/110.

Case 5

A man aged 61 (weight, 72.5 kg.), with severe hypertension and papilloedema, was admitted to hospital with hemiplegia and aphasia of recent onset and rapidly improving.

Examination showed B.P. 300/170; fundi, papilloedema, occasional exudates, and haemorrhages. 500 mg. 189c56—hypotension 14+ hours—upset by dryness of mouth and postural vertigo. Nevertheless incapacitated by giddiness when not receiving treatment. Mecamlamine, 17.5 mg. before breakfast, produced slight temporary hypotension and marked constipation, dryness of mouth, and visual disturbance. Mecamlamine, 20 mg., caused retention of urine, nocturnal frequency, strangury, constipation, though the blood pressure was as high as ever 4½ hours after this drug. Chlorothiazide, 1 g. daily for four days each week, did not augment hypotensive effect of 189c56. Not keen on taking any ganglion blocker in spite of knowing consequences of untreated hypertension.

Case 6

A man aged 61 (weight, 63 kg.), with severe hypertension and papilloedema, was admitted to hospital after mild cerebral catastrophe (cerebral thrombosis) with practically complete recovery. Fundi—papilloedema, exudates, and haemorrhages; B.P. 240/160. 500 mg. 189c56 gave 15+ hours of hypotension. Postural vertigo a nuisance; dryness of mouth slight. B.P. 4½ hours after 10 mg. of mecamlamine 270/140. Increased to 12.5 mg. with no appreciable hypotensive effect beyond constipation. Accepts treatment under duress. Has been under treatment for eight months.

Case 7

A man aged 63 (weight, 81 kg.) had essential hypertension with recurrent left ventricular failure. He was a known hypertensive of more than 20 years' duration, cardiomegaly and gross E.C.G. changes (left bundle-branch block). Recurrent attacks of left ventricular failure. B.P. 240/140; B.P. controlled for 12+ hours below 150-170/90-110 by 350 mg. of 189c56 daily and rauwiloid, 2 mg. at night. Chlorothiazide, 0.5 g. daily for four days each week, did not apparently augment hypotensive effect of 189c56, but produced an appreciable diuresis. He has been under treatment for six months.

Case 8

A woman aged 42 (weight, 56 kg.), with malignant hypertension, had a history of medical attention for preceding two years for severe recurrent headaches, vomiting, anorexia, vertigo, and gross emotional disturbance. Two weeks before admission she developed haematuria and was referred to the genito-urinary surgeon, who referred her to us.

On examination she was well covered; B.P. 260+/180; blood urea 55-60 mg. per 100 ml.; urine—much albumin, occasional R.B.C.s and granular casts; I.V.P. normal; cystoscopy normal; E.C.G.—L.A.D. and L.V. strain patterns; x-ray chest—L.V.++; fundi—papilloedema and numerous exudates and haemorrhages; profound emotional disturbance.

She was controlled satisfactorily on 500 mg. before breakfast, which gives hypotension below 150-160/100 for 18+ hours, and 2 mg. of rauwiloid at night. In hospital felt well, no headaches, no vomiting, bowels regular, slight dryness of mouth, good appetite, slept well, fundi practically normal, but blood urea remained up (last figure 72 mg. per 100 ml., and serum creatinine 3 mg. per 100 ml.). Said she felt better than she had felt for many years. Urine still contained 0.1% protein and some R.B.C. Under treatment for three months. Discharged home to attend out-patient departments. She took drug erratically—said it was because

she felt giddy. Emotional symptoms and vomiting recurred (? due to reappearance of hypertension). Stopped taking tablets. Vomiting and hypertension persisted. Readmitted with hypertension uncontrolled; blood urea, 220 mg. per 100 ml.; oliguria and albuminuria; papilloedema; and B.P. 240+/160 mm. Hg.

Case 9

A man aged 47 (weight, 75 kg.), with malignant hypertension, was a known hypertensive under care of a London teaching hospital for two years, first being treated with oral pentolinium and reserpine with no effective hypertensive control; was then transferred to mecamlamine and reserpine. Admitted to us as an emergency whilst receiving treatment with mecamlamine 10 mg. four times a day. Mecamlamine dose had apparently been halved some few months earlier owing to intolerable and incapacitating side-effects. History of recurrent episodes of severe dyspnoea for at least preceding nine weeks. Constant "asthma" for past nine days. Bowels not open. Continuous nocturnal and diurnal frequency of many months' duration.

Examination on admission: B.P. 300+/195; pulmonary oedema; fundi—gross papilloedema, numerous exudates, and haemorrhages; E.C.G.—L.A.D. and L.V. strain patterns; chest x-ray examination showed gross left ventricular enlargement, pulmonary oedema patterns; blood urea 180 mg. per 100 ml. Urine—albumin and R.B.C.

Given subcutaneous pentacynium methylsulphate, 10 mg. thrice daily for 24 hours, and then oral 189c56. Controlled with 800 mg. daily. Blood pressure below 160/100 for 16-22+ hours daily on this dose, with rauwiloid 2 mg. nightly. Chlorothiazide, 1 g. daily for four days each week, produced initial diuresis, but no apparent effect on degree or duration of hypotension. On admission he was found to have marked retention of urine. After catheterization on admission, and again in 12 hours, retention of urine cleared, and whilst having 189c56 with marked hypotension no residual urine could be demonstrated, and strangury and frequency did not occur. Bowels, previously intractably constive, opened regularly. Retention of urine due to mecamlamine. Renal insufficiency persisted, and renal function continued to deteriorate in spite of a vast improvement in his mental and physical condition, a controlled low B.P., absence of pulmonary oedema, and no retention of urine. He developed pericarditis and died two months after admission.

Necropsy: Cardiomegaly and pericarditis. No other macroscopic changes. Histology of kidneys showed evidence of malignant hypertensive changes, healed, much fine fibrosis in parenchyma, and a large renal cyst.

Case 10

A man aged 55 (weight, 74 kg.) had malignant hypertension and recurrent attacks of left ventricular failure. He had a four-months history of increasing dyspnoea and recurrent paroxysmal nocturnal dyspnoea.

Examination showed: B.P. 260+/150-170; fundi—occasional exudates and haemorrhages, early papilloedema; urine—albuminuria; blood urea, 82 mg. per 100 ml.; cardiomegaly; E.C.G.—L.A.D. and L.V. strain patterns. Adequately controlled by 600 mg. of 189c56 orally before breakfast; B.P. below 140/95 for 16+ hours. Steady improvement: no constipation; no dyspnoea. Blood urea falling over period of six weeks—last figures less than 30 mg. per 100 ml. At home, well controlled and feeling fit on 600 mg. of 189c56 before breakfast.

Case 11

A man aged 43 (weight, 83.5 kg.), with malignant hypertension, was a known malignant hypertensive of five years' duration, controlled on injections of pentacynium and daily rauwiloid. Now adequately controlled on 500 mg. of 189c56 daily before breakfast and rauwiloid 2 mg. nightly. Without treatment, B.P. 240-260/150-160; with treatment, B.P. below 150/100 for 20+ hours.

Conclusion

In patients with very severe hypertension, compared with all other ganglion-blocking (or presumed ganglion-blocking) agents commercially available for oral use, at comparable levels of induced hypotension, 189c56 has a longer duration of action, a far greater hypotensive action on the supine blood-pressure level, much less effect on the intestinal motility, and no effect on bladder function. It is our impression, too, that the general discomfort associated with the induced hypotension is less disabling than that associated with similar falls of blood pressure caused by these other ganglion-blocking agents.

Two features of the action of 189c56 which seem worthy of comment are: (1) A constant daily effect with predictable results is achieved with oral dosage, though the effective dose by mouth is far higher than either the effective intravenous or subcutaneous dose. (2) The separation in some degree of hypotensive action from effects on gastro-intestinal motility. The evidence suggests that the small intestine and bladder effects are due to high local luminal concentration of active ganglion-blocking agent (Locket, 1951), also with mecamlamine a direct effect on smooth muscle (Bennett, Tyler, and Zaimis, 1957). Salivary gland and visual effects appear to be due to systemic blood levels and not dependent upon high concentration of drug in the gut. However, ganglion-blocking hypotension too is related to blood levels of active drug. If the drug is given by mouth in an inactive or less active form, activated during or after absorption, we could avoid appreciable gut effect (but not eye or salivary gland effect). Similarly, prolonged excretion at low concentration, excretion of inactivated drug, or destruction of drug in the body would avoid any effects on bladder and ureteral motility. This mechanism might explain the demonstrable absence of ileus and retention of urine after the use of ganglion-blocking drugs by injection. It could also explain the minimal gut effects and the absence of bladder effects with oral 189c56.

Our clinical experience with the drug 189c56 in the treatment of hypertension extends to more than 18 months. During the past year we have used it only by mouth.

Owing to our very limited initial supply we have had to restrict its long-term use to a small group of the most severe hypertensives. We have no reliable experience of the extent of its long-term value in the less severe cases.

Summary

The valuable features of 189c56 would seem to be: (1) It is invariably effective when given by mouth. (2) When given daily, before breakfast and followed by this meal, it consistently produces the expected degree of hypotension. (3) Duration of action is such that single daily dose control of hypertension in some patients becomes possible for the first time. (4) Dosage is highly critical. A small alteration in the controlling dose of the order of 5-12% causes a marked effect on the extent and duration of the hypotension. (5) Constipation is absent or minimal, even with large doses. Ileus does not occur. (6) Disturbances of bladder-emptying do not occur.

Brief case reports are given and may help to amplify some of these points.

I am grateful to Burroughs Wellcome and Co. (Wellcome Foundation Ltd.) for a continuous supply of the hypotensive agents in this group. I wish to thank Dr. F. Prescott, Dr. P. O. Jones, Mr. J. W. Billingham, Mr. A. F. Green, of the Wellcome Research Laboratories, for their unstinted help and advice, and Mr. D. Stevenson, of the Wellcome Chemical Works, for his help with the pharmaceutical preparation of 189c56. I am grateful to Riker Laboratories Ltd., Mr. J. Lumley, and Mr. R. W. Richards for a continuous supply of the "alseroxylon" preparation of rauwiloid known as "rauwiloid." I am also grateful for the help of my housemen and registrars over a

number of years, and particularly to Dr. I. Todd, Dr. J. Tallack, and Dr. I. Gray. I am grateful to my secretary, Mrs. E. O. Price, without whose help in keeping records this work could not be done. Not least of all, I wish to thank my colleagues for referring these cases to me, and particularly our genito-urinary surgeon, Mr. F. J. Foster.

EFFECTS OF PENTACYNIIUM METHYL-SULPHATE ON RENAL CIRCULATION IN HYPERTENSION

BY

J. R. COX, M.B., Ch.B.
Senior House Officer

AND

J. J. DALY, M.R.C.P.
Research Assistant

The Medical Professorial Unit, Sheffield Royal Hospital

One of the disadvantages of some of the ganglion-blocking drugs used in the treatment of hypertension is the fall in renal blood flow that follows their systemic administration. Reports of the new ganglion-blocking drug pentacynium methylsulphate (139c55; "presidal") claim (Locket, 1956) that it is not associated with gross changes in renal blood flow or glomerular filtration rate and produces a prolonged fall in blood pressure with few side-effects. We have therefore studied the effect of pentacynium on the renal circulation in a number of patients with hypertension.

Present Investigation

Nine patients (seven women and two men), whose ages ranged between 50 and 70 years, were studied (Table I). The minimum basal blood-pressure reading was 230/130, and all showed clinical and electrocardiographic evidence of left ventricular hypertrophy. Cases 6 and 7 had been in heart failure some months previously but had responded

TABLE I

Case No.	Age and Sex	Basal B.P.	Retinopathy Grade	Left Ventricular Hypertrophy	Blood Urea mg./100 ml.	Previous Therapy
1	50 F	250/160	I	+	41	Pentolinium

8	51 F	260/150	IV	+	200	Nil
9	53 F	250/140	III	+	49	Hexamethonium bromide, pentolinium, and mecamylamine

to digitalis and diuretics and were free of this complication at the time of study. Hypertensive retinopathy of varying degree was present in all cases; six showed retinal haemorrhages, and exudates and papilloedema were present in Case 8. In six cases there was a trace of albumin in the urine, but with the exception of Case 8 there were no red cells or casts in the urinary deposits. The blood urea, in the absence of vomiting and heart failure, was above 40 mg. per 100 ml. in seven subjects. Seven patients had been treated for between 6 and 18 months with either pentolinium tartrate or hexamethonium bromide in combination with one of the reserpine alkaloids. Treatment was stopped because with the increasing dosage necessary to control blood pressure side-effects became intolerable. Case 8 presented with malignant hypertension and Case 3 had not been previously treated.

Methods

Each subject lay at rest in bed with the head raised to 30 degrees. Renal blood flow and glomerular filtration rate were measured by a technique previously described (Smith *et al.*, 1938) and inulin and para-aminobiphenyl acid (P.A.H.) were estimated, using a method as reported by Dick and Davies (1949). Mean blood pressure was calculated as the diastolic plus one-third of the pulse pressure.

Renal-clearance periods lasted 20 minutes. Each value for effective renal blood flow (E.R.B.F.) and glomerular filtration rate (G.F.R.) in Table II is the average of two consecutive measurements. Following the drug two clearance periods were estimated during the period of falling blood pressure. Two further estimations were carried out in six subjects when their blood pressure had remained at or near normal levels for an average of 30 minutes. Percentage changes of blood pressure E.R.B.F. and G.F.R. in Table II are related in all cases to control values. Blood pressures were recorded every two minutes during the study and then six-hourly for 24 hours in both lying and standing positions. Pentacynium was given subcutaneously; Cases 8 and 9 received 12.5 mg. and the remainder 25 mg.

Results

Blood Pressure.—A fall in blood pressure occurred in all subjects between 9 and 20 minutes after the drug. In six the figure was approximately 120/80 by 30 minutes. The diastolic pressure fell to 100 mm. Hg in Cases 1 and 9 by 50 minutes, while Case 4 showed little change in blood pressures at this stage. The average reduction in mean blood pressure for the whole group was 49% at 50 minutes. Diastolic blood-pressure readings in all patients had reached levels below 100 mm. Hg by 120 minutes and remained so for a further 16 to 24 hours.

E.R.B.F.—A mean reduction in E.R.B.F. of 53% occurred by 50 minutes, and the individual changes were closely related in time and magnitude to the alteration in blood pressure. Subsequent clearance values obtained between 30 and 110 minutes in Cases 2, 5, 6, 7, 8, and 9 reveal a mean percentage increase in E.R.B.F. of 28 above mean control value. This figure is largely accounted for by a rise in renal blood flow to above control levels in Cases 8 and 9. The remaining four cases show a rising E.R.B.F., but individually these were still well below control values.

G.F.R.—Changes in G.F.R. showed a similar trend to those of E.R.B.F. but were proportionately greater in amount, producing a fall in the filtration fraction. The reduction in G.F.R. occurred *pari passu* with the fall in blood pressure. Case 4 showed little initial change in blood pressure and a correspondingly small alteration in G.F.R. The initial mean reduction in G.F.R. for the nine patients occurred between 10 and 30 minutes, and was approximately 71%. Subsequent values for G.F.R. obtained between 30 and 110 minutes in six subjects reveal a mean rise of 9%. As with E.R.B.F., this striking rise in G.F.R. for the group is produced largely by the increase in Cases 8 and 9 to above control values. Cases 2, 5, 6, and 7

reveal a rising G.F.R. between 30 and 80 minutes, but individual levels are still well below control values.

Side-effects.—Bradycardia and dryness of the mouth occurred in all subjects by 15 minutes. Three complained of blurred vision; six developed nausea, and three of these vomited at 30 minutes. Moderate to marked drowsiness was a prominent feature in all nine subjects, occurring approximately 20 minutes following the drug.

Discussion

The changes in renal haemodynamics following pentacynium are similar in nature to those observed with other ganglion-blocking drugs. Pentamethonium iodide is associated with a reduction in E.R.B.F. and G.F.R. in hypertensive subjects when the blood pressure fall is minimal (Mackinnon, 1952), but observations of changes occurring up to 110 minutes after the drug are not available in all reports. Case selection introduces the difficulty of comparing results in this type of study.

The doses of pentacynium given were on average higher than those subsequently necessary to control blood pressure in the same group of patients, and this fact, with the high incidence of impaired renal function, may explain the degree of reduction in E.R.B.F. and G.F.R. observed. Following the initial fall, E.R.B.F. and G.F.R. had risen in Cases 2, 5, 6, and 7 to approximately 50% of their control values by 30 to 110 minutes. Data for Case 8 with malignant hypertension and Case 9 at 60 minutes showed that E.R.B.F. and G.F.R. had risen above their control values. Mackinnon reported a rise in renal blood flow, following an initial fall, in a patient with malignant hypertension given a small dose of pentamethonium iodide; the blood pressure at this stage had not reached normal levels.

These observations lend support to the view that the changes in E.R.B.F. are to some extent independent of changes in blood pressure. A rise in renal blood flow with fall in blood pressure has been observed following hydralazine hydrochloride ("apresoline"). However, use of this compound produces a high incidence of toxic effects, and no advantage appears to be gained by its combination with other hypotensive drugs. The increase in renal blood flow which immediately follows hydralazine hydrochloride may be due to renal vasodilatation; a similar mechanism may account for the unexpected rise in E.R.B.F. and G.F.R. in Cases 8 and 9. However, a partial redistribution of blood volume has been demonstrated following some of the ganglion-blocking drugs, and experimental evidence supports the view that this factor may produce the initial fall in renal blood flow (Combes *et al.*, 1957). It is possible that later changes are due to compensatory mechanisms dependent on vascular tone, so that E.R.B.F. is restored to its original level in spite of a persisting reduction in blood pressure.

We cannot state precisely when E.R.B.F. had returned to control level in all our subjects, but the rapid rise observed indicates that it probably had done so within three to four hours of giving a therapeutic dose of pentacynium. The effective blood-pressure reduction with a single daily dose of pentacynium is an advantage compared with other systemically given ganglion-blocking drugs, where presumably repeated injection is followed on each occasion by a fall in both G.F.R. and E.R.B.F. There is little evidence that prolonged administration of these compounds produces renal damage *per se* or hastens that already present. A blood urea of 60 mg. per 100 ml. has been quoted (Harington, 1956) as the upper limit desirable when using the more powerful hypotensive drugs. In this respect Cases 8 and 9 are worthy of further comment.

* Effective renal plasma flow.

Case 8.—This patient was suffering from malignant hypertension. The initial blood urea was 200 mg. per 100 ml. Following 12.5 mg. of pentacynium the patient complained of drowsiness and a dry mouth. Thirty minutes later she became unconscious, with a systolic pressure of 95 mm. Hg. Elevation of the foot of the bed raised the blood pressure to 130/95. Over the next 12 hours, with a constant pressure reading, consciousness returned. At the end of 18 hours after the injection the blood pressure had reached 250/140. Subsequent doses of 1.25 mg. of pentacynium subcutaneously reduced the B.P. to 140/110. The blood urea, however, rose to 419 mg. per 100 ml. and the patient died in coma three weeks later. Permission for necropsy was not obtained.

Case 9.—This patient, who had severe essential hypertension, cardiac enlargement, and a left-sided hemiplegia, had received a low-protein and low-salt diet for 18 months before admission. His blood pressure had not been controlled by large doses of parenteral pentolinium or mecamylamine by mouth. The initial blood urea was 180 mg. per 100 ml. A satisfactory fall in blood pressure occurred initially with 25 mg. of pentacynium subcutaneously, and normal blood pressure was later achieved with 6.25 mg. subcutaneously each morning. The patient's general condition improved over the next two weeks, and before discharge his blood urea was 80 mg. per 100 ml. He had not experienced any side-effects, and was back at light work.

The incidence of side-effects in our series appears high, and may be partially explained by the dose of drug used and the incidence of renal damage. Nausea and vomiting were probably aggravated by the water drunk in an attempt to maintain urinary flow. The fall in urine flow was marked in all instances and water intoxication might be precipitated under these circumstances.

Drowsiness occurred in all nine subjects, and does not seem to have been commented on previously. It appeared earlier than the maximum fall in blood pressure. This effect, which was not associated with hypotension, has not been recorded with other ganglion-blocking drugs, and may be due to a central action, possibly on the hypothalamus.

Eight patients of this series have been followed up for six months after the study. Blood pressures were still well controlled with 6.25-12.5 mg. of pentacynium once daily, combined with a reserpine preparation three times a day.

Summary

The effect of pentacynium methylsulphate (presidal) on the renal circulation in nine subjects with hypertension has been studied.

A fall in blood pressure to normal levels occurred in all subjects and persisted for at least 16 hours.

Reduction in E.R.B.F. and G.F.R. occurred initially in all subjects by 30 minutes. In four subjects the mean E.R.B.F. and G.F.R. had risen to 50% of the mean control value by 60 to 110 minutes. In two subjects with severe renal damage the values for E.R.B.F. and G.F.R. had risen to greater than their control values by 110 minutes.

The significance of these findings is discussed, and it is noted that satisfactory control of blood pressure may be obtained with a single daily injection of pentacynium.

We thank Professor C. H. Stuart-Harris for his help and advice, and Mrs. S. Bradford for technical assistance.

FOLIC-ACID STUDIES IN MEGALOBlastic ANAEMIA DUE TO PRIMIDONE

BY

I. CHANARIN, M.D., D.C.P.

P. C. ELMES, B.M., M.R.C.P.

AND

D. L. MOLLIN,* M.B., B.Sc.

Departments of Haematology and Medicine, Postgraduate Medical School of London, W.12

It is well known that a megaloblastic anaemia may develop in patients being treated with barbiturate-like anticonvulsants such as phenytoin sodium (Badenoch, 1954; Hawkins and Meynell, 1954), primidone (Fuld and Moorhouse, 1956), and, very occasionally, other barbiturates (Hobson, Selwyn, and Mollin, 1956). The cause of the anaemia is uncertain. The patients resemble patients with folic-acid deficiency in that their serum vitamin B₁₂ concentrations are normal, and they fail to respond, or they respond suboptimally, to treatment with vitamin B₁₂, while responding excellently to treatment with folic acid. However, as there is no evidence of malabsorption of folic acid in these patients it has been generally assumed that the drugs act by interfering with the metabolism of folic acid. In this paper we report studies made on the utilization of folic acid in a patient who developed severe megaloblastic anaemia while receiving primidone ("mysoline").

Case Report

An Anglo-Indian woman aged 44 was admitted to Hammersmith Hospital on May 28, 1957, under the care of Dr. J. G. Scadding. She had lived in India until August, 1956, when she was brought to England. She had a bilateral hemiplegia, probably due to a birth injury, and at 13 years of age began to have major and minor epileptic fits. She was looked after at home, and until two years before admission had been given bromides and various barbiturates for her fits. Two years before admission treatment with primidone (1 to 2 g. daily) was started and treatment with other barbiturates was stopped. Until six months before admission she was reasonably well and took a well-balanced diet. Shortly after arriving in England she became lethargic, lost interest in her surroundings and refused food, and from this time until the time of admission she ate only tea, bread, biscuits, Horlicks' milk, and an occasional banana. She became progressively weaker and paler, had episodes of diarrhoea, and shortly before admission became incontinent of urine and faeces.

Examination.—The patient was a well-nourished Anglo-Indian, crying out incomprehensibly but able to respond to simple commands. Her mucous membranes were very pale, but there were no skin lesions, purpura, or haemorrhages, and her gums were normal. The lymph nodes were not enlarged and the spleen was not palpable. Her temperature was 97° F. (36.1° C.), she was slightly dyspnoeic, the jugular venous pressure was 10 cm. above the sternal angle, but there was no oedema. Her pulse rate was 120 a minute and blood pressure 110/30. Her heart was not grossly enlarged, but there was a soft apical systolic murmur. Signs of a bilateral hemiplegia were present, more marked on the left than on the right side. There were scars around the left eye, and the left retina appeared disorganized.

* In receipt of a grant from the Medical Research Council.

Investigations.—A blood count showed red cells, 600,000/c.mm.; Hb, 2.9 g./100 ml.; P.C.V., 9%; reticulocytes, 3.9%; M.C.V., 150 cubic microns; M.C.H.C., 32%; leucocytes, 4,500/c.mm. (neutrophils 68%, lymphocytes 27%, monocytes 4%); platelets, 95,000/c.mm. A stained film revealed macrocytosis, poikilocytosis, anisocytosis, with occasional polychromatic megaloblasts and myelocytes. A sternal-marrow biopsy showed severe megaloblastic change. The serum vitamin-B₁₂ level measured by the *Euglena* assay, was 190 µg./ml. (normal range, 100 to 900 µg./ml., Mollin and Ross, 1954). The serum protein was 6.6 g./100 ml. (albumin 3.6 g., globulin 3 g.), serum bilirubin 0.6 mg./100 ml., and urea 28 mg./100 ml. The fractional test meal showed the presence of free acid in the gastric

FIG. 1.—Haematological response to treatment.

juice; and the absorption of radioactive vitamin B₁₂, measured by the hepatic uptake method of Glass (1954), was normal, an estimated 0.4 µg. being absorbed from a 1-µg. dose of ⁵⁷Co-vitamin B₁₂. A three-day fat balance was normal, the patient excreting 4.3 g. daily while on a 50-g. fat diet. Fat absorption, using ¹³¹I-labelled fat, was studied by Dr. K. Ibbertson; the blood level of iodine in the patient was similar to that found in normal subjects. Vitamin-A absorption was also normal, the blood level rising from 38 to 584 I.U. after a dose of 300,000 units. A glucose-tolerance test and a barium-meal examination revealed nothing abnormal. The urine contained numerous pus cells, and culture gave a heavy growth of *Escherichia coli*.

Course and Treatment

Haematological Response.—The haematological response to treatment is shown in Fig. 1. On the day of admission and on the following day 0.69 mg. of folic acid was injected intravenously. Then 15 mg. of folic acid was given twice daily, by intramuscular injection during the first week, and daily, by intramuscular injection subsequently by mouth. A third intravenous injection of 0.69 mg. of folic acid was given on the ninth day. A single dose of ascorbic acid (500 mg.) was given on the second day. Treatment with primidone was continued until the third day.

There was a reticulocyte response with a peak of 49% on the fifth day. The red-cell count rose rapidly, but evidence of iron deficiency appeared at the end of the first week with a fall in the M.C.H.C. to 24%. Ferrous sulphate, 3 gr. (0.2 g.), was given three times a day. Seven weeks after admission the blood count was: red cells, 4,600,000/c.mm.; Hb, 14.4 g./100 ml.; P.C.V., 44%; M.C.H.C., 33%.

Other Treatment.—On the fourth day after admission she developed a temperature of 101° F. (38.3° C.), which was due to a urinary infection. She was then given sulpha-

furazole ("gantrisin"), 2 g. at the start of treatment and 1 g. three times a day for 10 days. With this treatment her fever subsided and her urine became sterile. Phenobarbitone, ½ gr. (32 mg.) three times a day, was also given, and on this regime her fits appeared to be well controlled.

Folic-acid Studies

The absorption of folic acid was studied by measuring the changes in the concentrations of folic acid in the serum after an oral dose of 3 mg. (Chanarin *et al.*, 1958a).

The utilization of folic acid was assessed by measuring the rate of disappearance from the blood of a small dose of folic acid given by intravenous injection (Chanarin *et al.*, 1958b). The dose used for this test was 15 µg. per kg. body weight.

Folic acid in serum was estimated by microbiological assay, using *Streptococcus faecalis* R as the test organism, as described by Tepy and Elvehjem (1945), Jukes (1955), and Chanarin *et al.* (1958a).

Absorption.—The peak serum folic-acid level in the patient after the oral dose was normal (73 µg./ml.) (Fig. 2). The peak serum folic-acid concentrations in 55 normal subjects ranged from 40 to more than 140 µg./ml. The results of three normal subjects and three patients with treated folic-acid deficiency associated with idiopathic steatorrhoea are included in Fig. 2 for comparison.

Utilization.—The rate of clearance of folic acid from the plasma was studied after an intravenous dose of 15 µg./kg. body weight (0.69 mg.): (1) before treatment was started, while the patient was still receiving primidone; (2) on the following day, when treatment with primidone had been stopped and after the patient had received a large dose of ascorbic acid; and (3) on the ninth day, after the patient had received large doses of folic acid. Fig. 3 shows that the clearance of folic acid in all three tests was similar to the clearance found in normal subjects and unlike the very rapid clearance found in patients with a megaloblastic anaemia due to folic-acid deficiency.

FIG. 2.—Changes in serum folic-acid concentration after a single oral dose of 3 mg. in three normal control subjects, three patients with idiopathic steatorrhoea, and the patient. Interrupted horizontal line denotes lowest peak level (40 µg. per ml.) of folic acid found in 55 control subjects.

FIG. 3.—Rate of clearance from plasma of an intravenous dose of folic acid: in the patient 1—1=before withdrawal of primidone; 2—2=after a large dose of ascorbic acid; 3—3=after treatment with folic acid. A, In 35 control subjects. B, In 11 patients with megaloblastic anaemia due to folic-acid deficiency.

Discussion

The megaloblastic anaemia in this patient appeared to be due to the anticonvulsant drug primidone. She was not suffering from a gastro-intestinal malabsorption syndrome, for she absorbed vitamin B₁₂, folic acid, fat, vitamin A, and glucose normally. Although her diet was probably defective in vitamin B₁₂, there was no evidence of vitamin-B₁₂ deficiency and her serum vitamin-B₁₂ concentration was normal.

The megaloblastic anaemia in these patients resembles that seen in pregnancy and in certain patients with intestinal malabsorption syndrome who develop uncomplicated folic-acid deficiency. The serum vitamin-B₁₂ concentration in each of these three groups of patients is usually normal and the patients respond optimally only when they are treated with folic acid. In a general sense, therefore, patients developing a megaloblastic anaemia on treatment with anticonvulsants may be considered to be suffering from "folic-acid deficiency." Our results, however, suggest that the pathogenesis of the "folic-acid deficiency" in these patients is different from that in the pregnant patients and in the patients with folic-acid deficiency associated with intestinal malabsorption syndrome. These latter patients clear a small intravenous dose of the vitamin from their plasma very rapidly (Chanarin *et al.*, 1958b), and this has been interpreted as indicating true folic-acid deficiency with depleted tissue stores. In this patient, however, the rate of clearance of intravenously injected folic acid was normal. Hence it seems that there was no tissue deficiency of folic acid in this patient. The anaemia is thus probably not due to deficiency of folic acid but to interference by the anticonvulsant drug with the action of available folic acid in cellular metabolism. That tissue stores of folic acid are present in these patients is supported by the observation that the withdrawal of primidone will itself bring about relief of the anaemia (Christenson *et al.*, 1957).

The development of megaloblastic anaemia in patients receiving anticonvulsants is analogous to the megaloblastic change which develops in patients with leukaemia who are treated with 6-mercaptopurine or with various folic-acid antagonists. As one would expect, the folic-acid clearance in patients with leukaemia who develop such megaloblastic change remains unaltered (Chanarin *et al.*, 1958c).

The action of folic acid in producing a response in patients with megaloblastic anaemia associated with anticonvulsants is also presumably analogous to the action of folic or folinic acid in reversing the megaloblastic change in patients being treated with folic-acid antagonists, and similar to the action of *para*-aminobenzoic acid in overcoming sulphonamide inhibition in micro-organisms.

Although these observations provide a satisfactory explanation for the action of the anticonvulsant drugs, they do not explain why relatively few patients develop frank megaloblastic anaemia. The observations of Hawkins and Meynell (1957) suggest that about one-third of patients receiving anticonvulsants develop a macrocytosis which responds to folic acid. The effectiveness of these drugs in converting these minimal haematological changes into frank megaloblastic anaemia must depend on other factors such as associated vitamin-B₁₂ deficiency (Kidd and Mollin, 1957), associated ascorbic-acid deficiency (Gydell, 1957; Kidd and Mollin, 1957), and probably the dietary intake of folic acid.

Summary

Folic-acid studies were carried out on a patient who developed a severe megaloblastic anaemia while being treated with the anticonvulsant drug primidone.

The absorption of folic acid was found to be normal.

However, by contrast with megaloblastic anaemia due to folic-acid deficiency the tissue stores of folic acid were normal.

It is concluded that the anaemia was not due to folic-acid deficiency but to interference with the tissue metabolism of folic acid.

We thank Dr. J. G. Scadding for permission to carry out these studies on his patient; Professor J. V. Dacie for his interest and advice; Dr. K. Ibbertson for carrying out an ¹⁵I-labelled fat-absorption test; and Miss B. B. Anderson for help with folic-acid assays.

Speaking at the opening of the Commonwealth Chest Conference in London on July 10, the MINISTER OF HEALTH, Mr. Derek Walker-Smith, said that the advances of recent years had brought total eradication of tuberculosis increasingly within the range of possibility. During the ten years since the start of the National Health Service, new cases of tuberculosis had fallen in England and Wales by 38% and deaths by 78%. This striking decline had brought both social and economic benefit, reflected not only in enhanced well-being of individuals but also in freeing hospital resources for the treatment of other ills. In tuberculosis more than in most diseases, continued the Minister, Government action could claim a good deal of credit. As Sir William Osler had said, tuberculosis was a social disease with medical aspects. The recent history of tuberculosis in this country illustrated the value of preventive measures. In England and Wales 27 million x-ray examinations had been carried out since the introduction of M.M.R. in 1943; and in recent years over 20% of all cases of tuberculosis had been detected by this means. Since 1949 over a million people had received B.C.G. vaccination.

TREATMENT OF BOILS WITH ERYTHROMYCIN AND WITH ANTIBIOTIC E 129

BY

ALLENE SCOTT, M.D.

Registrar, Department of Dermatology,
St. Bartholomew's Hospital, London

WITH THE TECHNICAL ASSISTANCE OF

PAMELA M. WATERWORTH, F.I.M.L.T.

The well-known propensity of strains of *Staphylococcus aureus* to develop resistance to the effects of bactericidal and bacteriostatic drugs has been a major factor in the search for newer antibiotics. E 129, one of the most recently produced of these, has already been described and tested in the laboratory (Garrod and Waterworth, 1956). The present study records the results of a clinical investigation of this alternative therapeutic agent. Its purpose was to compare the efficacy of E 129 in the treatment of a relatively "standard" clinical infection—a furuncle—with that of an established antistaphylococcal antibiotic, erythromycin, to which E 129 is related. In addition to judging therapeutic effect by clinical criteria, laboratory studies were carried out to determine the effect on the staphylococcus itself, and in particular on its sensitivity to each of the antibiotics used in treatment.

Methods

Patients were a consecutive series, 210 in all, who attended the out-patient department of St. Bartholomew's Hospital for the treatment of boils. The period of study occupied the year from February, 1957, to February, 1958. No patients under 16 were treated in this series, largely because of the difficulty presented for children by the ingestion of the large quantity of E 129 tablets (12 daily) during their treatment. The ages ranged from 16 to 67 years, with a mean of 27. There was a slight preponderance of males—3:2.

Several criteria were used to decide whether the patient was suitable for inclusion in this series: (1) the lesion must have been fresh, (2) no treatment of the patient with antibiotics in the preceding six months, and (3) no secondary space infections (such as may be seen on the hand).

Classification of Boils.—(1) Localized infection of diameter under 1 cm., and with no surrounding reaction. (2) Localized infection, larger than above, with minimal adjacent reaction. (Neither of these two groups had any systemic symptoms or signs.) (3) Local infection of diameter over 2.5 cm., with marked surrounding cellulitis, moderate regional lymphadenopathy, some tissue destruction, occasional mild fever. (4) Large area of local infection, with marked peripheral cellulitis, regional lymphadenopathy, and systemic signs—for example, fever, fatigue. The first part of the study included patients with boils of all four types, but the main series included boils of the last-named two groups only.

Therapy.—All patients received local applications of mercury perchloride, 0.1% aqueous solution. In approximate consecutive rotation, therapy was conducted in successive patients with (a) local application alone; (b) erythromycin patients with (a) local application alone; (c) E 129, 250 mg. four times daily per os for seven days; (d) E 129, 750 mg. four times daily per os for seven days. The larger dose of E 129 was decided on for three reasons: as obtainable at the time of the investigation, this substance included about one-half of the activity of the latter against *Staph. aureus*. Eleven patients on placebo therapy whose condition was deteriorating rapidly were removed from the series and given treatment as indicated.

Observations.—Swabs were taken from the boil of each patient before the beginning of therapy, and on the second, fourth, and seventh days of treatment. Further cultures were taken until the area healed. In addition a clinical assessment of each case was made on the above days until healing was complete. Further examinations were made in the third and sixth weeks after therapy.

Results

General Observations

In the treatment of boils categorized as 1 and 2 no substantial difference was noted in the results obtained with either placebo or antibiotic routines. This prompted us, therefore, to limit our further patients to those who had boils of group 3 or 4—a total of 165 patients.

A comparison of results obtained in the treatment of boils of less than four days' duration with those of longer than four days demonstrated that the latter tended to be of greater severity (22% in contrast to 12% classed as group 4), with a prolonged healing-time (30% required over two weeks), and a higher incidence both of necessary surgical drainage (22% in contrast to 9%) and of fresh outbreaks (40% in contrast to 17%). Cultures became negative over a slightly longer period.

A consideration of the mean duration of boils prior to treatment in each of the three therapeutic groups showed these values to be almost the same. Hence for the purposes of the remainder of the results the boils of varying duration are discussed together.

Comparison of the Results of Placebo and Antibiotic Therapy

The results are stated in the Table. The evolution of the boil process continued in 42% of the placebo-treated group for over four days, in contrast to the course in patients of the antibiotic group, in which only 2% were observed to progress after therapy was started. In 24% of the former group the boil was not controlled even after one week.

Comparison of the Results of the Treatment of Boils Using Placebo, Erythromycin, and E 129

	Form of Therapy Employed		
	Placebo	Erythromycin	E 129
No. of cases	55	55	55
Duration of boil (average in days)	4 (3-10)	4.2 (2-7)	4 (2-7)
Progression of boil during therapy:			
1-2 days	10 (18%)	26 (47%)	31 (56%)
3-4 "	23 (42%)	27 (50%)	23 (42%)
5-7 "	10 (18%)	2 (4%)	1 (2%)
8-21 "	12 (22%)	0	0
Duration of healing:			
4-7 days	5 (9%)	16 (29%)	24 (44%)
8-14 "	27 (50%)	29 (53%)	29 (53%)
15-21 "	9 (16%)	8 (14%)	1 (2%)
22-28 "	9 (16%)	2 (4%)	1 (2%)
29-42 "	5 (9%)	0	0
Degree of final tissue damage:			
Grade 1	10 (18%)	39 (71%)	45 (82%)
" 2	18 (32%)	13 (23%)	10 (18%)
" 3	27 (50%)	3 (6%)	0
Last positive culture:			
Within 4 days	20 (36%)	26 (47%)	29 (53%)
5-7 days	21 (36%)	16 (29%)	18 (32%)
8-14 "	10 (18%)	7 (12%)	6 (11%)
15-21 "	2 (4%)	1 (2%)	1 (2%)
Over 21 days	2 (4%)	0	0
New lesions during therapy	14 (25%)	5 (9%)	5 (9%)
" after "	5 (9%)	8 (14%)	5 (9%)
Drainage required	11 (20%)	8 (14%)	3 (6%)

Healing-time was less than a week in only 9% of the placebo group, while 25% required over three weeks for healing.

Of those having no antibiotic therapy, 50% suffered marked local necrosis, with subsequent scarring after the infection; in contrast to this only a small number of antibiotic-treated patients showed this complication.

Eventual surgical drainage of the boil area was required in 20% of the first group, while an even greater number (34%) developed fresh lesions within the observation period of six weeks. It is interesting that antibiotic therapy in the other group did not appear to influence the tendency of some patients to recurrent furunculosis.

Various systemic complications were observed in the placebo-treated group; these included fever in 36% of cases, usually lasting about three days.

Although most of the untreated boils showed only a slightly slower rate of disappearance of positive cultures, 8% of the tests still yielded a positive result even after 14 days.

Clinical Comparison of the Results of Treatment with Erythromycin and E 129

Both antibiotics showed approximately the same ability to arrest the progress of the boil—about 50% controlled within two days, and only 2% uncontrolled after four days. The development of the boil appeared to be halted slightly more rapidly with E 129.

The boils treated with E 129 healed more rapidly than those given erythromycin; 44% healed within the first week, in contrast to only 29% of those in the latter group. It can be shown, using the χ^2 test for a trend (Armitage, 1955), that the difference in rates of healing is statistically significant at the 5% level ($\chi^2=5.7$; $0.01 < P < 0.05$).

Tissue damage was not marked in either of the two groups—over 80% of the E 129 group and 72% of the erythromycin group could be placed in stage I, although three patients in the latter group did show sufficient damage to be classified as grade 3.

Surgical drainage was necessary in slightly more (8) of the erythromycin group, while the incidence of fresh lesions was about equal.

Diarrhoea associated with the presence of *Candida* in the stools followed erythromycin therapy in four patients. No such complication was observed with E 129.

Bacteriological Findings

Coagulase-positive staphylococci were found in the initial culture from 159 of the 165 patients: the few negative cultures are attributable to the fact that the lesion was sometimes still closed when the first swab was taken. Although 37 (23.3%) of these strains were resistant to penicillin and 3 (1.1%) to tetracycline, they were uniformly sensitive to both erythromycin and E 129, the respective minimum inhibitory concentrations almost invariably found, using the method of Garrod and Waterworth (1956), being 0.12 and 0.25 $\mu\text{g./ml.}$: no strain differed from this figure by more than one (doubled) dilution.

Negative cultures were obtained after about the same time in both groups—within four days in 47% of the erythromycin group and 53% of the E 129 group. All strains of coagulase-positive staphylococci recovered from the original boil after the seven-days period of treatment (8 in the erythromycin group and 7 in the E 129), and those from fresh lesions developing during or after treatment (13 and 10 respectively) were retested and found to have undergone no change in sensitivity to either antibiotic.

Discussion

The apparent lack of effect that antibiotics had on less severe boils is in keeping with our knowledge of the adequacy of the body's natural defences against such infections. In the treatment of more severe infections it is clear that the use of antibiotics promotes more rapid recovery with fewer sequelae such as post-necrotic scarring, although the better results appear to depend not so much on the rapid elimination of the infecting organisms as on limitation of their destructive activity.

By each of the criteria used the effect of E 129 was slightly superior to that of erythromycin, and by one of these—the rate of healing—the difference has a statistical significance. Against this advantage has to be set the fact that a larger dose of E 129 was given. Reasons for adopt-

ing this dose have been stated, and, allowing for the impurity of the E 129 and its less complete absorption, the effective doses of the two antibiotics must have been approximately equivalent. It would be unwise, however, to base any final conclusion about the relative merits of these two antibiotics on these findings.

It was thought possible that a difference between them might be found in another direction. Staphylococci acquire resistance to erythromycin rather readily and to E 129 less so (Garrod and Waterworth, 1956). It has been a common practice to restrict the use of erythromycin severely for fear of breeding resistant strains, and it would not have been surprising if in some of these patients with persisting or recurrent infections increased resistance to the antibiotic had been found. In fact, no instance of increased bacterial resistance to either antibiotic was seen in the whole series. Whether this is to be credited to strict limitation of the treatment to seven days, or whether the nature of the lesion is unfavourable to change in bacterial resistance, is uncertain. It is nevertheless encouraging to know that this form of staphylococcal infection can be treated in this way apparently without serious risk of producing such a change.

Summary

Patients with severe boils were treated with erythromycin (1 g. daily) and E 129 (3 g. daily) each for one week, or by the local application of mercury perchloride only. There were 55 patients in each group.

As judged by each of four criteria, patients in both antibiotic-treated groups recovered more rapidly and more satisfactorily than the controls. Slight differences between the treated groups were in favour of E 129.

All strains of staphylococci found in these patients were normally sensitive to both antibiotics, and none cultivated again after seven days' treatment had acquired resistance to either of them.

The advice of Dr. R. M. B. MacKenna and Professor L. P. Garrod on the clinical and bacteriological aspects respectively of this work is gratefully acknowledged. Mr. M. P. Curwen kindly made the statistical calculation referred to in "Results." Antibiotic E 129 was kindly supplied by Glaxo Laboratories Limited.

EFFECT OF ABDOMINAL OPERATIONS ON TOTAL LUNG CAPACITY AND ITS SUBDIVISIONS

BY

ANTHONY R. ANSCOMBE, M.S., F.R.C.S.
Senior Lecturer, Surgical Unit, St. George's Hospital,
London

AND

ROGER ST. J. BUXTON, M.B., B.S., D.C.H.
Department of Physiology, King's College Hospital,
London

Although serious pulmonary complications of an inflammatory nature are becoming less frequent after abdominal operations, atelectasis and bronchitis still occur. One of the main factors is the interference with the mechanical efficiency of the lungs. The effect of laparotomy on vital capacity has been extensively studied (Churchill and McNeil, 1927; Powers, 1928; Overholt, 1930; Anscombe, 1957) and reductions of up to 80% of the pre-operative figure may occur after an upper abdominal operation.

Other effects on pulmonary function have not been examined in such detail. Beecher (1933) measured the

total lung capacity and its subdivisions in 35 patients before and after abdominal operations. He found that reductions occurred in the total lung capacity and functional residual capacity. As the decreases in the vital capacity may be due to the effect of the operative trauma on the efficiency of the respiratory musculature, he argued that the total lung capacity and vital capacity readings were not indications of the "real state" of the lungs. The functional residual capacity, which did not depend on the voluntary efforts of the patient, was a better guide, and Beecher found that this was reduced to 20%.

More accurate methods are now available for the measurement of the gas volume of the lungs, and it was thought that a further investigation would be of interest. In this series a modification (Buxton and D'Silva, 1956) was used of the helium dilution described by Bates and Christie (1950).

Procedure

A total of 26 male patients comprising three groups was investigated, the same procedure being adopted in each group. Group I consisted of 10 patients admitted to medical and surgical wards, none of whom suffered from conditions likely to affect the respiratory system in any way or who underwent any operation during the period of study. The selection of those patients depended upon their availability for the investigation, and they serve as a control group. Group II consisted of 13 patients upon whom abdominal operations were performed. The operations consisted of seven inguinal herniorrhaphies and six upper abdominal operations (five partial gastrectomies and one cholecystectomy). Group III contained three patients only, and in each case an operation of similar severity was performed upon an extremity.

Two measurements were made on each patient. In groups II and III the first measurement was made within the 24 hours preceding the operation, the second within the first 48 hours post-operatively, depending upon the general condition and availability for study of the patient. In the control group two measurements were made within a period of 48 hours. The surgical patients were ambulant before operation, and then confined to bed in the period between the two measurements. As it has been shown that recumbency reduces the residual capacity (Whitfield, Waterhouse, and Arnott, 1950) the same regime was followed so far as was possible in the control group, and all measurements were made with the patients in this position.

The patients were brought by wheel-chair or in their beds to the apparatus, which was housed in an adjacent side ward. They then assumed the recumbent position, and after a brief explanation the mouth-piece was inserted and the nose clipped. The patient then breathed oxygen for 10 minutes in order to replace the nitrogen of the functional residual capacity. This period also allowed the state of the pulmonary circulation to become stabilized. At the end of a normal expiration the patient was admitted to the circuit, which contained pure oxygen and about 10% helium. The fall in helium concentration was followed on a katharometer until no further change was apparent.

Finally, two measurements of the vital capacity were made, and the results calculated and corrected to 37° C. at saturated water-vapour pressure. Assessment of the findings was made by use of the analysis of variance, or Student's *t* test.

Results

The first or pre-operative examination values for groups I and II were studied. The difference between the means of the subdivisions of the total lung capacity was not significant, but the total lung capacity showed a significant difference ($P=0.02$) (columns a and c, Table I). The changes in the three groups are shown in Fig. 1.

TABLE I.—Total Lung Capacity and its Subdivisions (in litres) in Control Group and Patients with an Abdominal Incision

	Group I (Control)			Group II (Abdominal)			
	a	b	Dif.	c	d	Dif.	
Functional residual capacity	3.3	3.4	0.1	3.8	3.2	0.6	0.05 > P > 0.02

a and b represent the observed values in Group I at the first and second measurements, while c and d were the figures noted before and after operation in group II.

It was found (Table I) that a small difference occurred between the first and second measurements in group I, depending on the reproducibility of the method, but that the corresponding pre-operative and post-operative figures in group II were grossly different. When these changes were investigated further, significant reductions were found to have occurred after laparotomy in the functional residual capacity, inspiratory capacity, expiratory reserve volume, vital capacity, and total lung capacity. This reduction was mainly due to a decrease in the vital capacity, although the functional residual capacity was reduced to a less extent.

The post-operative results in the three patients of group III showed no significant change compared with the pre-operative measurements (Table II). This is in accordance

FIG. 2

FIG. 3

By subdividing group II into those patients with inguinal herniorrhaphies and those with upper abdominal operations, the effect of the site of operation on these changes was studied (Table III and Fig. 2). The difference between the observations in these groups was significant only for the vital capacity ($0.05 > P > 0.02$) and the total lung capacity ($0.05 > P > 0.02$). This finding emphasizes further the importance of the decrease in vital capacity in reducing the total lung capacity and also stresses the fact that upper abdominal procedures cause a greater reduction than those of the lower abdomen. The findings in the subject who underwent cholecystectomy are illustrated in Fig. 3.

Discussion

A significant reduction in total lung capacity after laparotomy could be due to closure of part of the bronchial tree, to interference with the normal function of the muscles of respiration, or to a combination of these factors.

The bronchial tree may become obstructed actively by bronchospasm or passively by blockage with mucus or inflammatory exudate. The upper abdominal cases in group II showed an average reduction in total lung capacity of 2.4 litres. Passive obstruction of the air passages leading to atelectasis of this degree should be demonstrable on clinical and radiological examination, but there was no evidence to support this. In the present study, 0.25 g. of aminophylline was given intravenously to two patients before and after partial gastrectomy. No significant change was noticed pre-operatively or post-operatively in the total lung capacity and its subdivisions. It is likely that if any bronchospasm had been present after operation the exhibition of a bronchodilator would have caused some increase in at least one component of the total lung capacity.

Electromyographic studies (Campbell, 1952) have shown that the muscles of the anterior abdominal wall play no part in quiet breathing when the subject is lying supine. They do assist in the terminal portion of forced expiration, and their contraction is a limiting factor in maximal voluntary inspiration. We have confirmed with records from the rectus abdominis that no activity occurs during respiration at rest. But if the subject adopts a sitting posture or is inclined on a bed in such a way that his abdominal musculature is participating in maintaining his posture, then the recti will be involved more in expiration than in inspiration. Where respiration is forced against resistance then all the abdominal muscles are used in both phases of breathing. After laparotomy the potentials recorded were reduced, and this finding was more marked in those patients recovering from an upper abdominal operation.

Dysfunction of the muscles of the anterior abdominal wall may occur after operation as a reflex secondary to peritoneal inflammation or may be due to the local trauma of an incision. When the results obtained from patients after an abdominal operation (group II) are examined, reductions are seen to have occurred in both the inspiratory and the expiratory components. Impairment of the muscular power available to complete forced expiration will reduce the expiratory reserve volume. But the reduction in the vital capacity (mean 1.2 litres) was due mainly to a reduction of the inspiratory capacity (mean 0.9 litres). This is presumably due to the abnormal contraction of the abdominal muscles acting as a limit to the depth of maximum inspiration.

Those patients who had emphysema presented figures which followed the same general pattern as those not so affected, but the mean reduction in five emphysematous cases as compared with five without chest disease was 0.88 and 1.6 litres for the vital capacity, 0.5 and 1.3 litres for the inspiratory capacity, and 0.8 litre in both sets for the functional residual capacity.

Thus it appears that an abdominal operation, especially one in the upper abdomen, is followed by a reduction in the subdivisions of the lung volume, and that similar changes occur post-operatively in subjects with evidence of pre-existing lung disease. This effect occurring in a patient

whose lung function is already impaired is more likely to cause respiratory insufficiency in the immediate post-operative period. It is suggested that any such patient should have the pulmonary function assessed before operation so that measures may be taken to combat any post-operative anoxia which may arise.

Summary

Measurements of the total lung capacity and its subdivisions were made on 26 male patients.

Significant reductions occurred in the total lung capacity, inspiratory capacity, expiratory reserve volume, vital capacity, and functional residual capacity after abdominal operations, and these changes were more marked after those on the upper abdomen.

Possible causes of these changes are briefly considered.

We thank Professor J. L. D'Silva for much helpful advice and criticism, and the surgical staff of the London Hospital for permission to study their patients. Figs. 1-3 are from *The Pulmonary Complications of Abdominal Surgery* by one of us (A. R. A.), and are printed by permission of Lloyd-Luke, London. This work was done during the tenure of one of us (R. St. J. B.) of a postgraduate Research Fellowship.

OPEN HEALING OF TUBERCULOUS CAVITIES

RESULTS IN 40 PATIENTS TREATED CONSERVATIVELY

BY

Baguley Hospital, Manchester

With the development of rational chemotherapy the phenomenon of open-cavity healing in pulmonary tuberculosis is becoming increasingly evident. From the extensive literature on the subject a few observations are summarized.

Auerbach and Small (1957) state: "For practical purposes it is the opinion of the writers that those cases should be accepted as open healing in which the lumen of the cavity is free of necrotic contents, the inner aspect contains no pyogenic membrane or necrotic lining, and the cavity wall contains no necrotic foci." The same writers comment that, although open healed cavities often appear cystic, the radiological appearances are deceptive in that a thin-walled cavity may present evidence of active disease and a thick-walled cavity may be healed. They believe that open-cavity healing is less common than might be supposed and point out that, despite the absence of tubercle bacilli from the sputum for many months, a resected cavity may show the

presence of a necrotic lining. They admit, however, the increasing frequency of open healing after long-term chemotherapy and suggest that where the sputum has been negative for tubercle bacilli for more than seven months four out of five cyst-like cavities prove to be instances of open healing. In their experience isoniazid has not significantly increased the incidence of healing.

Corpe and Stergus (1957), on the other hand, believe that isoniazid is of great importance in this connexion. In their cases open healing was observed to occur most often when a triple-drug regime of streptomycin, P.A.S., and isoniazid had been used. They are not sanguine about the conservative management of such cavities, and state: "The possibilities of rupture, suppuration, haemorrhage, and reactivation of tuberculosis are well recognized. Accordingly, it is believed that when these openly healed or healing cavities are unilateral, or bilateral, they should be excised if the patient is otherwise fit for surgery." A similar opinion has been expressed by Chenebault (1954). Caffey (1950) explains the pathogenesis of pulmonary cysts during respiratory infections. Such cysts may develop during the course of treatment and may be indistinguishable radiologically from thin-walled cavities. Auerbach (1955) states: "After chemotherapy such healed cavities may be mistaken for lung cysts or emphysematous blebs. It is believed that such areas may be accepted as open healed cavities if they occupy the site of a cavity visualized in the roentgenograms, if bronchi communicate with them and if they do not surround an inspissated cavity or radial scar."

Most papers on the subject are concerned with the pathological findings in resection specimens. Little is known of the fate of patients who continue to receive drug therapy alone without resection therapy after they have achieved presumptive open healing of tuberculous cavities. Douglas and Horne (1956) have reported on six such patients. Corpe and Stergus (1957) indicate that they are in the process of making such a study. Raleigh and his co-workers (Raleigh 1957; Bell, Decker, and Raleigh, 1957) have reported unfavourably on the conservative treatment of patients in this category.

This paper records our own experience with indefinitely prolonged chemotherapy in 40 cases of advanced pulmonary tuberculosis with persistent cavitation. The cases recorded are the most grossly diseased of a large series of patients treated by prolonged chemotherapy in this unit over the past five years. They have been observed for periods ranging from one and a half to five years. The distribution of the patients is shown in Table I. Twenty-nine patients have been observed for more than two years and 17 for more than three years.

Methods and Materials

By virtue of age, advanced disease, or poor respiratory function 37 of the patients were judged unsuitable for surgical treatment. A further three refused surgery. All were sputum-positive at the beginning of the study, the finding of a positive culture for *Mycobacterium tuberculosis* being considered obligatory to their inclusion in the

series. Thirty-five had received no previous treatment and five had had previous chemotherapy with drug combinations considered unlikely to produce drug-resistant organisms. In every case the organisms were fully sensitive to streptomycin, P.A.S., and isoniazid, as judged by the standard M.R.C. techniques. Cavitation, the total diameter of which was not less than 5 cm., was present in every case.

All were treated in hospital for periods ranging between 4 and 35 months, the average duration of stay being 14 months.

Thirty-two of the patients received a triple-drug regimen for at least the first year of treatment—streptomycin (usually streptoduoicin), 1 g. daily, intramuscularly with P.A.S. (sodium salt), 10 g. daily, and isoniazid, 0.2 g. daily, by mouth in two divided doses. Triple-drug therapy was thereafter continued until resumption of employment or other circumstances made it difficult to arrange the administration of streptomycin. Eight patients received varying drug combinations for reasons stated in Table II. Particular care was taken to "sell" long-term chemotherapy to each patient. At each visit to the chest clinic patients were questioned in detail about the drugs they were taking;

10 PH=P.A.S. 10 g. daily, isoniazid 0.2 g. daily.

they were invited to discuss any difficulties they might have with chemotherapy, and were repeatedly encouraged and advised about the security afforded by careful adherence to the prescribed regimen. All of the patients, except one, continue to take antituberculosis drugs. This individual (Case 4) passed to the care of another physician, who stopped the drugs after 30 months' continuous chemotherapy. In hospital chest x-ray films were taken every six weeks; out-patients were x-rayed at intervals of not more than three months. Tomograms were taken roughly at the end of each year of treatment. (In any instance where the persistence of cavitation was uncertain, tomograms have been taken during the past two months. In this connexion it should be recorded that there were originally 60 patients in the series, of whom 20 were discarded because of failure to demonstrate beyond any doubt the persistence of cavitation. No patient was withdrawn from the series for any other reason.)

The sputum of in-patients was examined each month by smear and culture, and sensitivity tests were carried out on all positive cultures. For out-patients the sputum was similarly examined on three consecutive days each three months. At the end of each year of treatment all antituberculous drugs were withheld for a period of four weeks. During the fourth week daily specimens of sputum, or a series of laryngeal swabs, were obtained.

Results

A detailed list of patients is given in Table III. All showed marked clinical and radiological improvement, which usually continued into the second or third year of treatment. Tomograms taken during the second and third years of treatment showed marked resolution of disease: in all instances the appearances did not suggest the persistence of large residual necrotic foci. Multiple cavities persisted in 28 patients; the remainder had solitary residual cavities. Twenty-five patients had thin-walled cyst-like

cavities; in 12 the residual cavities were apparently thick-walled; and in 3 both varieties persisted.

The rate of sputum conversion is indicated in Table IV. In most instances this was rapid, 37 patients becoming sputum-negative within six months. Of the remainder, two

Average time for sputum conversion, 2.7 months.

became negative during the seventh and ninth months respectively. The last patient remained intermittently positive for 15 months. In this patient (Case 2) the last positive culture was obtained two months after the start of treatment. During the ensuing 13 months the sputum was positive on direct smear on four occasions, but no growth was obtained on culture. One patient (Case 9) produced a solitary positive sputum culture during the third year of observation. The organisms cultured were fully sensitive to streptomycin and P.A.S. and partially resistant to isoniazid. Eight subsequent examinations were negative. The remaining 39 cases remained consistently sputum-negative after conversion.

Apart from the instances listed in Table II, prolonged chemotherapy presented few problems. Two patients became allergic to streptomycin, the first (Case 30) after one year's treatment and the second (Case 11) after two years' continuous therapy. Table V shows that the majority were fit enough to return to work. With two exceptions the patients remained well during the period of observation. During the fourth month of treatment Case 29 developed

multiple tension cysts, which subsided spontaneously (Figs. 1, 2, and 3). During the fourth year of treatment Case 2 developed repeated episodes of secondary infection in a cavitated right upper lobe. (This patient has deteriorated both clinically and radiologically, and has developed hypertrophic osteoarthropathy. Right upper lobe resection is being arranged.)

Discussion

The results of treatment in this incomplete investigation, although inconclusive, are none the less gratifying. They do not support Raleigh's (1957) adverse findings: this, however, is not surprising, as his patients received insufficient chemotherapy for his observations to be valid. It is clear that with adequate chemotherapy even the most

FIG. 2.—Case 29. Radiograph, showing multiple tension cysts, taken at four months of treatment.

FIG. 1.—Case 29. Radiograph taken before treatment.

FIG. 3.—Case 29. Radiograph showing spontaneous subsidence of cysts.

extensive disease can be controlled and rendered non-infectious. The findings support the claim of Corpe and Stergus (1957) that a triple-drug regimen of streptomycin, P.A.S., and isoniazid is the most effective drug combination in present use. There is as yet no statistical proof of this contention, but it is perhaps significant that the results obtained in the present series, using daily streptomycin, P.A.S., and isoniazid, are superior to those reported where only two drugs were used in combination. This aspect will be discussed in a subsequent communication. The fact that little difficulty was encountered with long-term chemotherapy is probably due to a number of factors. Firstly, the patients were well indoctrinated while in hospital. Secondly, they have remained under the care of the same medical attendants throughout their treatment. Thirdly, throughout their treatment the patients have been constantly reminded of the necessity to take the drugs prescribed. Lastly, but by no means least, general practitioners have co-operated admirably in the supervision of chemotherapy.

Two striking features in the patients observed have been the rapid disappearance of tubercle bacilli from the sputum and the degree of resolution of pulmonary disease as judged radiologically by the apparent absence of large residual necrotic foci. The findings suggest that, where prompt sputum conversion is associated with considerable resolution of disease with apparent absence of large residual necrotic foci, the persistence of pulmonary cavitation need not present an indication for surgical treatment provided adequate chemotherapy has been employed from the beginning of treatment, accompanied by careful bacteriological control.

How long should chemotherapy be maintained? This problem remains unsolved. The available evidence suggests that two years is the minimum effective period. Our experience of chemotherapy is of not less than three years' duration. In view of the advanced disease of the cases in this series it has been decided to administer drugs for a minimum period of five years. Since secondary infection occurring in only one patient is the only serious complication that has been encountered here, the reported hazards in persistent cavitation of rupture, suppuration, haemorrhage, and reactivation of tuberculosis must be accepted with some reserve. At the same time it must be stressed that the patients have been followed up for only a short period. There is plenty of time for the development of late complications.

Summary

The phenomenon of open healing of tuberculous pulmonary cavities is briefly described.

A study is presented of 40 patients with advanced pulmonary tuberculosis treated by means of prolonged chemotherapy who remained sputum-negative despite the persistence of cavitation. The patients were followed up for periods ranging from one and a half to five years.

Success of the treatment is attributed to the use of a triple-drug regimen of daily streptomycin, P.A.S., and isoniazid. In certain cases the persistence of pulmonary cavitation need not necessitate surgical treatment.

Secondary infection in a cavitated lobe in one patient was the only late complication observed.

We are grateful to Dr. K. V. Lodge, and to her staff in the department of pathology at Baguley Hospital, for carrying out the bacteriological investigations of the patients in this series.

DISTURBED CHRONIC PSYCHOTIC PATIENTS: PILOT TRIAL OF "STELAZINE"

BY

M. E. FORRESTER, M.B., D.C.H., D.P.M.

Assistant Psychiatrist, Park Prewett Hospital, Basingstoke, Hants

In the search for a more efficacious drug with which to treat long-stay psychotic patients in hospital, "stelazine" (SKK5019; trifluoroperazine) was given a trial. In the U.S.A. it had been described as having nine times the potency of chlorpromazine in blocking conditioned response. Its specificity was also stated to be greater than that of chlorpromazine. Jaundice had not been seen, but extrapyramidal signs and symptoms as in Parkinsonism had been described. Other side-effects noted included rashes, dizziness, drowsiness, lactation, lacrimation, and, on occasion, anxiety.

Method

Twenty-five female chronic psychotic patients who were extremely disturbed in behaviour unless treated with tranquillizing drugs or E.C.T. were chosen. All except three voluntary patients were detained under certificate. The duration of illness ranged from 5 to 31 years, and the average length of stay in hospital was 13 years. Twenty-three were chronic schizophrenics, of whom eight had been leucotomized, and two were oligophrenics with psychosis. In the past, 10 had had deep I.S.T. and 24 E.C.T. more recently.

All other treatment was suspended during the trial. The dosage of stelazine was built up gradually over a period of two weeks to 30 mg. daily, and in one case to 40 mg. and in another to 45 mg. daily. Treatment lasted four weeks, and the dosage was reduced gradually in discontinuing the drug.

Benzhexol hydrochloride, 6-8 mg. daily, was used to counteract side-effects.

Side-effects (see Table).—These were pronounced and consisted chiefly of the Parkinsonian syndrome. Only seven patients did not seem to suffer from this, but one of them complained of feeling unsteady. Benzhexol was effective in decreasing the salivation but had little effect on tremor. On one occasion a patient had a pyrexia of 101° F. (38.3° C.) which persisted at 99° F. (37.2° C.) for several days until the dose was reduced. Twelve patients needed to be nursed in bed and five required feeding and full nursing attention. These patients were a constant source of worry to the nursing staff in preventing them falling out of bed or otherwise hurting themselves by their restlessness. After discontinuance of the drug these effects were apparent for more than a week, although subsiding gradually.

	Side-effects	No. of Patients
Masklike facies	..	6
Tremor	..	12
Salivation	..	7
Rigidity	..	7
Flushing	..	3
Pallor	..	2
Restlessness	..	13
Nursed in bed	..	12
Needed feeding and full nursing attention	..	5

Loss of weight was noted in 18 cases. One patient had lost 14 lb. (6.4 kg.) (as she was obese, this was acceptable) and two patients lost 7 lb. (3.2 kg.). Seven patients had gained moderately.

The changes in behaviour were: very slightly improved, 6; no change, 10; worse, 6; and much worse, 3.

The improvement that occurred in six cases was marred by side-effects in all but two. The little progress made could have been obtained by other means without such untoward

effects. Two patients were reported as being more coherent in asking for their needs. On investigation it was found that they felt so ill that they clamoured for the doctor and, although previously mute, asked to have the bedclothes removed: it is doubtful whether this can be looked upon as real improvement.

The nine patients who were worse required so much attention that the routine of the ward was disorganized. One became so violent that she needed to be secluded. One of the oligophrenics began to bite and fight. She had a tendency to behaviour of this type but had been controlled on chlorpromazine. The other oligophrenic was extremely nervy and agitated. Two patients were too restless to work, another became depressed, and one was continually stripping herself and her bed. Others were restless and shouting, and one threw the chairs she dusted about and broke them.

Those who showed no marked change were worried in three cases by the side-effects.

Summary and Conclusions

A short pilot trial of the drug stelazine was undertaken with 25 chronic psychotic patients. Marked side-effects, chiefly of the Parkinson type, were apparent. To these benzhexol hydrochloride gave partial relief.

With the dosage used, the side-effects of stelazine were so marked and unpleasant that it is doubtful whether the drug would be acceptable for routine use. In some cases the adverse effect on behaviour has been such that its reliability is in question. Higher dosage is unlikely to be helpful in view of the side-effects already encountered. In view of the lag of time between stopping the drug and the subsidence of side-effects, it would appear that the drug is cumulative in the body. The amount of improvement in a few cases was not sufficient to encourage further use of the drug.

I thank Messrs. Smith Kline and French Ltd. for the supply of stelazine; Dr. I. Atkin, physician-superintendent of Park Prewett Hospital, for his encouragement and advice; and the nursing staff of C ward for unfailing help in this work.

PROGNOSIS OF CEREBRAL EMBOLISM IN RHEUMATIC HEART DISEASE

BY

G. KEEN, M.B., F.R.C.S.

Surgical Registrar

AND

V. M. LEVEAUX, M.D., M.R.C.P.

Research Assistant to the Cardiac Department, Westminster Hospital, London

Cerebral embolism is a well-recognized complication of rheumatic heart disease. Wood (1954) reported an incidence of 13% of systemic embolism in 300 cases of mitral stenosis, and the site of the embolism was cerebral in three-quarters of these. Of 150 patients undergoing mitral valvotomy (Sellors *et al.*, 1953), five suffered a cerebral embolism; two died within 12 hours, two remained permanently hemiplegic, and one recovered.

Brain (1955) considered that cerebral embolism, as such, was rarely a fatal condition unless the embolus lodged in the internal carotid artery. Harris and Levine (1941), however, reported that one-third of 72 patients with mitral stenosis complicated by cerebral embolism died within a few days or weeks of the latter. Daley *et al.* (1951) found that 49% of 130 patients with rheu-

matic heart disease suffered from cerebral embolism. They concluded that the mortality of this complication was high, and that the residual disability was often severe and crippling in those who survived.

Present Investigation

The present investigation is concerned with the prognosis of cerebral embolism in rheumatic heart disease, and is based on records of patients under the care of members of the consultant staff of Westminster Hospital.

Of a total of 172 patients with rheumatic heart disease, 34 (20%) have been accepted as having shown evidence of cerebral embolism or having a convincing history of this complication. One of these embolic cases has eluded follow-up, and the detailed analysis is of the remaining 33 patients, in whom 39 embolic episodes were recorded.

Of these 33 cases, 28 had dominant mitral stenosis, 1 dominant mitral incompetence, and 4 an admixture of stenosis and incompetence. Aortic valve disease occurred in 8 cases. At the time of the first embolus atrial fibrillation was present in 29 cases, the remaining 4 being in normal rhythm. There were 27 females and 6 males, with ages ranging from 18 to 66 years, average 42.3 years. No attempt has been made to assess the relationship between mitral valvotomy and cerebral embolism. For completeness, however, it is recorded that only three embolic episodes occurred after valvotomy—two immediately and one six hours later. These survived and were followed up for seven months, nine months, and four and a quarter years. Eleven cases coming to valvotomy had had previous cerebral emboli, but none of these had subsequent embolic episodes.

The details of the analysis are as follows:

Main disabilities resulting from 39 embolic episodes: hemiparesis: mild 8 (4 right, 4 left), moderate 16 (11 right, 5 left), severe 10 (3 right, 7 left); aphasia accompanied right hemiparesis in 14, and left hemiparesis in 3. Atypical episodes: (1) dysarthria with euphoria, (2) brief unconscious attack followed by numbness of left arm, (3) transient dysphasia, (4) nominal aphasia, (5) faintness. In addition, hemi-anaesthesia was noted in two cases and hemianopsia in one.

The probable site of embolism in 34 episodes was left hemisphere in 18 and right hemisphere in 16.

The degree of recovery in 39 episodes was: full or almost full in 26, moderate in 6, and slight or nil in 2; and 5 patients died within one month (1 was a case of malignant melanoma).

The time interval to the commencement of recovery in 22 episodes ranged from 0 to 21 days, average 5.5 days. Six further cases were noted to begin recovery within "a few" days or weeks.

The time interval to maximum recovery in 23 episodes was: up to 1 week in 8, 1-6 weeks in 6, 6-12 weeks in 2, 3-6 months in 2, 6 months to 1 year in 4, and 1-2 years in 1; the average was 130 days.

The duration of the follow-up from the first embolic episode is shown in the Table.

Duration of Follow-up in 33 Cases from First Embolic Episode

Time:	Up to 2 w.	2 w. to 3 m.	3 m. to 1 yr.	1-2 Yr.	2-3 Yr.	3-4 Yr.	4-5 Yr.	5-6 Yr.	6-7 Yr.	7-8 Yr.	8-9 Yr.	9-10 Yr.	10-11 Yr.	11-12 Yr.	17 Yr.
Total No. ...	4	1	6	4	3	4	3	1	2	1	0	2	0	1	1
No. followed to death	4	1	1	1	1	1	0	0	0	0	0	0	0	0	0

Average duration of follow-up, 3.8 years.

Discussion

In this series of 172 cases of rheumatic heart disease cerebral embolism complications occurred in 34, the right and left cerebral hemispheres being involved with almost equal frequency. Hemiparesis was the major resultant disability, being severe in 10 episodes, moderate in 16, and mild in 6. Aphasia accompanied right hemiparesis in 14 episodes and left hemiparesis in 3.

Recovery was full, or almost so, in 26 of 39 episodes (67%), moderate in 6, and slight or nil in 2 patients followed up for 10 and 12 years respectively. Four patients died within two weeks of a single embolism. One patient who had made a complete recovery from two previous embolic episodes occurring within a short time died nearly two years later, within a month of her third embolism, and had also malignant melanomatosis. Four other cases followed to their death survived nearly four years, two and a half years, eight months, and three months respectively after their embolus. Clinical recovery commonly began immediately after the embolism, or could be delayed for as long as three weeks. On the average improvement began by the end of the first week.

Maximum recovery was achieved by some patients within hours or days, but progressive improvement was observed to occur in individual cases for a year or more. In the average case maximum recovery was reached after a period of four months. Although no cases of associated epilepsy such as those described by Baker and Finnegan (1957) occurred in this series, they might occur if observation were continued over a longer period.

Summary

Cerebral embolism occurred in 34 out of 172 patients (20%) with rheumatic heart disease.

Thirty-three cases are analysed, with the following results: (1) less than one-fifth died within three months; (2) two-thirds of the patients made a virtually full clinical recovery; (3) the average time to the beginning of recovery was one week, and to maximum recovery four months.

The hopeful outlook for patients with this complication of rheumatic heart disease as regards neurological recovery is stressed.

We thank Sir Clement Price Thomas and Dr. C. J. Gavey for their encouragement and criticism of this investigation, and the members of the staff of Westminster Hospital whose cases we have studied.

Medical Memorandum

Acute Haemolysis Following P.A.S.

A woman aged 24 was admitted to the National Iranian Oil Company Hospital, Abadan, on October 6, 1957. For the previous five months she had been an in-patient in an isolation hospital on account of sputum-positive bilateral pulmonary tuberculosis. There was infiltration in the right upper zone and the left upper and middle zones. On the left side there was also marked fibrosis, and several large cavities could be seen. During the five months of treatment the sputum had remained positive, acid-fast bacilli being found on August 11 and October 3. The haemoglobin on August 11 was 14.6 g./100 ml. (95%).

Treatment had consisted of streptomycin and isoniazid only, but on the morning of October 4 she had been given 6 g. of P.A.S. in solution by mouth. An hour or two later she felt weak, experienced epigastric pain, and vomited. She had a sense of suffocation and was restless. No further P.A.S. was given. Her condition remained about the same for the next 24 hours, and on the morning of October 6 she again vomited and noticed that her urine was reddish in colour.

On admission to the general hospital she was restless, was sweating profusely, and was so weak that she was unable to sit up in bed. Her temperature was 99.6° F. (37.5° C.), pulse 100 a minute and weak, and B.P. 70/0. She was extremely pale and there was marked icterus of the skin and conjunctivae. The liver and spleen were not palpable, but the uterus was enlarged to the size of a 20-weeks pregnancy. The urine was reddish in colour and contained a large amount of albumin, many casts, and a few pus cells and red cells. The test for occult blood was strongly positive, but no bile could be detected. The haemoglobin was 3.7 g./100 ml. (24%), colour index 0.8, and W.B.C. 22,000/c.mm.; the bleeding, clotting, and prothrombin times were normal. There were 6 normoblasts per 100 leucocytes and the blood group was O.

She was immediately transfused with 2 pints (1,140 ml.) of group O blood. The next day the urine contained a large quantity of albumin, red cells, and pus cells, and on October 8 the haemoglobin was 5.3 g./100 ml. (34%), while the urine was free of albumin. The jaundice faded rapidly, and on October 10, four days after admission, the serum bilirubin was 0.3 mg./100 ml. On October 12 the haemoglobin was 6.3 g./100 ml. (40%) and reticulocytes 4%.

"Imferon," 100 mg. by intramuscular injection daily, was started on October 14, and during the next five weeks the haemoglobin rose to 11 g./100 ml. (70%), her general condition improved greatly, she gained 6 lb. (2.7 kg.) in weight, and she felt foetal movements for the first time. From admission until this time no chemotherapy had been given at all.

In view of the fact that the sputum had remained positive for acid-fast bacilli during the whole of the treatment with streptomycin and isoniazid, it was thought desirable to give her P.A.S., and it was decided to attempt to desensitize her. This was started on November 16 with 1/100 g. by mouth. Thereafter the daily single dose was doubled and the haemoglobin estimation carried out each day. After eight days the dose was 1 g., and during the following six days this was raised to 3 g. six-hourly, during which time the haemoglobin rose to 12 g./100 ml. (76%). At the beginning of the course of P.A.S. the sputum was still positive for acid-fast bacilli.

COMMENT

It would appear that an acute haemolysis began an hour or two after a single dose of 6 g. of P.A.S. given orally for the first time. This was so severe that it reduced the haemoglobin to 3.7 g./100 ml. (24%) during the next 48 hours. The fact that the serum bilirubin was normal four days later suggests that the haemolysis stopped as abruptly as it had begun. Immediate treatment with 2 pints (1,140 ml.) of blood followed by imferon, 100 mg. daily, raised the haemoglobin to 12 g./100 ml. (76%) over the next six weeks, during which time there was no evidence of further haemolysis. By starting with a very small dose of P.A.S. it was possible to raise this to 12 g. a day without any ill effects.

It remains to be seen whether P.A.S. will be any more effective than streptomycin and isoniazid in rendering the sputum negative for acid-fast bacilli. It is interesting that the foetus survived the period of extremely low haemoglobin level.

I thank Dr. M. Rouhani, principal medical officer, N.I.O.C., Abadan, for permission to publish this report.

H. A. K. ROWLAND, D.M., M.R.C.P.Ed., D.T.M.&H.,
 National Iranian Oil Company Hospital, Abadan, Iran.

At the leprosy research centre attached to the Vellore Christian Medical College and Hospital in South India, a team of workers is engaged in the rehabilitation of those cured of leprosy. Their most striking success has been in the reconstructive surgery of claw hands. Mr. PAUL BRAND, F.R.C.S., director of orthopaedics to the Mission to Lepers, described this work at a recent meeting in London of the Friends of Vellore.

Reviews

SIR CHARLES BELL

Sir Charles Bell: His Life and Times. By Sir Gordon Gordon-Taylor, K.B.E., C.B., F.R.C.S., and E. W. Walls, M.D., Ch.B., B.Sc., F.R.S.(Ed.) (Pp. 288+xi; illustrated. 42s.) Edinburgh and London: E. and S. Livingstone Ltd. 1958.

Jeffery, in writing to Horner in 1804, commented: "All the world migrates towards London." He was referring to Charles Bell, who was then moving from Edinburgh to London, where, after much hard work and worry, he won great fame but only a moderate fortune. It is altogether fitting that the life of Charles Bell should be written by an equally famous migrant from the North—Sir Gordon Gordon-Taylor—who himself came to London almost exactly a century later and became, and still is, the beloved surgical doyen of the metropolis. Sir Gordon has been fortunate in obtaining the collaboration of his colleague—Professor E. W. Walls—to assist in the task, which must indeed have been a labour of love. They have written a delightful story of Bell's hard struggle in London, his final success, and his late return to his native Edinburgh. In addition they have painted a wonderful picture of the contemporary life in the London of that period. We get interesting glimpses of the origins of London University and of Middlesex Hospital Medical School; we are told the story of the Great Windmill Street School of Anatomy; and we are taken to the field of Waterloo, whither Bell went to assist in the treatment of the wounded after the battle. There is also a long and equitable discussion of the controversy between Bell and Magendie as to the relative parts they took in the discovery of the functions of the nerve roots. Then comes an appendix of 100 pages in which 21 different subjects are considered. This section is full of fascination from both the historical and the clinical points of view.

Every surgeon will find this book interesting, and all faithful alumni of Middlesex Hospital Medical School will surely hasten to possess a copy of this beautifully produced and well-illustrated record of one of its most famous teachers.

ZACHARY COPE.

CEREBRAL PALSY

Cerebral Palsy in Childhood (the Aetiology and Clinical Assessment with Particular Reference to the Findings in Bristol). By Grace E. Woods, M.D., D.P.H., D.C.H. Foreword by Peter Henderson, M.D., D.P.H. (Pp. 154+xi; illustrated. 27s. 6d.) Bristol: John Wright and Sons Ltd. 1957.

The increased interest in cerebral palsy is indicated by several new publications, now joined by the elaboration of an M.D. thesis by Dr. Grace E. Woods entitled *Cerebral Palsy in Childhood*. It is based largely upon a survey in Bristol of 301 children, conducted through the medium of a special assessment clinic set up to deal primarily with the educational placement of children of school age or approaching it. After a chapter on the history of the group of clinical syndromes now called cerebral palsy, and an account of the clinical examination, the book goes on to discuss incidence in general and, in more detail, seven selected types. The relation of abnormalities at birth is summed up in a short chapter, and shows that, broadly speaking, less than 50% of the affected children were born after a normal than 50% of the affected children were born after a normal full-time birth following sensory defects and epileptiform disturbances, and a valuable concluding chapter on the assessment of educability. The nature of the survey mainly excluded the pre-school child, so that the important aspect of early diagnosis and "treatment" does not receive attention. This book is packed with facts and will no doubt be freely used by workers in other centres. Dr. Peter Henderson, of the Ministry of Education, contributes a foreword.

ALAN MONCRIEFF.

ADVANCES IN GASTRO-ENTEROLOGY

Modern Trends in Gastro-enterology. Second series. Edited by F. Avery Jones, M.D., F.R.C.P. (Pp. 416+xx; illustrated. 78s. 6d.) London: Butterworth and Co. (Publishers), Ltd. 1958.

The second volume of this series, the first of which appeared in 1952, has been written by a group of contributors chosen with discrimination by the editor, Dr. F. Avery Jones. He has combed not only Britain but Australia, South Africa, America, and Scandinavia for talent. As Professor Illingworth points out in a foreword, the contributors comprise physicians, surgeons, anatomists, radiologists, pathologists, and biochemists, all making their contribution to a common pool of knowledge. Though we may sometimes deplore the fragmentation of medicine into various rather watertight compartments, we should note, on the other hand, that the old rigid divisions between what is purely medical and what surgical are vanishing; and the close co-operation of a variety of specialists in pulmonary disease, neurology, cardiology, endocrinology, and gastro-enterology has come to stay. It may well be that the separation of patients into medical and surgical wards is becoming an anachronism.

This volume does not attempt to be a comprehensive treatise on gastro-enterology, but rather concentrates on those aspects of the subject in which advance is taking place. It is apparent that remarkable progress is being made in a variety of directions: improved methods of determining gastric secretion; new devices for recording pressure changes in and the motility of the alimentary tract; the gluten-free diet in the treatment of coeliac disease; the clinical and biochemical aspects of carcinoid tumours; the importance of the blind-loop syndrome in the production of steatorrhoea and anaemia; the metabolic effects of massive resection of the small intestine; the factors concerned in hepatic coma; the modern methods of investigating the biliary tract and pancreatic function. These and many other advances are clearly described and critically reviewed. The volume is beautifully printed on fine paper and admirably illustrated. This is a very good book indeed, and, as gastro-enterology remains—perhaps more than other specialties—a part of general medicine and surgery, it is bound to have a wide appeal.

D. M. DUNLOP.

SOFT TISSUES

Textbook of Orthopaedic Medicine. Volume I—Diagnosis of Soft Tissue Lesions. By James Cyriax, M.D., M.R.C.P. (Pp. 711+xiv; illustrated. 45s.) Third edition. London: Cassell and Co. Ltd. 1957.

At some time during life most of us suffer from one or more episodes of pain and stiffness in the limbs and trunk. Fortunately most of these episodes are of short duration and little significance, and only a minority represent the onset of serious and crippling disease. Dr. Cyriax has developed a useful system of accurate anatomical diagnosis of the source of pain, based upon clinical examination of the moving parts. He then proceeds to deduce pathological changes from clinical observations, and bases prognosis and treatment upon these deductions. At this stage much of the material in this book becomes highly speculative, since the author often ignores the pathological changes that have actually been observed in morbid anatomical studies; because of this he probably introduces more fallacies than he claims to dispel. Much of the treatment proposed seems of unproven value, since most of the complaints he is dealing with are naturally of short duration, and some measures he advocates, such as manipulation of the cervical spine for pain and stiffness, seem unnecessarily dangerous. In this the author shows a disregard for the dangers of spinal-cord lesions which have been so clearly demonstrated in recent neurological work and morbid anatomical studies of the cervical spine. The best that can be said of the book is that, like the curate's egg, it may be good in parts; but the danger is that the reader without special knowledge will be unable to tell which these are.

J. H. KELLGREN.

ORTHOPAEDIC SURGERY OF CHILDREN

Orthopaedic Surgery in Infancy and Childhood. By Albert Barnett Ferguson, jun., B.A., M.D. (Pp. 508+xii; illustrated. £6.) Baltimore: Williams and Wilkins. London: Baillière, Tindall and Cox Ltd. 1957.

The editor and five contributors have included in one volume most of the subject-matter of orthopaedic surgery required in childhood. The acute phase of fractures is omitted, but a number of complications are mentioned. Reference is made to the observations and writings of British surgeons. There is a regional arrangement of the greater part of the text, but some studies, such as plastic surgery of the hand, are not in sequence. Affections of special tissues, such as bone and muscle, are collected in separate chapters. There is an up-to-date and clear description of the clinical and therapeutic features of most congenital and acquired conditions of childhood. Information on tuberculosis of the knee, hip, and spine will be found. The conception of metabolic disease is overshadowed by regional conditions, so that there is little evidence of the importance of studying a child's general health when spine, knees, or feet are brought to the doctor's notice by the parent. However, the description of each condition is exactly what the general practitioner or aspiring graduate requires, and it is noticeable that the more recently recognized lesions appear to be regarded as of somewhat greater importance than well-established syndromes, such as birth palsy.

The chapter on affections of bone, which is lavishly illustrated, will attract the reader's attention in that the defective formation of bone from cartilage is a feature; and Robert Klein writes well on rickets and scurvy. Recommendations for treatment of congenital dislocation of the hip are made according to the child's age. The article on scoliosis is of some length and amply illustrated. The surgery of cerebral palsy, poliomyelitis, and progressive muscular atrophy is described. Readers may consider that the reproductions of a number of radiographs are insufficiently clear to exemplify the author's text. The book has a place in any surgical library, but it should be appreciated that it is not a complete textbook of orthopaedic surgery of children.

ST. J. D. BUXTON.

CARE OF CHRONICS IN U.S.A.

Chronic Illness in the United States. Volume II: Care of the Long-term Patient. By the Commission on Chronic Illness. (Pp. 606+xv. 68s.) Cambridge, Mass.: For Commonwealth Fund by Harvard University Press. London: Oxford University Press. 1956.

American hospitals and institutions for the care of the "chronic sick" were improvised to meet the needs of widely separated communities with differing conceptions of social responsibility. It is not surprising, therefore, that this encyclopaedic survey by the Commission on Chronic Illness paints a picture of chaotic confusion and disparity of standards like that of the Nuffield Hospital Surveys in this country a few years ago. By 1954 most of the American hospitals for chronic sickness, mental disease, and tuberculosis were already the responsibility of the State, but the patients in acute general and special hospitals controlled by "non-government" authorities outnumbered those in similar government institutions more than three times. The American Commission recognizes that care of the chronically ill is inseparable from general medical care in acute hospitals, and recommends that much more should be done for the patient in his own home than has been attempted hitherto; it suggests that "the most desirable approach to providing hospital care to long-term patients is through . . . co-ordination of the services of general hospitals both private and public" and reform of out-patient practice. But the co-ordination of hospitals under different authorities has always been difficult—at all events in England—and it will not be achieved in America merely by saying that it ought to be. This report lacks precision; nowhere is there any

exact analysis of hospital patients in a single region in terms of their medical, nursing, and social needs such as that which enabled Professor T. McKeown recently to formulate a plan for an integrated hospital community which might be applied on an experimental basis without great difficulty. On finance the conclusion is that "there is no alternative to the basic proposition that society as a whole through taxation must meet the deficit" until the time when plans and programmes of insurance are adequate. An unexpected tribute to the Welfare State.

A. P. THOMSON.

REACTION TO STRESS

Mastery of Stress. By Daniel H. Funkenstein, M.D., Stanley H. King, Ph.D., and Margaret E. Drolette, M.P.H. (Pp. 329+xv. 48s.) Cambridge: Harvard University Press. London: Oxford University Press. 1957.

In this book are described the results of experiments conducted on a group of Harvard students who were all subjected to artificial stress-inducing situations. A large battery of physiological and psychological tests were given so as to examine the acute immediate emergency responses produced, and to test the ability of each person to master, or his liability to succumb to, the stresses imposed over a longer period of time. The book will be useful for those interested in stress research because of the detailed description of the methodology used. It is harder going for the ordinary reader unacquainted with, and perhaps uninterested in, the numerous physiological and psychological tests that were employed.

Interesting conclusions were arrived at. The authors found that the initial types of reactions to stress were generally constitutionally predetermined. However, whether the subject was able to master stresses or succumbed to them often appeared less related to constitution and more to early upbringing and previous life experience and training. But I believe that if something like somatotyping had also been attempted it would have been shown that the power to persist with and to master difficulties also has a strong constitutional component. The absence of any detailed study of bodybuild and somatypes seems a possible weakness in this particular investigation.

CLINICAL CHEMISTRY

Chemical Methods in Clinical Medicine: Their Application and Interpretation with Techniques of Simple Tests. By G. A. Harrison, B.A., M.D., B.Ch.(Cantab.), M.R.C.S., L.R.C.P., F.R.I.C. Fourth edition. (Pp. 667+xi; illustrated. 65s.) London: J. and A. Churchill Ltd. 1957.

The fourth edition of Harrison, 27 years after the first, illustrates the advantages and difficulties of the one-man book in modern medicine. It attempts to survey apparatus, techniques, and interpretations throughout the field of chemical pathology, and, although much is gained from the unified approach of a single author, and from the stimulating outlook of this particular author, one senses that the task is becoming so burdensome that no one person can keep a book up to date in the whole of these subjects. For instance, 10 pages are spent on faecal fat without a mention of the daily output; the section on gastric analysis includes outdated procedures such as the Ewald and Boas meals; and the chapter on indicanuria might well be omitted. The section on acidosis repeatedly emphasizes that it is not equivalent to diabetic ketosis—a notion which is not likely to need stressing nowadays. The author omits determination of steroids because he regards it as useless. However, new sections on flame photometry, paper chromatography, paper electrophoresis, and photoelectric colorimetry are clear and concise, and these, combined with the fundamental reliability of most of the book, make it a worth-while addition to the library of clinical chemical laboratories.

COMFORT IN THE SURGICAL WARD

Although E. Ries¹ advocated early ambulation after operation in 1899, it did not become established practice in Britain until many years had passed. Eventually, advances in anaesthesia and surgical management contributed so much to the well-being of patients that many are now fit enough to get out of bed within 48 hours of operation. The increased mobility of the patient and the quick and uncomplicated recovery after operation have made fresh problems—for the hospital staff an increased turnover of patients, for the patient the difficulty of finding somewhere to sit comfortably in the ward. Approximately three-quarters of the patients in a surgical ward are ambulant, and yet very few hospitals have a recreation- or day-room attached to the surgical wards. The result is that patients are left all too often to stagnate by the ward fireplace or on a chair by their bedside. Controlled series^{2,3} have shown the advantages of early ambulation without increasing the risk of wound dehiscence or incisional hernia. Pulmonary complications and atelectasis in particular are much less common. Normally the vital capacity on the first day after operation is reduced to 70-80% with an upper abdominal incision and by 30-40% with a lower abdominal incision.⁴ Afterwards recovery is progressive, so that full function is present about ten days later. D. J. Leithauser⁵ showed that with early ambulation not only was the initial reduction less but the rate of recovery was greater, so that in some patients vital capacity returned to normal within seven days: this, he suggested, might be due to the effect of gravity on the abdominal viscera, allowing an increased excursion of the diaphragm.

Lying in bed after operation also carries the risk of deep vein thrombosis, with the possible dislodgement of emboli. Early ambulation should in theory reduce these dangers, but the incidence of pulmonary embol-

ism is if anything increasing,⁶ and J. B. Blodgett and E. J. Beattie² found deep vein thrombosis more common in the ambulant group of their controlled series. Deep vein thrombosis is due to a combination of factors of which the most important are local anoxia of the vessel wall, venous stagnation, and changes in the constituents of the blood. The injurious effect of the first two of these factors is at its maximum during the operation, and on the return to the ward before recovery of consciousness, so that by the time the patient becomes ambulant thrombosis may quite probably have already begun. The increased movement later can prevent further venous stagnation and extension of the clot, especially since the plasma fibrinogen rises in the first few days and the increase in the number of platelets does not reach a maximum until about the sixth day. The time of the greatest risk of pulmonary embolism is the eighth to twelfth day, when the clot has extended to the larger veins and the flow of blood is sufficient to separate it from the vein wall or the entrance to a tributary. One result of the rapid recovery of surgical patients is that this period of risk now comes after discharge from hospital, when the patient may be under the care of the general practitioner.

The principal beneficial effect of early ambulation is psychological. Once any initial apprehension has been overcome and the patient is up and about he no longer feels an invalid, and the ordeal of the operation is a thing of the past. As the more serious causes of discomfort after operation disappear, the seemingly trivial causes assume a major importance to the patient. One of these is the assumption of a comfortable posture. An ideal posture must not only reduce pain to a minimum but also it must not increase the risk of any complication. In a letter to this *Journal* H. L. Marriott⁷ has recently suggested from personal experience that for parts of the first few days after operation the patient might be much more comfortable sitting in a chair and leaning well forward on to a pillow on a low table. There is much physiological evidence to support this. Electromyographic studies⁸ have shown that the abdominal muscles play no part in normal quiet breathing, but their contraction is a limiting factor in forced inspiration. Elsewhere in this *Journal* Mr. A. R. Anscombe and Dr. R. St. J. Buxton suggest that this effect may be responsible for most of the reduction in the total capacity of the lungs that occurs after operation. If this hypothesis is correct, the posture suggested by Marriott, by relaxing the anterior abdominal wall, will facilitate breathing. In addition, the vertical distance needed to expel viscid pellets of sputum is decreased, coughing is made easier, and the risk of pulmonary complications is reduced. One possible disadvantage

of this position may be that the flexion of hips and knees may obstruct the return of blood from the legs and increase the risk of thrombosis. Even so, there is much evidence in its favour, and looking round a surgical ward one can see patients trying to adopt it with inadequate facilities.

RADIATION AND CHILDHOOD MALIGNANCIES

Two years ago Dr. Alice Stewart and her colleagues made a comparison between the mothers of children who had died of malignant disease and the mothers of children who had not, and they found that a greater proportion of mothers in the first group had been x-rayed during their pregnancy.¹ At that time the investigation was still incomplete, but the authors put forward evidence to show that the association held only for x rays of the mother's abdomen and that there was no association with irradiation before or after the relevant pregnancy. It seemed likely, therefore, that the association was real. Quantitatively the results suggested that about 8% of all deaths due to leukaemia or other forms of malignant disease in children under 10 years of age might be attributed to x-ray examination of the mother's abdomen during pregnancy and that about 1 in every 1,000 of such examinations might be responsible for the death of a child from malignant disease. Other investigations reported at about the same time showed a high incidence of cancer of the thyroid and of leukaemia among children who had received moderate doses of irradiation in infancy for enlargement of the thymus,^{2,3} and that the incidence of leukaemia among patients who had been irradiated for ankylosing spondylitis might be directly proportional to the dose.⁴ If, therefore, the tissues of the foetus were regarded as particularly radio-sensitive, it was not unreasonable to believe that even the very small doses given in the course of a pelvimetric examination (of the order of 1 to 5 rads) might be carcinogenic.

This conclusion was not an easy one to accept. Experimental evidence of a carcinogenic effect had never been obtained at such low doses, and many cases of radiation-induced cancer in man appeared to develop against a background of widespread tissue damage. The possibility had therefore to be considered that the method of investigation might have biased the results of Dr. Stewart and her colleagues or that some other factor had been overlooked which both caused malignant disease in the child and

increased the risk of irradiation for the mother. The full results of the Oxford inquiry—published in this *Journal* last month⁵—have therefore been awaited with special interest. Altogether, information was collected from the mothers of 1,299 children who died from malignant disease before reaching 10 years of age during the period 1953-5. Information obtained from the same number of mothers of living children was used for purposes of comparison. The results accord well with those already published. The frequency with which the mother's abdomen was x-rayed during the relevant pregnancy was 1.9 times as great for the children who died of malignant disease as for the living children. The figures lead to almost identical estimates of the risk—that is, about 8 in every 10,000 prenatal abdominal x-ray examinations lead to death of the infant from malignant disease before the age of 10 years, and about 6.5% of all deaths from malignant disease in this age group may be attributed to prenatal irradiation. The specificity of the association is, however, less close than appeared from the preliminary data, for the mothers of the dead children also reported an excess of abdominal x-ray examinations before marriage (1.69:1) and a slight excess (1.16:1) of other types of x-ray examination. It is possible that the first of these two results indicates an effect of irradiation on the mother's gonads, but the numbers of women involved were very small (44 to 26), and it is not unreasonable to regard the difference as a chance finding. The excess of other types of irradiation occurred more or less equally at all periods of the mother's life, and it thus seems to point to relative under-reporting on the part of the control mothers. If this were so, the control mothers might also have under-reported previous abdominal x-ray examination, and the estimates given for the risks of abdominal x rays would have been exaggerated by about 20%. But confidence in the interpretation which has been given to the results is strengthened by the finding that the excess exposure to x rays among the mothers of the dead children was greater when it was known that four or more films had been taken than when fewer films had been used, and it was greater when the mothers had been x-rayed during the first five months of their pregnancy than when the examination had been made later. Here again the numbers were small in both groups, and there was no regular relationship between the risk and either the number of films or the period of gestation.

A particularly interesting aspect of the investigation is that the excess of irradiation appeared among the mothers of 6 out of the 8 groups of malignant disease studied—the greatest proportion of irradiated mothers being recorded for the children who had

died of malignant tumours of the suprarenals and of a heterogeneous group of other tumours, including retinoblastomas and teratomas. The differences recorded between the different types of tumour were, however, not very great, and they could reasonably be attributed to chance. The simplest conclusion seems therefore to be that, if x-ray examination of the mother's abdomen does in fact carry a risk of inducing malignancy, the risk applies more or less equally to all those tissues which can be subject to malignant change in childhood—and certainly not only to the bone marrow or reticulo-endothelial system.

Dr. Stewart and her colleagues also studied many other aspects of the mother's and the child's environment and the details of their heredity. In the main the facts elicited were closely similar in both the malignant and the control series, and the few points of difference that did emerge did not seem to be of much significance.

In an investigation of this type it is never easy to be certain of the meaning of the results. Dr. Stewart and her colleagues have quite rightly asked themselves whether their results can have been due to an unequal recording of the data in the study and the control series, to an unequal reporting of events by the mothers concerned, or to an unrepresentative selection of patients for examination, and against all these possibilities they provide good arguments. It is, however, difficult to exclude the possibility that the mothers of the dead children, by virtue of their bereavement, may have searched their memories more effectively than have the mothers of the living children and so reported some events more accurately. There is some evidence that this may be true—for example, a small excess was found in the study series for a number of factors which it is difficult to envisage as causes of malignant disease. Such an excess was, however, not constant for all factors, and it would be necessary to postulate that the more efficient (or more exaggerated) recall of past events applied only to certain items; it would, in particular, be necessary to postulate that the effect was greater for abdominal irradiation during pregnancy than for any other of the items studied. Unlikely though this may seem, some scientists would regard it as not more unlikely than that such small doses of radiation should be capable of causing so many different types of cancer. It is therefore important to test the hypothesis by obtaining data directly from medical sources and so excluding any bias which might be introduced through the almost inescapable tricks of memory. That this has already been done by Dr. J. C. S. Paterson in the U.S.A. must carry great weight in favour of the conclusions originally reached by Dr. Stewart

and her colleagues. As yet Dr. Paterson has reported only in a personal communication to Dr. Stewart, and the publication of his full data will be awaited with great interest.

The importance of this work is perhaps less related to the immediate prevention of disease than to the central problem of carcinogenesis. The mortality which may be attributed to the effects of antenatal irradiation forms only a small proportion of the recent increase in the incidence of deaths from malignant disease in childhood. The smallness of the risk must mean that the dangers of not making a radiological examination will often outweigh the attendant risk of malignancy. In practice, therefore, the total number of pelvimetric examinations may not be greatly reduced, though greater care will certainly be taken to ensure that the dose of radiation given is kept to the minimum. If, however, it is accepted that doses which may amount to only a fraction of a rad are carcinogenic, it is difficult to conceive of any mechanism which could produce the result other than that of a change in the genetic structure of the cell, comparable to a genetic mutation.

THE CIRCULATION IN CIRRHOSIS

Some patients with portal cirrhosis have the clinical signs of a hyperdynamic circulation: warm skin, a bounding pulse with an increase in pulse pressure, a forceful cardiac impulse, and often a systolic ejection murmur. Recent studies^{1,2} have shown that the cardiac output is increased and that peripheral vascular resistance falls, the latter implying peripheral vasodilatation. In general the changes occur in patients who have extensive portacaval anastomoses, but they do not bear any constant relation to the presence of spider naevi or palmar erythema. It is significant that in extrahepatic portal hypertension, where shunts are equally prominent but the liver is normal, the cardiac output is normal. This implies that some degree of liver damage plays a part in the circulatory changes, a view that is supported by the presence of a similar hyperdynamic state in a proportion of patients with severe hepatitis. Levels of serum albumin tend to be lower in the hyperdynamic group, but this may be merely the result of haemodilution, since the plasma volume is known to be increased. The latter finding also cannot be explained solely by the presence of portacaval anastomoses as was originally suggested,³ since the blood volume is

normal in patients with extrahepatic obstruction. Comparable circulatory changes are seen in association with anaemia and vitamin-B₁₂ deficiency, both of which may occur in portal cirrhosis, but neither of these factors provides an adequate explanation, and it is tempting to postulate a general vasodilator substance of the type described by E. Shorr and his colleagues.⁴

There is, however, an interesting alternative which might possibly account for the circulatory changes. Some years ago⁵ it was observed that the arterial blood was not fully saturated with oxygen in patients with portal cirrhosis. This suggests that venous blood is being shunted into the arterial system, and indeed a few cases of juvenile cirrhosis have been recorded in which cyanosis and clubbing were so marked as to suggest a diagnosis of congenital heart disease. Extensive pulmonary arteriovenous anastomoses have been detected in a recent case.⁶ Though admittedly rare, this finding may be of some significance in view of a comparable phenomenon in some adults with severe portal hypertension.

Post-mortem injection studies⁷ have shown that communications exist between the portal and pulmonary venous systems via the azygos and bronchial veins. Normally the pressures in both systems are similar, but with portal hypertension it would be theoretically possible for blood to flow from the portal vein into the pulmonary veins, thus causing a slight reduction in arterial oxygen saturation. Similarly reduction in the reverse direction might explain the occasional finding of oesophageal varices in patients with heart failure. Prominence of the azygos vein has been reported as a radiological sign both in heart failure and in portal hypertension. Whether such arteriovenous communications bear any relation to the circulatory changes in cirrhosis remains to be seen. That there may be a link between the pulmonary and portal circulations will come as no surprise to those who have noticed certain similarities in some of the clinical features of cardio-pulmonary and hepatic disease.

FARMER'S LUNG

Pneumoconiosis following exposure to mineral dusts has long been recognized as a serious occupational hazard, but, except in the cotton industry, the importance of vegetable dusts has been less fully appreciated. Farmer's lung is an acute respiratory illness which may follow exposure to a wide variety of vegetable dusts, particularly those encountered when handling mouldy hay, grain, or silage. Most of the British cases have been reported from western country districts,¹⁻⁷ where a wet summer may result in crops of poor quality being stored, often in ill-ventilated, closed barns. When the hay is forked out

to feed cattle, the barn swept out, or the grain threshed, clouds of white, irritant dust, laden with fungus spores, fill the barn, and if inhaled by a previously sensitized farm worker may cause an alarming lung reaction.

After a few minor episodes of breathlessness the established picture is one of severe dyspnoea immediately after exposure, increasing over the next few days and frequently resulting in complete incapacity. There may be rigors at the onset; fever, sweating, a dry, irritant cough, and loss of weight complete the picture. On examination the main findings are cyanosis, with moist sounds throughout the lung fields. Pleurisy is rare, there is no bronchospasm, and haemoptysis does not occur.⁸ Over a period of three to six weeks gradual spontaneous improvement occurs, but breathlessness on exertion may persist for months, and, in a few cases, permanent disability may result. Despite recovery, re-exposure may lead to recurrence, and after repeated episodes there may be progressive limitation of exertion, pulmonary fibrosis, and eventually right-sided heart failure.⁸ The economic significance of the disease is stressed by R. C. Frank,⁸ and seven of his 27 cases had to give up farming entirely because of their illness.

Laboratory findings help little in establishing a diagnosis. Occasional polycythaemia, leucocytosis, and elevation of the erythrocyte sedimentation rate have been reported. Sputum culture may yield a growth of fungi comparable with the flora of the barn dust, and monilia may also be found.⁹ Skin tests for fungi, monilia, and histoplasma have no proved diagnostic value.¹⁰ Radiological changes at the onset may be minimal, but in the established case there is a ground-glass opacity extending to the periphery of the lung fields, fading to a granular mottling in the areas of least involvement. The granularity has been described as a "sandstorm," the densities being a millimetre or less in diameter. E. Tornell⁹ and Frank⁸ noted a similarity to sarcoid, but hilar adenopathy is absent in farmer's lung. Clearing is gradual, and though after a single attack radiography shows a return to normal appearance progressive pulmonary fibrosis and emphysema may be seen after continued exposure.

The effect of treatment is difficult to assess in any disease with a natural tendency to remission. Iodides have been recommended in the acute attack by R. Fawcitt^{2,3} and Frank,⁸ but T. C. Studdert⁵ found them of no value. Antihistamines, antibiotics, and cortisone have been tried, with equivocal results. Any patient with serious symptoms should avoid re-exposure to dust.

The pathogenesis of farmer's lung is not yet clear. It was first described in 1932 by J. M. Campbell¹ as

"acute symptoms following work with hay" in Westmorland. Fawcitt,^{2,3} reporting several cases from Cumberland, believed that the condition was a true fungus infection and used the term "broncho-mycosis feniseiorum" to describe it. Tornell,⁹ describing an apparently identical condition in Sweden under the name of "thresher's lung," regarded it as a form of pulmonary moniliasis. J. T. Duncan¹⁰ first noted the clinical similarity to byssinosis, pointed out that the finding of fungus spores in the sputum meant only recent exposure to mouldy dust, and considered that the lung lesion was an irritation by fine vegetable dust. Studdert⁵ and C. J. Fuller,⁴ from Cumberland and Devonshire, independently reached the same conclusion that the probable cause was a sensitization reaction in the lung tissues to the actual fungus spores, and Fuller⁴ drew attention to the experimental work of L. Zettergren,¹¹ who produced granulomata in rabbits' lungs following inhalation of both sterile and monilia-contaminated barn dust. These lesions bear at least a superficial resemblance to sarcoid granulomata, and Frank,⁸ carrying out a lung biopsy on one of his cases, found non-caseating granulomata of sarcoid type. He also reported similar findings from a rather doubtful fatal case of many years' duration, complicated by nephritis and uraemia.

Lung changes apparently identical to farmer's lung occur in maple-bark strippers when the cork layer of the tree is infected with *Coniosporium corticale*,¹² in workers handling mouldy sugar-cane pulp (bagassosis),¹³ and in the cotton industry when mildewed yarn is used (weaver's cough).¹⁴ It seems reasonable to postulate that in all of these conditions there is a comparable sensitization reaction, possibly of sarcoid type, in the lung tissues, but further work is needed to clarify the picture.

EPIDEMIOLOGY OF CANCER

For over 30 years Dr. Percy Stocks has been working on the epidemiology of cancer. In 1924 he showed that in Switzerland death rates due to stomach cancer were highest in those cantons where there was most goitre,¹ and now he has published, in the form of a special supplement to the Annual Report of the British Empire Cancer Campaign, the fruits of his labour in North Wales and Liverpool.² His earlier interest has been maintained in his study of a possible relation between stomach cancer and soil content. Within the well-known "pocket" of high incidence of this disease in North Wales there is some evidence of an association between mortality from stomach cancer and the amount of organic carbon in the soil, but as this does not apply in other parts of the survey area it is clearly not the only causative factor. Another characteristic which appears to be related to stomach cancer is the frequency of eating fried foods, but since North Wales is not peculiar in that respect it does not account for the excess in that area. However, in spite of his return to this theme no one could accuse Dr. Stocks of having a one-track mind. His survey covers the incidence of cancer of all sites, and he has studied factors as diverse as diet, water supply, method of cooking, place of work, and

method of travelling there, "race" (Welsh, Irish, or Jewish), smoking, snuff-taking, use of a petrol lighter, age at marriage and parity, and history of previous infections and vaccination. He claims to have shown, for instance, that Welsh blood is not associated with a higher incidence of cancer of any site; that among light smokers beer-drinking is associated with a higher incidence of cancer of all sites except the stomach; that in Cheshire and Merseyside frequent milk-drinking is associated with a reduction in lung cancer no matter what the beer-drinking or smoking habits have been; that pipe-smoking, which hardly affects the incidence of lung cancer, is in some districts associated positively with cancer of the larynx, oesophagus, and intestines; that cancer of the cervix uteri is associated with early marriage, parity being a relevant factor only when marriage is late, and that death rates are high in seaports and textile towns. He found no association between cancer of any site and the use of oil lamps or petrol lighters, or with a history of streptococcal infection or vaccination.

Dr. Stocks's findings on smoking and lung cancer are in general agreement with those of other workers. Only 40 of the 2,101 men aged 35 to 74 who died of lung cancer had not smoked at all, against 188 expected from a control group: 593 had smoked more than 150 cigarettes a week compared with 325 expected. There appears to be an urban factor adding a constant risk which is independent of the number of cigarettes smoked up to about 200 a week, and Dr. Stocks suggests that this might indicate a saturation point for the combined action of smoking and urban carcinogens, or that only a proportion of heavy smokers are liable to cancer, and at this level most of the "susceptibles" have become affected. The report provides more detailed information on the distribution of polycyclic hydrocarbons and certain trace elements in the air of both urban and rural areas than has hitherto been available, but so far it has not been possible to incriminate any particular substance as contributing to the urban factor in lung cancer.

Some may ask whether, with such a multiplicity of factors being investigated simultaneously, apparently "significant" results are not bound to emerge. D. D. Reid in his recent Milroy lecture³ quoted Sir William Gull as saying that the only way to extract the truth in such matters was "to put a definite question, and, that being settled, follow it up by another and so on in series. Nature must at last be driven into a corner and be obliged to say 'Yes' or 'No.'" There is great strength in this argument, and perhaps most epidemiological research should follow such rigorous lines. But there is surely an important place for such all-embracing studies as Dr. Stocks's: they are in the nature of reconnaissances, exploring avenues which would be by-passed by the main strategical attack. In unskilled hands such inquiries may prove misleading; unless electronic equipment is available to analyse all the possible correlations (and there may be a profitable field of inquiry here in the future) it must be a matter of personal judgment

¹ Stocks, P., *Biometrika*, 1924, 16, 364.

how to analyse and interpret the data: statistical theory gives little guidance. For many years to come research workers, before embarking on an investigation to test, for example, whether tea-drinking causes cancer of the stomach, will look up the book "to see what Stocks found," and will have ample cause to be grateful for the painstaking way he has prepared the ground.

ANTIBIOTIC TREATMENT OF BOILS

Although antibiotics are much used for lesser forms of sepsis, actual proof of their efficacy is not easily obtained. It should be obtainable by the study of a constant type of lesion if enough cases treated in different ways were closely observed. Such study is that described by Dr. Allene Scott on p. 83. The boils treated were graded in four degrees of severity, and the first conclusion, reached comparatively early in the investigation, was that antibiotic treatment did not affect the course of boils in the two minor grades. Thereafter the study was restricted to the two major grades, and 165 such cases were allotted randomly to three groups, treated respectively with erythromycin, antibiotic E 129, and no antibiotic. Effects were judged by the time taken to arrest the progress of the lesion, time of healing, time of disappearance of the staphylococcus from the lesion, the degree of final tissue damage, and by the frequency of development of fresh lesions during treatment. On all these counts it is quite clear that treatment with either antibiotic gave better results than those in the control group. On the other hand, there is no evidence of any diminished liability to develop further boils after one episode is over. What little difference there was between the efficacy of the two antibiotics was in favour of E 129, but for several reasons, including its impurity and less complete absorption, this was given in larger doses. E 129 is an antibiotic still undergoing clinical trial to determine its degree of usefulness: according to L. P. Garrod and Pamela M. Waterworth¹ it is related, although not closely, to erythromycin, and differs from erythromycin in that staphylococci acquire resistance to it more slowly.

It was one object of this study to determine whether a course of treatment limited to seven days was one during which any bacterial resistance might appear. All the strains of staphylococci were initially sensitive to both antibiotics to a very constant degree, although 23% were resistant to penicillin and a few also to tetracycline: all those re-isolated during or after treatment were retested and none were found to have become more resistant. There were 16 re-isolations from patients treated with erythromycin after 5 to 7 days' treatment, and 7 more during the succeeding week: the numbers from cases treated with E 129 were similar. These are not large numbers, but they do at least show that after seven days' treatment of this type of lesion the development of bacterial resistance must be exceptional. It is well recognized that staphylococci can develop resistance to erythromycin during treatment and that the rate of increase in resistance can be fairly rapid, and because of this the use of erythromycin was much restricted

during a period of several years when it appeared to be the last resort for the treatment of otherwise antibiotic-resistant infections. With the advent of such newer antibiotics as novobiocin and vancomycin it no longer occupies this position of doubtful privilege, and can consequently be used more freely. The findings in the present study, in so far as they exemplify a situation in which apparently resistance to erythromycin is not acquired, suggest that we might with advantage know more about the circumstances in which it is. Is the determining factor the nature of the lesion, dosage, or duration of treatment, or a property in the staphylococcus itself? The scattered records of individual patients in whom this change has occurred may not answer this question, but there must be an answer, and further study directed to this end might provide it.

BEAT KNEE

In the first schedule of the National Insurance (Industrial Injuries) (Prescribed Diseases) Regulations, 1948, beat knee is described as "a subcutaneous cellulitis or acute bursitis arising at or about the knee." If beat knee is a term commonly associated with coal-mining it is not a surgical entity by this definition. It does nothing more than cover a list of conditions not necessarily related except in so far as they affect those whose occupation demands the kneeling position. A recent study of 899 cases, encountered within a period of eighteen months in the North Derbyshire coalfields, focuses attention on the importance of the problem in the mining industry.¹ It is perhaps not surprising to learn that among the miners these affections are most common in coal-face workers and are related to the height of the seam in which they work. The possible influence of environment is shown by the wide variation in incidence between collieries. In some, 13.25 per 1,000 are affected; in others, it is as high as 195.4 per 1,000 men who work underground. But if heat, hygiene, and height of seam are factors, hardness of the surface knelt upon is not. Prepatellar bursitis is the traditional disease of housemaids. Even carpet-layers suffer from it. Therein lies the explanation of the failure of protective pads in prevention. It is not pressure which is the cause of bursitis. It is constant friction between skin and the front of the knee. Some miners aver that the knee-pads in current use aggravate rather than alleviate by harbouring fragments of coal between pad and skin. Early treatment can reduce the loss of working time.² It is no paradox that pressure should have been found so valuable: simple elastic compression was always more effective than irritation in the treatment of effusions in superficial joints or bursae. Ablution and antibiotics look after the infection. The disabling scars of incisions used to drain a cellulitis should be relics of the past. Housemaid's knee disappeared with housemaids. The advent of housewife's knee was saved by the vacuum cleaner. The incidence of beat knee in coal-miners can be reduced. But the problem will remain just so long as men are required to work on their knees to get coal.

MEDICAL ELECTRONICS

[FROM A SPECIAL CORRESPONDENT]

A conference on medical electronics, instigated by Dr. V. K. ZWORYKIN, of the Rockefeller Medical Electronics Center, was held in Paris from June 26 to 28, under the aegis of the Council of International Organizations of the Medical Sciences and the Rockefeller Institute for Medical Research, New York. The President was Professor FESSARD, professor of electroneurophysiology at the Collège de France, Paris.

Dr. Zworykin, himself a pioneer of modern television, the electron microscope, the image converter, the ultra-violet television colour translating microscope, and the "radio-pill" which signals pressure or pH changes from the intestines, contends that medicine is not taking full advantage of the electronic aids now available. He believes that the new developments in this field could be used more effectively than they are to assist both research and clinical practice. The conference was attended by 60 delegates from nine countries. The British contingent of nine observers was assembled by a combined medical and engineering committee* of the Institution of Electrical Engineers.

Cinédensigraphie

The conference gave no support to the view that America has a monopoly in this field. Of the 34 papers from different parts of the world many were of considerable interest. Dr. M. MARCHAL and his colleagues from the Hôpital St. Antoine, Paris, surprised everyone with his "Cinédensigraphie." This depends on the fact that the periphery of organs such as the lungs or liver varies in opacity to x rays with each respiratory and cardiac cycle. These variations are recorded from a small röntgen dosimeter placed behind the patient, and the recordings provide information of air entry and vascular mobility which is of value in locating the boundaries of neoplastic changes and chronic diseases. Dr. Marchal and his colleagues have used this technique for the differential diagnosis of primary and secondary neoplasms of the lung, chronic bronchitis and emphysema, thrombosis, and tricuspid valve disorders.

From the United States, Dr. STUART MACKAY, of California, described the use of a pressure-sensitive paint for manometers for internal use. The paint's electrical resistance varies with the pressure to which it is exposed. Dr. ZWORYKIN gave further technical information of his U.V. colour-translating microscope.† From the British side, Dr. P. BAUWENS discussed advances in electrodiagnosis, Dr. R. E. GEORGE transistor techniques for electromyography, and Dr. B. SHACKEL the measurement of ocular co-ordination. Dr. C. N. SMYTH described the ultra-sound telescope with which he hopes eventually to visualize the foetus *in utero* and the heart valves in action.

Electronic Computers in Medicine

Dr. CARL BERKLEY (Rockefeller Institute) and M. LE GUENEDAL (France) introduced what was perhaps the most popular subject—namely, the use of electronic computers in medical research and practice. The computer with its punch-card, magnetic tape, or photographic store of coded information can classify and select medical literature automatically. Once a machine is allocated to this purpose and the systematically fed with classified abstracts of papers, the preparation of bibliographies of single subjects or combinations of subjects or details of their content is an effortless process. What can be done for a library can also be done for patients' records, and later case histories can be added to former records and the changes tabulated.

*The Committee on Radiological and Electromedical Apparatus.
†See *Science*, 1957, 126, 805.

Dr. Berkley's computer has been programmed for the diagnosis of haematological diseases. The machine considers some 50 diagnoses. Coded information, received, for example, by telephone, of a patient's symptoms, signs, and laboratory findings is passed to the computer. A few moments later a typed form lists the changes in the patient's state since the last entry, gives the differential diagnosis, and enumerates the tests necessary to make the diagnosis definite. Any excess information is recorded in case a multiple diagnosis is necessary. It is only one step further for the computer to define the best treatment (from its own previous experience?) and provide a list of suitable diagnostic laboratories and, if desired, the name of a specialist. One major snag, of course, is that the data fed to the machine must be accurate, and the human factor here is bound to impose limitations on the practical usefulness of such expensive clinical aids.

There was also some informal discussion on the possibilities of what is known as paramagnetic nuclear resonance in biological analysis and even treatment. This technique depends on the response of different molecules to specific electrical frequencies, so that it is possible to impart a rotatory movement to only one specific type of molecule in a tissue. This opens up prospects of perhaps using the method at the cellular level to detect the presence of particular molecules, or even by taking advantage of the heat generated by their rotation to disrupt their biological attachments.

Future Plans

The conference showed that many medical research workers who devote their time to circuit research and the design of instruments are often just repeating work already done in industry or struggling with problems that a trained electrical engineer could do speedily. To remedy this state of affairs those present at the conference formed themselves into an interim committee and interim executive council with four objectives: (1) To encourage the formation of national committees representative, if practicable, of their learned societies; (2) to arrange a further international conference to be held in Paris next June; (3) to assist in the preparation of an international bibliography of medical electronics as already started by the Rockefeller Institute; and (4) to draft a constitution for an international body. The interim executive officers are: President, Dr. V. K. Zworykin (U.S.A.); vice-presidents, Dr. M. Marchal (France) and Dr. C. N. Smyth (Britain); treasurer, Dr. B. Shackel (Britain); secretaries, M. C. Berkley (U.S.A.) and Dr. A. Rémond (France); advisers, Professor Sakamoto (Japan), Professor O. Wyss (Switzerland), and Dr. Bekkering (Holland).

New Appliances

SIMPLE DEVICE FOR LOCATION OF PERFORATING VEINS

Mr. D. W. BRACEY, surgeon, Memorial Hospital, Peterborough, writes: The material of the simple device for the location of perforating veins in the treatment of varicose veins consists of (a) a flat rubber tourniquet 1½ in. (3.8 cm.) wide; and (b) two rubber rings of sponge rubber covered with latex; the small ring has an inside diameter of 2½ in. (7 cm.) and an outside diameter of 5 in. (12.5 cm.); the measurements of the larger ring are 3½ and 5½ in. (8.2 and 14.6 cm.) (Fig. 1). The small ring is used for the leg between the ankle and knee, and may, in a thin patient, serve for the thigh. The larger ring is used above the knee in obese patients.

The small ring is rolled over the foot to just above the ankle (Fig. 2). The rubber tourniquet is then applied just

¹ Garrod, L. P., and Waterworth, Pamela M., *Brit. med. J.*, 1956, 2, 61.

below the ring and so adjusted by means of its hook and eyelets as to exert sufficient pressure to stop the venous flow coming upwards in the superficial veins. With the patient standing on a stool, the ring is rolled up the leg to the knee, emptying the superficial veins as it moves up. As soon as it passes a perforating vein the blood will be seen to enter the superficial vein, especially if the patient is asked to work his foot up and down. The exit site of the perforating vein or veins is then marked with an inverted T.

FIG. 1

The horizontal portion of the T marking the site of entry of the perforating vein into the superficial vein. When all the perforating vein exits have been marked the tourniquet is then moved up to the knee just below the new position of the ring. The ring (or the large one if the thigh is obese) is then rolled upwards over the thigh towards the groin and the marking repeated (Fig. 3).

FIG. 2

FIG. 3

The importance of the perforating veins of the leg in varicose veins and ulcers has been stressed by Cockett (1956), and for the past year, in 103 cases, a method of closing these incompetent veins at their exit has been successfully accomplished by a perivenous injection of sclerosing solution (15% phenol in arachis oil 1-3 ml.) at the point where the vein perforates the fascia covering the muscles.

The injection is carried out with a 5-ml. syringe and a No. 1 serum needle, entering the skin at the top of the vertical limb of the inverted T marking. The needle is inserted obliquely downwards for about 1-1 1/2 in. (2.5-3.8 cm.) until its point is felt to penetrate the deep fascia at one side of the perforating vein, and one-half of the total quantity of the solution is injected. The needle is then withdrawn slightly and placed in a similar position on the other side of the perforator and the rest of the solution injected. Accidental penetration of the vein does no harm.

The patient is seen again after a minimum period of six weeks, when the superficial veins will be found to be much less prominent and the symptoms abated. If thought necessary the superficial veins can be sclerosed by an intravenous injection of ethanolamine (1-4 ml.). Examination of the sites of the perivenous injections will reveal a small area of thickening. All the injections, whether perivenous or intravenous, are carried out with the patient lying on a couch.

The initial procedure of examination and injection occupies between 5 and 10 minutes, depending on the number of perforating veins found. The method of perivenous injection is painless and free from complications.

The material used to locate perforating veins has been made for me by Charles S. Bullen, 93, Mount Pleasant, Liverpool, 3.

To-day's Drugs

In this column we publish from time to time authoritative notes on a selection of drugs in current use.

Neo-Rybax (Rybar Laboratories Ltd.).—This is an antispasmodic inhalant which contains papaverine 0.2% and atropine methonitrate 0.1%, ethyl *p*-aminobenzoate (benzocaine) 0.2%, pituitary (posterior lobe) extract and pituitary (anterior lobe) extract, of each 0.2%, and adrenaline 0.4% in an unspecified detergent base.

Papaverine and atropine methonitrate are both alkaloids having a relaxing effect on smooth muscle, but how far they are effective on bronchial muscle by inhalation is doubtful. Benzocaine is a local anaesthetic. Pituitary posterior lobe extract has some vasoconstricting action, but its effectiveness by local application is doubtful. The purpose of the pituitary anterior lobe extract is not clear. The active ingredient of this inhalant is the adrenaline. Some asthmatic patients claim greater relief from inhalants containing a variety of agents whose pharmacological action is obscure, though their essential ingredient is adrenaline or an adrenaline analogue.

N.H.S. basic price: 1/2 fl. oz. (15 ml.), 4s.

Neo-Eudrine (John Wyeth and Brother Ltd.).—This is a solution for local application to the nasal mucosa, designed to relieve nasal congestion by shrinking swollen mucosa. It contains mephentermine sulphate 5 mg., neomycin base 3 mg., and cetrimide 0.25 mg. in each ml.

Mephentermine is a vasoconstrictor having a relatively sustained action. Neomycin is an antibiotic which has a wide antibacterial activity. It is not suitable for parenteral administration, and may therefore be used more freely for local application than those antibiotics which may need to be given to combat systemic infections, since the effects of sensitization to it are not so disastrous; and in any case it is said to be less apt to cause sensitization on local application. Cetrimide is a cationic detergent, and is presumably included both for its action as a wetting agent, encouraging spreading of the compound across the mucosa, and also because it has a mild antiseptic effect.

There are certain circumstances in which temporary shrinkage of a congested nasal mucosa is of value—for example, in the presence of an acute nasal sinusitis—but the use of compounds of this sort in more chronic conditions is rarely advisable.

N.H.S. basic price: 15 ml., 4s. 4d.

Rhinocort (Ward, Cassenne, Ltd.).—This preparation is intended for local application to the nasal mucosa for the relief of mucosal swelling due to inflammatory and allergic conditions. It contains phenylephrine hydrochloride 0.12%, ephedrine hydrochloride 0.5%, prednisolone 0.01%, and neomycin sulphate 0.06% in an aqueous vehicle. The phenylephrine and ephedrine have a local vasoconstricting action. Prednisolone is included for its anti-inflammatory and anti-allergic effects; and neomycin is an antibiotic agent which, since it cannot be used parenterally, it is permissible to use by local application.

This preparation includes vasoconstrictors, a corticosteroid, and an antibiotic. If a precise diagnosis has been made, occasions on which all these drugs are required would probably be rare. In hay-fever and vasomotor rhinitis, the vasoconstrictors and the prednisolone have a useful symptomatic effect, but an antibiotic is unnecessary. In acute infections it is doubtful whether the local use of prednisolone is advisable. These powerful agents are probably best prescribed individually rather than in a compound of this sort.

N.H.S. basic price: 15 ml., 9s.

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Heat Illness

SIR,—Your annotation on "Heat Illness" (*Journal*, June 28, p. 1351), in which you discuss the article "A Classification of Heat Illness" (p. 1533), draws attention to the difficulty of distinguishing between "heat stroke" and "heat hyperpyrexia" as described in the latter article. It may reasonably be assumed that, in a tropical climate, "heat hyperpyrexia" as described in the appendix to this article will become "heat stroke" unless quickly treated, but for this very reason no one would be willing to withhold treatment to observe this transition. I have seen it happen under circumstances where no treatment at all could be given, and the progression "heat hyperpyrexia"—"heat stroke"—death was rapid. Observation of a graded series from "heat hyperpyrexia" through "heat stroke" to death is not often possible at one and the same time when comparisons can be made, but such an opportunity occurred in the Middle East Force during the recent war. I saw all these cases and agree that if distinction between "heat hyperpyrexia" and "heat stroke" is at all possible the former diagnosis will have become the latter in a brief spell in the absence of treatment.

The inclusion of convulsions as a manifestation of "heat stroke" is interesting and, no doubt, correct. If "heat stroke" and "heat hyperpyrexia" are lumped together, my experience produced no example of this until some hours after treatment by cooling had been carried out. At this stage, and when they were quietly resting but still comatose, I provoked a bad epileptic fit in two adjacent patients by applying the gentle stimulus in each case of feeling the radial pulse. These are the only cases of convulsions I have seen associated with heat stroke.—I am, etc.,

London, W.1.

Delay in Treating Cancer

SIR,—Thoracic surgeons often deplore the stage at which patients with bronchial carcinoma reach them. My experience with my latest such patient may be of interest, as it occurred in London, where teaching hospitals abound. I would stress that this particular case is an exceptional one in that the delay in obtaining admission to hospital was unusual, and the delay was at variance with my usual experience of the particular hospital concerned as well as with others which deal with my patients. For convenience I list the stages of the man's illness in days.

Day 1.—Male aged 57 with no significant previous illnesses complains of cough which provokes pain in the right chest and of small haemoptyses, both for 48 hours. He is pyrexial and there is an obvious right lower lobe pneumonia. Suspecting that this might mask a carcinoma I had a miniature skiagram done at a chest clinic, E.S.R. 105 mm./hour.

Day 3.—Miniature skiagram report: "Round opacity right costophrenic angle."

Day 5.—Large skiagram report: "Pneumonitis."

Day 13.—E.S.R. 200 mm./hour, in spite of antibiotics. Chest clinic reports there is a strong suspicion of bronchial carcinoma.

Day 20.—Thoracic unit report "X-rays suggest carcinoma of bronchus. I think it is worth while getting him into hospital for investigation."

Day 24.—Admitted.

Day 28.—Bronchoscopy report. "A carcinoma is just visible in the posterior basal segment on the right. Histology showed a squamous carcinoma. There was no evidence of glands although x-rays suggest their presence. His name has been put on the waiting-list for admission for thoracotomy."

Day 29.—Discharged.

Day 44.—Not yet admitted for thoracotomy. I telephoned to expedite admission.

Day 50.—7 lb. (3.2 kg.) weight lost since Day 1.

Day 64.—I telephoned again to ask for early admission. Acute tonsillitis developed, again of possible sinister significance. Appropriate treatment begun.

Day 74.—Patient complained of hoarseness. I found his right vocal cord immobile. I telephoned the hospital again and was told that the patient would be admitted "probably in 10 to 14 days' time."

I submit, Sir, that this man, although we shall never know at what stage of his illness he was when I first saw him, needed admission more urgently after the first ten days of his illness than, for example, almost any patient with acute appendicitis, which can be, and is, treated conservatively. In appendicitis admission can be arranged within minutes and operation within the hour. Is my sense of perspective about the urgency of treatment for bronchial carcinoma wrong, or is it that we just do not have enough thoracic units and people trained to work in them? The man whose case I have described was eventually admitted on the 89th day of his illness, and at thoracotomy on the 101st day of the illness "a firm mass 3 inches (7.6 cm.) in diameter was palpable in the lower lobe with a mass of growth at the hilum which had infiltrated the pulmonary artery. There was also peribronchial growth within half an inch (1.25 cm.) of the carina."

In view of the possibility of this patient being identified, I beg to sign myself

London.

GENERAL PRACTITIONER.

Mercurial Diuretics and Nephrosis

SIR,—We have read with interest the articles of Dr. Margaret Riddle and her colleagues and of Dr. J. Burston and his colleagues (*Journal*, May 31, pp. 1274 and 1277) and the letter from Dr. J. F. Goodwin (*Journal*, June 14, p. 1413) in which the onset of marked proteinuria in patients in congestive cardiac failure is discussed. There was no mention, however, of one possible factor—potassium depletion—which we feel may be of significance in these patients. This is known to cause disturbances of renal function with proteinuria¹ and to be associated with histologically demonstrable changes in tubular structure.² Moreover, most patients in congestive cardiac failure have some degree of potassium depletion, which may be gross.^{3,4} The occurrence of a normal serum level of potassium in the patient reported by Dr. Burston *et al.* does not exclude the possibility of depletion.⁵ Neither Dr. Riddle *et al.* nor Dr. Burston *et al.* say whether supplements of potassium were given, nor does Dr. Goodwin, although we understand that in Dr. Goodwin's patients potassium supplements were given during the period when recovery from the nephrotic syndrome occurred despite the continued use of mercurial diuretics.

Whilst not wishing to deny that mercurial diuretics may occasion the onset of the nephrotic syndrome, we would emphasize that potassium depletion also may cause proteinuria, and also we would stress the importance of ensuring an adequate potassium intake during congestive cardiac failure.—We are, etc.,

Sequelae of Cardiac Arrest

SIR,—In their article describing a case of recovery from neurological sequelae after cardiac arrest (*Journal*, June 28, p. 1521), Dr. D. W. Blair and his colleagues give an excellent description of cerebral oedema following anoxia due to cardiac arrest. I venture to suggest that, if the patient had

been treated for cerebral oedema on the lines suggested by Raison¹ or Argent and Cope,² recovery might have been much quicker.

It is not possible to comment on the cause of cardiac arrest in this case, as there are insufficient details given of the anaesthetic technique and drugs used.—I am, etc.,

Birmingham, 29.

Alcohol and Driving

SIR,—I have read with interest the "Drunk-in-Charge" articles in the *Journal* of June 21 (pp. 1438 and 1442). I assume that Colonel T. E. St. Johnston's figures, quoted in Appendix 2 of the paper by Professor John Cohen and his colleagues (p. 1438), apply to the county of Lancashire, because the local police surgeons are convinced that figures for the Preston Quarter Sessions are more striking still. It is currently believed that on an average 8 out of 10 of the persons electing to go for trial to Preston Sessions are not convicted.

Some will claim that this is a strong argument in favour of the jury system, others that there is no greater indictment against it. I am sure that police surgeons are just a bit tired of the baiting and badgering that goes on at Sessions in an attempt by the defence to establish a case, especially when no doctor is called for the defence. Doing one's best for one's clients seems to involve a clash between what is legal and what is justice, and the barrister most likely to impress the jury stands a very good chance of winning his case—but is that really justice?

I had a case a few years ago on which a Preston jury could not agree; it was reheard at Liverpool with the same evidence, and ended in a verdict of guilty and a sentence of five months' imprisonment—so strongly did the judge feel about it. Did the Liverpool jury show more acumen? Were they less impressed by the same barrister who appeared at Preston? Did the change of judge make any difference? No doubt many other factors could be considered as well. I believe that juries are chosen far too easily, and I would favour a jury of magistrates, who have far more experience than other persons. It is an obvious commentary on these cases that many are advised to go to Sessions for trial because, with juries composed as they are, they have a far better chance of escaping conviction. When will it be realized by juries that no doctor in his senses is going to appear at Sessions unless he is absolutely convinced of the justice of his case? And when will it be realized that of the persons examined at police stations approximately 40–50% are not sent for trial at all?—I am, etc.,

Preston.

W. A. SIMPSON.

Do Sebaceous Cysts Exist?

SIR,—My former teacher, Dr. J. L. Edwards, is right to draw attention to the rarity of sebaceous cysts (*Journal*, June 21, p. 1480). As a surgeon I seldom, if ever, see one, but the common epidermoid cyst is still described as sebaceous by most medical men, and even by the recently qualified. Yet in 1897 S. G. Shattock¹ gave a true description of their nature, and, if I rightly recall, he described the cyst as lined with an extension of the general epidermis. Besides, the cyst usually arises in a hair follicle and not in a sebaceous gland.—I am, etc.,

Doncaster.

DAVID AIKEN.

REFERENCE

- 1 Shattock, S. G., *Trans. path. Soc. Lond.*, 1897, 48, 254.

SIR,—No doubt Dr. J. L. Edwards (*Journal*, June 21, p. 1480) is right when he says that most of the cysts clinically diagnosed as "sebaceous" are in fact of epidermoid structure microscopically, but one often receives such cysts which have a distinctly, and often repulsively, strong sebaceous odour. Yet the lining is stratified squamous epithelium

without appendages and the contents are shed keratin. May it not be that they originate as sebaceous cysts and undergo squamous changes later?—I am, etc.,

Chertsey, Surrey.

C. F. ROSS.

Suffocation in Infancy

SIR,—My newspaper recently reported the case of a baby of 5 months being smothered within the normal environment of a playpen whilst her mother was answering the telephone. One wonders how often very young children are accidentally killed by mechanical occlusion of the respiratory apparatus. The discovery that tracheo-bronchitis accounts for a number of deaths formerly considered to be due to smothering may have attracted attention away from the purely mechanical hazards which still exist.

Some months ago my partner was called to see the cyanosed body of an 18-months-old baby that had just been found dead in its pram. There was a pressure mark on the neck. Apparently this was caused when the baby got its head trapped between the end of the pram and one of the lifting floor-panels which this vigorous and healthy infant had managed to lift on its hinge. This picture, of course, suggested that death was due to prolonged moderate strangulation, but the pathologist, being unable to demonstrate any of the classical signs of asphyxia at post-mortem examination, told the coroner that in his opinion death was due to vagal inhibition of the heart caused by pressure on the nerve.

About three months ago I myself, as coroner, came across a case of smothering that was confirmed by post-mortem examination, though terminal inhalation of vomit appeared to have completed the asphyxia. This was a very healthy and normal infant 3½ months old that had been fed as usual and then for the first time put down to sleep on its belly in an otherwise normal night routine including a very reasonable and practical cradle arrangement. The mother, wife of a professional man, was rearing her first infant with meticulous care and largely according to instructions in the *Sunday Express Baby Book*. She had deliberately put the baby down on its belly with the face turned to one side as illustrated in this book and recommended by it for babies who had attained the age of 2 months and were able to raise their heads from this position unaided. This unlucky infant apparently survived the experiment for only half an hour, during which time it was heard to be crying as the mother was led to expect from the description given in the *Baby Book*. It was not until she went to feed it about eight hours later that she discovered that death and not sleep had put an end to its crying. The book had advised that the experiment should be commenced when baby was very sleepy and had just been fed, and it would appear that both these conditions were factors contributing to the fatal outcome. On the whole I would agree with the opinion of the doctor who gave evidence in this case: that infants should not be compelled to adopt attitudes that they do not select naturally; though it must be conceded that in many countries it is customary to put babies down on their abdomens from birth.

My latest case of this sort occurred only a month ago; the victim was the 5-weeks-old son of an American serviceman: in the opinion of the doctor reporting the case and of the pathologist who performed post-mortem examination, the baby died of asphyxia shortly after being placed face downwards and left for the night. This infant had been healthy apart from a discharging navel; and, like most American babies, was accustomed to the prone position. However, it may be significant that the post-mortem lividity of the face was interrupted by white pressure areas on the nose and around the mouth, and that the air passages in this case, as in the previous one, were full of what the pathologist reported as "terminal vomit."

These tragedies are appalling even to those who come across them merely in a professional capacity. They suggest that there may be here a category of infant mortality which would merit a little investigation with publicity.—I am, etc.,

Eye, Suffolk.

J. SHACKLETON BAILEY.

Aortic Thrombosis

SIR,—I read with great interest the article by Dr. F. Starer and Dr. D. Sutton (*Journal*, May 31, p. 1255). Under aetiology mention is made of one case with fused kidneys who also had retinitis pigmentosa. The Grönblad-Strandberg syndrome¹ consists of typical pseudoxanthomatous

skin lesions associated with angioid streaks of the retina, which on occasion can prove difficult to distinguish from the changes of retinitis pigmentosa.

Sheie and Freeman² showed that angioid streaks of the retina could be associated with peripheral vascular disease, and others have reported angioid streaks in association with hypertension, cardiac arrhythmias, and bleeding from the gut and even from the uterus. Finnerud and Nomland³ have precisely shown the skin lesion of the Grönblad-Strandberg syndrome to be heavily impregnated with calcium phosphate. Sheie and Freeman found findings in the skin are those of swelling and fragmentation of the elastic elements. The degenerate fibres may occur in coils, and the presence of occasional giant cells has been noted. I¹ described a case of this syndrome in which radiology revealed calcification in the line of the femoral arteries, although there was no history of intermittent claudication, hypertension, or angina pectoris and no signs of inadequacy of the peripheral circulation.

The Grönblad-Strandberg syndrome is thought to be due to a generalized degenerative process of the elastic tissue of the body, and it would be of interest to know if any of the cases of Drs. Starer and Sutton showed evidence of pseudoxanthomatosis or angioid streaks of the retina, and also to know the histology of the involved aortic segments in their cases of aortic thrombosis, with especial reference to the elastic elements. An interesting speculation is the possibility of a generalized degenerative process of elastic tissues, as in the described syndrome, leading to fracture of the intima, atheromatous changes, and finally thrombosis in the aorta or other vessels. Although not dangerous to life, the prognosis in cases of the Grönblad-Strandberg syndrome is poor as regards visual acuity, blindness often being an end result.—I am, etc.,

Tropical Hazards of Pentachlorophenol

SIR,—The article by Dr. J. A. Menon on tropical hazards associated with the use of pentachlorophenol (*Journal*, May 17, p. 1156) was of considerable interest to me, as the sodium salt ("santobrite") has been in daily use in our sawmills both here and in Nigeria for the past 10 years.

Our local conditions are very similar to those in Sarawak. The climate is practically the same, and our employees also mostly have mixed worm infestations. Their general standard of physique is definitely better than that of the Dyak. The sawmills in each country are the same in design and each has two dip-tanks. In the one, sodium pentachlorophenol is used in a solution of 1.34% concentration, and in the other the concentration is 3.5%. The increased strength in the latter tank is due to the fact that, being in the boxwood mill, the boxwood is stacked whilst wet and the boxwood mill, the manufacturing process. These two is not seasoned in the manufacturing process. The concentrations remain constant throughout the year, as opposed to the practice described by Dr. Menon. The lumber is mechanically handled both in and out of the tanks and the solution is sprayed on to it by a series of multiple jets. Employees handling lumber after it has passed through the tanks wear protective rubber gloves, are provided with a barrier cream, and have washing facilities within a few yards of the tank site. There is no rotation of employees in this job and no dietary supplement is given.

There has been no case of an illness arising in any of these employees attributable to sodium pentachlorophenol since we started using this compound. In the boxwood mill the dip-tank, which has the higher concentration of 3.5% in the solution, there is also ethyl mercuric phosphate in a concentration of 0.1%. Though this is a well-known toxic compound (Agriculture, Poisonous Substances, Organo-

Mercury Compounds, Order, 1956), again we have had no cases of an attributable illness arising out of its use.

I would like to thank the General Manager for permission to publish this letter.

—I am, etc.,

Medical Officer,

Samreboi, Ghana.

African Timber & Plywood (Ghana) Ltd.

Intravenous Pethidine

SIR,—Mr. C. E. P. Markby's interesting article (*Journal*, June 14, p. 1397) on the use of intravenous pethidine in conscious patients brings to mind a personal experience which may in a small way illustrate further some of his observations, though applicable to another age group and occurring under different conditions. While serving in the British Commonwealth General Hospital in Kure, Japan, during the last eighteen months of the Korean campaign, I had an opportunity of trying intravenous pethidine in doses of up to 300 mg. in some hundred or so cases of burns suffered by men of the Commonwealth Division in Korea.

The burns were caused mainly by space-heaters exploding in a confined space. The heaters, fired by oil and water, were re-introduced into service in the autumn of 1952 to help to protect troops against frost-bite, which had the previous winter taken its own toll. It may well be argued that the cure in this instance was more deadly than the disease. The patients arrived in Japan by air convoy, having previously received first-aid treatment and bandaging for their burns in either a U.S. or Norwegian Mobile Army Surgical Hospital (M.A.S.H.).

As the "exposure" method of treatment was current, the problem was to find a pain-free method of removing the dried and sticking dressings, cleansing the burnt areas, and excising eschars and dead skin without increasing the nursing problems or interfering with the surgical management of battle and other casualties which formed the bulk of the evacuation convoys. Without doubt, after a trial with intravenous procaine, inhalational analgesia, and inhalational anaesthesia, the most satisfactory answer was intravenous pethidine, and it became standard practice to use an average of 200 mg. per patient, injected in 50 mg. doses over a period of a few minutes. It was thus possible to produce safe and almost ideal operating conditions for the British, Australian, and Canadian surgeons working on the four tables available. At the same time the willing co-operation of, and adequate analgesia for, the patients were obtained.

Respiratory depression was not a problem. Any slight slowing in respiratory rate was more than compensated for by an increase in depth. A further advantage in these cases was the relative ease with which transfusions could be set up owing to the vasodilatation provided by the pethidine.

Worthing, Sussex.

P. J. C. BURTON.

Dysgerminoma in Pregnancy

SIR,—It may be of interest to report the following case, a dysgerminoma complicating pregnancy.

A primigravida, aged 18, was admitted on April 10, 1958. She gave a history of intermittent colicky lower abdominal pain for one month, with a brown vaginal discharge for 24 hours. The last menstrual period had commenced four months previously, on January 7. The menstrual cycle was regular, 5–6/28 days. On examination, the uterus was found to be enlarged to the size of a 14-week pregnancy. The cervix was normal and the os was closed. A mobile, firm swelling above and to the right of the uterus, the size of a foetal head, was noted. A diagnosis of threatened abortion with an ovarian cyst complicating pregnancy was made. The pain was thought to be due to partial torsion of the pedicle. The pain and bleeding subsided with rest in bed, and she was discharged a week after admission to return for removal of the cyst one month later.

On readmission the ovarian swelling was thought to have increased in size. At laparotomy a solid ovarian tumour was found on the right side. The pedicle was twisted through 180°. The left tube and ovary, and the uterus, were normal for the duration of pregnancy. There was no evidence of metastases in the abdominal lymph nodes or on the peritoneum. The ovarian tumour and the right tube were removed. The patient made an uneventful recovery. The pathological report on the specimen was: "The tumour consists of an irregularly shaped, white soft

mass, measuring 20 by 20 cm. The cut surface showed it to consist of soft white tissue. Several areas of haemorrhage were seen. Section showed a dysgerminoma; the capsule appears to be intact in the sections examined, but histologically this tumour is certainly malignant." To date the pregnancy is progressing normally.

I should like to thank Mr. D. Jefferiss for permission to record this case.

—I am, etc.,

Exeter.

JILL M. EVANS.

Oesophageal Atresia

SIR.—The article by Mr. C. Parrish and Mr. C. F. A. Cummings on oesophageal atresia (*Journal*, May 17, p. 1140) and the correspondence arising from it (*Journal*, May 31, p. 1297, and June 14, p. 1414) have been of great interest. My own experience of 16 cases has been very similar to that of the authors and most of the correspondents; i.e., an overall recovery figure of a little more than 50%, which would have been better but for associated abnormalities. There are some points of technique and management which have arisen in my experience and which may be of interest.

In general I agree with Miss Isabella Forshall and Mr. P. P. Rickham (*Journal*, June 14, p. 1414) that operative detail is of little importance compared to post-operative management, but there are two points which arise at the time of operation which have a great bearing on the survival prospects. The first of these is that these infants are often found to be reluctant to regain consciousness, and poor breathers, at the end of operation. This may wrongly be attributed to shock or to overdosage with anaesthetic agents; in fact it is due to a hypothermic state, and we have recorded temperatures as low as 88° F. (31.1° C.). This is not entirely due to exposure during operation, because a low temperature is also found pre-operatively; this seems due to the general exposure which the infants suffer during radiographic screening, the setting up of intravenous drips, transfers from one ward to another, or from one hospital to another, etc. This hypothermy is of little significance, and responds readily to simple warming in an incubator; it is important only in that it must be recognized.

A second point is that survival depends to some extent on the size of the fistula; usually this is a pin-point, and, if so, successful operation may be carried out several days after birth; but sometimes the fistulous orifice is the full diameter of the oesophagus, allowing free reflux of gastric contents and bile, which set up a far deadlier pneumonitis than does inhaled milk. Two such cases have come my way. Both succumbed from pneumonia, though operated upon within 24 and 36 hours, respectively. A narrow lower oesophageal segment may be a disadvantage to the surgeon, but it confers some protection on the patient. There is invariably a great disparity in size between the thick upper segment and the tenuous lower oesophageal segments. This can be overcome by not using for the anastomosis the ½-in. (6.4 mm.) of lower oesophagus which entered the trachea. Mr. R. H. R. Belsey has maintained (unpublished) that this small length derives its blood supply from the trachea, and is avascular when detached from it; this may well be true, but it seems to me that it is also fibrotic and the lumen cannot be dilated easily; a little lower down, however, the oesophagus, though very thin, dilates easily, and the disparity in size to the upper segment can be reduced to a useful extent by gentle dilatation prior to anastomosis.

In the post-operative management, for fear of damage to the suture line, I have avoided an indwelling tube, and have relied upon intravenous fluids for a few days before breast-feeding is recommended; but, since the advent of the very fine, soft polythene tubing, these objections have been overcome. But whether intravenous or tube feeding is used, there is no doubt that it should be in the hands of paediatricians especially skilled in this work. I have been fortunate that Dr. H. V. Finlay has always been readily available to undertake the all-important post-operative management of my cases.—I am, etc.,

London, W.1.

KENNETH S. MULLARD.

Unusual Case of Herpes Zoster

SIR.—A case of herpes zoster is reported on account of an unusual feature—namely, the association of a relatively very small area of sacral herpes with a large area of petechial rash extending from the groin to the ankle on the same side as the herpes.

On February 4, 1958, a garage mechanic aged 41 complained of pain in the sacral region just to the right of the midline where, in the second lumbar and perhaps third sacral dermatomes, was a single patch of zoster vesicles of about 4 sq. in. (26 sq. cm.). The pain radiated to the thigh. Two days later the herpetic area was no larger but pain was much worse, and by February 10 it made the patient stay in bed. There was still no extension of the herpes, which had become haemorrhagic, but the buttock, thigh, and leg now showed a petechial rash (flat, discrete, bluish macules 1-2 mm. across) which did not blanch on pressure. On the external aspect of the buttock and thigh the petechiae were in the second lumbar dermatome, but not lower than about 3 in. (7.5 cm.) below the great trochanter. On the inner aspect of the

limb (see photograph) they extended from the groin to just above the internal malleolus, in the third sacral and second, third, and fourth lumbar dermatomes. No petechiae were seen over the rest of the body. Blood taken on February 11 showed: Hb 105%; W.B.C. 5,300, neutrophils 55%, lymphocytes 42%, monocytes 2%, eosinophils 1% (Dorset County Laboratory).

On February 13 the petechiae had begun to fade. Pain in the thigh and calf still prevented walking. By February 18 the petechiae had become invisible while the patient stayed in bed, but became obvious whenever he had been up for 10 minutes. On February 20 the sacral patch of herpes, still its original size, was red and scaly. The pain, still disturbing sleep, seemed to be in the femur and tibia; by the 25th it was spasmodic, and pruritus was a new and troublesome symptom. Rubbing or scratching served only to aggravate the pain. The petechiae were still to be seen whenever the patient had been up for 10 minutes, and blanching on pressure. The area of sacral herpes was now a pigmented scar. On March 1 the petechial rash had considerably faded, and the patient, now in less pain, returned to work. By March 6 the petechiae were scarcely visible. Not one of them had become vesicular.

Winfrith, Dorset.

Prevention of Lung Cancer

SIR.—The letter from Dr. Lennox Johnston, president of the National Society of Non-smokers (*Journal*, June 21, p. 1483), provokes me to say something on this subject. Dr. Lennox Johnston castigates the Medical Research Council for not having made any recommendations for preventing lung cancer by stopping people smoking. This side of the problem was not theirs to deal with, so far as I know.

Without denying some, but only some, causal connexion between smoking and lung cancer, it must be evident to anyone who has studied the many observations and letters of independent thinkers on this subject of smoking and lung cancer that the case against cigarettes has been very much overstated, and when one does that one spoils one's case.

No amount of frightening talks or warnings will stop the habit unless one can offer a reliable and easy cure. We can take our experience of drinking as a guide—and would one totally absolve alcohol as a contributory cause? What we need now is research to find a cure for those who wish to give up smoking. So far, we doctors have very little to offer, and to ask people to exercise will power is futile.

There is much more in the air we breathe all day and night in a city like London than thirty or more cigarettes a day. Has not industrial expansion, multiplication of laundry and other chimneys, etc., gone on *vis-à-vis* smoking? Coal smoke with sulphur dioxide and benzpyrene and paraffins in automobile exhausts and half-burnt crude oil in a diesel engine are not to be ignored. We cannot ask the Chancellor to surrender his handsome revenue until we can completely eliminate the undeniable influence of all these other factors.

—I am, etc.,

B. J. BOUCHÉ.

London, S.W.19.

Acepromazine in Schizophrenia

SIR.—We were interested to read Drs. Jessie F. Collard and R. Maggs's account of their assessment of the value of acepromazine maleate ("notensil") in schizophrenia (*Journal*, June 21, p. 1452). The nurses' reactions to drug trials which they report have been noted previously.¹

If any trials of this sort are to be used we suggest: (1) The nursing staff can be told that two forms of a new drug are being tried out. This ensures that the curiosity of the nursing staff as to which is the dummy tablet is not aroused. (2) The active and inactive tablets must be identical in respect of taste, smell, colour, shape, size, and texture if the results of the trial are to be considered definitive. An elementary precaution in all drug trials is therefore to assess the similarity of the tablets before the trial is carried out. (3) Assessments of patients should be based on objective rather than subjective evidence. Statistical evaluation of subjective opinions, particularly when the active preparation has observable side-effects, is of doubtful value.

Finally, we were a little disappointed to see such elaborate statistics reported without a simple statement of the average ratings obtained by each group before and after treatment. Our rating scale² can be used to describe schizophrenic patients in objective terms, and to match the treatment and control groups in order to increase experimental precision.—We are, etc.,

Sutton, Surrey.

Littre's Hernia

SIR.—The excellent article on Littre's hernia by Mr. B. R. Meyerowitz (*Journal*, May 17, p. 1154) prompts me to send you the following report on a case of strangulated Littre's hernia, and also further statistics in connexion with the incidence of Littre's hernia.

A man aged 73 was admitted to the Manor House Hospital, Golders Green, on March 3, 1958, by ambulance from his home 35 miles away. He had noticed a lump in the right groin for a week and had several attacks of nausea but had not vomited. During the course of his journey by ambulance he had vomited three times, and on admission was suffering from abdominal distension. A diagnosis of strangulated right femoral hernia was made, and he was submitted to operation, the approach being made by a radical incision dividing the inguinal ligament transversally. The abdomen was opened above the constriction. The gangrenous covering of the hernia was incised, and it was noted that the Meckel's diverticulum was dragging on and it was noted that a part of the wall of the intestine into the small intestine, pulling a part of the wall of the small bowel was almost the hernial sac so that the lumen of the small bowel was almost occluded. The diverticulum was freed and excised. The gangrenous covering and the hernial sac were also excised, and a repair of the inguinal ligament was carried out. He made an uneventful recovery and was discharged fit and well on April 2.

Pathological examination revealed the following: *Specimen*.—A plum-coloured diverticulum, 3.5 cm. long by 2 cm. broad. The wall was swollen by oedema and the inner lining was somewhat roughened. There was no macroscopic evidence of ectopic tissue. *Histology*.—Early strangulation of Meckel's diverticulum. The diverticulum was lined by small-intestine mucosa. There were no ectopic tissues.

In a series of 5,325 operations for inguinal herniae and 210 operations for femoral herniae, personally performed at the Manor House Hospital, all in male patients, there was no case in which a Meckel's diverticulum was found in the hernial sac.—I am, etc.,

London, N.W.11.

J. W. NICOLSON.

"Nacton" in Elderly Patients

SIR.—The articles by Drs. A. H. Douthwaite, J. N. Hunt, and I. Macdonald (*Journal*, August 3, 1957, p. 275) and by Drs. A. H. Douthwaite and J. N. Hunt (*Journal*, May 3, p. 1030) on the use of 1-methyl-2-pyrrolidyl methyl benzilate methyl methosulphate ("nacton") have doubtless established the value of this drug in the management of peptic ulcer and hyperchlorhydric dyspepsia. Recent clinical observations at the Walnut Tree Hospital suggest, however, that it may have other important, entirely different and equally significant effects which deserve to be observed.

I recently gave nacton to a small series of 20 elderly patients suffering from emotional disharmony of the kind that follows atherosclerotic cerebral episodes or is associated with anxiety states. These apathetic, largely unmanageable people who either do not respond or become worse when receiving drugs usually described as "tranquillizers" were given nacton in varying dosage from 4-30 mg. daily. In 70% of these patients the drug was observed to have a noticeably beneficial action: the apathetic patient became alert, more interested in his surroundings, the appetite was improved, and the management of the patient consequently facilitated. In 50% of cases restlessness and confusion were controlled, although this effect diminished after a week's administration of the drug. When placebo tablets were substituted for the active drug the beneficial results described above were not obtained. Moreover, in the dosage given, which is well below the therapeutic maximum, no significant side-effects of any kind were observed and no drowsiness was induced.

The cases observed in this series were under the care of Dr. H. Bathurst Norman, who has kindly given me permission to publish these preliminary observations.

—I am, etc.,

Sudbury, Suffolk.

A. E. GIBBS.

Induction of Labour

SIR.—I was interested in the results of surgical induction of labour reported by Professor G. Gordon Lennon and Mr. E. M. Edwards (*Journal*, June 14, p. 1413). They induced labour at the 38th week of pregnancy in all cases of pre-eclamptic toxæmia and essential hypertension not requiring intervention before that time. Under our care there has been a similar group of cases, to which were added a few with a history of previous toxæmia. Treatment consisted of diet, rest, in some rauwolfia drugs, and, if necessary, admission to hospital, especially about the 28th week, in patients with a rising blood pressure or an initial severe hypertension.

Our series consisted of 950 patients, of whom the large majority went into spontaneous labour at term. The induction rate by rupture of the membranes was 7.3% and in approximately the same percentage medical induction was used. There were 11 stillbirths and 7 neonatal deaths, an uncorrected perinatal mortality of 18.9 per 1,000. Maceration prevented an accurate estimation of foetal abnormalities, but three deaths were due to haemolytic disease.

In attempting to improve our mortality figures, one of our big problems has been the prevention of foetal maceration. Of 11 stillbirths in our series, 7 were macerated, 6 before the 38th week of pregnancy. As regards the neonatal deaths, these have been greatly lessened by more exacting antenatal care, which reduces the need for interference and secures a healthier and more mature baby.—I am, etc.,

London, W.1.

D. J. MACRAE.

Medical War Crimes

SIR,—I would like to add my voice to those of your other correspondents (see *Journal*, June 28, p. 1546) who deplore that Dr. Herta Oberheuser should be allowed to resume practice after such flagrant betrayal of the spirit of the Hippocratic Oath, and agree that an official protest should be made on behalf of British doctors. The German medical fraternity should know exactly what we feel about it. There must be hundreds of doctors, if not thousands, at home and abroad who feel strongly about this, but just have not the time to sit down and write to tell you so.—I am, etc.,

Eldoret, Kenya.

H. LIVINGSTONE PEAKE.

SIR,—Dr. A. P. Tait's suggestion (*Journal*, July 5, p. 51) that Dr. Herta Oberheuser might now be a "dedicated practitioner, doing good work," is staggering in its naïveté. Does he not realize that the very idea is an insult to her countless victims?

This war-criminal, found guilty of crimes against humanity so dreadful that the mind boggles at the thought, has forfeited all right to be accepted by civilized people. I came into contact with many of the victims of these monsters in Belsen towards the end of the war, and the experience was shattering. It might perhaps be more adult of Dr. Tait if he spared a thought for these people rather than for their torturers.—I am, etc.,

London, N.2.

S. BENNETT.

Malignant Exophthalmos

SIR,—Mr. Lionel M. Green (*Journal*, June 21, p. 1479) does not say what treatment had been used before acetazolamide gave such an excellent result. We have had very good results from irradiation in such cases, avoiding the need for orbital decompression.—I am, etc.,

Broadstairs.

R. A. D. CRAWFORD.

Dummy Tablets

SIR,—The suggestion of Dr. E. C. Atkinson (*Journal*, June 21, p. 1478) that the *British National Formulary* should contain control tablets of inert substances rather flatters the *Formulary* by suggesting it does not do so now. I would hardly consider soda mint or calcium lactate tablets likely to produce striking pharmacological results.

If one is trying to find the remedy most likely to help a patient there seems no point in wasting time on dummy tablets. Ascorbic acid or strong vitamin B compound tablets would help a proportion of one's cases in some surprising ways. For instance, one patient demanding sleeping-tablets claimed that three vitamin B compound tablets per day kept her doped all day and asleep all night. On the other hand, if the doctor is doing pharmacological research on new treatments, it would seem logical to compare them with those previously in use and abstain from adopting them unless clearly superior.

Incidentally, giving inert tablets to cure inertia smacks of homeopathy.—I am, etc.,

Shipley.

H. S. RUSSELL.

Diagnosis of Premature Rupture of Membranes

SIR,—A symptom I have often encountered in antenatal work, particularly in general practice, is the complaint in the later months of pregnancy of loss of fluid from the genital region. Sometimes this is caused by premature rupture of the membranes, and treatment consisting of hospitalization, complete rest, and the administration of prophylactic antibiotics should be instituted as soon as possible. On the other hand, I find that this symptom is more often due to incontinence of urine.

A useful aid to diagnosis, which I have used with success over the last two years, is that of administering a dye which is rapidly excreted in the urine. "Pyridium" marketed as

a urinary analgesic contains an orange dye and is a suitable oral preparation. On being confronted with such a patient, I send her home to bed and tell her to wear a sanitary pad. Two tablets of pyridium are then given by mouth. Some three hours later a urine-soaked pad will be stained bright orange, whereas one soaked with liquor amnii will not be discoloured.

I have been assured by the manufacturers of this preparation that there is no evidence whatever that pyridium appears in sufficient concentration to produce such a colour change in the liquor. I consider that this is an important test, enabling a general practitioner to quickly diagnose premature rupture of the membranes and thus help to reduce the high neonatal mortality rate associated with prematurity.—I am, etc.,

Leamington Spa.

JOHN R. LAMB.

Management of Tetanus

SIR,—May I add a comment to my letter on the management of tetanus in the *Journal* of June 7 (p. 1354), which also contained a report (p. 1350) of a recent discussion of the subject at the Royal Society of Medicine? In the report of this discussion there was no allusion to the treatment of the wound, yet here there are differences of opinion. In accordance with one view, on the appearance of tetanic symptoms the wound should be excised in order to diminish the absorption of toxin. No evidence has hitherto been adduced to support this view; on the other hand, interference with the wound may be followed by an exacerbation, sometimes fatal. This appears to apply particularly to extensive wounds; in small superficial wounds the danger seems less, and in selected instances amputation may bring rapid improvement. With regard to non-interference with the wound, in several recent records of recovery from tetanus no local surgical treatment had been given. Looking back at my war cases of 1916 (see my earlier letter), severe tetanic symptoms subsided under A.T.S., sloughs and missiles being left undisturbed.

In the attempt to reduce the high mortality of tetanus, more information is needed. In the discussion at the R.S.M. Dr. A. Crampton Smith is reported as describing seven very severe cases of tetanus with three deaths. In these and similar cases details of the treatment of the wound would be of great value.—I am, etc.,

Sheffield, 10.

R. G. ABERCROMBIE.

POINTS FROM LETTERS

The Fear of Death

Dr. S. G. PAPADOPOULOS (Nicosia, Cyprus) writes: I was interested to read the report of Dr. Eliot Slater's lecture "The Biologist and the Fear of Death" (*Journal*, April 12, p. 885). This reminded me of the often repeated statement by the late Lord Horder that in striving to keep alive people who are dying and beyond any human aid, one does not prolong life, one prolongs death. Some years ago we brought back a patient suffering from advanced leukaemia to a fairly good state of health with deep x-ray therapy. This lasted for two to three months, when suddenly one day after a severe headache he became unconscious and was taken back to the clinic for further treatment. The patient, a young man of 35 of some considerable social and financial status, came from abroad and his mother was staying with him. Lord Horder explained to her the hopelessness of the case and asked her whether we should leave him to die in peace or revive him for a short time with further treatment. It was then that he said, "My dear, we are not going to prolong his life by doing this, but we will prolong his death." She, however, expressed the wish that she would like to speak to her son again and also ask him about his last wishes on various family matters. With further treatment he came round and was able to have a few hours tête-à-tête with his mother. Soon afterwards he fell into a deep coma, one could feel that nothing further could be done, and he was left in peace.

Asphyxia by the Cord

Lines 18-20 of Dr. C. W. Walker's letter (*Journal*, July 5, p. 47) should have read: "Dr. Reiss's case illustrates very clearly that foetal distress appeared during the first stage" (not "second stage").

Obituary

MORAY MELVIN, M.D.

Dr. Moray Melvin, one of the best-known medical practitioners in the West Riding, died at his home at Lofthouse, near Wakefield, on June 20. He was 62.

Moray Melvin was born at Fraserburgh, Aberdeenshire, on March 14, 1896. He had a distinguished career as a student at Edinburgh University, winning the two Cunningham medals in anatomy and graduating M.B., Ch.B., with honours, in 1918. He proceeded to the M.D. in 1933. Immediately after graduating he joined the Army and as a captain in the R.A.M.C. served with the British Expeditionary Force in the North Russian campaign. At the end of hostilities he returned to his university for a time as demonstrator in anatomy. But there was not enough scope for his agile, questing mind, so he forsook the scalpel for the hurly-burly of general practice. Seldom has a man been better equipped for the job, for in addition to his undoubted ability as a doctor he had the human touch. For nearly forty years in the Rothwell and Lofthouse districts of the West Riding he dedicated himself to the care of his patients and quickly built up a large practice. His capabilities were also rewarded when he was appointed medical superintendent of St. George's Hospital, Rothwell, and medical officer of the Yorkshire Copper Works. He was also joint secretary of the Leeds Advisory Council on occupational health and lecturer to disablement resettlement officers. Not content to be simply the family doctor in a mining practice, he was keen to do something for the profession as a whole, and this he achieved by his devoted services to the Yorkshire Branch and Leeds Division of the B.M.A. He was chairman of the latter in the last year of his life. Enthusiastic in his support of the National Health Service, after its inauguration he became vice-chairman of the Wakefield "A" group hospital management committee and chairman of its general purposes committee. A member of the West Riding local medical committee, he was chairman of the local obstetric committee and of the liaison committee of the West Riding health and general practitioners committees. A fluent and cultured speaker, he was president of the Leeds Medico-Chirurgical Society in 1950-1. His death at the height of his powers will be much regretted. The manner of his going was something to marvel at, for he fought a losing battle with unflinching courage. His knowledge of medicine had made him brutally aware for some three years that his days were numbered, but despite cruel disabilities he spent them selflessly visiting the sick in the home, the hospital, and the workshop right to the very end. For him there could be no more fitting epitaph than the words with which the Vicar of Leeds closed his address at the funeral service: "Moray Melvin, beloved physician."

Dr. Melvin is survived by his wife, who is a West Riding J.P., and two married daughters.

CHARLES MARKUS, M.D., M.R.C.S., L.R.C.P.

Dr. Charles Markus, consulting ophthalmic surgeon to the German Hospital, Dalston, died suddenly on July 27, aged 83 years.

Dr. HUGO RAST writes: After studying medicine in Munich, Strasbourg, and Freiburg, Charles Markus graduated in 1898 with the degree of M.D. (Freiburg). He was subsequently first assistant at the ophthalmological clinics of the university hospital at Göttingen and Halle a/S. Leaving this post to settle permanently in London, he passed the conjoint examination in 1903. Later he joined the staff of the German Hospital, first as assistant, then as full ophthalmic surgeon. He retired during the second world war. Markus was a man of the kindest disposition—modest,

loyal, upright, and unselfish to a degree, ever ready to help without considering the remuneration. Although of rather a retiring nature, he was a fellow of the Royal Society of Medicine and a member of the Ophthalmological Society of the United Kingdom, taking a keen interest in the work of both bodies, and he was a member of the B.M.A. for 53 years. In his spare time Markus was an ardent reader of philosophical literature. We have lost in him a kind and likable colleague, a philanthropist in the true sense of the word.

Dr. F. PARKES WEBER writes: Markus's name was especially associated with the so-called Markus's or Adie's ocular syndrome, which at one time could easily be confused with a well-known pupillary phenomenon of tabes dorsalis. There can be no doubt, however, that this peculiar form of "myotonic pupil" associated with absent tendon reflexes was first described by Dr. Markus (*Trans. ophthalm. Soc. U.K.*, 1906, 26, 50). Adie made the subject widely known by his excellent paper on the possible confusion of the syndrome with tabes dorsalis. It was my privilege to be able to demonstrate Markus's original patient at a meeting of the Clinical Section of the Royal Society of Medicine in March, 1933, 27½ years after Markus's original description ("More Forgotten Nosographs," *Med. Press*, 1957, 237, 266).

G. H. GARLICK, M.R.C.S., L.R.C.P., D.M.R.E.

Dr. G. H. Garlick, medical director of the Singapore Antituberculosis Association, died while on leave at Lucerne, Switzerland, on June 6.

George Herbert Garlick was born in London in 1886, the son of Dr. George Garlick. From Epsom College he entered St. Mary's Hospital Medical School, and qualified in 1912. After holding the appointments of house-physician, resident anaesthetist, and house-surgeon at St. Mary's Hospital, and assistant medical superintendent of Highgate Infirmary, he went to Malaya in 1914 as medical officer to a tin-mining company at Trengganu. Three years later he became a medical officer to the Johore Government, and as assistant to the principal medical officer in Johore Bahru he was actively engaged in hospital and public health work in the State, as well as with the medical supervision of the gaol. At that time there were only two other medical officers in Johore State. In 1930 he was appointed principal medical officer, a position which he held until his retirement in 1942. Radiology became one of his special interests, and he took the Cambridge D.M.R.E. in 1927.

N. C. S. G. writes: During his service in Johore Dr. G. H. Garlick proved himself to be an able, energetic, and progressive medical administrator. He was responsible for much rural public health work, the establishing of a modern nurses' training school, and the building of a first-class modern hospital with many unique features. In recognition of his valuable services he was accorded the title of Dato—an honour given by the Sultan of Johore. During the second world war he joined the British Army as a radiologist, and was a prisoner of war in Changi Gaol. Serving with the British Military Administration after the war, he re-established civil radiology at Kandang Kerbau Hospital, and after a period as medical officer in charge of officials he became assistant radiologist at the General Hospital, Singapore. In 1948 he was appointed radiologist and medical director of the Singapore Antituberculosis Association and continued in this dual capacity until 1955, when the appointment of a radiologist enabled him to devote his whole time to his greatly increased responsibilities as medical director, work which he carried out with ability, enthusiasm, and far-sightedness. The growth of S.A.T.A.'s clinic, the steady expansion of its services, and the efficiency of its organization have been contributed to by many, but it was Dr. Garlick's vision, tenacity of purpose, unremitting toil, and human interest which built up in Singapore an institution worthy of the cause it serves. The clinic and its

services stand as a permanent memorial to his unselfish and humanitarian work. Those who had the privilege of working with him learned to know him as a man of thoughtful consideration, singleness of purpose, and unselfish endeavour; a man who acted and spoke, even at cost to himself, for what he believed to be right and in the best interests of the cause to which he devoted himself wholeheartedly.

H. E. HARGREAVES, M.R.C.S., L.R.C.P.
D.T.M.&H., D.O.M.S.

Dr. H. E. Hargreaves, who was a medical missionary in Persia for a quarter of a century, died suddenly on June 4. He was 60 years of age.

Henry Ellison Hargreaves was born at Bath in March, 1898, and was educated at the Stanborough Park Missionary Training College, Watford, where his studies were interrupted by service in the first world war. After demobilization he became a medical student at Charing Cross Hospital, qualifying in 1924. He then held the appointments of house-surgeon at Huntingdon County Hospital and resident medical officer at the Royal Victoria and West Hants Hospital, Bournemouth. In 1925 he went out to Persia as a medical missionary under the Seventh-Day Adventist Mission Board. The prevalence of eye diseases in that country stimulated his interest in ophthalmology, and while on periods of leave he studied the subject at Moorfields, obtaining the Diploma of Ophthalmic Medicine and Surgery of the English Royal Colleges in 1936. Earlier, in 1929, he took the D.T.M.&H. at the London School of Hygiene and Tropical Medicine. After 25 years in Isfahan, Sultanabad, Tabriz, and Tehran, he accepted an invitation to serve as medical secretary of the Australasian Mission Board of Seventh-Day Adventists, and in that capacity supervised the medical work of the denomination, especially in the islands of the South Seas. In 1953 he joined the Commonwealth Repatriation Department in Sydney, in his chosen field of eye specialist, and held the position until the time of his sudden death from a coronary occlusion. He was much beloved by all those who knew him in Persia, England, Australia, and the South Seas. Unfailingly cheerful, he brought his strong Christian faith into all that he undertook. He leaves a widow, a son, and three daughters.

OLOF HULT, M.D.

Professor Olof Hult, the Swedish medical historian, died recently at Stockholm. He was 89 years of age.

Olof Torgny Hult, the son of a schoolmaster, was born in Stockholm on December 2, 1868, and educated there and at Upsala. He qualified in medicine in 1899, proceeding to the M.D. in 1914. He was in practice from 1901, specializing in gastroenterology. Appointed medical adviser to the Swedish Navy, he was personal physician to the Crown Prince, afterwards King Gustav V. Hult held teaching posts at the Karolinska Institutet in epidemiology (1916) and history of medicine (1924) and was given the rank of professor in the latter subject in 1934. In later life Hult devoted more and more of his time to the medical history of Sweden, being a pioneer in this field. He wrote accounts of the historical aspects of relapsing fever, plague, leprosy, scarlet fever, and other infectious diseases occurring in Sweden, and also contributed many biographies of Swedish physicians of the past. He was chairman of the medical history section of the Swedish Medical Society and a staunch supporter of the International Society for the History of Medicine. He married in 1902 Gertrud Rinman.

HELEN ASHTON, M.B., B.S.

Dr. Helen R. Ashton (Mrs. Arthur Jordan) died at her home near Lechlade on June 27, aged 66. She retired from the practice of medicine many years ago, but as a novelist she was known to many under her maiden name of Helen Ashton.

Helen Rosaline Ashton was born on October 18, 1891, the daughter of Arthur J. Ashton, K.C., Recorder of Manchester, and sister of Sir Leigh Ashton, formerly director of the Victoria and Albert Museum. After working as a V.A.D. in the first world war she decided to study medicine, qualifying from the London Hospital in 1921. In the following year she graduated M.B., B.S. at London University. Not long after she had completed resident hospital appointments at the Evelina Hospital for Children she married Mr. Arthur Jordan and gave up medicine. She continued, however, to write novels, and in 1930, with the publication of *Doctor Serocold*, she had her first major success. *Yeoman's Hospital* (1944) was later made into a film under the title of *White Corridors*. Besides novels Miss Ashton wrote a number of books about literary figures of the past, including William and Dorothy Wordsworth, Henry Vaughan, and Jane Austen. In many of her books she used her medical knowledge to advantage, though never displaying it obtrusively.

J. F. COATES, M.D., M.R.C.P.

The obituary of Dr. J. F. Coates was printed in the *Journal* of June 14 (p. 1424).

R. S. H. writes: The passing of Jack Coates exemplifies again the fallacy that "we are none of us indispensable." Jack Coates is irreplaceable. His characteristics were many. He was widely and deeply read, but his erudition was informed throughout with what can only be described as "lovingkindness." He was loved and trusted by his patients, by his colleagues, and by his staff. His enthusiasm was a very real thing, and more than one of us benefited by it continuously. He had wisdom and humility. We shall mourn him for a long time. Our sympathy for his widow is deep and lasting, but we should like to share, if we might, in the pride that she must feel for him.

Medico-Legal

"FAIR COMMENT"

[FROM OUR LEGAL CORRESPONDENT]

It is a function of the law of libel in England to hold the balance between the right of the individual to the protection of his reputation, and the interest of the community as a whole in the free propagation of news and opinion. This is fulfilled in part by the defence known as "fair comment," available to anyone against whom an action for libel is brought. The underlying principle is that the individual has to surrender part of his right where the circumstances of the publication complained of are such that the good of the community requires freedom to publish, if necessary at the expense of the individual's reputation. The interest of the community may require the individual to make such a surrender where the publication is made with no improper motive.

Price of being a Public Figure

Where libellous words are published in the form of comment upon facts which are truly stated and which are of public interest, those responsible for the publication have a good defence provided that the comment is fair and is made without malice. Part of the price which a man must pay for becoming a public figure is that he submits himself to criticism which may lower his reputation in the eyes of right-thinking people, and will have no redress provided it is fair, is made without malice, and is made upon facts truly stated. This defence of fair comment is of course a great help to the freedom of the press, though it is equally available to individuals and gives the press no higher or different protection than is enjoyed by anyone else.

A good example of its operation was given in the action recently brought (*The Times*, June 10 and 11) by Lord

Silkin against Beaverbrook Newspapers Ltd. and the editor of the *Sunday Express*. The *Sunday Express* had published a paragraph entitled "Sugar for Silkin," which criticized him by contrasting his speeches in the House of Lords against arming the Germans with the fact that he was chairman of the English company which distributed the Heinkel bubble car which was selling very well in England during the petrol shortage following upon the Suez crisis.

In his summing-up to the jury Mr. Justice Diplock said that after hearing the evidence they might think that it was not seriously contended that any of the facts in the article were misstated. A good deal was heard nowadays about the intrusion of the press into private life, but Lord Silkin the public man and his attitude towards Germany and the Germans was a matter of public interest on which the newspaper was entitled to comment. As to what was "fair," the limits were quite rightly very wide. People were entitled to hold and express strong views, which members of the jury might think to be exaggerated, obstinate, or prejudiced. The basis provided that those views were honestly held. The basis of our public life was that the crank, the enthusiast, could say what he wanted just as much as the reasonable man or woman. The true test was, was the opinion one honestly held by the writer? In a matter of this kind, relating to views held about Germany and the Germans, the jury ought to be extremely liberal because it was a matter on which men's minds were moved and they entertained very, very strong feelings. If they used strong language every allowance should be made for it.

The jury found in favour of the defendants, and judgment was entered for them accordingly with costs.

SUFFOCATION IN INFANCY

[FROM A PAEDIATRIC CORRESPONDENT]

Elsewhere in this issue (p. 104) a correspondent draws attention to those sudden asphyxial deaths in infancy which from time to time are the subject of coroners' inquiries.

To find a baby dead in its cot, without any previous hint of illness, must be one of the most shocking experiences a parent can undergo. In addition the publicity given to such cases, and the old tales of asphyxia from overlying and from soft pillows, add greatly to the anxiety of many mothers, especially with their first child.

True Cause of Death

How common are these cases? In his *Statistical Review*¹ the Registrar-General records that in 1956 in England and Wales 441 deaths in children under 1 year were registered as due to accidental mechanical suffocation (see Table).

Deaths in England and Wales in 1956 Registered as Due to Accidental Mechanical Suffocation

	Age at Death					Total Under 1 Year
	Under 4 Weeks	4 Weeks and Under 3 Months	3-5 Months	6-8 Months	9-11 Months	
Male	21	96	98	29	18	262
Female	25	63	64	21	6	179
Total	46	159	162	50	24	441

Two points stand out from these figures. One is that the great majority (83.5%) of these deaths occurred before the age of 6 months, but with no preponderance in the first month, when a baby is most helpless. This could be because the babies, as they get stronger and more mobile, turn over and push themselves into positions where asphyxia can occur. The other point is the remarkable preponderance of males in each age group, except the first. Both these observations have been repeatedly made in the past.

When a previously healthy baby is found dead in its cot suffocation is the first possibility that springs to the minds

of both relatives and doctor. This diagnosis condemns the mother to the agonizing thought that she may have been responsible for her child's death, that the position in which she put down her child was to blame. In Britain it is customary to lay an infant on its side, while in the United States the prone position is adopted, on the grounds that vomit is less likely to be inhaled. There is in fact no good evidence that the position in which a baby is laid down is ever responsible for its suffocation, at any rate after the first few weeks of life. In an infant of 2 months or more its position can be ruled out as the cause of death, and it should certainly be one of the first duties of a doctor to dispel from the parents' minds any idea that there may be reproach on that score.

In a recent case the asphyxia was attributed to a plastic bib becoming adherent to the child's face and obstructing its nose and mouth, and instances of other ways in which accidental mechanical asphyxia may occur are known, such as entanglement with the straps of a harness, passage of the head or body through the bars of the cot, and so on. A recent report in this *Journal*² concerned an infant in whom a "junior" aspirin tablet became impacted in the larynx, causing asphyxia. Another possibility—though purely speculative—is that regurgitation and inhalation of part of a feed might initiate laryngeal spasm and thus lead to asphyxia. Cyanotic attacks in infants are not rare and can occur when a baby is being changed or laid down immediately after a feed; in the ordinary way the child recovers as soon as it is turned over and patted on the back, but it is possible to see how an unattended infant might become asphyxiated.

Apart from asphyxia, however, much pathological evidence has accumulated in the past 20 years to show that a number of unexpected deaths in infancy have been due to acute and overwhelming infection, and statistical analysis of the place of death, whether in cot or bed, has been adduced by Swinscow³ in support of this. Carroll,⁴ writing from the office of the Chief Medical Examiner of Virginia, recently declared that "the diagnosis of suffocation . . . was no longer tenable. Better to make a diagnosis of unknown cause than to state that death was due to suffocation. . . ." Arey and Sotos⁵ think that the diagnosis of suffocation should not be made "simply because an infant is found dead, face down in bed, nor . . . because significant lesions are absent . . . at autopsy." On the other hand Barrett,⁶ in a carefully reasoned article, concluded that only a few cases of unexpected death in infancy are "due to fulminant infections caused by familiar organisms," although others might be due to unknown organisms or a virus: he thought that inhalation of regurgitated food into the lungs might be responsible for the majority.

It is thus clear—as was said in this *Journal* recently⁷—that the main cause of cot deaths is still undetermined. It also seems clear that a diagnosis of accidental suffocation should not now be made unless there is an obvious mechanical cause for it, and unless detailed histological, bacteriological, and perhaps also virological studies have been made at necropsy to exclude a fulminating infection. The view that these deaths may be due simply to the position of the child, without complicating circumstances, is no longer tenable.

The MINISTER OF HOUSING AND LOCAL GOVERNMENT has made an order setting up a statutory advisory committee to help to solve water supply problems in Kent. This is the first committee of its kind, and its members will represent both water undertakers and consumers in the county.

Medical Notes in Parliament

LORDS REVIEW OF HOSPITAL SERVICE

Divergent opinions on the system of merit awards were expressed in the House of Lords debate on the hospital service on July 2, when Lord NATHAN, who is chairman of the board of governors of Westminster Hospital, invited the House to review the 10 years since the National Health Service Act came into operation.

Lord MORAN enumerated three reforms which had come about. First, consultants had been decentralized and redistributed. They had also been greatly increased in number, and the patient could, without financial anxiety, call them to his home. Second, this decentralization had made possible the up-grading of hospitals throughout the country. The third great reform was concerned with the remuneration of specialists. The merit award meant that his material prosperity now depended on his professional efficiency.

Speaking on the finance of the Service, Lord Moran indicated that in his opinion the time might come when the regions might have to be given a sum of money and told to get on with it, to restore the spirit of economy that was prevalent in the voluntary hospitals and was not quite so evident to-day. He also hoped that the Ministry would take its courage in both hands and bid in the open market—the universities—for the men of promise, competing with the other professions.

He was not happy about the quality of the entry to the medical schools, though this was only an impression and had no roots in statistical facts. Lastly, Lord Moran spoke about discontent among general practitioners, which he attributed not to remuneration but to a general decline in status. The remedy—no doubt this was highly controversial—was that in time the pick of the general practitioners must follow their patients into hospital and would become part of the staff of the hospitals. He believed that to be the most important administrative move in the next decade.

Merit Awards

Lord UVEDALE OF NORTH END, who expressed a critical view of the merit award, also had something to say about the causes of dissatisfaction among doctors. He put first the loss of independence; the introduction of a State medical service had meant more supervision, more attention and records, and more reliance on methods of treatment recommended by the Ministry. The "family doctor," friend and confidant of the patient, was being replaced by the State practitioner. Another cause was the overcrowded surgeries that had resulted from the Health Service, and the increase in the cases of imaginary illness. The distinction awards to specialists should engage the attention of the House. In 1957 there were 2,343 specialists in England and Wales receiving them, at a cost of £2 million to the State. These were secret awards, a principle contrary to what had always been the conception of public policy. The system had been referred to in the medical profession as one of "diabolical secrecy." Where public money was spent the public should know how and why the liability was incurred.

Don't Starve the Teaching Hospitals

Lord EVANS, in a maiden speech, put in a plea for the teaching hospitals, for which he said little had been done in the past 10 years except the provision of funds to keep the machinery going. Out of the 12 in London only two—the Middlesex and the Westminster—had been rebuilt, yet many others were badly blitzed during the war. The comparative cost of the care of patients in teaching and non-teaching hospitals had been recently reviewed. To him the difference between the figures—£67 average cost per patient of a teaching hospital, compared with £41—was surprisingly small, and he could not agree with the Select Committee on Estimates. It must be absurd for the teaching hospitals

virtually to mark time until every other hospital caught up with them. It was essential to maintain the teaching hospital at the highest possible level, whatever the cost, if British medicine was to maintain its high standard.

True and False Economy

Lord AMULREE, viewing a considerable improvement in the hospital service in the past 10 years, was concerned lest too low a limit was placed on the amount of money available for future development. The need was to ensure that hospitals were run with as much economy as possible, not with as much saving of money as possible. Lord DOUGLAS OF BARLOCH presented the case of the senior registrars, and still more, he said, of the senior hospital medical officers, for improved salaries and better prospects of promotion. Viscount ASTOR thought the time had come for another inquiry into hospital administration, going deeper than that of the Guillebaud Committee, who seemed to have felt that they had to protect the service against a potential "Geddes Axe"; and the EARL OF CRANBROOK would include the whole of the administrative side of the Health Service Act.

For the Government, Lord STRATHCLYDE, Minister of State, Scottish Office, seemed to sum up policy and prospects in the assurance that the Government would do everything they could, while maintaining the health of the national economy, to enable the service to consolidate the progress it had made in the first 10 years—which he illustrated with a formidable array of statistics—and to make further advances in the future.

QUESTIONS IN THE COMMONS

Complaints Against Doctors

Mr. J. NIXON BROWNE, Under Secretary, Scottish Office, replying to a question by Mr. H. HUGHES (Aberdeen, North, Lab.) on July 1, stated that nothing in the new administrative arrangements relating to the Franks Report affected any existing rights of objectors and appellants to appear in person or be represented at inquiries or hearings.

Mr. HUGHES asked if that meant that persons making complaints against doctors in the Health Service might be legally represented at all hearings. Mr. BROWNE replied "No." The Franks Committee did not recommend such a change. All matters relating to Health Service procedure of this kind were under consideration, in consultation with the professions concerned.

Attack Rate of Poliomyelitis

Mrs. JOYCE BUTLER (Wood Green, Lab.) asked the Secretary of State for Scotland on July 3 what was the attack rate of paralytic poliomyelitis for children under 15 years, and for persons over 15 years for each of the years 1950 to 1957 inclusive. Mr. J. S. MACLAY stated that separate figures in respect of paralytic poliomyelitis were not available. Experience had shown that about 65% of all the notifications related to this form of the disease, and the following table gave rates on this basis:

Rates Per 100,000 Population		
	Children Under 15 Years of Age	Persons Over 15 Years of Age
1950	47.3	2.5
1951	11.7	1.5
1952	8.9	0.7
1953	15.3	1.2
1954	17.2	1.5
1955	25.5	1.8
1956	10.7	1.1
1957	6.1	0.9

He also informed Mrs. Butler that during 1957 notifications were received that poliomyelitis developed in eight of the 290,000 children who had been vaccinated in 1956 and 1957. Of these eight, only three were affected by paralysis in any degree. The total number of children under 15 who contracted poliomyelitis in 1957 was 122.

Duty on a Gift from U.S.

Mr. RONALD BELL (Buckinghamshire, South, Con.) asked the Chancellor of the Exchequer why an instrument designed for the diagnosis of bowel cancer and given for use at Amersham, Buckinghamshire, by the Memorial Center for Cancer and Allied Diseases, New York, was subject to long delay and to duty on admission to this country. Mr. J. E. S. SIMON, the Financial Secretary, stated that the gift of this instrument was both unsolicited and unexpected, with the result that additional information had to be sought and all necessary formalities completed after its arrival. There was no general exemption from Customs duty in respect of gifts, but he was looking into the possibility of making a concession in this particular case.

W.H.O. Malaria Fund

Mr. A. BLENKINSOP (Newcastle upon Tyne, East, Lab.) asked the Minister of Health on July 7 whether he would make a contribution to the World Health Organization's Malaria Fund. Mr. R. THOMPSON, Parliamentary Secretary, stated that it was not possible in present circumstances to supplement the contributions which the Government made to the regular budget of the World Health Organization. They were in any case already making substantial contributions in this field. Mr. BLENKINSOP asked him to recognize that there was an urgent problem, to attempt to get rid altogether of malaria, a chance that might be lost unless action was taken quickly. The regular budget of the W.H.O. did not provide anything like the funds needed. Why did the Government not follow the example of the United States, who had made a special contribution? Mr. THOMPSON replied that the Government need not stand in a white sheet. They contributed heavily to United Nations funds, but were opposed to the creation of special funds.

Dr. Percy Stocks's Report

Mr. B. JANNER (Leicester, North-west, Lab.) asked the Minister what action he proposed to take on the report by Dr. Percy Stocks to the British Empire Cancer Campaign following his survey of cancer incidence in North Wales and Liverpool (see p. 99); and whether he would arrange for similar surveys to be carried out officially in other parts of the country. Mr. WALKER-SMITH said he understood that cancer research under official auspices was already devoting much attention to epidemiological studies of the causes of cancer with similar aims to those pursued by Dr. Stocks. He did not think that the publication of his results, interesting as they were, called for any special action by him.

Drink and Road Accidents

Mr. G. PAGE (Crosby, Con.) asked if the Minister was able to indicate an early date for the publication of the report from the Medical Research Council on the relation of drink and road accidents. Mr. WALKER-SMITH: The report on the experimental work upon the effect of alcohol on the skill of drivers of motor vehicles has now been considered by the joint committee appointed by the Medical Research Council and the Road Research Board, under whose auspices the work was carried out. It is at present undergoing revision, and will be published as soon as possible.

Imported Egg-whites

Mr. BLENKINSOP asked the Minister what action he was taking to ensure that imports of egg-white were fully inspected before release to manufacturers. Mr. THOMPSON informed him that port health and other local authorities had been asked to pay special attention to the sampling of had been asked to pay special attention to the sampling of imported egg products for bacteriological examination. At present the authorities tried, whenever possible, to sample every batch. It would not, of course, be practicable to sample every tin.

Morphine at Port Medical Centres.—After consultation between the Home Office and other Departments the Home Secretary has decided, as a special case, to authorize the keeping of supplies of morphine for use by nurses in an emergency at port medical centres where suitable safeguards can be arranged. Details will be settled as soon as possible in consultation with the Port Health Authorities and the Port of London Authority.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending June 21 (No. 25) and corresponding week 1957.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the whole of England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Week Ending June 28

Only small fluctuations occurred in the notifications of infectious diseases in England and Wales during the week ending June 28. The largest were a decrease of 82 for measles, from 6,108 to 6,026, and an increase of 35 for dysentery, from 838 to 873.

The largest decreases in the incidence of measles were 111 in Devonshire, from 256 to 145, 105 in Somersetshire, from 205 to 100, and 91 in Middlesex, from 474 to 383; the largest rises were 91 in Staffordshire, from 86 to 177, 78 in Sussex, from 155 to 233 (Littlehampton U.D. 98), 61 in Essex, from 178 to 239. The notifications of scarlet fever numbered 662 and were 5 more than in the preceding week; the largest variation in the local returns was a fall of 24 in Lancashire, from 103 to 79. The number of notifications of whooping-cough, 783, was 17 fewer than in the preceding week, and the largest variations in the local trends were increases of 24 in Monmouthshire, from 1 to 25, and 21 in London, from 21 to 42. Diphtheria reappeared, after a fortnight without a case, with 5 notifications; 3 of these were from Liverpool C.B.

All the 8 cases of paratyphoid fever were notified in Lancashire.

The notifications of acute poliomyelitis numbered 43; the 29 paralytic cases were 7 more than in the preceding week and the 14 non-paralytic were the same number. The largest returns were Yorkshire West Riding 12 (Leeds C.B. 3, Wakefield C.B. 2), Staffordshire 7 (Cheadle R.D. 6), London 4 (Islington 2), Lancashire 4 (Manchester C.B. 2), Yorkshire East Riding 4 (Driffield U.D. 4).

The largest centres of dysentery were Yorkshire West Riding 182 (Barnsley C.B. 45, Thorne R.D. 20, Sheffield C.B. 17, York C.B. 16, Huddersfield C.B. 15, Rotherham C.B. 12), Lancashire 169 (Liverpool C.B. 40, Preston C.B. 29, Manchester C.B. 17, Oldham C.B. 11, Rawtenstall M.B. 10), London 85 (Bermondsey 18, Islington 16, Camberwell 10, Southwark 10), Staffordshire 61 (Brierley Hill U.D. 17, Rugeley U.D. 17, Kidsgrove U.D. 11), Durham 47 (Hartlepool M.B. 22, Waikham U.D. 13), Shropshire 30 (Oswestry R.D. 17, Oswestry M.B. 13), Gloucestershire 29 (Bristol C.B. 29), Warwickshire 25, Middlesex 22, Yorkshire North Riding 22 (Middlesbrough C.B. 21), Hampshire 21 (Droxford R.D. 12), Cambridgeshire 21 (Cambridge M.B. 21), and Essex 21 (Walthamstow M.B. 11).

The largest outbreak of food-poisoning was 42 cases in Margate M.B.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1949-57 are shown thus -----, the figures for 1958 thus ————. Except for the curves showing notifications in 1958, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

On July 3, after lecturing at the Middlesex Hospital Medical School on "Cancer of the Prostate," Professor CHARLES HUGGINS, of Chicago, was presented with the Comfort Crookshank award for cancer research. The award, which consists of a medal and cheque, is made triennially by the council of the Middlesex Hospital Medical School. This was the third time the award has been made.

Medical News

International Cancer Congress.—The Seventh International Cancer Congress opened in London on Monday, July 6, under the presidency of Sir STANFORD CADE. The congress is being held under the auspices of the International Union against Cancer. The opening ceremony was performed in the Festival Hall by the DUKE OF GLOUCESTER. After his installation as president by Professor J. H. MAISON, president of the International Union, Sir Stanford Cade delivered his presidential address, and the congress then adjourned for its scientific sessions. Over 2,000 delegates are attending the congress.

Chair of Surgery, Sheffield.—Mr. A. W. KAY has been appointed to the chair of surgery at Sheffield University in succession to Professor R. P. JEPSON. Mr. Kay is lecturer in clinical surgery at Glasgow and on the staff of the Western Infirmary. He graduated from Glasgow with honours in 1939, gaining the M.D. with honours and the Bellahouston gold medal in 1944, and the Ch.M. with honours in 1949. From 1941 to 1945 Mr. Kay was at the Western Infirmary in various capacities. He then spent two years in the R.A.M.C. in charge of a surgical division at Millbank, afterwards returning to the consultant staff of the Western Infirmary and a lectureship in surgery at Glasgow University. Mr. Kay has written on gastro-enterological subjects and on the treatment of shock.

Royal College of Surgeons.—Mr. F. W. HOLDSWORTH, of Sheffield, and Mr. J. CRIDLAN BARRETT, V.C., of Leicester, were elected to the College council on July 3. Mr. E. W. RICHES and Sir ARTHUR PORRITT were re-elected to the council at the same time.

Royal Medico-Psychological Association.—The association's 118th annual meeting was held in London from July 1 to 4 under its president Dr. L. C. COOK, physician superintendent of Bexley Hospital. The scientific part of the meeting included sessions on the selection of patients for out-patient psychotherapy, experimental studies on the regulation of sexual activity, and physical treatment; a visit to Bexley Hospital; and sectional meetings on child psychiatry, mental deficiency, and psychotherapy and social psychiatry. The annual dinner on July 2, under the chairmanship of Dr. Cook, was attended by some 200 members and guests. In proposing "The Guests" Dr. W. GORDON MASEFIELD welcomed first two distinguished colleagues from the United States, Professor L. J. MEDUNA, of Chicago—"pioneer of convulsive therapy and our most recent honorary member"—and Dr. L. B. KALINOWSKY, of New York. Miss PAT HORNSBY-SMITH, deputizing at short notice for the Government Chief Whip, Mr. Edward Heath, responded, and delighted her audience with the account of her new duties at the Home Office. She still had her links with psychiatry, she said, as both the Royal Commission's report on the law on mental illness and the Wolfenden Report concerned her department. Lord MONCKTON, himself a former chairman of St. George's Hospital, and whose wife is at present a governor of St. George's and also of the Bethlem Royal and Maudsley Hospitals, proposed the toast of the Royal Medico-Psychological Association. Founded in 1841, it was the oldest association of its kind. Its membership, now 1,700, was increasing at a rate of 100 a year. Dr. COOK replied to the toast.

Birmingham Mental Hospitals.—On June 26 two new 40-bed pavilions at Hollymoor Hospital, Birmingham, were opened by Dame ENID RUSSELL-SMITH, Deputy Secretary, Ministry of Health. To mark the occasion the Birmingham No. 6 Group Hospital Management Committee has published an illustrated booklet about the modernization of Rubery Hill and Hollymoor Hospitals, both mental hospitals, and the difficulties which beset such endeavours in old and outdated buildings.

Music in Hospitals.—In 1956, following a transatlantic example, a society was formed in Britain to foster interest in music therapy in hospitals, and to assist hospitals by providing the services of professional music therapists. This society, now the Association for Music Therapy in Hospitals, held its first annual meeting in London recently. Last year over £3,000 was raised towards the cost of therapists' fees. The chairman is Lady MONCKTON, and Dame MYRA HESS is chairman of the artists' committee. The association's office is at 50, Belgrave Road, London, S.W.1.

Jerusalem Ophthalmic Hospital.—Despite the Suez crisis and difficulties due to the use of converted buildings, work at the ophthalmic hospital of the Order of St. John of Jerusalem continued satisfactorily last year, it is stated in the annual report. Sir STEWART DUKE-ELDER, the hospital, visited the Middle East, and progress was made with the building of the Warden's House and the Sisters' Home for the new ophthalmic hospital. Members of the research team studying trachoma virus moved from Jordan to the Gambia and London, where the work was continued. While in Amman Sir Stewart Duke-Elder received the Star of Jordan (first class) from KING HUSSEIN.

Haemolytic Disease of the Newborn.—A pamphlet on the aetiology, antenatal diagnosis, and management of haemolytic disease of the newborn is being circulated to all N.H.S. general practitioners and M.O.H.s. The pamphlet, which was prepared by the standing medical advisory committee of the Central Health Services Council, opens by stating that the condition causes each year 300 neonatal deaths and 400-500 stillbirths; and ends: "Planned action can save some 150 liveborn infants annually, and possibly a small number of stillbirths."

Harveian Society of London.—£3,000 has now been raised towards the restoration of the tower of Hempstead Church, Essex, where William Harvey's remains are buried. Mr. A. DICKSON WRIGHT announced this after a service there during the society's annual summer meeting last month.

Hospital Car Service.—Last year 1,836,000 patients were transported over 15 million miles by the Hospital Car Service. Some 5,000 owner-drivers in England and Wales belong to the service, and they do this job in their spare time. The service grew out of the wartime Voluntary Car Pool, and it is organized by the St. John Ambulance Brigade, the British Red Cross Society, and the Women's Voluntary Service for Civil Defence. It is intended for patients who are not fit enough to use buses or trains, the great majority being those needing regular treatment. The work is undertaken at the request of local authorities, who pay a small mileage rate to cover running costs.

Amateur Boxing.—The London Amateur Boxing Association has produced a booklet describing its "London Medical Scheme," for the convenience of boxing clubs. The aims of the Scheme are defined as: (1) To prevent any boxer competing who is not physically fit to box; (2) not to prevent any boxer from competing who is physically fit to box; and (3) to ensure that an injured boxer has completely recovered before recommencing boxing. The booklet discusses the medical examination, the medical record card, and the welfare of boxers. Copies are obtainable (price 1s.) from the L.A.B.A., 69, Victoria Street, London, S.W.1.

W.H.O. in 1957.—The director-general's report to the Eleventh World Health Assembly, which ended on June 13 in Minneapolis, has now been published as No. 82 in the series *Official Records of the World Health Organization*. It describes the work of the World Health Organization in 1957. The report is obtainable from Her Majesty's Stationery Office (price 6s. 9d. net).

Commonwealth Bursaries.—Professor T. GILLMAN, professor of physiology at Natal University, Professor R. J. ROSSITER, professor of biochemistry at the University of Western Ontario, and Dr. T. B. TEOH, lecturer in pathology at Hong Kong University, are among the 13 scientists whose awards under the Royal Society and Nuffield Foundation

NEW ISSUES

SPECIALIST JOURNALS AND ABSTRACTS

The Journals listed below are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Venereal Diseases.—Issued quarterly (£3 annually). The new issue, Vol. 34, No. 2, includes:

COMPARISON OF THE IN VITRO SENSITIVITY OF GONOCOCCI TO PENICILLIN WITH THE RESULTS OF TREATMENT. F. R. Curtis and A. E. Wilkinson.
RESULTS OF LOCAL CORTISONE THERAPY IN SYPHILITIC INTERSTITIAL KERATITIS. A. N. Ashworth.
PRELIMINARY EVALUATION OF THE TRYPANEMAL WASSERMANN REACTION. I. N. Ordwood Price.

PREVALENCE OF VENEREAL DISEASE IN PROSTITUTES. T. Rosenthal and J. Vahdow.

EARLY SYPHILIS. A CASE WITH SOME UNUSUAL FEATURES. Gerald Knight.
ACUTE GONOCOCCAL AND NON-GONOCOCCAL URETHRITIS. W. V. Macfarlane and Hilda M. Johns.

EVALUATION OF THERAPY IN NON-SPECIFIC URETHRITIS. W. Fowler.
BOOK REVIEW.

SERO-REACTIVITY FOR SYPHILIS IN BOMBAY. M. D. Mungale, H. I. Jhala, and W. N. Welinkar.

ORAL PENICILLIN FOR GONORRHOEA. SOME EXPERIENCES WITH PHENOXYMETHYL PENICILLIN (PENICILLIN V) IN WHITE AND NEGRO PATIENTS. R. R. Wilcox.

FILARIASIS WITH CHYLURIA. J. K. Oates.

Abstracts of World Medicine.—Issued in the first week of each month, this journal contains abstracts of important papers selected from the current medical literature of the world. Annual subscription £4 4s.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Tuesday, July 15

LONDON UNIVERSITY.—At St. Thomas's Hospital Medical School, 5 p.m., special university lecture in medicine by Dr. Frank Gerbode (U.S.A.): Some Aspects of Intracardiac Surgery.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—3.30 p.m., Professor I. S. Ravdin (Pennsylvania): Recent Advances in Blood Transfusion.

Wednesday, July 16

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. A. C. Cunliffe: Cutaneous Hypersensitivity.

Friday, July 18

BIOCHEMICAL SOCIETY.—At Department of Biochemistry, Sheffield University. 2 p.m., 375th meeting.

CAMBRIDGE MEDICAL SOCIETY.—At Geography Department, Downing Place. 3 p.m., B.M.A. Lecture by Dr. R. F. Tredgold: Preventive Psychiatry.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. R. Bignall: clinical demonstration.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—4 p.m., Charles Tomes Lecture by Professor H. G. Radden: Local Factors in Healing of the Alveolar Tissues.

APPOINTMENTS

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—H. G. Smyth, M.B., B.Ch., Senior Registrar in Mental Deficiency and Child Psychiatry, Little Plumstead Group of Hospitals; N. A. Samaan, M.B., B.Ch., Dip. of General Medicine (Alexandria), M.R.C.P.Ed., Medical Registrar, North Cambridgeshire Hospital and Clarkson Hospital, Wisbech; S. S. A. Jaffery, M.B., B.S., Anaesthetic Registrar, Ipswich and East Suffolk Hospital.

EASTON, ALFRED L. T., M.B., B.Chir., F.R.C.S., M.R.C.O.G., Consultant Obstetric and Gynaecological Surgeon, London Hospital, Whitechapel, E.

HIRD, GORDON, M.B., Ch.B., D.P.H., Medical Officer of Health and Port Medical Officer to the Borough of Boston, Medical Officer of Health to the Rural District of Boston, and Assistant County Medical Officer, Holland (Lincs) County Council.

LEATHAM, AUBREY G., M.B., B.Chir., F.R.C.P., Part-time Assistant Consultant Physician, National Heart Hospital, Westmoreland Street, London, W.

MACGREGOR, G. A., M.D., M.R.C.P., Part-time Consultant Physician, Guildford Group of Hospitals.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Downie.—On June 7, 1958, at the Memorial Hospital, Chapel Hill, North Carolina, U.S.A., to Jean (formerly Paine) and Allan W. Downie, M.B., M.R.C.P., a sister to Susan, Robert, and Timothy—Katherine Marie.

DEATHS

Berry.—On June 24, 1958, at The Corner House, Bramhall Park Road, Bramhall, Cheshire, Arthur William Berry, M.B., B.S., aged 76.

Booth.—On June 25, 1958, at his home, Long Acre, Hurn Way, Christchurch, Hants, Norman Booth, M.B., B.S., aged 75.

Evans.—On June 20, 1958, in Jersey, John Jackson Whatley Evans, F.R.C.S.

George.—On June 16, 1958, at Harold Wood Hospital, Essex, Archibald Louis George, M.R.C.S., L.R.C.P., L.D.S.

Sinclair.—On June 20, 1958, at Southgate, Epping, Essex, George Ian Sinclair, M.B., B.Chir., aged 25.

White.—On June 1, 1958, at his home, Parklands, Edzell, Angus, James White, M.B., Ch.B., D.M.R.E., aged 44.

Wise.—On June 18, 1958, at Meopham, Kent, Harry Mortimer Wise, M.B., late of 206, Burrage Road, London, S.E., aged 85.

Commonwealth Bursaries Scheme were announced this month. Professor Gillman and Dr. Teoh will come to London, and Professor Rossiter will go to Canberra.

Anglo-French Exchange Bursaries.—The following have been awarded bursaries for work in France under the exchange scheme between the Institut National d'Hygiène, Paris, and the Ciba Foundation. All will work in Paris:

Miss J. Carey, demonstrator in pharmacology, St. Mary's Hospital Medical School, to the Institut Pasteur; Dr. Evan Fletcher, physician, City Hospital, Belfast, to the Hôpital Lariboisière; Dr. J. G. Howard, Wright-Fleming Institute, London, to the Hôpital Broussais; Dr. E. M. Jepson, medical registrar, Westminster Hospital, to the Hospice de la Salpêtrière; Mr. J. F. O. Mitchell, assistant surgeon, Royal Infirmary, Dundee, to the Hôpital Boucicaut and other E.N.T. clinics; and Dr. P. M. Peacock, fellow in pathobiology, Johns Hopkins Hospital, Baltimore, to the Institut Gustave Roussy.

Laboratory Animals Bureau.—The bureau's title and address have been changed to the Laboratory Animals Centre, M.R.C. Laboratories, Woodmansterne Road, Carshalton, Surrey (telephone: Wallington 5512).

Lord Stamp, professor of bacteriology at the Postgraduate Medical School of London, has been accorded the honorary Freedom of the Barbers' Company.

COMING EVENTS

The R.M.B.F.—The annual general meeting of the Royal Medical Benevolent Fund will be held on July 30 at 5 p.m. at 11, Chandos Street, London, W.1.

Blood Transfusion.—Professor I. S. RAVDIN, of Pennsylvania, will lecture on "Recent Advances in Blood Transfusion" at the Royal College of Surgeons of Edinburgh on July 15, at 3.30 p.m.

B.B.C. Television.—"Children in Hospital" in the series "Lifeline," July 17, 10.20 p.m.

International Congress on Psychotherapy.—Barcelona, September 1-7. Closing date for registration and for contributions July 31. Details from the Cátedra de Psiquiatria, Facultad de Medicina, 143, Casanova, Barcelona. The congress includes a Section on Psychopharmacology, details of which may be obtained from the Cátedra de Farmacología, Facultad de Medicina.

Course in Nutrition.—The International Children's Centre is organizing a course in nutrition for medical practitioners, to be held in Paris for four weeks from September 15. The course will be in French. Anyone interested should apply to Dr. NATHALIE P. MASSE, International Children's Centre, Château de Longchamp, Bois de Boulogne, Paris, 16.

7th International Congress on Hydatid Disease.—September 20-22, in Beirut, Lebanon. Details from Dr. ELIAS SADER, c/o Lebanese Order of Physicians, P.O. Box 640, Beirut.

British Veterinary Association.—Annual Congress in Douglas, Isle of Man, September 21-26. Details from the general secretary, 7, Mansfield Street, Portland Place, London, W.1.

Aviation Medicine.—Third European Congress, September 23-27 at Louvain, Belgium. Details from Dr. ANDRÉ ALLARD, Melsbroek Airport, Brussels.

Third International Congress of Angiology.—San Remo, September 24-28, on "Experimental and Clinical Pathology of the Peripheral Vascular Diseases." Details from the secretariat of the congress, c/o Clinica Dermatologica, Università di Pisa, Italy.

South African Paediatric Association.—Paediatric congress, October 16-18 in Pretoria. Details from Dr. E. FASSER, 201, Medical Centre, 319, Pretorius Street, Pretoria.

International Society of Audiology.—Sixth congress, October 2-5 in Italy. Details from the secretary general, Dr. CLERC, 45, Rue de Courcelles, Paris, 8.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Animal Fat-free Diet

Q.—What foods should be taken in a diet in which saturated fatty acids are replaced by unsaturated fatty acids?

A.—Many commercial preparations are available containing very unsaturated fatty acids, such as linoleic acid, but a similar effect can be obtained by cooking in olive oil and consuming a small quantity of maize oil each day.

The following is a list of suitable foods, low both in animal fat and cholesterol content:

Cereals.—Bread, toast, crispbreads, waterbiscuits. Biscuits, cakes, pastry only if made with vegetable oil. All breakfast cereals, porridge. Rice, sago, semolina, cornflour, spaghetti.

Eggs.—Egg white (e.g., in meringues), apple snow.

Milk.—Machine-skimmed milk, fresh, tinned, or dried.*

Fats.—Peanut butter and vegetable oils only, such as olive oil, arachis (peanut) oil, corn oil, or sunflower seed oil.

Cheese.—Cottage cheese or home-made from skim milk.

Fish.—All kinds of fish, including shell-fish.

Meat.—Very lean meat, ham, chicken, rabbit.

Soups.—Clear meat, chicken, or vegetable soups only.

Vegetables, salads, fruits, nuts.—All kinds.

Beverages and sweets.—Tea, coffee, fruit juices. Boiled sweets, fondant, marshmallow. Sugar, glucose, jam, honey, syrup, marmalade, jellies. Vinegar, pickles of all kinds.

Fats to use on bread.—At present the only suitable vegetable fat is peanut butter. However, if great distaste is experienced, use a scrape only of butter or margarine.

*To obtain Machine-skimmed Milk:

London.—Contact the manager of the local Express Dairy, United Dairies, or London Wholesale Dairies, and give regular order.

Outside London.—Some large dairies supply skimmed milk; or write to Wilts United Dairies, Trowbridge, for nearest supplier. This wholesale firm covers many parts of England. Some farms have a separating machine.

Halitosis

Q.—What may be the cause of halitosis in a patient who has no infection in the mouth or respiratory tract?

A.—Offensive breath must come from either the nose, mouth, stomach, intestines, or the lungs, and one must exclude the possibility of chronic sinusitis, chronic tonsillitis, dental sepsis, oesophageal pouch, gastric stasis, and bronchiectasis. If these can be excluded the most likely remaining cause is absorption of volatile fatty acids from the intestines, which pass from the blood into the lungs. There is no reason why belched air should cause halitosis. It is merely ordinary air swallowed as the result of relaxation of the upper end of the gullet. Some passes into the stomach, but most of it inflates the oesophagus and is then brought up, often explosively.

Scorpion Stings

Q.—I have heard of a treatment for scorpion stings by a decoction made from scorpions themselves. Is it effective?

A.—Venomous animals are commonly resistant to their own venoms. For instance, the common European viper can withstand four hundred times, and the tiger snake no less than one hundred and eighty thousand times, the dose of its own venom lethal to a guinea-pig. The mechanism of this protection is not understood. Antitoxins to homologous venoms have, however, been reported from time to time in the sera and body fluids of certain snakes, scorpions, and spiders, and neutralizing substances to its own venom,

believed to be auto-antibodies, have recently been demonstrated in the liver and serum of *Heloderma*, the Gila monster.

Nevertheless, the employment of various anatomical parts, physiological fluids, or extracts of poisonous animals for the relief of symptoms of envenomation, although ancient and widespread, is largely futile. Active antivenins can, however, often be prepared from the venom itself. Venoms of scorpions, extracted from excised venom sacs or discharged by electrical stimulation of the end segments of the abdomen, are now used for the production of antivenins, usually in horses. Such antivenins are relatively specific, but sera with fairly wide neutralizing powers have recently been prepared in South Africa, North Africa, Egypt, Turkey, South and North America. They are usually given intramuscularly or subcutaneously. Successful antivenins have also been prepared from spider venoms, especially those from *Latrodectus* spp. (including the black widow). These are potent and specific.

Goat's Milk

Q.—Has goat's milk any advantages over cow's milk for normal healthy adults, children, and babies?

A.—Goat's milk is similar in composition to cow's milk. The fat content, some 4.5%, is much the same as in the milk of Channel Island breeds, but higher than in the milk of Friesian and Shorthorn cows. Goat's milk looks whiter than cow's milk because it contains hardly any carotene, and its vitamin A activity is derived almost solely from vitamin A. In the nutrition of normal people the milk of the two animals may be taken as of equal value, it being understood that both are so treated as to be bacteriologically safe. In allergy to cow's milk, goat's milk may be used to advantage. The vitamin B₁₂ content of goat's milk is decidedly lower than that of cow's milk, but it is not known whether this low content is in any way connected with "goat's milk anaemia" sometimes observed in infants reared on goat's milk.

The principal pathogenic bacteria to be found in cow's milk as secreted—i.e., as the result of disease of the animal—are the tubercle bacillus and *Brucella abortus*. Goats rarely suffer from tuberculosis, but their milk may contain *Brucella melitensis*, which causes a rather more severe form of undulant fever than does *Brucella abortus*. The milk of either animal may become contaminated after milking with other pathogenic bacteria, such as those of the enteric group.

Digital Fungoid Infection in a Cook

Q.—A cook in a canteen has a chronic fungoid infection of most of her fingers. What are the risks to others?

A.—No doubt if this cook handles food some fungal elements will be deposited on the food. However, no secondary growth is likely to take place and such contamination will not give rise to food-poisoning. If the cook uses the same towels and handles dish-cloths, etc., which are used by her co-workers there is no doubt a risk that she will pass the infection to them.

The treatment of such a condition is difficult and indeed often fails. It depends upon the efficient application of fungicide ointments, of which Whitfield's is as good as any. The hands should be kept bandaged, or alternatively cotton gloves may be worn, so that plenty of the ointment will remain in contact with the skin. In many such cases there is also an infection of the feet and possibly of the finger- and toe-nails. These other sites of infection should be sought out and treated at the same time.

Trigeminal Neuralgia

Q.—What is the treatment of trigeminal neuralgia?

A.—The term trigeminal neuralgia is sometimes used inaccurately to include a great variety of scalp and face pains. Genuine trigeminal neuralgia is characterized by sudden stabs of lancinating pain which "paralyse" the patient

while they last, and which are referred to the distribution of the trigeminal nerve only. A similar pain may develop in association with disease of the teeth, gums, the temporomandibular joint (Costen's syndrome), or tumours of the Gasserian ganglion, and can be relieved by attention to the local lesion.

When local abnormalities have been excluded, relief of pain often becomes the first consideration, and it should be emphasized that severe cases can be relieved only by blocking the branches of the nerve concerned, and this is in general by far the most useful measure. Usually the nerve must be blocked by alcohol or sectioned by a surgeon, but there is much to be said for repeated procaine blocks in less severe cases. Such local analgesia may be followed by relief of pain for several days, or even weeks, and it may be repeated as often as desired. This procedure also produces the numbness which the patient will have to tolerate if the nerve is cut, and lets him appreciate what to expect. Simpler methods include frequent self-administered massage or galvanism to the sensitive areas when the pain is absent. Protecting a sensitive area lowers pain thresholds, while vigorous counter-irritation does the opposite. Drugs are of limited value, but some mild cases seem to benefit from large doses of vitamin B₁₂ or vitamin B₁.

Antibiotic Level in Blood Stream

Q.—Is there an accurate method of estimating the level of antibiotics in the blood stream, particularly of streptomycin?

A.—Some antibiotics, such as chloramphenicol, can be assayed by a chemical method, but for most such examinations it is necessary to determine the highest dilution of the serum or other body fluid which will inhibit the growth of a standard sensitive organism. A control series of tubes containing known dilutions of the antibiotic is inoculated in the same way. Since doubled dilutions are usually employed, this is not an accurate method, but it serves to show whether adequate or excessive concentrations are being attained by the treatment employed. Different species of organism are used for the assay of different antibiotics: that usually adopted for streptomycin is *Kl. pneumoniae* (Friedländer's bacillus). If a more accurate method is desired, a similar test can be done, but instead of reading an absolute end-point the degree of reduction of growth in borderline tubes can be estimated by turbidimetry. An alternative is the cylinder plate method, in which dilutions of the fluid to be tested and of a standard solution of the antibiotic are placed in cylinders on plates inoculated with a sensitive organism, and the resulting zones of inhibition are measured.

Sunglasses

Q.—What are the best type of sunglasses? If polaroid are best, may they be worn permanently without ill effect? How do tinted glasses compare with those that are made of transparent metallic mirror?

A.—The best types of sunglasses are those which absorb the sun's rays selectively and cut out the ultra-violet and infra-red rays while transmitting the visual spectrum. Suitable glasses of this sort are those made by Zeiss ("umbral" and "uropol") and also the various tints of Crookes lenses. Chance's Crookes sunglasses are preferable, as they maintain the old Crookes standards. The name Crookes is no longer proprietary, and has been applied to improperly standardized products. Polaroid are quite good as plain sunglasses, but it is difficult to incorporate lens corrections in them and they are expensive. The ordinary dark glasses obtainable from chain stores are efficient in cutting off glare, but they impair visual acuity much more than the quality products for the same degree of protection. Metallic mirror glasses are useful for night driving, as it is easy to cover one segment only of a lens with sprayed metal. There is no selective absorption of rays, however, and as sunglasses they are not very efficient.

"Premenstrual Spotting"

Q.—What is the cause of premenstrual spotting, and is there any satisfactory treatment?

A.—Premenstrual spotting in an otherwise normal woman may occur as a functional disorder, the underlying fault being said to be "irregular ripening of the endometrium." It is postulated that this can be the result of (1) poor function and early breakdown of the corpus luteum, or (2) failure of the endometrium and its vascular apparatus to respond to a normal progesterone stimulus. In either case the endometrium does not develop the secretory phase to the full, or does so only patchily. This feature might be revealed by careful examination of many areas of endometrium removed by curettage at the time when spotting commences. If the endometrial response is at fault no treatment is likely to help. If the corpus luteum is defective then the administration of progesterone, 10-20 mg. intramuscularly daily for 7 to 10 days premenstrually, should arrest the bleeding. Ethisterone is unlikely to give a result unless given in very large doses. It is just possible that an oestrogen (say ethinyl oestradiol 0.05 mg. one to three times daily by mouth) premenstrually might also be effective, but the following period might be excessive. Either progesterone or oestrogen should be discontinued two days before the expected onset of a period.

The difficulty in this case, as in all cases of functional uterine haemorrhage, is that the diagnosis can only be made by excluding an organic cause in the uterus and ovaries. Inspection of the cervix to exclude an erosion and curettage and routine histological examination do not constitute a full investigation. Even some simple condition such as an endometrial polyp is often missed with a curette. Pelvic endometriosis is another possibility, especially if the patient suffers from dysmenorrhoea. Other investigations worthy of consideration are cytological study of cervical scrapings; cervical ring biopsy; hysterosalpingography; culdoscopy; and possibly assay of the pregnanediol excretion during the second half of the cycle.

NOTES AND COMMENTS

Pustular Psoriasis.—Dr. JAMES FAIRLEY (Newtown, I.W.) writes: Your expert ("Any Questions?" June 21, p. 1494) is certainly correct in stating that the treatment of this condition can be extremely difficult. To bind up the hands or feet with any ointment is a misery, and tar preparations can be particularly aggravating. After suffering myself for six years I got immediate relief and within a few days permanent cure on applying friar's balsam with tannic acid (pulv. acid. tann. gr. 60 (4 g.), tinct. benzoin. co. 1 oz. (28 ml.)). This is dabbed on and allowed to dry, and, if then the skin feels harsh and dried up, a little ung. aquos. or "nivea" cream may be applied. For the feet it is a relief to wear open-sided sandals.

Collected Articles from the "British Medical Journal"

The following books are available through booksellers or from the Publishing Manager, B.M.A. House. Prices, which include postage, are now the same for both inland and overseas.

- Emergencies in General Practice* (26s. 9d.).
- Refresher Course for General Practitioners*, Volumes 2 and 3 (26s. 9d.).
- Clinical Pathology in General Practice* (22s. 3d.).
- Any Questions?*, Volumes 2 and 3 (8s. 3d. each).

President's Address

REFLECTIONS ON MEDICAL PRACTICE

BY

A. P. THOMSON, M.C., M.D., F.R.C.P.

Professor of Therapeutics and Dean of the Medical School, University of Birmingham

Within my lifetime medical practice has been completely transformed. Progress in fundamental science and the development of technical skill in its application have changed the whole aspect of the venerable structure of empirical medicine which I explored as a student, and radical reconstruction has been necessary in many directions. It is not of these things, however, that I propose to speak on this occasion. The new knowledge, the new drugs and techniques, enable us to do much more for our patients: these things make our lives more interesting and satisfying, and we are grateful if at times uneasily aware of the difficulty of keeping pace with all of them.

My purpose is to direct attention to the increasing responsibilities that society imposes upon its doctors and to examine some of the consequences that may flow from a wider range of medical activity.

A Duty to Society

Early in the nineteenth century Jeremy Bentham conceived the idea that medicine had a duty to society as well as to individual patients, and he is the spiritual father of Preventive Medicine as it was developed by Thomas Southwood Smith, Edwin Chadwick, and John Simon. Despite their work it was not until 1899 that an Infectious Diseases Notification Act was approved, and it is salutary to recall the spirited resistance to it from those who believed that it infringed the passage in the Hippocratic Oath which proclaimed that whatsoever a doctor saw or heard in the course of his profession should not be published abroad.

Although the opposition to the notification of infectious disease now seems to us a little peculiar it was probably based on the same jealous, but not unhealthy, instinct to preserve the traditional relationship of confidence between a doctor and his patient that has stimulated criticism of much medical legislation in the past fifty years. However that may be, there is now no doubt that a doctor in clinical practice encounters types of responsibility which were never contemplated by Hippocrates, nor by the statesmen who advised her late Majesty Queen Victoria. His primary and ineluctable duty to ensure the best possible investigation and treat-

ment for his patient remains, but, in addition, he must often decide whether or not the issue of a certificate is warranted to obtain pecuniary benefit from the State or to justify absence from work; in many ways the doctor has become a custodian of part of the public purse, a sort of State almoner. Authority, not unnaturally, insists on supervision, so the cost of prescribing and the number of certificates become subject to comparison with the average of an area and a matter for inquiry if either appears to the Minister to be unreasonable.

It is not surprising that novel disciplinary checks of this kind caused resentment in many members of a profession bred in a long tradition of individual freedom, but I see no escape from them so long as a Welfare State remains the ideal of society.

We may justly plead, on the other hand, that administration should be flexible and tolerant and be guided by those who have first-hand knowledge of the difficulties and problems of practice. To a considerable extent, and particularly at certain levels, this has been achieved by the work of this Association and by the co-operation of doctors in the activities of executive councils, regional boards, and hospital management committees. It is disconcerting nevertheless that a general impression prevails that problems of policy tend more and more to be determined by officials in the Ministry of Health who know little of the stress of clinical work and less of the human problems inherent in it. Is it improper in me to suggest that those in official positions at the Ministry might be refreshed by quitting the shelter of Savile Row to share, from time to time, the perplexing duties of a doctor in clinical practice in hospital or in the home?

The Supreme Problem

But contemporary domestic difficulties, important though they sometimes seem, are trivial in comparison with the supreme problem that now confronts the world—the danger of atomic war. Four years ago Lord Adrian, in his presidential address to the British Association, said bluntly that our fate was now squarely in our own hands, and he stressed the urgent necessity for increased knowledge of how the mind of man could be influenced to avoid the catastrophe of conflict. With great authority he pointed out that it was not likely that the most detailed knowledge of brain

physiology would help mankind towards living more peacefully, though it might achieve clearer heads and a more even temper. Our knowledge of human behaviour is based on simple empiricism, and there is a clamant need for the branches of social science to make dispassionate studies of what actually happens in human societies. In Lord Adrian's judgment these large-scale investigations were too important a plant to be left in the hot-house atmosphere of research institutions and Unesco teams, and he made a plea for the recruitment of more social scientists in the universities and added the critical comment that their methods were not yet sufficiently objective and precise.

With all that Lord Adrian said I think we would agree, and when I read his speech I wondered whether medicine had not a duty to take some part in the study of the most urgent problem of our day and generation. For, surely, there is no group of men better equipped and more advantageously placed to contribute to this work than the family doctors of this country. They enjoy the trust and confidence of the vast majority of their patients: the nature of their work admits them to the most intimate aspects of family life, often over long periods of time. They are already aware of many of the motives that determine human behaviour in society, but their knowledge is rarely recorded in permanent form and dies with them.

For this misfortune there are several reasons. In the curricula of most medical schools little attention is given to the functions of medicine in relation to society. The dramatic success of scientific methods in the treatment of individuals appeals to the young, and in teaching hospitals absorbs their attention so exclusively that they tend to ignore that large part of clinical practice which is not measurable in terms of science and which often has no relation to organic disease. The recent revision of the Recommendations of the General Medical Council will enable Licensing Bodies to amend their curricula if they wish, but to avoid any misunderstanding I feel it necessary to say that for my part I would not sacrifice the rigorous discipline of fundamental science in the training of medical students, because it constitutes the firm foundation for future progress and stimulates a critical approach to the problems that confront us. Opportunity should be found, however, to encourage students at some stage to examine the wider functions of medicine in society.

Signs of Renascence

The principal factor that limits any activity by practising doctors in this direction may be simply stated. Most of them are too busy and lack the leisure that is essential to independent thought and fruitful investigation. Despite this difficulty there are signs of a developing renascence of family practice, and we should pay tribute to the remarkable achievements of the College of General Practitioners in recent years. I suggest to the members of that College that they should consider an approach to university departments of social science to examine the techniques that have been developed for the study of human behaviour and the methods for recording information in forms suitable for analysis and in the hope that co-ordinated research may be established.

When I submitted the first draft of this address to the Editor of the *British Medical Journal* he was good enough to send me a report from the *New Scientist* (June 5, 1958) of a lecture by Canon Raven as Visiting Professor of the Philosophy of Science at the College of Medicine of the University of Cincinnati, Ohio. I quote a passage: "I should like to see the province of medicine extended; I should like to see certain departments of the great profession equipped to study the diseases of corporate life. I believe there is room here for the application of precisely the same skills in diagnosis and treatment which the social worker does not have and which the medical man does. I am not depreciating the work of the social worker at all. But I am suggesting that between sociology and medicine there might well be established the same sort of unity which has been established between psychology and medicine."

Canon Raven was particularly concerned with such things as mass hysteria, the ethics of advertising, and the publicity which established enthusiasms with so little factual basis. These are large and important problems admittedly, but I doubt if they are the most suitable for first attempts in joint research. It might be better for us to begin with humbler topics, and I suggest a few at random.

Topics for Research

There has lately been considerable controversy about the eleven-plus examination. Some have contended that the success of a child in gaining admission to a grammar school when its brothers or sisters fail may lead to intense and disintegrating stress in a family, and for this reason plead that all schools should be comprehensive. Is it true? I believe that family doctors could well supply the information necessary for rational policy. What exact knowledge have we of the effects of the employment of married women on their children and their homes? And who could supply more reliable information than the doctors of those families? Does moderate consumption of alcohol and tobacco contribute to the peace and happiness of family life or the reverse?

In a recent book Lord Pakenham reviewed the evidence on which we base our opinions about the problems of juvenile delinquency and criminal conduct. He found that there was very little factual information on which we could rely: opinions were often conflicting and little was done to establish truth. Has not medicine something to contribute in this direction? Family doctors see the delinquent from his birth: they are familiar with his environment and often with his descent.

Study of these matters and many like them might yield information of great practical importance, and in my judgment we, as doctors, should welcome any opportunity to take part in them. To be of value, however, such studies must be serious and not casual, and I fear they are impossible for most doctors in the present conditions of practice. Lists are too large and leisure too restricted to permit sustained effort, but it might be possible for this Association and the College of General Practitioners to find ways and means to sponsor a preliminary trial of a scheme for joint research by a team of family doctors linked with a university department of sociology, and it would be an interesting experiment.

Adventure of this kind, a study of human behaviour in society, would surely restore interest in another problem of fundamental importance which we share with the whole company of thinkers and which medicine, absorbed in the application of its new therapeutic resources, has neglected of late. What is the nature of man? How should we regard the individuals who consult us?

It is a hundred years since Charles Darwin published *The Origin of Species* and about forty since we became aware in this country of the work of Sigmund Freud, and I am fully conscious, like William James, that every opinion must be forged in the face of stubborn and irreducible facts.

The Basis of Continued Life

The broad conclusion from biology is that man to-day is what he is as the result of evolution, natural selection, and the invention of conventional speech and of symbols such as numbers and formulae which not only record and store his past experience and achievement for the benefit of future generations but also bring order to his conceptual thought and enrich it in every field of activity—in literature, art, mathematics, and science. To that we may add that all life depends on green plants, including, of course, the algae of the seas, for they furnish the food of animals and so the nourishment of man. Plants alone seem able to fashion the stuff of life—proteins, sugars, and fats—from stable inorganic material in the air and soil with no other help but the light of the sun. This wonderful photosynthesis is the basis of continued life, and not unnaturally it has been studied diligently. What seems to be emerging is that there

are chemical and physical phenomena common to the activity of plant, animal, and human cells, and much that is now mysterious will become clearer when we know more of the exact role of nucleic acids in living processes.

Man, it seems, is one with nature—not merely with the organic nature of plants and animals but also through photosynthesis with the inorganic world—he has emerged from it and belongs to it. Fifty years ago that opinion had little to support it. Physics and chemistry then were widely separate subjects and there was a gulf between the organic and the inorganic. Pasteur in the 1860's had shattered the hypothesis of spontaneous generation, and we believed that all living things came from living forebears. So, indeed, they do. But was it ever so on this planet? The atmosphere in which we now live is very different from that which surrounded the earth when it first revolved upon its orbit, and it is conceivable, nay almost probable, that conditions may then have favoured the formation of the protein molecule, the stuff of life, from inorganic material in a manner that would be impossible to-day. The identity of man with nature I do not find discouraging; he remains a manifestation of the creative energy that formed the cosmos, and each of us may be, as Rupert Brooke thought, a pulse in the eternal mind, no less.

If we admit the truth of that opinion, are we committed to the belief that all human conduct is determined by forces beyond the control of the individual; that we are passengers in the evolutionary car and have no say in its direction? The irrefutable facts to which I have referred suggest it may be so, and to these might be added the evidence from genetics, for it seems certain that the limits of personal potential are set by genetic constitution, though accident and environment may restrict or encourage its development.

Human Behaviour

Has clinical experience anything of value to add to the discussion of this problem? There are facts in medicine that appear to support the full determinist position. As physicians we are familiar with the disorder of behaviour and the deterioration of character that are a consequence of acquired pathological lesions or inborn errors of constitution, and we are tempted at times to believe that human tution, and we are tempted at times to believe that human personality depends solely on physical conditions. But the fact that in some cases disease overwhelms or distorts an individual does not prove that personality is determined by physical processes alone. On the contrary, is it not general experience that patients show an astonishing variety of attitude and response to illness? Many who are crippled by injury or disease radiate happiness and energy and accomplish much, while others in identical conditions give up the struggle and become a burden to themselves and their kin. This is the common stuff of our daily work, and surely it encourages a belief that free will and courage are not illusions and that to each of us falls the duty of choice in our behaviour. The Freudians to account for such variation in conduct invoke the subconscious, but, important as that may be, I am still persuaded that conscious resolution plays as large if not larger a part.

It may be argued, justly, that research by scientific method is still in its infancy and that as it proceeds it will win knowledge of material processes that determine human behaviour. Equally true is it that research may also reveal much about the self-conscious human individual which defies explanation in measurable terms of matter; the curious sense of guilt, for instance, and the inhibition which have no parallel in animals.

Whatever the future may hold I think it is fair to say categorically at the present time that our scientific knowledge does not warrant the assertion that human life is entirely determined by physical factors, though their influence is great, and our daily work as doctors intimates the existence of free will and the capacity for choice, which in some inexplicable way have "emerged" in the course of the evolution of a self-conscious human being.

My friend Professor Roy Pascal, with whom I discussed this matter, reminded me of *Dichtung und Wahrheit*, the autobiography in which Goethe made a determined effort to define the factors that had influenced him and made him what he was. At first he seems convinced of the dominance of the material: he even says at the beginning that if he had been born a year or two later he would have been a different man. Yet as he proceeded he became more and more impressed by the unpredictable element in his personality and life. In the last book he refers to it frequently. He calls it the "daemonic" element which surged up within him, involuntary and unaccounted for. "It was like chance, since it evinced no sequence of causality: it resembled Providence, for it hinted at coherence."

Conclusion

If, as I believe, we may properly at the present time act on the assumption that man is something more than a completely determined animal, an important conclusion about medical practice follows. The relationship between doctors and their patients is deeper than that entailed by the solution of scientific and measurable problems: it is in truth a personal relationship in which intuition, sympathy, and compassion play a considerable part. To avoid any misunderstanding let us acknowledge that most of the manifest achievement of recent years has been due to distinguished work in basic and clinical science, and that it is our responsibility to encourage all such work and to accept its verified conclusions, but we must never forget the large part of clinical practice which depends on qualities that science cannot yet measure and possibly never will.

Our duty is clear; we have to put at the service of the patient, when it is necessary, all the resources of scientific investigation and treatment, but, in addition, we have to maintain in him the personal interest and concern of a friend.

SITTING, STANDING, AND WALKING*

BY

MICHAEL KREMER, M.D., B.Sc., F.R.C.P.

Physician, Department for Nervous Diseases, the Middlesex Hospital, London; Physician, National Hospital, Queen Square, London

It must be clear that what has so far been said about the orientation of the body when attempting to sit might well be repeated for standing, and indeed for any activity in which the individual desires to assume a definite relationship with and towards the outside world; there is therefore no point in repeating all this to serve the same purpose. I propose, therefore, to consider the mechanism of standing upright and how this is upset in such interesting syndromes as the drop attack and syncope.

As in any postural activity, the peripheral mechanism is primarily of reflex order—simple stretch reflexes which are modified by the afferent nerves from neck muscles, vestibular organs, eyes, and so on. It is of interest to mention the important driving function of the muscle spindles and the so-called servo mechanism described by Hammond, Merton, and Sutton (1956), who have given a far-reaching explanation of continued smooth-muscle contraction at the tonic level and the part played by the cerebellum in this mechanism. This is discussed below, after some of the clinical cases have been considered.

*The second of two Oliver Sharpey Lectures delivered before the Royal College of Physicians of London on February 11 and 13, 1958. The first lecture appeared last week at p. 63.

Case 6

The first patient to draw my interest sharply to the sudden failure of the upright posture was a young soldier who was digging a slit-trench. The sudden noise of a passing aircraft upset him and he looked up to make sure it was not a dive bomber—for it was in the days when dive-bombing occurred. He fell at once into the trench. He soon picked himself up, apparently mildly confused, for he attacked the man next to him—very inefficiently—as he felt he had been struck down. He said he thought he had been hit on the back of the head or neck, and that it was for this reason that he had fallen. He was uncertain whether he had lost consciousness, but did not remember hitting the ground.

Full examination and investigation showed that he had a moderately large ependymoma of the fourth ventricle, and I interpreted the sudden falling or drop attack, as it may well be called, as due to sudden medullary compression producing loss of function in that vital region, rather than to a blockage of the flow of cerebrospinal fluid producing an acute hydrocephalus, as is said to occur in colloid cysts of the third ventricle. I did not attempt to decide how the loss of function occurred or to what the fall was due.

Case 7

Some four years later I saw a young man with this story. While running through a bulkhead opening on board ship he struck his head on the low beam and fell sharply to the ground. He remembers that his legs tingled a bit, but he soon picked himself up. He felt a little odd but thought this was due to the blow on his head, though he admits it was not very severe. The same thing happened a second time while playing some deck game. He again ran through an opening, struck his head, and once again fell to the ground and his legs tingled for a short time. This occurred on a troopship, and his companions were so intrigued that they tried the dangerous experiment of pressing on the top of his head. He said that this made his legs tingle and fold up. Fortunately they didn't try this more than twice, and seemed content to achieve a minor response. He was sent to hospital, and there I found that he had a mildly stiff neck and a very minor paraparesis with increased deep reflexes and equivocal plantar responses. There was no sensory change. In his previous history it appeared that while at school, aged 12, he dived into the shallow end of the swimming-pool and struck his head forcibly on the bottom. He was rendered powerless, but was pulled out and carried to bed. There he lay for 10 days unable to move or feel his legs, and with very feeble arms. He improved, however, and in four weeks was up and about, soon playing games, though with a stiff neck that lasted some months. According to the patient at no time were any investigations carried out.

On admission x-ray examination showed that he had an old fracture-dislocation of the odontoid peg which was rotated so that it lay at right angles to its former position with its apex pointing to the lower medulla. Tomograms showed that the medulla and upper cervical cord would have to carry out a considerable bend in order to negotiate the top of the odontoid. It was clear that each time he struck his head the violent impact squeezed the medulla and caused a failure of function, and the legs gave way. Close questioning disclosed no loss of consciousness or something so brief that the patient did not remember it.

Case 8

Some two months ago I saw a 30-year-old man who for two years had been having difficulty with his legs. They had become increasingly weak and he would tend to fall. In the last year he fell often, and if, as was usual, he pulled his head back to avoid striking his face on the ground, then his feet would get much weaker and fail to carry his weight, and if he were picked up he would fold up again. Usually he would ask to be left alone, and after three or four minutes he would regain enough power to pick himself up

and walk on. He said that if he put his head back voluntarily then his lower back and legs would tingle and his feet and legs would get weak so that he could not remain standing. Naturally, he never voluntarily carried out this manoeuvre long enough to produce falling. In its essence this case sounded very like that of the young man with the fractured odontoid; but, as this was 12 years later, I was able to plan some clinical investigations.

Straightforward examination showed that he had no abnormalities in the skull, but his neck could not be extended more than 10 degrees from the vertical before bringing on the tingling, which I suppose might be called the reversed electric sign of Lhermitte. There were no abnormal findings in the upper limbs. In the lower limbs there was a moderate spastic weakness with increased knee- and ankle-jerks, bilateral plantar responses, and about a dozen beats of ankle clonus. Sensory testing showed only a very minor impairment of sense of passive movement in the toes and of vibration sense on the feet, approximately equal on the two sides.

The experiment consisted merely of extending the neck so that tingling was just produced. The only change on examination, which of course had to be rapid, was of a slight depression of touch sensation in the feet. Whether this was genuine depression or merely due to the interference produced by paraesthesiae I cannot say. That ischaemic and post-ischaemic paraesthesiae interfere with sensory testing is well known, and the same may have been happening here. Gently and cautiously the head was taken a little further back. The patient was unaware of anything much happening except an intensification of his paraesthesiae, but his voluntary power was definitely impaired at the ankle and knee—mainly in the dorsiflexors and extensors and also, though not so much, at the hips—again mainly in the extensors. I must stress that this was all done hurriedly—that is, in a short period of time—and that no accurate measurements of power were made, but I had no doubt there was a real difference of power, and the patient had no doubt there was diminution. The deep reflexes remained brisk as before and the plantars were extensor, but tone was very definitely reduced, and the ankle clonus was abolished. Sensory testing showed further increase in the cutaneous impairment to touch and also for two-point discrimination, but the paraesthesiae had increased also.

All these results were confirmed on several occasions. The main point which emerged was that coincident with the onset of weakness there was a profound diminution of tone as estimated by the sense of resistance to passive stretch. Yet the deep reflexes and plantar responses were unaffected. This patient had a compressive lesion extending through the foramen magnum.

The Drop Attack

Here, for the first time, so far as I was concerned, appeared a possible explanation of the drop attack—that it might be due to a cessation of postural tone in the lower limbs. The weakness on voluntary movement was increased but did not appear sufficient to cause the sudden fall to the ground that occurs in the drop attack, the so-called idiopathic form of which is described below. On the other hand, there was the curious observation that the tendon reflexes remained as brisk as before and the plantar responses just as extensor. How can one reconcile these findings? Now, every clinical neurologist at some time or another has seen just such an apparently paradoxical combination and has had as much difficulty in explaining this as I had. Being brought up in the traditional school of neurophysiology which was developed by Sherrington, I believed that the deep reflex such as the knee-jerk was dependent on the degree of tone in the muscle stimulated—the more tone the greater the response, the less tone the smaller the response; in other words, that the deep reflex was a fractional stretch reflex. Yet here were tendon reflexes unaffected by the tone in the muscle. Definite hypotonia had been produced, yet the reflexes were as brisk as ever.

The answer has now been provided by the results of Merton and his co-workers in a series of brilliantly planned experiments both in animals and in man on the nervous control of muscular contraction (see Diagram). So important are these for a proper understanding of the drop

The muscle spindle lies in parallel with the main muscle and its fast conducting afferent is in synaptic connexion with the large α motor neurone supplying the main muscle fibres. A slow conducting γ motor efferent (thin line) supplies the contractile poles of the spindle and thus can alter the bias on the spindle sensory ending. The muscle can be made to contract either by impulses from higher centres exciting the α motor neurone direct (the α route) or by impulses in the γ efferents (the γ route) which activates the muscle indirectly via the stretch-reflex arc (the "follow-up" servo). A subsidiary feedback loop via the recurrent axon collateral and an inhibitory Renshaw interneurone may be concerned in stabilizing the response of the α motor neurone to its excitatory input. (From Hammond, P. H., Merton, P. A., and Sutton, G. G., *Brit. med. Bull.*, 1956, 12, 214.)

attack and the paradoxically increased deep reflex in the hypotonic limb that I make no excuse for summarizing them here.

A muscle is brought into action by motor impulses, but the degree of that contraction is estimated by sensory receptors in the muscle, and in the light of this information, called the "feedback," it modifies the rate of motor discharge. It is true that visual information may modify the motor discharge as may cutaneous impulses, but it is the muscle sense organs which play the major part in assessing or monitoring the performance of the muscles themselves.

The muscle spindles are the sensory organs of muscles. They lie among the main muscle fibres, having the same attachments and therefore altering in size with contraction or relaxation of the muscle itself. It must be remembered that the poles of these muscle spindles are contractile and receive very fine-fibred efferent supply, the γ fibres, whereas the main muscle fibres receive large or α fibres. The reflex connexions of the muscles are such that impulses set up by stretching the spindles excite the muscles' own motor neurones. Thus extension of the muscle results in an augmented contraction which tends to resist the extension. This is the stretch reflex of Liddell and Sherrington (1924). This has the properties of a closed loop self-regulating mechanism using information from the spindles to maintain a constant muscle length. It is clear that this has enormous advantages over a straight-through system in which posture

is maintained by a steady stream of motor impulses without sensory modification or feedback, in that it automatically compensates for changes in load or for fatigue.

This type of stretch reflex would maintain a fixed posture well, but it is clearly inflexible and needs modification for ease of changing muscle-lengths while maintaining postural tone. This modification is carried out by means of the contractile poles of the muscle spindles. The sensory portion of the spindle lies between these poles, hence shortening the poles by impulses along the γ efferents will stretch the sensory spindle so that the stretch reflex will be activated just as if the muscle itself had been stretched. The muscle will then shorten reflexly until the increased rate of spindle discharge has been offset, and that will be when the muscle has shortened to the same extent as the contractile poles of the spindle.

Merton and his associates have named the loop mechanism of the simple stretch reflex the "length servo" mechanism and the modification next mentioned the "follow-up servo."

Experiments have, however, shown also that in de-afferented limbs, in which this whole servo mechanism must be out of action, movements can occur without it: sudden movements almost invariably do through the α efferents to the muscle, and in further work Granit (1955) has shown that the cerebellum and associated structures determine whether the length servo or the straight-through mechanism is to be used in contraction. As Hammond *et al.* (1956) say: "This fits in with, and extends the current notion that the cerebral hemispheres decide what is to be done, and the cerebellum has the job of arranging how it is to be carried out."

We are now coming to the crux of the matter. There is evidence that even when the α route is used, the motor-neurone discharge is subject to servo control. Branches from the motor axons run back into the ventral horn and excite internuncial cells named after their discoverer, Renshaw (1941), which in turn inhibit the neighbouring motor neurones. It may well be that this mechanism provides the stabilizing influence on the motor-neurone pool. Certainly recurrent collaterals which might function in this way are to be found throughout the nervous system.

It has been shown that this Renshaw loop on the α fibres has an appreciable delay of some 2–5 msec., and therefore a brief afferent volley may pass through the loop while the sensitivity is high before the stabilizing influence of the collateral loop can be exerted; the tendon jerk gives just such a brief synchronous nerve volley and it need not necessarily be related to the status of tone in the muscle. In other words, the tonic mechanism is motivated through the muscle spindles and the γ efferents, the tendon jerk through the α efferents. The two are not necessarily related. The γ servo loop is under control from the cerebellum, and when the latter is put out of action this tonic mechanism will fail and hypotonia result. The brief synchronous afferent volley due to the tap on a muscle tendon will get through the motor unit pool and produce a brisk twitch, but the α fibre mechanism cannot respond as a tonic mechanism because of the controlling influence of the Renshaw loop. This comes into action too late to prevent the passage of the impulses necessary for a brief reflex response, but prevents a prolonged reflex response.

Considerable further evidence exists for the α and γ fibres in muscle. In 1919 it was shown by Liljestrand and Magnus that procaine injected into animal muscles abolished tone in the decerebrate state long before there was any alteration in either reflex response or that due to motor-nerve stimulation. In 1924 F. M. R. Walshe showed that injection of procaine into the muscles in Parkinsonism or spastic hemiplegia reduced the tone considerably but left voluntary power, if anything, rather better. This was interpreted by both authors as a selective knock-out of the afferents from the muscle. Recent work, however, has shown that the γ afferents are far more sensitive to procaine, and Matthews and Rushworth (1957a, 1957b) have found experimentally

that this is the probable explanation for the selective action in the previous authors' works.

A further most interesting finding indicating the separate nervous mechanism is that of Gilliat (1954), who produced peripheral nerve ischaemia by means of pneumatic tourniquets. In patients with severe pre-existing spastic weakness the diminution of muscle tone following local ischaemia may outlast any increase in muscular weakness caused by the procedure, and patients report improvement in the mobility and usefulness of the limb for several hours. This must be due to a selective action on the efferent tonic mechanism; in other words, the γ fibres.

Here, if we accept this work—and I have not quoted all the compelling experimental evidence on which it is based—is an explanation which will serve for the paradox of the hypotonic limb with brisk deep reflexes, and here, I would like to submit, is the explanation for the drop attack.

Clinical Description of Drop Attack

The clinical description of such an attack is of a middle-aged individual who for no obvious reason suddenly falls where she stands. Most, though not all, patients are sure they do not lose consciousness. There is no warning, and they do not try to save themselves because the whole episode is so sudden. They often say that they folded up at the knees, and many women have complained about ruining their stockings at the knees, which certainly indicates a falling forward and might support the folding-up suggestion. Many of these patients rise almost as soon as they have reached the ground, without confusion or disturbance other than being shaken by the episode, though some may hurt themselves during the fall or, if frail and elderly, they may well be very shaken and dazed. All these patients are quite sure that they do not trip, that they felt well before the incident, that only their legs gave way, and that they can continue walking as soon as they are on their feet again. Physical examination and investigation of these patients rarely reveals anything of note to explain the happening.

On the basis of Cases 6 and 7 I would like to suggest that it is the lower brain stem which is the site of the dysfunction that produces the event. The nature of the possible lesions are discussed below, but the mechanism is probably best explained on the lines suggested by the physiological work of Granit and of Merton. Interference at brain-stem level, with the connexions of the cerebellum, deprives the postural-tone mechanism of the control by γ -fibre servo loops which go out of action. This causes a failure of postural tone, and the individual folds up and falls to the ground suddenly. The α mechanism cannot take over at such short notice, and in any case is not suited, as has already been shown, to the maintenance of steady postural contraction.

Case 8, in which we could fractionate the drop attack, gives every indication that this hypothesis is feasible if no more, for we were able to produce definite hypotonia yet the deep reflexes were brisk, the former indicating a diminution in γ activity, the latter the integrity of the α pathway.

Given the site of the syndrome, what could produce such happenings? My three opening cases indicate that this can occur with compression of the brain stem. In each of these cases, however, the condition was reversible, which is an important feature of the drop attacks, and it is probable that the compression acted on the vascular supply. In each case a special manoeuvre to produce compression was necessary, and on reversing the process the condition was reversed. It is tempting to suggest that in most cases of this type of drop attack the mechanism is a transient change in the blood supply of the brain stem. There is some evidence that this may be so. In a recently described series of aneurysms of the vessels of the posterior fossa Dimsdale and Logue (1957) were very positive that weakness and collapse of the lower limbs were characteristic of the condition, while Williams and Grahame Wilson (1957) have shown examples of basilar atheroma in patients with the syndrome.

Syncope and Epilepsy

The other types of falling attack of major importance are, of course, those due to syncope and epilepsy, and these often need differentiation. The work of Sharpey-Shafer (1956a) has elucidated many of the mechanisms of syncope. He defines the condition as an acute decrease of the cerebral blood flow producing loss of consciousness. The rapidity of the decrease in flow determines the length of warning symptoms. In cerebral flow it is mainly the arterial pressure which is the governing factor, and when this falls below 50 mm. Hg for a few seconds syncope results. As the arterial pressure depends on the cardiac output and the peripheral resistance it is clear that a fall in either, or of both to a less degree, will be the mechanism involved. The compensating factors are the baroreceptor reflexes which usually keep the cardiac output and peripheral resistance working in opposite directions.

The clinical varieties may be split into several groups.

A. Decreased Filling Pressure and Stroke Output

Normally the diminished output in the upright position due to diminished filling of the heart is compensated by the baroreceptors, but standing for long periods on a hot day may cause overfilling of the lower veins and grossly decreased filling pressure, so that no amount of peripheral vasoconstriction can compensate for this and the individual faints. A rise of intrathoracic pressure as in the Valsalva manoeuvre will cause acute decrease of filling, depending on the height of the intrathoracic pressure, especially if there has been a degree of previous vasodilatation as produced by the warmth of a bed or a bath. Similarly, coughing (Sharpey-Shafer, 1953a) in the powerful short-necked man may raise the intrathoracic pressure high enough to prevent adequate filling of the heart and so decrease output-producing cough syncope.

B. Decreased Stroke Output

This is best seen in the Stokes-Adams syndrome. Here it must be said that if the cerebral anoxia is prolonged enough the convulsion will occur together with voiding of urine.

C. Decreased Filling Pressure and Stroke Output with Vasodilatation

This is best seen in squatting (Sharpey-Shafer, 1956b), for in this state blood is pressed out of the veins of the legs and cardiac filling pressure rises. This gives rise to reflex vasodilatation. If one then stands erect suddenly the hydrostatic fall of filling pressure and cardiac output takes place while this vasodilatation is still present, and this may be sufficient for a few seconds to lower the arterial pressure to a syncope level. This in a minor form is a very common happening.

D. Nocturnal Fainting

These cases are labelled nocturnal, though they need not occur strictly at night. They are, however, given a separate grouping because they are relatively frequent and almost always raise the problem of epilepsy. Usually the subject gets out of bed during the night to empty the bowel or bladder. In the normal person just getting out of bed alone usually has no effect, for the baroreceptors respond very rapidly and constrict the peripheral resistance, thus countering the vasodilatation produced by the warmth. If for some reason the baroreceptors cannot act, then this compensation cannot occur and fainting will result, often quite suddenly on assuming the erect position. Failure of baroreceptors can occur because of the effective use of ganglion-blocking drugs which break the efferent part of the pathway; extensive sympathectomies would do the same. Sharpey-Shafer (1953b) has shown that the pathway can be blocked on the afferent side of the baroreceptor reflex in diseases of the nervous system, such as tabes dorsalis. If after the subject jumps out of bed he empties the bowel there may be sufficient straining to constitute a Valsalva manoeuvre, and this, associated with the warmth vasodilatation, may be enough to cause syncope.

Standing to empty the bladder at night may produce syncope by another mechanism. My attention has been drawn to the pressor effect of the distended bladder by my colleague Dr. Roger Gilliat. This was shown in patients with spinal transection (by Guttman and Whitteridge, 1947), when distension of the bladder could give a blood pressure well over 200 mm. Hg. It may well be that, modified perhaps, this is effective in the whole man and that emptying the bladder reduces this pressor stimulus while the rest of the body is in a state of vasodilatation produced by warmth, and in the upright position may well lower the arterial pressure to a syncope level. There is no doubt that those of us who see many "fitters" and fainters are bound to see a fair number of cases that occur at night in these circumstances.

E. Reflex Fainting

This can be emotional or produced by pressure on the carotid sinus or the eye—the oculo-vagal reflex of Gastaut and Fischer-Williams (1957). In the former the characteristic feature is an acute peripheral vasodilatation taking place in the muscles, but there is associated pallor of the skin suggesting that the cutaneous capillaries are intensely vasoconstricted. With this there is a preceding gasp, a feeling of uneasiness, and nausea, and then the features of cerebral anoxia supervene. Sharpey-Shafer (1956a) points out that in fact there is a decrease of cardiac filling pressure before the vasodilatation, and postulates that owing to the decrease in filling pressure the afferents in the heart are stimulated which then sets off the rest of the reflex. Bradycardia occurs after the vasodilatation, and it is clear that the compensating reflexes are temporarily out of action. The intense vasoconstriction of the skin is due in part to liberation of the posterior pituitary vasopressin, and the skin may remain pale for many minutes after the attack and large amounts of the hormone may be found in the urine after either an emotional or a haemorrhagic faint (Taylor and Noble, 1950). It is interesting that patients with heart failure do not faint—which is attributed to the continued maintenance of the cardiac filling pressure.

Carotid sinus and ocular-vagal reflexes produce their effects by cardiac slowing or arrest and not by vasodilatation primarily. Where vasodilatation occurs it is due to the baroreceptors having been overcome. In Stokes-Adams attacks peripheral vasoconstriction is usual, as can be seen by the overswing of the arterial pressure during recovery.

The work of Gastaut and Fischer-Williams (1957) is most interesting in their attempt to separate syncope from epilepsy. They used the oculo-vagal reflex—that is, firm pressure on the eyeball—to induce syncope which resulted from reflex cardiac inhibition. They studied 100 patients who had had one or more attacks of loss of consciousness in association with pallor, sweating, nausea, malaise, and sometimes convulsions resembling grand mal, but in whom the resting E.E.G. was normal. They recorded the electroencephalogram, the electrodermogram, which measured the amount of sweating on the forehead, and the electrocardiogram.

They observed two types of syncope—the immediate and the delayed. The immediate occurs within one to five seconds of ocular compression and is due to reflex vagal inhibition of the heart. Delayed syncope may occur from 20 to 70 seconds after the compression, when the most important factor is vasodilatation with fall in blood pressure, though bradycardia or cardiac arrest may occur at the same time. These two forms may occur separately or follow one another in the same patient.

When cardiac arrest lasted three to six seconds there were no clinical or electrical abnormalities, but there was some desynchronization of the E.E.G., which is the usual finding with pain of any kind, and there is no doubt that ocular compression is painful. When cardiac arrest lasts about 7 to 13 seconds slow waves appear in the E.E.G., usually but not always associated with disturbance of consciousness. These slow waves have no resemblance to epileptic waves. The relationship of the slow waves to loss of consciousness varies from patient to patient: sometimes there may be complete unconsciousness from the beginning; sometimes there may be a minor absence only. If cardiac arrest lasts more than 14 seconds there is always complete loss of consciousness and then one or two myoclonic jerks. Following this the patient suddenly develops an intense generalized tonic spasm in extension with opisthotonos looking like decerebrate rigidity or a tonic posterior fossa fit. If the tone is different in the two sides then lateral deviation of the head may occur. During the time of the tonic phase the E.E.G. is absolutely flat with no rhythms appearing at all. The spasm lasts 10 to 20 seconds, and during this time heart beats reappear. Even if they appear at the beginning of the tonic spasm they do not prevent its evolution; once initiated it must go on to completion.

As soon as the spasm is over, slow bilateral large waves appear in the E.E.G. and again a myoclonic jerk may be found. This lasts 24 to 30 seconds. The rhythm takes several minutes to reach normality, however, and during this whole period the patient feels odd and faint. The loss of consciousness is certainly due to cerebral anoxia coming on rapidly owing to asystole in these patients, and the critical period of asystole is about 14 seconds. The tonic spasm in the seizure is regarded by these workers as due to a liberation of the reticular substance in the brain stem from the control of higher structure, together with a possible anoxic stimulation of the reticular substance itself. The flattening of the E.E.G. is interpreted as a cessation of function in the cortex which spreads downwards to involve all structures until the reticular substance is reached, where increased activity

takes place. This has been shown also in experimental animals (Ward, 1947). Slow synchronization of E.E.G. rhythm which follows is due to a recovery of the higher structures.

Gastaut and Fischer-Williams go on to analyse the difference between epilepsy and syncope with convulsion. They suggest that the tonic phase in both syncope and epilepsy is due to a similar overaction of the reticular substance in the brain stem. In syncope this is due to the cerebral anoxia causing cessation of function above this level with liberation of the lower structures, which may also be directly stimulated by the anoxia. In epilepsy the brain as a whole is functionally active, as can be seen by the abnormal rhythms in the E.E.G., and it is this epileptic activity which, occupying the brain as a whole, allows the liberation of the reticular substance to produce the tonic phase. The clonic phase of epilepsy is due to attempted inhibition produced in the cortex breaking up the tonic phase. This is impossible in syncope because the higher parts of the brain are functionally dead owing to the precipitating cerebral anoxia. This is an attractive hypothesis, but it still needs some further proof. Gastaut and Fischer-Williams make it quite clear, however, that on E.E.G. studies and on clinical inquiry syncope should be distinguishable from epilepsy. Some of these observations have been made before, though not the same interpretation has been put on them.

An intriguing example is given in the discussion which took place at the Royal Society of Medicine in 1950 on "fits and faints." This case was quoted by Symonds (1950), though the observations were made by Ashby and Denis Williams. The patient was referred as a case of epilepsy by a doctor who was an eye-witness of an attack. In hospital he had an attack, when the pulse stopped completely for 45 seconds. After ten seconds he had a fit, with rolling eyes, rigidity, and a few convulsive movements. In a subsequent induced attack the E.E.G. showed no epileptic activity. This, it must be admitted, is a very similar observation to that of Gastaut and Fischer-Williams. It makes the differentiation between fit and faint both easier and more difficult, for, apart from the E.E.G., the important difference is that of the presence of a true clonic phase in epilepsy, whereas in syncope only a minor myoclonic jerk may be seen. Most neurologists have been brought up on the classical writings of Gowers (1901, 1907) on epilepsy and have believed that frequent and chronic fainters will usually turn out to be sufferers from epilepsy. In fact, Gowers says that "if a patient faints often enough he is sure to have a fit some time." If this new work is accepted, then we must surely alter this sentence to, "If a patient faints often enough he is likely to have a tonic fit sometimes, perhaps an epileptic fit never."

Walking

We now come to walking, which I will deal with very briefly because it is again compounded of the various phenomena already discussed. We find that to walk straight requires the ability to stand straight and to transfer the weight from one leg to the other without any disturbance of equilibrium.

To walk accurately requires also a knowledge of where one's legs are, otherwise they go in the wrong direction, trip one up, and generally misbehave in a way that makes progression a hazardous process.

There must also be an effective mechanism to give information which will grade the amount of muscular contraction necessary to give a smooth performance. Of course, all this has to take place for artificial legs as well as for natural ones.

I saw a 50-year-old man who had a lower limb removed in the mid-thigh region for Buerger's disease. I had to see him for some trivial neurological condition while he was convalescing from this operation, and I saw him subsequently from time to time for the same reason. He was provided with an artificial limb, and eventually he learned to walk moderately well with this. He was brought to my out-patient clinic one day because of an attack—clearly a cerebral thrombosis—which had affected the arm on the side of his amputation. He had minor weakness only, but a moderate sensory loss affecting all modalities and making his hand very clumsy. He said he didn't know where it was or what it was doing. In fact, he now had the greatest difficulty in walking. One could, I suppose, argue that he had lost the sense of position in the artificial limb; which sounds absurd, although no more absurd than the amputee who suffers from chilblains on the toes of the leg which had

been lost. The clue was provided by the patient saying that after the stroke he had lost his phantom leg. This is the patient I mentioned in the first lecture as resembling the patient of Head and Holmes (1912) who lost his phantom after a parietal vascular lesion. From this patient it would appear that to walk adequately one must know the position of the limb in space, and, if one is walking on an artificial limb, then it is only effective if it is possessed by a phantom leg which supplies it with the knowledge that is necessary to make it function as a limb rather than just as a support, and an inefficient one at that.

The ataxic walk of the individual with severe cerebellar disturbance must be due in part to the inefficiency of the automatic grading of muscle effort produced by the disorganization of the γ fibre mechanism as already suggested in an earlier part of the lecture, and the use of the more forceful, but uncontrolled α fibre system, so that improper force is used. If one watches the feet of a patient with inadequate cerebellar control it is possible to see constant contraction and relaxation of the foot muscles going on, so that the toes are clawing into the ground—again this is due to the use of a nervous control not designed for the purpose.

There is, however, another side to cerebellar control, and that is equilibration. For it is possible to have the cerebellum so disorganized in its older part—the flocculo-nodular lobe which forms the greater part of the roof of the fourth ventricle—that there may be gross disorder of equilibration. The patient staggers violently from side to side and is quite unsafe on his feet. Yet on formal testing for cerebellar ataxia as in the heel-knee-shin test there is no disorder. This is because the control of the γ system is intact.

It is remarkable how difficult it is for the patient with a severely damaged cerebellum to compensate alone—how simple it is for the compensation to be effected by another. The patient who can walk only with a stagger from side to side may, if he links an arm with a normal person, walk reasonably well. I have seen such a patient do ordinary relatively sedate ballroom dancing apparently so well and so disproportionately to his ordinary walk that he came labelled as a hysteric.

It appears, therefore, that for the equilibration difficulty sufficient stabilization can be provided by another person, but only so long as the γ system is intact. I remember Riddoch demonstrating this with great verve and ending the demonstration by saying that "clearly one cerebellum was enough for two."

Fatigue

I am brought finally to a few words on fatigue in muscle performance, as in walking or in running. At one time the theory of fatigue in profound effort was attributed to fatigue in the central nervous system, but it has been shown that this is inaccurate, and that fatigue is a peripheral phenomenon due to the failure of the circulation to remove metabolic products of muscular contraction. This is easily demonstrated by fatiguing a limb and arresting the circulation at the moment of cessation of muscular contraction, when there will be no recovery of power until the circulation is established. This is evident as applying to severe effort, as when doing heavy muscular work, but it is also the case for skilled fine movements. It was found experimentally that in skilled tasks, even in the lightest such as writing, the muscles are often working nearer the limit of muscular endurance than is imagined, but that owing to the muscles' proprioceptive servo control fatigue is compensated for automatically until considerable fatigue occurs, when the muscle will suffer a relatively sudden breakdown in its performance.

Conclusion

I have dealt with certain aspects only of the means by which we sit, stand, and walk. These lectures have been really a consideration of not sitting, not standing, and walking very badly, but it is only by study of the dissolu-

tion of such processes that we can ever hope to elucidate the means by which we manoeuvre ourselves into a desired posture as when sitting; the means by which we maintain it, as when standing; and the means by which we co-ordinate all our muscular activity and keep the muscles contracting without overdue fatigue, as in walking.

HAEMORRHAGIC THROMBOCYTHAEMIA

REPORT OF TWO CASES TREATED WITH RADIOACTIVE PHOSPHORUS

BY

JAMES R. FOUNTAIN, M.D., M.R.C.P.Ed.

Tutor in Medicine, Department of Medicine,
the General Infirmary, Leeds

Epstein and Goedel (1934) first suggested the term "haemorrhagic thrombocythaemia" for the bleeding disorder which is characterized by a persistently raised platelet count. Although bleeding accompanying thrombocytopenia is commonly seen in hospital practice, the association of haemorrhage and thrombocythaemia is extremely rare, and probably no more than 30 cases have been reported in the world literature. Fanger *et al.* (1954) reviewed 28 cases of thrombocythaemia, but in six of them haemorrhagic manifestations were not present. Hardisty and Wolff (1955) analysed the clinical and haematological features of 18 reported cases of haemorrhagic thrombocythaemia plus a further five of their own. Of these 23 patients, 19 were over the age of 40 and there were almost equal numbers of males and females. Bleeding most commonly occurred from the nose and alimentary tract, and,

although bruising was not uncommon, purpura was rarely observed. Blood loss invariably resulted in a hypochromic anaemia, and all cases showed a raised platelet count and leucocytosis.

In addition to bleeding, patients with haemorrhagic thrombocythaemia may have thrombotic episodes. Presumably, these are closely related to the excessive number of platelets, but the mechanism of the bleeding is unknown. Approximately half of the reported cases showed abnormal bleeding-times; otherwise the standard tests of haemostatic function were normal. Hardisty and Wolff (1955) found a qualitative deficiency of the platelets in their five cases, as evidenced by their behaviour in the thromboplastin generation test, but were of the opinion that this was not the only factor involved.

The object of this paper is to present clinical and haematological details, including investigation of the blood-clotting mechanism, of a further two cases of this rare bleeding disorder and to report the beneficial effects of treatment with radioactive phosphorus (^{32}P).

Case 1

A road-worker aged 58 was referred to the department of surgery of Leeds General Infirmary on October 9, 1956, because of chronic bleeding from the alimentary tract for at least six years.

A history was obtained of good health until 1944, when he began to have attacks of abdominal pain. They were at first infrequent, and he was not seen at hospital until April, 1950, when he was found to be anaemic and tender in the epigastrium and right iliac fossa. Occult bleeding from the bowel was detected, and blood examination showed: haemoglobin, 8 g./100 ml.; red cells, 3,410,000/c.mm.; colour index, 0.79; white cells, 16,400/c.mm. (polymorphonuclears 74%, lymphocytes 23%, monocytes 3%). Radiological examination of the alimentary tract failed to reveal any source of bleeding. A diagnosis of peptic ulcer was considered most likely, and treatment of the anaemia with oral and later parenteral iron was advised.

In November, 1950, tonsillectomy was carried out. A good deal of haemorrhage occurred and a bleeding point had to be ligated.

During the following six years he was admitted to various hospitals on numerous occasions because of recurrent alimentary bleeding. Investigations carried out during this period revealed a chronic hypochromic anaemia with leucocytosis, but repeated radiological examinations of the alimentary tract, gastroscopy, and sigmoidoscopy failed to reveal a source of haemorrhage. In April, 1953, a laparotomy was performed, but no abnormality of the stomach, duodenum, small gut, liver, gall-bladder, or spleen was observed. The possibility of a bleeding disorder was apparently not considered, and there is no record of a platelet count having been done, although in 1955 a blood film was reported as showing abundant platelets.

During 1956 the bleeding became more severe and he was admitted to hospital for blood transfusions on eight occasions between January and September. In October a second laparotomy was performed (Professor J. C. Goligher). The stomach and duodenum were explored, but they contained no obvious blood. The jejunum and ileum also looked normal, and blood was first encountered in the terminal normal, and blood was also present in 2-3 ft. (30-60 cm.) of the ileum. Blood was also present in the colon, but no source of haemorrhage was discovered. The liver and spleen looked normal. Repeated blood transfusions were necessary post-operatively, and, in addition to melaena, epistaxis and haemoptysis occurred. On October 24, haematological investigation was requested.

Physical examination showed only anaemia. Blood examination gave the following results. Blood group B, Rh positive; haemoglobin, 6.8 g./100 ml.; red cells,

2,620,000/c.mm.; reticulocytes, 1%; mean cell volume, 89 cubic microns, mean corpuscular haemoglobin concentration, 29%; E.S.R. (Westergren), 21 mm. in the first hour. Platelets numbered 2,110,000/c.mm. and the platelet layer in the haematocrit tube measured 11 mm. The bleeding-time was five minutes (Duke), and Hess's capillary resistance test was negative. White cells 73,600/c.mm. (metamyelocytes 1%, neutrophils 89%, eosinophils 2%, basophils 1%, lymphocytes 4%, monocytes 3%). The blood film showed hypochromia and target cells were present. Bizarre forms of platelets, abnormal in shape and size, were present. Fifteen nucleated red cells per 100 white cells were observed, but no megakaryocytes were seen in the peripheral blood. Sternal bone-marrow aspirate was hypercellular, and erythropoiesis and granulocytogenesis were normal. Mature megakaryocytes were abnormally numerous and surrounded by sheets of platelets. Many immature forms were also present (Fig. 1).

Investigation of Blood-clotting Mechanism.—

Clotting-time (Lee and White), 4 minutes; one-stage prothrombin time (Quick), 15 seconds (control, 15 seconds); prothrombin consumption (Biggs and McFarlane), normal; clot retraction (McFarlane), normal. Calcium clotting time of normal plasma was not increased by addition of patient's plasma. The thromboplastin generation test (Biggs and Douglas, 1953) was normal when the patient's serum was added to the control platelet suspension and the control alumina-adsorbed plasma. It was also normal when the patient's alumina-adsorbed plasma was added to the control serum and control platelet suspension and when the patient's platelet suspension, before dilution and after dilution 1 in 8, was added to the control alumina-adsorbed plasma and control serum. No defect of blood clotting could therefore be detected and the platelet factor seemed normal.

Progress and Treatment (Fig. 2)

During the six weeks from the end of October to mid-December repeated blood examinations showed a hypochromic anaemia, leucocytosis, and thrombocythaemia, the platelet count ranging from 1 to 2.5 million/c.mm. The bleeding-time was usually normal, but occasionally prolonged up to 10 minutes. Melaena continued and blood transfusions were necessary on nine occasions. Cortisone was administered for three and a half weeks in November, without any beneficial effect. On December 14, 3 millicuries of radioactive phosphorus (^{32}P) was given intravenously, the platelet count at that time being 2 million/c.mm. and leucocytes 58,000/c.mm. Two further blood transfusions were necessary during the next 10 days, and the patient was discharged from hospital at his own request on December 24. When seen a week later the haemoglobin had fallen to 6.9 g./100 ml. and a further transfusion was given.

On January 21, 1957, he was seen as an out-patient and was feeling well. No obvious bleeding from the bowel had been observed since his discharge from hospital two weeks earlier and blood examination showed: haemoglobin, 11 g./100 ml.; white cells, 7,600/c.mm.; platelets, 860,000/c.mm. By February 8 the platelet count was 340,000/c.mm. and the haemoglobin 11.5 g./100 ml. Two weeks later the platelets had risen to 910,000/c.mm. and

FIG. 1.—Case 1. Bone-marrow film from sternal puncture (Wright's stain), showing increased number of megakaryocytes surrounded by masses of platelets. ($\times 70$.)

occult blood was again found in the stool. A further injection of 3 mC of ^{32}P was given and a course of intramuscular iron ("imferon") prescribed. Thereafter the blood picture returned to normal. Repeated testing of the stool for occult bleeding was carried out, but no further bleeding was observed and the patient regained full activity.

microcytosis, and a polymorphonuclear leucocytosis. Blood transfusions were given, and in October a splenectomy was performed at the Otley General Hospital (Mr. D. Chamberlain).

Pathological Examination of Spleen.—It weighed 568 g. and on section had a rather "beefy" appearance. Microscopically, considerable fibrosis was evident with dilatation of sinuses, the appearances being consistent with a diagnosis of portal hypertension.

FIG. 2.—Effect of radioactive phosphorus (^{32}P) on the blood picture and bleeding tendency in Case 1.

A third injection of ^{32}P was given on September 20, when the platelet count rose to 600,000/c.mm. When last seen on November 25, 1957, the patient was symptom-free and blood examination showed: haemoglobin 14.8 g./100 ml.; red cells, 4,800,000/c.mm.; white cells, 3,800/c.mm.; platelets 320,000/c.mm.

There had been no evidence of bleeding for over nine months, whereas during the year prior to treatment with ^{32}P he had continuous melaena requiring blood transfusions at intervals of between 7 and 28 days.

Case 2

A maintenance engineer aged 53 gave a history of recurrent episodes of bleeding from the alimentary tract since 1944. Details of his case up to 1952 are deficient, but in February of that year he was admitted to Otley General Hospital under the care of Dr. R. N. Tattersall, complaining of weakness and increasing pallor. The liver was enlarged, hard, and irregular, and the spleen was palpable. Blood examination revealed an iron-deficiency anaemia (haemoglobin, 8 g./100 ml.; red cells, 4,150,000/c.mm.; white cells, 12,800/c.mm.), and the sternal marrow aspirate showed a reactive hyperplasia of the red-cell series. Portal hypertension was diagnosed. Liver-function tests were, however, normal and a barium swallow showed no evidence of oesophageal varices. Improvement in the blood picture followed a course of intravenous iron ("ferrivenin") and a satisfactory haemoglobin level was maintained thereafter until June, 1953, when a hypochromic anaemia again developed. In September, 1953, the blood findings were: haemoglobin, 5.8 g./100 ml.; red cells, 3,700,000/c.mm.; white cells, 17,400/c.mm.; platelets, 145,000/c.mm. A blood film showed marked hypochromia, anisocytosis, and

recurrent melaena. Thrombosis of the splenic vein, spreading to the portal vein, was observed, and the liver was enlarged and cirrhotic. Gastric varices were ligated and the pyloric region was devascularized. A month later he developed pyloric obstruction and a gastro-enterostomy was carried out. Intermittent bleeding from the bowel, however, continued.

When first seen by me in December, 1956, the patient was anaemic and the liver was enlarged, hard, and irregular. Blood examination showed: blood group A, Rh positive; haemoglobin, 9.6 g./100 ml.; red cells, 3,500,000/c.mm.; colour index, 0.9; reticulocytes, 2%; M.C.V. 87 cubic microns; M.C.H.C., 29%; white cells, 57,600/c.mm. (neutrophils 90%, eosinophils 1%, lymphocytes 9%); platelets, 2,100,000/c.mm. The bleeding-time was five minutes and Hess's capillary resistance test was negative. A blood film revealed three nucleated red cells per 100 white cells and numerous platelets, many of which were abnormal, but no megakaryocytes. Sternal marrow aspirate showed a cellular bone marrow with normal erythropoiesis and granulocytopenia. Megakaryocytes were increased in number and many were observed disintegrating into masses of platelets.

Investigation of Blood-clotting Mechanism.—Clotting-time, 10 minutes; one-stage prothrombin time, 17 seconds (control, 15 seconds); clot retraction, normal. Thromboplastin generation was investigated as in Case 1 and was found to be normal when the patient's platelet suspension was mixed with control alumina-adsorbed plasma and control serum. Thromboplastin generation was not impaired when the patient's platelet suspension was diluted 1 in 8. As in Case 1, no defect in blood coagulation could be detected and the platelet factor seemed normal.

Post-operative Course

Six days after operation melaena was observed. Blood transfusions were given and blood examination a week later showed: haemoglobin, 10.1 g./100 ml.; white cells, 37,000/c.mm. (polymorphs 83%, lymphocytes 17%, nucleated red cells, 2 per 100 white cells); platelets, 1,140,000/c.mm.; bleeding-time, 7½ minutes. Melaena persisted during the following two months and repeated blood transfusions were necessary. Spontaneous improvement then occurred and the patient was discharged home on December 21. Thereafter he was seen as an out-patient at regular intervals during the succeeding three years, but melaena necessitating admission to hospital for blood transfusions still occurred. Blood examination always revealed a similar picture—namely, hypochromic anaemia, thrombocythaemia (range 880,000 to 2,100,000/c.mm.), and leucocytosis (range 20,000 to 64,000/c.mm.).

In November, 1954, he was admitted to the Leeds General Infirmary and a laparotomy was performed (Mr. G. H. Wooler) on account of

Although the possibility that the alimentary bleeding was a direct consequence of portal hypertension had to be considered, the blood picture was characteristic of haemorrhagic thrombocythaemia, and it was decided to treat him accordingly.

Progress and Treatment

He was admitted to the Leeds General Infirmary on February 15, 1957, for treatment with radioactive phosphorus. Blood examination then revealed a hypochromic anaemia: white cells, 56,000/c.mm.; platelets, 2,400,000/c.mm.; and the bleeding-time was raised to 8½ minutes. The faeces were examined daily for the presence of occult blood, and on each occasion a positive result was obtained. On February 22, 3 mC. of ^{32}P was given intravenously. A month later the platelet count had fallen to 410,000/c.mm. and bleeding had ceased. A course of intramuscular iron (imferon) was given, and on April 12 a further blood examination showed: haemoglobin, 13.8 g./100 ml.; red cells, 4,700,000/c.mm.; white cells, 18,000/c.mm.; platelets, 230,000/c.mm.

Thereafter he has been seen as an out-patient at monthly intervals. Examination of the faeces for occult bleeding has been consistently negative and the haemoglobin level normal. In June, the platelet and leucocyte counts rose and a further 3 mC. of ^{32}P was given. The red cells at this time had risen to 8,250,000/c.mm., and although the platelets and leucocytes returned to normal following treatment polycythaemia has persisted. When last seen, nine months after the start of treatment, he was symptom-free and the blood findings were: haemoglobin, 15 g./100 ml.; red cells, 8,400,000/c.mm.; white cells, 9,600/c.mm.; platelets, 265,000/c.mm.

There has been no evidence of bleeding for over eight months, whereas before treatment with ^{32}P melaena and chronic hypochromic anaemia were invariably present.

Discussion

The aetiology of thrombocythaemia and the mechanism of the associated bleeding tendency remain largely unexplained. Two factors concerning the aetiology of thrombocythaemia are, however, worthy of mention. Firstly, it is now generally recognized that the myeloproliferative disorders are closely related (Dameshek, 1951), and, whereas orders are myeloid leukaemia and polycythaemia vera are characterized by a proliferation of myeloid and erythroid tissue respectively, excessive platelet production is the predominant feature in thrombocythaemia. The occurrence of episodes of polycythaemia in cases of thrombocythaemia, the high leucocytosis, and the presence occasionally of a small proportion of immature white cells and nucleated red cells in the peripheral blood support this concept. Similarly the occasional coexistence of haemorrhagic thrombocythaemia with myeloid leukaemia (Brugsch, 1933; Hardisty, and Wolff, 1955), myelofibrosis (Hardisty and Wolff, 1955), and polycythaemia vera (Epstein and Goedel, 1934; Uotila, 1938; Mortensen, 1948) also suggest that it is intimately connected with other proliferative disorders of the bone marrow.

The role of the spleen is a second important consideration. Hardisty and Wolff (1955) found that of 23 patients with haemorrhagic thrombocythaemia, approximately half had the spleen removed previously or the spleen was found to be atrophic. Splenectomy invariably gives rise to a temporary increase in the platelet and leucocyte counts, and on rare occasions haemorrhagic thrombocythaemia appears to follow directly on the removal of the spleen as in Case 2, in which the platelet count rose from a normal pre-operative level to 1,140,000/c.mm. within two weeks of splenectomy, accompanied by an increased bleeding-time and severe haemorrhage from the alimentary tract. The association of atrophy of the spleen with haemorrhagic thrombocythaemia was first observed by Epstein and Goedel (1934). The spleen in their case weighed only 7 g.; they considered it to be the most significant aetiological feature and concluded that the

disorder was due to "splenic subfunction." Although in some instances the spleen would appear to be quite normal and in others enlarged, there seems little doubt that in a high proportion of cases of haemorrhagic thrombocythaemia the spleen, or rather its absence, is of direct aetiological significance.

Attempts have been made by several authors to divide thrombocythaemia on an aetiological basis into primary or idiopathic, and secondary types. Rarely it is primary or idiopathic, when it is not associated with any other pathological process and does not follow removal of the spleen. Case 1 appears to belong to this category. More often thrombocythaemia is secondary and follows splenectomy or is associated with splenic atrophy, polycythaemia vera, chronic myeloid leukaemia, or myelofibrosis.

The mechanism of the bleeding tendency in haemorrhagic thrombocythaemia remains unexplained. The bleeding-time in some instances is prolonged, otherwise routine investigations such as the clotting-time, clot retraction, prothrombin time, and capillary resistance are invariably normal. Hardisty and Wolff (1955) were of the opinion that the platelets were functionally abnormal, and in five patients demonstrated an abnormal thromboplastin generation test due to a qualitative deficiency of the platelets. In two of their patients the highly concentrated platelet suspensions yielded normal thromboplastin generation tests, but dilution of the suspension until it contained approximately the same number of platelets per c.mm. as the control suspensions resulted in deficient production of thromboplastin and delay in thromboplastin generation. In the remaining three patients abnormal results were obtained with both concentrated and diluted platelet suspensions. With the use of a similar technique, the thromboplastin generation tests in the two cases reported above were, however, unimpaired both before and after dilution of the patient's platelet suspension, in contrast to the findings of Hardisty and Wolff. In view of these contradictory results further studies on platelet function in thrombocythaemia are obviously indicated.

That the platelets are in some way intimately concerned with the bleeding tendency would seem to be borne out by the effect of treatment with radioactive phosphorus. In previously published papers little reference has been made to the treatment of this disorder, although Mortensen (1948), who regarded thrombocythaemia as allied to polycythaemia and leukaemia and therefore possibly amenable to radiotherapy, observed some beneficial effects of total-body irradiation. It was on similar grounds that treatment with ^{32}P was given a trial in the two cases described. The response in both instances was highly satisfactory and bleeding ceased as the platelet count returned to normal. Further injections of 3 mC. of ^{32}P were given when the platelet count again rose above normal, and on this regime both patients have continued in good health and free from bleeding episodes for nine and eight months respectively. In addition to lowering the platelet count ^{32}P also resulted in a fall of the leucocyte count to normal, and in Case 2 control of the haemorrhagic tendency was followed by a rise in the red-cell count to a polycythaemic level, which was further evidence of the close association of thrombocythaemia and other myeloproliferative disorders.

Summary

The clinical and haematological features of haemorrhagic thrombocythaemia are described and two further examples reported.

Haemorrhagic thrombocythaemia is usually associated with other myeloproliferative disorders or splenic atrophy. It may follow splenectomy but is rarely primary in that it is unassociated with other pathological processes. Case 1 belongs to the latter category, while Case 2 followed splenectomy.

The mechanism of the bleeding tendency is unknown. The bleeding-time is occasionally prolonged, but other

routine tests of haemostatic function are invariably normal. No deficiency of platelet factor as evidenced by the normal thromboplastin generation tests was detected in either of the above patients.

In both patients the platelet count returned to normal and bleeding ceased after treatment with radioactive phosphorus.

I thank Professor J. C. Goligher, Dr. R. N. Tattersall, and Mr. G. H. Wooler for permission to study patients under their care, and Dr. W. Goldie for investigation of the coagulation factors.

CUSHING'S SYNDROME IN CHILDHOOD

REPORT OF CASE OF ADRENOCORTICAL CARCINOMA WITH EXCESSIVE ALDOSTERONE PRODUCTION

BY

W. P. U. JACKSON, M.D., M.R.C.P., D.C.H.

B. ZILBERG, M.B., M.R.C.P.Ed., D.C.H.

B. LEWIS, Ph.D., M.B., A.R.I.C.

AND

D. MCKENZIE, M.Med.(Path.)

From the Endocrine Clinic and Laboratories of the Department of Medicine; and the Departments of Paediatrics and Pathology, Groote Schuur Hospital and the University of Capetown, South Africa

Adrenocortical overactivity in childhood may produce two distinct syndromes. The adrenogenital syndrome is caused by excessive production of androgens, and may manifest itself in three ways. If it starts in intrauterine life in a female, pseudohermaphroditism results; post-natally in a girl it produces virilism; in a boy the "pocket Hercules" variety of isosexual precocity results. An excess of glucocorticoids, on the other hand, gives rise to Cushing's syndrome, without masculinization.

Almost all cases of Cushing's syndrome in childhood are caused by adrenocortical carcinoma. Wilkins (1948) collected 70 cases of cortical carcinoma from the literature, and in his book (Wilkins, 1950) he reviewed 26 cases of Cushing's syndrome, all under the age of 10 years. Twenty-two of these were in girls; as in the adult, Cushing's syndrome in childhood is more common in females. A few other cases have been reported since then, and Guin and Gilbert (1956) produced a further review. The two cases of Cushing's syndrome not associated with carcinoma were reported by Chute *et al.* (1949) (bilateral nodular hyperplasia) and Powell *et al.* (1955) (bilateral cortical adenomas).

Functioning adenomas of the adrenal cortex at any age produce either pure Cushing's syndrome or a pure adrenogenital syndrome. Overproduction of the other two groups of adrenocortical hormones, the oestrogens and mineralocorticoids, appears to be of little importance in childhood. Oestrogen excess, leading to precocious pubertal development of female type, is ex-

tremely rare, while primary aldosteronism has not, to our knowledge, been described in childhood.

Unlike adrenal adenomas, carcinomas are biochemically pluripotent and produce excessive quantities of androgens, glucocorticoids, and also oestrogens (where these have been measured). In the case described below aldosterone was also found in great quantities in the urine. Consequently it is logical that the clinical picture may also be a mixed one in cases of carcinoma, being composed of features of Cushing's and the adrenogenital syndrome:

Since virtually all cases of Cushing's syndrome in childhood are caused by carcinoma one may expect to find evidence of the adrenogenital syndrome in all of them. On the other hand, only some adrenogenital cases (those with carcinoma) will show features of Cushing's syndrome. Now, in some ways the androgens and the glucocorticoids are mutually antagonistic, so that the resultant syndrome of excess of both may be variable. Thus androgens promote rapid skeletal growth and maturation, whereas cortisol (the chief glucocorticoid) abruptly terminates these. Androgens increase muscle bulk and power; cortisol diminishes these, producing fat from muscle and so increasing weakness. Cortisol actually opposes anabolism, leading to porosis of bone and gluconeogenesis with raising of blood sugar. Androgens tend to counteract these by promoting protein anabolism. In the case presented below the two opposing forces seemed so well titrated against each other that bone and tooth age and density, muscular configuration and power, and blood-sugar level did not appear to depart from the normal.

Case Report

A coloured girl was admitted to Groote Schuur Hospital at the age of 2½ years. Since the age of 1 year there had been an abnormally rapid gain in weight. At this age pubic and axillary hair first appeared. Three weeks before admission a facial eruption was noticed. There was no history of menstruation.

Physical examination revealed an obese child, with a Cushing-like facies and signs of virilism (Fig. 1). The obesity included limbs as well as trunk. Her height was 31½ in. (80 cm.) and weight 39 lb. (17.7 kg.). She had a plethoric appearance and a well-marked "buffalo-neck." There was an eruption on the face, which resembled adenoma sebaceum. Axillary and pubic hair were present and the clitoris was enlarged. Strong body odour was obvious. There was no true breast development. Her B.P. was 130/90; Hb, 15 g./100 ml.; P.C.V., 45%. The specific gravity of the urine was 1015. E.C.G. was normal. Blood chemistry: serum Na,

133 mEq/l.; serum K, 5.5 mEq/l.; serum Cl, 102 mEq/l.; CO₂-combining power, 57 vols.%; blood urea, 32 mg./100 ml.; serum alkaline phosphatase, 5.3 units (Bodansky-Shinowara); serum albumin, 4.19 g./100 ml.; serum globulin, 2.89 g./100 ml.; thymol turbidity, 6.3 units; fasting blood sugar, 88 mg./100 ml.; urine concentration test, S.G. rose to 1025.

Radiographs of the long bones showed normal bone age and no osteoporosis. An intravenous pyelogram revealed normally functioning kidneys. The left kidney was depressed and a mass was visible above this kidney. Chest x-ray examination revealed no abnormality.

The 24-hour urinary output of 17-ketosteroids was 39 mg., that of 17-ketogenic steroids (Norymberski) 11.6 mg., and of aldosterone 75 µg. (expected normals for these three steroids are, respectively, under 2 mg., under 3 mg., and under 10 µg. per 24 hours).

Urinary sodium and potassium studies were made over six consecutive days. During this time basal readings were obtained and the effects of a potassium load and of prednisone administration were observed. (See section on steroids below.)

The combination of features of Cushing's syndrome and virilism at this age strongly suggested adrenocortical carcinoma, which was supported by high urinary steroid output. Pyelography indicated that the tumour was on the left side.

Course and Treatment

On March 24, 1957, 50 mg. of cortisone was given by intramuscular injection. On the morning of the 25th this was repeated, and that afternoon left-sided adrenalectomy was performed (Professor J. H. Louw), while the patient received an intravenous infusion of N/2 saline with 50 mg. of soluble cortisol (hydrocortisone). Twelve hours post-operatively the blood pressure dropped from 140/90 to 100/70. Fifty units of soluble cortisol was given intravenously and 50 mg. intramuscularly. 50 mg. of cortisone was then given intramuscularly twice daily for three days. This was replaced by oral cortisone in decreasing dosage until it was withdrawn after five days, when corticotrophin Z, 25 units, was injected intramuscularly on two occasions. Intravenous infusions were maintained for two days after operation. The subsequent post-operative course was uneventful.

Five weeks after the operation the patient had lost 3 lb. (1.4 kg.). She was no longer as plethoric as before; the facial eruption had diminished, and the body odour was less obvious. Blood pressure had dropped to 105/70. Twelve weeks after the operation her appearance had changed dramatically (Fig. 1). She had lost 4 lb. (1.8 kg.) more, her facial skin was quite clear, the buffalo-hump had disappeared, the body odour had disappeared, and the clitoris was smaller. Hirsuties was still considerable. The 24-hour urinary output of 17-ketosteroids had fallen to 1 mg.

Seven months after the operation the clitoris was of normal size and the pubic hair had almost disappeared.

Endocrine Studies

In addition to estimation of hormone output levels in basal state, the effect upon these of potassium loading and of prednisone was investigated. In primary hyperaldosteronism (due to adrenal adenoma) the aldosterone output may become demonstrably abnormal only during periods of high potassium intake (Eales and Linder, 1956). The tumour in such instances resembles the normal adrenal glomerulosa in its secretory response to hyperpotassaemia. In the present case we therefore observed the effect of an extra 100 mEq of potassium in the diet.

Secondly, the dependence of the adrenal tumour on the pituitary was studied by following the plasma cortisol and urinary steroid hormone excretion during the administration of Δ¹-cortisone (prednisone) in doses of 5 mg. twice a day. Prednisone is one of the most potent suppressors of the secretion of corticotrophin by the pituitary.

Estimations of intake and urinary output of sodium and potassium were undertaken at the same time, to ascertain whether the cortical steroids were producing excessive retention of sodium or loss of potassium.

The urinary 17-ketogenic steroids and 17-ketosteroids were determined by the method of Norymberski, Stubbs, and West (1953), plasma cortisol by that of Lewis (1957), and urinary aldosterone by the physico-chemical procedure of Neher and Wettstein (1956). The ketogenic steroids are a measure of the metabolites of cortisol predominantly, but the excretory product of 17-hydroxyprogesterone also contributes to these urinary steroids. 17-Hydroxyprogesterone is andro-

FIG. 1.—Appearance before (1a and 1c) and 12 weeks after (1b and 1d) adrenalectomy.

genic, but is probably not secreted by the normal adrenal: it is an intermediate product in the course of the biosynthesis of glucocorticoids. Further confirmation of the nature of the substance measured by the Neher and Wettstein procedure was provided by chromatography of the acetylated urinary extract in benzene/formamide, whereby the appropriate quantity of a substance with the Rf value of aldosterone diacetate was demonstrated. The material also migrated with aldosterone in the system iso-octane/tert-butanol-water (Eberlein and Bongiovanni, 1955).

Results

The steroid determination (Table I) showed a striking excess of aldosterone, 17-ketosteroids, and 17-ketogenic steroids in the urine and of cortisol in the plasma, represent-

ing hypersecretion of mineralocorticoid, androgen, and glucocorticoid. Fractionation of the 17-ketosteroids showed an abnormal amount of dehydroepiandrosterone. This is the main constituent of the "β-fraction" as segregated by digitonin precipitation, and is believed to be strongly suggestive of adrenocortical carcinoma.

Potassium loading (100 mEq in addition to normal diet) failed to augment the massive aldosterone output. Prednisone (given for only 48 hours) showed a possible suppressing effect on cortisol and 17-ketosteroid secretion on the second day, but the results were not conclusive and this suppression, if present, was not great.

Sodium and potassium "balance" data are presented in Table II. Urine collections were difficult, and were analysed only on those days when collections were virtually complete.

TABLE II.—Electrolyte Balance

	Sodium (mEq/24 Hours)		Potassium (mEq 24 Hours)	
	Intake	Urine	Intake	Urine
March 5: Normal diet	45.4	22.3	63.9	32.3
" 6: High K intake	43.8	41.0	149.9	74.9
" 8: High K intake and prednisone	47.0	36.4	157.2	78.8
" 9: " "	45.1	33.0	152.9	81.4

We observed no evidence of any considerable retention of sodium, and certainly no excessive loss of potassium. The high potassium intake appeared to augment the urinary sodium. The prednisone had no effect on the electrolyte balance.

The gratifying clinical response to adrenalectomy was mirrored in the hormone studies, which declined to normal levels (and have remained so during a six-months follow-up).

The Adrenocortical Tumour

The specimen (Fig. 2) consisted of a triangular mass of tissue weighing 36 g. and measuring 5 cm. along each border and 3 cm. in thickness. The outer surface was smooth and encapsulated. A small breach at one point was apparently due to operative trauma. At one pole there was a projecting tag of orange-yellow tissue measuring 1.5 by 2 by 1 cm.

On cut section the greater portion was lobulated and bright orange-yellow, a smaller portion appearing more fleshy and brown.

Sections stained with haematoxylin and eosin showed a highly anaplastic carcinoma (Fig. 3). The majority of the cells of the tumour were extremely bizarre in shape and varied considerably in size. The cytoplasm of many cells was finely granular and vacuolated. The nuclei showed many irregularities and mitotic figures were numerous. The tumour cells were divided haphazardly into groups by a fairly extensive network of thin-walled vessels. There was no haemorrhage into the tumour, and no obvious vascular infiltration was noted.

Closely applied to the tumour on its external surface was a well-marked fibrous tissue capsule. On the outer surface of this, and separated by it from the tumour, was a tag of compressed normal-looking adrenal gland tissue.

FIG. 3.—Photomicrograph of the tumour and its "capsule." (×500.) Note extreme pleomorphism of cells, and large hyperchromatic nuclei with several mitotic figures.

A frozen section showed varying amounts of fat in different areas. In some areas cells were loaded with fat; in others it was evident as fine droplets in the cytoplasm.

Poncau-fuchsin staining of a section fixed in formal-saline showed the cytoplasm of the tumour cells to be loaded with vivid red fuchsinophil granules which were not evident in the attached portion of normal adrenal.

Discussion

Diagnosis.—In this child the clinical features of Cushing's syndrome and virilism suggested the diagnosis of adrenocortical carcinoma. The very high urinary output of 17-ketosteroids provided confirmatory evidence. An interesting

FIG. 2.—Left adrenal gland after removal.

feature here was the apparent metabolic "balance" produced by the concomitant hypersecretion of glucocorticoids, mineralocorticoids and androgens. Thus there was no disturbance in muscular strength, bone growth, or electrolyte balance. The marked body odour probably was due to excessive apocrine activity. The tumour was lateralized by intravenous pyelography combined with tomography. Presacral air insufflation was rendered unnecessary by this manoeuvre. It is noteworthy that the length of this history (18 months) was not incompatible with a localized carcinoma in this case.

Steroid Findings.—Despite the probable zonation of function within the normal adrenal cortex (Chute *et al.*, 1949; Landing, 1955), the tumour, a strikingly undifferentiated carcinoma, possessed the ability to synthesize all the three major groups of adrenal hormones. While the simultaneous hypersecretion of glucocorticoid and androgen by adrenal tumours is commonplace, and that of glucocorticoid and aldosterone has been described, the present case offers a remarkable example of pluripotency of an adrenal tumour. The increase in aldosterone excretion was notable not only for its magnitude but also for the absence of its expected effect on electrolyte excretion or serum potassium level. The opposing effect of androgens in promoting potassium retention may be relevant in this connexion. In common with some cases of Conn's syndrome of primary aldosteronism, sodium metabolism was not grossly disturbed; arterial hypertension was, however, present. Possible explanations for lack of electrolyte disturbances include the simultaneous hypersecretion of an unknown sodium-diuretic hormone; alternatively, some combination of known hormones may possess sodium-diuretic activity, or conceivably the renal tubular epithelium may lose its responsiveness to aldosterone.

Treatment.—When there is no evidence of secondary deposits, adrenalectomy is indicated in cases of adrenocortical carcinoma. When there is doubt about which adrenal is involved, the transperitoneal approach is favoured. Adrenalectomy may be followed by a period of hypoadrenalism, because the opposite adrenal is usually atrophic. To prevent this, cortisone is usually given pre-operatively and continued during the operation and in the immediate post-operative period. When cortisone is withdrawn, corticotrophin may be given in an effort to stimulate the remaining adrenal gland. In our patient there was a precipitous drop in the blood pressure 12 hours post-operatively. This was believed to be an indication for intravenous cortisol. It suggested that the remaining adrenal was atrophic and not also carcinomatous. The change in the appearance of the patient 12 weeks after the operation was very gratifying. A striking feature was the disappearance of the strong body odour. Though androgen overactivity as judged by the 17-ketosteroid excretion was now controlled, the hirsuties and clitoral enlargement did not disappear until a further four months had passed. These signs of virilism usually take a long time to regress and may in some instances be permanent, in which case clitoridectomy may be necessary.

Prognosis.—If the offending adrenal is removed before metastases have developed, the chances of complete cure appear to be good. Unfortunately, in many cases of Cushing's syndrome in childhood the progress is rapid and adrenalectomy useless. Our patient seems to be fortunate, and the probability of cure must be considered high, since steroid excretion has returned to a normal level.

Summary

The relationship between Cushing's syndrome in childhood and adrenocortical carcinoma is briefly considered. A "mixed picture" of Cushing's and adrenogenital syndromes is characteristic, and is illustrated by a reported case. In this patient an excessive production of glucocorticoids, androgen, and mineralocorticoids (aldosterone) was demonstrated. In some ways the

usual clinical effects of each of these steroids were annulled by the opposing effects of the others.

The offending adrenocortical carcinoma was removed. Its histological appearance is described. The operation was followed by a remarkable improvement, with return to normal in the child's appearance and her hormone output.

We thank Professors J. F. Brock, G. C. Linder, F. Forman, J. H. Louw, and F. J. Ford for their continued help and interest. The patient was under the care of the latter two professors while in hospital. Dr. T. Sacks took the photomicrograph. The costs were covered by grants from the Council for Scientific and Industrial Research of South Africa and the Staff Research Fund of the University of Capetown.

MULTIPLE EPIPHYSIAL DYSPLASIA

BY

HERBERT BARRIE, M.D.

CEDRIC CARTER, B.M., M.R.C.P.*

AND

JOHN SUTCLIFFE, M.B., M.R.C.P., F.F.R.

Hospital for Sick Children, Great Ormond Street, London

Multiple epiphyseal dysplasia is an uncommon condition, but is likely to be of interest to general practitioners on account of its marked familial features. Although Fairbank (1947) did not stress the genetic aspect in his original description, a number of affected families have since been recorded. Often a correct diagnosis in one member of a family will uncover several previously undiagnosed or misdiagnosed cases. Recognition of this condition is of more than academic interest, since many patients derive benefit from appropriate physiotherapy, while harm may result from treatment based on the wrong diagnosis. To make this condition more widely known, we report three further affected families, with descriptions of the clinical, radiological, and genetic features of these and previously published case reports. The family trees are shown in Figs. 1, 2, and 3. The clinical features are summarized in the Table.

Historical Note.—In 1935 Fairbank suggested the term "epiphyseal dysplasia" for a patient with multiple irregular epiphyseal ossification. To this title "generalisata" was added, but it was changed later to "multiplex" when the epiphyseal changes were found to be multiple rather than generalized. Twelve years later he published a masterly account of the clinical and radiological features of the disease based on a study of 20 patients, many of whom had previously been reported as atypical examples of a variety of conditions, including achondroplasia, stippling of the epiphyses (dys-

*Medical Research Council, Clinical Genetics Research Unit.

plasia epiphysialis punctata), and Morquio-Braileford's osteochondrodystrophy. Since then a number of cases have been reported in this country—for example, three sisters by Waugh (1952); one case by Scott (1952); four cases, two of them siblings, by Watt (1952); 14 cases in three families by Maudsley (1955); three cases in three generations of one family by Shephard (1956); and, in America, six cases by Jackson *et al.* (1954)—two sporadic and four from one family—and one case by Levy *et al.* (1957).

Clinical Features

Definition.—Fairbank defined multiple epiphysal dysplasia as "a rare developmental error characterized by mottling or irregularity in density and outline of several of the developing epiphyses, dwarfism, and stubby digits."

Age at Onset.—Symptoms invariably begin in childhood, but most adults cannot recall their age at onset with any accuracy. The youngest recorded case is that of a 19-months-old infant by Gardiner-Hill (1937), while Shephard (1956) reported a probable example of the condition in an 80-year-old woman. In the present series the ages range from 2 to 71 years.

Symptoms

The most prominent symptoms are joint pain and stiffness, with a variable degree of disability. Since the lesions are multiple rather than generalized, symptoms often predominate in specific joints. Most joints have been incriminated at some time, the hips and knees being the commonest, probably because they are the most liable to weight-bearing strain. In this series the ankles, hands, and spine have also been affected, while the shoulders and elbows have caused disability in other reported cases. However, it must be emphasized that the distribution of symptomatically affected joints does not parallel the radiological distribution, which is often severest in the epiphyses of the wrists, hands, and ankles.

The degree of disability varies from slight discomfort to marked impairment of function. In family A all affected members were fully active and readily able to follow a variety of occupations, such as domestic, manual, and clerical work; none of them was able to indulge in athletic sport without after-effect, and the two youngest members often limped. In family C, in contrast, symptoms were almost continuous, and one patient could walk only with the help of a stick. With severe pain in the hip or knee,

patients may have great difficulty in negotiating stairs. Flexion deformities have been described, particularly of hips, knees, and elbows, while, paradoxically, hyperextensibility of joints due to laxity of the ligaments has also been reported.

Although the changes in the epiphyses are permanent, the symptoms are characteristically transient and fluctuating. Pain and stiffness are the invariable aftermath of strenuous exercise, and for this reason children and young adults are the most likely to seek medical attention. Failure to recognize the true nature of the condition may lead to a false assessment of whatever form of therapy is used, since symptoms usually subside spontaneously after a few days and may not reappear for several weeks. In later life the gradual superimposition of osteoarthritis accounts for the common complaint of pain after rest. All the affected adults of family A noticed stiffness after sitting for a few hours, and, similarly, felt worse on rising in the mornings. This has also been observed in children, and may well be a specific symptom of the disease.

Signs

Dwarfism.—Patients are characteristically short. The reduction in height is of the short-limb type, but epiphysal changes in the spine may also contribute to the shortness. Marked dwarfism is rare, but the affected members of a family can usually be singled out in being several inches shorter than unaffected members. Here comparison with relatives is more important than reference to so-called normal standards.

Stubby Digits.—This feature is probably present to some degree in all cases, and is often striking. The hand is broad, while the fingers are short, squat, and stumpy (see Fig. 4);

FIG. 4.—Broad hands; fingers short and stumpy

the nails may be deformed. The appearance is due to stunting of the phalanges and metacarpals, but gives rise to surprisingly little disability.

Enlargement of Epiphyses.—The affected epiphyses are often enlarged, and this may be accentuated by the presence of muscular wasting. Affected knees have a typical knobby appearance (see Fig. 5), which has earned one of our patients a prize in a seaside competition for knobby knees. Epiphysal bossing may be irregular and lead to secondary deformities such as genu varum or valgum.

Limitation of Movement and Deformity.—In family A only one patient showed slight limitation of extension of the knees; family B and the father in family C, who were more severely affected, showed marked limitation of hip movement, particularly flexion and abduction. Involvement of the lower limbs leads to abnormalities of gait and posture, and a limping or waddling gait is common. Other described abnormalities include dislocation of the patellae, spinal abnormalities, platybasia, and subluxation of the elbows.

Intelligence and General Development.—The occurrence of subnormal intelligence (Fairbank, 1947), sexual infantilism (Buxton, 1930), and osteochondritis dissecans (Watt, 1952) in isolated cases is probably coincidental. No abnormalities of blood chemistry have yet been described. The association of cleft-palate in all three of Waugh's (1952) patients can hardly be coincidental; the family pattern does not fit dominant inheritance, and there was premature closure of the epiphyses, which has not been seen in other affected families, suggesting that some other condition operated in this particular family.

Complications

Osteoarthritis is an inevitable complication, beginning, as may be expected, in early adult life. Severe hip involvement may cause difficulty in natural childbirth and was the reason for termination of pregnancy in one member of the present series; six years later this patient underwent a cup arthroplasty for relief of marked superimposed arthritis of the hips.

FIG. 5.—Knees have a knobby appearance.

Radiographic Features

Radiographic features have been well described previously, notably by Fairbank (1951). Multiple epiphysal dysplasia is a possible diagnosis in any case showing abnormal ossification of more than one epiphysis, particularly when like abnormalities can be demonstrated in other members of the family.

Typical radiographic signs are often found in the epiphyses at symptom-free joints. The changes are not necessarily generalized, and the normal appearance of many epiphyses may lead to the diagnosis not being considered. Some epiphyses may show slight irregularities of shape or ossification which assume significance only if the condition is suspected. Although the changes are usually symmetrical, there may be marked differences between the two sides, especially by the time adult life is reached. This was so in one patient (A, III 9; see Fig. 6) in whom there was gross deformity of the right femoral head; the left femoral head showed a slightly wavy outline, but the significance of this by itself might easily escape notice. Gross delay in the

appearance and development of epiphyses can also occur as in the patient (C, III 2) in whom no ossification of the femoral heads could be seen at the age of 4 years (see Fig. 7); other epiphyses were thought to be normal, and the diagnosis was not made until the significance of slight thinning of the lateral part of the lower tibial epiphyses was realized. Advanced changes were then found in the hips of the child's father (see Fig. 8).

FIG. 7.—Absence of ossification of the femoral heads at the age of 4 years.

FIG. 8.—Showing advanced changes in the hips of the father of the case illustrated in Fig. 7.

Epiphyses may be seen to be arising from more than one centre of ossification. However, the appearance is quite different from that in dysplasia epiphysialis punctata, as in the condition under consideration the main bulk of the epiphyses arises from a single centre and the accessory centres are few in number and are scattered at the periphery of the cartilaginous epiphysis (see Fig. 9).

There is usually marked similarity in the radiographic features between affected members of the same family but considerable variation from one family to another. The distribution of the major changes appears to be a family characteristic. Even within families, however, some variation can occur. Moreover, members of an affected family may show such slight anomalies of epiphysial growth that it is sometimes difficult to decide, in early childhood, if they are affected or not.

Fairbank (1947) lists a number of conditions in which irregularity of the epiphyses is a feature, including cretinism, stippling of the epiphyses, osteochondrodystrophy, Perthes's disease, and dyschondroplasia. In our experience, the correct diagnosis has been neglected in favour of more common conditions. Thus in family A symptoms had been ascribed to osteoarthritis and rheumatism, two members of family B were thought to have bilateral Perthes's disease, and the father in family C had been told that he had bilateral dislocation of the hips. The radiographic appearances of multiple epiphysial dysplasia are quite distinct,

however. Attention to the following points has been thought to be of most use in diagnosis:

Hands.—The carpus is small in depth and the carpal bones are irregular in shape. During childhood there is marked delay, in ossification of the carpal centres, although their abnormal configuration makes accurate comparison with normal standards impossible. The central parts of the lower radial and ulnar epiphyses are thinner than normal, so that in adult life the lower ends of radius and ulna make a distinct V. The metacarpals and phalanges are not involved in all families, but are usually very short and stubby, with square angular heads.

Ankles.—There is marked thinning of the lateral part of the lower tibial epiphyses during childhood, leading in adult life to a characteristic downward inclination of the ankle-joint from the lateral to the medial side.

Knees.—The femoral and tibial condyles are square and angular. The lower end of the femur is flat and the intercondylar notch notably shallow. Irregularity of the ossification of the femoral condyles may lead to an appearance suggestive of osteochondritis dissecans.

Hips.—The femoral heads show great variation in that they may be absent, grossly deformed, irregularly ossified (as in Perthes's disease), or normal. Progressive flattening and enlargement of the femoral heads similar to that in Perthes's disease may also be seen and lead to permanent deformity and secondary osteoarthritis.

Spine.—This was not radiographed in most of our cases. One child (family B, IV 3) showed changes in the dorsal spine which, without the changes at other epiphyses, would have been indistinguishable from Scheuermann's disease. In the other affected members of this child's family the vertebral bodies appeared flat but normally ossified.

FIG. 9.—See text.

Genetic Aspects

The families were investigated by taking radiographs, so far as was possible, of the knees, ankles, and hands of all the offspring of affected individuals. It was found, however, that clinical examination was reliable for picking out those affected, and the only individuals possibly misclassified are some of the younger members of family A.

The first genetic problem is whether all cases are determined by dominant genes. Fairbank (1947) observed: "It affects both sexes, and as a rule is not inherited or familial." However, one boy appeared to have inherited from his mother, while two sisters are also included in this series. In addition he reported: "J. A. Cholmely has furnished me with details of two cases, who are brothers and apparently the only affected in a family of 10." A number of the families reported since then are similarly inconclusive from the point of genetic determination. But in 1954 Jackson *et al.* reported the disease in a mother, two sons, and a daughter, and in 1955 Maudsley reported its presence in three families. He noted that in the first of these the pattern of inheritance, with 10 of 17 members in three generations affected, strongly suggested that a dominant gene was concerned. His other two families were not fully investigated, but are compatible with determination by a dominant gene. In 1956 Shephard reported a family with three affected members in three generations, again suggesting dominant inheritance.

The three index cases in our families were unselected and were all that could be found among the children attending

the Hospital for Sick Children, Great Ormond Street. A search for further possible cases among children with the diagnostic labels "bilateral Perthes's disease" and "multiple osteochondritis" produced no cases other than one child already known to be a member of family B. In two of these families a dominant gene is clearly responsible, and the third, with father and son both affected, also suggests this type of genetic determination.

All the known examples of the condition to date, with the exception of those reported by Waugh (1952), can be ascribed to dominant inheritance. On this hypothesis, where only sibs were affected, an abnormal parent would have been found on investigation; for example, Watt (1952) notes that the parents of his patients were dead but that the father "was said to be a small man with a large body and short limbs, and had occasional trouble with his hips." On this hypothesis, also, sporadic cases will occur due to fresh mutations, as in the family with one boy affected and both parents and four sibs normal on radiographic examination (Levy *et al.*, 1957). It would appear that, while the gene may not always cause symptoms, it always leads to the development of abnormal radiographic signs.

The second genetic problem is raised by the suggestion made by Maudsley (1955) that there is a similarity of the type of affection within each family. In two of our families the affected members all showed dwarfism and major lesions in the hips, and all the adults had considerable disability. In one of these families, B, all affected members in addition had stubby hands. In family A, on the other hand, the hands were less stubby, and in some instances nearly normal, some patients were normal in height, and patients mostly complained of pain only in the knees, while several had never sought medical advice. The resemblance of the radiological features within families has already been mentioned. This suggests that two genes at least are responsible—one for the relatively mild form seen in some cases, and another for the more severe form; but to prove this point conclusively it would be necessary to take more radiographs than is justified for a point of purely theoretical importance.

Treatment

Although the pathological basis of the condition cannot be influenced in any way, it is of interest that those patients who received physiotherapy, particularly in early life, experienced considerable relief at the time and developed less disability later on. Frequent attacks of pain and stiffness are likely to cause disuse and local muscular weakness, which, in turn, favours instability of the affected joints and recurrence of further attacks of pain. Where benefit was derived from physiotherapy it could be ascribed to the measures directed to improving muscular support of the affected joints, such as non-weight-bearing exercises. One member of the second family had long remissions after courses of underwater exercises, and the children in the present series are attending regularly for non-weight-bearing exercises which they continue to practise at home, in the hope that these will prevent muscular wasting, reduce the number of acute episodes, and delay the development of osteoarthritis, which, however, will eventually dictate the form of treatment.

Illustrative Case Histories

A boy (family A, IV 16) aged 9 was referred to the Hospital for Sick Children, complaining of recurrent pain in the legs since infancy, in acute attacks at intervals of three to four months, when he would be almost completely disabled for as long as a week. Attacks were often precipitated by exercise and resolved spontaneously. His milestones were not delayed and he walked at the age of 18 months. On examination he looked thin and unwell, his height, 50 in. (127 cm.), was normal for his age, but his fingers were short, his knees knobby, and his right leg was of poor musculature (see Fig. 5). Radiographs showed the typical changes of multiple epiphysial dysplasia in him and other members of his family.

A boy (family B, IV 3) was referred to the Hospital for Sick Children at the age of 7 years with a two-year history of pain and stiffness in the left knee. On examination he had a rolling gait and slight shortening of the left leg, and it was thought that the pain in the knee was referred from the hip. Abnormality of the upper femoral epiphyses was noted on x-ray examination and on investigation of similar symptoms in several members of his family; the diagnosis of multiple epiphysial dysplasia was subsequently confirmed. He still has severe pain and stiffness in both hips and usually walks with a limp. On examination at the age of 12 there was some limitation of movement at both hips, his height, 56 in. (142 cm.), was below average for his age, and his fingers and toes were short and stubby. He recently developed inversion of the left foot. Skeletal survey showed dysplasia of the epiphyses of the tibiae, femora, radii, humeri, and lower dorsal spine.

A male child (family C, III 2) was referred to the Hospital for Sick Children at the age of 19 months because his parents had noticed a waddling gait, that his left leg turned out, and that he seemed short for his age. His father was said to suffer from congenital dislocation of the hips, but has since been confirmed as suffering from multiple epiphysial dysplasia. On examination the child was short—28 in. (71 cm.)—and he had a rolling gait and a lumbar lordosis with a protuberant abdomen. The main radiological abnormality was delay in the appearance of the upper femoral epiphyses, which were still not present at the age of 4 years (Fig. 7). He was otherwise well and there had been no delay in the appearance of his milestones.

Summary

Multiple epiphysial dysplasia is a genetically determined condition in which there is irregular and often retarded ossification in several of the epiphyses. Disability may be severe, with recurrent attacks of joint pain and stiffness; subsequently, osteoarthritis may lead to severe limitation of movement. The commonest sites for symptoms are the hip and knee, and the most marked signs are dwarfism and stubbiness of the fingers. The symptoms and signs are remarkably similar in the various affected members of the same family.

Three families, consisting of 15 affected members, are reported, the family pattern being that of dominant inheritance. It is suggested that dominant genes are responsible for all examples of the disorder, although more than one mutation may be concerned to account for differing degrees of severity in different families.

We thank Professor A. A. Moncrieff, Dr. B. E. Schlesinger, and Mr. G. C. Lloyd Roberts for permission to investigate the families of their patients; Sir Thomas Fairbank, Dr. F. B. Kiernander, and Dr. J. A. Fraser Roberts for their good advice; and the photographic department of the hospital for the illustrations. We also thank Dr. C. Worster-Drought, Mr. E. P. Brockman, Dr. O. A. Savage, Mr. J. G. Bonnin, Dr. A. P. Barry, and Miss E. Sheridan for their kind help with various members of the families and the loan of radiographs.

ERGOMETRINE WITH HYALURONIDASE: SPEED OF ACTION

BY

MOSTYN P. EMBREY, M.D., F.R.C.S.Ed.
M.R.C.O.G.

AND

WILLIAM J. GARRETT, D.Phil., M.B., F.R.C.S.Ed.
M.R.C.O.G.

Nuffield Department of Obstetrics and Gynaecology,
University of Oxford

Intravenous ergometrine given at the crowning of the foetal head or with the delivery of the anterior shoulder is a most effective means of expediting delivery of the placenta and preventing post-partum haemorrhage. This procedure was first introduced by Davis, of Chicago, in 1940. Lister (1950), in Liverpool, and Martin and Dumoulin (1953), of University College Hospital, have demonstrated its efficacy in well-planned clinical trials, and the method is now firmly established in obstetric practice.

Although the technique is widely used by obstetricians, it has one great drawback in that midwives, who in this country conduct the majority of public hospital and domiciliary deliveries, are denied its use because normally they are not trained to give intravenous injections. For this reason a simplified method is often used in which ergometrine is given by intramuscular injection instead of by the original intravenous route (Flew, 1947; Daley, 1951). Although some of the speed and reliability of the intravenous method is sacrificed in this modification the much greater general applicability of the intramuscular injection has led to its general acceptance.

In an attempt to enhance the value of the intramuscular method still further, Kimbell (1954) has advised that hyaluronidase ("hyalase," "rondase," "wydase") be added to the ergometrine injection. The rationale of this method is that hyaluronidase, acting as

a "spreading factor," aids absorption of the drug from the injection site and so shortens the latent period inherent in all intramuscular methods. Kimbell has published results that are superior to those obtained by the plain intramuscular method and even approach the efficiency of the original intravenous technique. The merits of the ergometrine-with-hyaluronidase method justify, he believes, its routine adoption by midwives in their unsupervised practice.

FIG. 1.—External records comparing speed of action of (a) intravenous ergometrine, (b) intramuscular ergometrine with hyaluronidase, and (c) intramuscular ergometrine without hyaluronidase.

This paper reports exact measurements of the delay between injection and response of (a) intravenous ergometrine, (b) intramuscular ergometrine, and (c) intramuscular hyaluronidase-ergometrine mixture.

Method

Records of uterine contractility were obtained from 30 healthy volunteer patients in the early days of the puerperium either, externally, by the "Oxford" tocograph (Embrey, 1955, 1958) or, internally, by the older intra-uterine balloon method (Moir, 1932a, 1932b). After a suitable control period, 0.5 mg. of ergometrine maleate with added hyaluronidase was given by intramuscular injection to 12 patients (main series), and its effect on uterine contractility recorded graphically. In each case the time

than the intravenous injection, which clearly must remain the method of choice in dealing with sudden post-partum haemorrhage. However, for the midwife who normally is not trained to make an intravenous injection, intramuscular ergometrine-with-hyaluronidase may well be worth while in such circumstances, though in practice any advantage may be annulled by the extra time required to prepare the mixed injection.

Another aspect of the matter must be considered. The present work shows that the addition of hyaluronidase confers upon the intramuscular injection of ergometrine a uniformity of action it does not otherwise possess. Without hyaluronidase the latent period before ergometrine takes effect varies considerably, and in some cases there has been a delay as long as 10 or 11 minutes (see Table). Given with hyaluronidase there is good expectation that intramuscular ergometrine will act within five minutes. The longest delay recorded with hyaluronidase in this series has been just over six minutes, which is a distinct improvement on the figures obtained when using the plain intramuscular method. It may be that in this element of uniformity lies the chief merit of the ergometrine-with-hyaluronidase injection. This could help explain the good results obtained by Kimbell in his clinical series, for the use of the hyaluronidase combination avoids the delays that may occur with the plain ergometrine.

While the addition of hyaluronidase slightly increases the speed and uniformity of action of intramuscular ergometrine, it does not follow that the plain intramuscular method is outmoded. Ergometrine alone has some advantages peculiar to itself. It is simple, more quickly prepared, quite efficacious, and better than no method at all. Finally, if midwives are to use ergometrine routinely at the end of the second stage of labour (as distinct from its use in emergency haemorrhage) supervising authorities should not lose sight of the fact that, at present, the addition of hyaluronidase to the injection quadruples the cost.

Summary

The methods of giving ergometrine by (a) intravenous injection, (b) intramuscular injection, and (c) intramuscular injection with added hyaluronidase at crowning of the foetal head, are reviewed and examined.

It is questionable whether the increased speed of action achieved with hyaluronidase added to the intramuscular injection of ergometrine warrants the adoption of the method routinely in the second stage of labour.

Results

In all cases the well-known oxytocic response to ergometrine was recorded, the only difference between the various groups tested being the length of the latent period from the moment of injection to the onset of the oxytocic effect. The average times were: intravenous ergometrine, 41 seconds; intramuscular ergometrine with hyaluronidase, 4 minutes 47 seconds; and intramuscular ergometrine without hyaluronidase, 7 minutes.

Examples of records obtained with the external apparatus are shown in Fig. 1, and with the internal balloon method in Fig. 2.

Comment

The studies show that the addition of hyaluronidase to the injection undoubtedly quickens the speed of action of intramuscular ergometrine. The mean figures indicate an approximate gain of two minutes, reducing the latent period from seven minutes to five minutes. Valuable as this gain may be in a particular case, the real merit of the method has to be judged by the degree to which hyaluronidase accelerates the action of intramuscular ergometrine and approximates it to that of the intravenously injected drug. Viewed in this context, it is questionable whether a gain of two minutes is sufficient to justify the use of the ergometrine-hyaluronidase mixture routinely at the end of the second stage of labour. Again, it will be noted that even with the addition of hyaluronidase the intramuscular ergometrine still takes almost five minutes to exert its effect. This is certainly too slow for the treatment of the emergency haemorrhage. It is more than five times slower

On June 26 the DUCHESS OF DEVONSHIRE opened a new out-patient department at the Children's Hospital, Sheffield, to replace one which is now too small for its purposes. The new building, costing £110,000, has been insulated so as to lessen noise, and is provided with small "waiting areas" for the clinics instead of the usual large waiting-hall. To please the children, primary colours have been used for the decorating. The department represents the first stage in the development of the hospital.

A COMPARATIVE STUDY OF THE USE OF FERRIC CHELATE IN IRON-DEFICIENCY ANAEMIA

BY

C. F. HERRIDGE, M.B., B.Chir.

Resident Clinical Pathologist, St. George's Hospital, London

This paper presents a report on the response of iron-deficient children and young adults to three haematinics. The investigation was designed to compare established iron preparations with a recently introduced iron chelate compound in the way suggested by Cope *et al.* (1956).

Ferrous gluconate ("ferlucon") and ferrous succinate ("ferromyn") in elixir form were chosen as the established preparations. "Sytron" elixir, then on clinical trial, is a ferric sodium salt of ethylenediamine tetraacetic acid (E.D.T.A.), and has the following structural formula:

Present Investigation

The subjects were selected from the patients in a hospital for mentally deficient children; they comprised severe mental defectives of both sexes aged 5 to 18 years. Initially, 250 patients were screened by capillary haemoglobin estimations, and those with a level below 11.5 g./100 ml. were included in the trial. Almost all of these patients were completely helpless, and had to be fed by the nursing staff: that only 30 qualified for inclusion is a tribute to the patience and devotion of the sisters and nurses.

The subjects were divided into three groups of 10 each, the groups being matched as closely as possible according to age and sex. Each group received one of the haematinics for six weeks; at the end of this period, therapy was stopped. The dose was determined according to age and the utilization factor of the haematinic used (Table I).

TABLE I.—Doses Given

Drug	Age in Years	Dose	Dose in mgms.	Daily Elemental Iron (mg.)	Utilization Factor	Daily Utilization (mg.)
Ferric chelate	5-10	2 dr. b.d.	600 b.d.	142.0	Regarded as ferrous sulphate = 14%	{ 19.9 29.8
	11-18	2 dr. i.d.s.	600 i.d.s.	213.0		
Ferrous succinate	5-10	1 dr. t.d.s.	75 t.d.s.	52.5	42% (Nelson, 1955)	{ 22.4 29.4
	11-18	1 dr. b.d.	150 b.d.	70.0		
Ferrous gluconate	5-10	1 dr. b.d.	300 b.d.	68.0	28% (Haler, 1952)	{ 19.0 28.5
	11-18	1 dr. i.d.s.	300 i.d.s.	102.0		

As no utilization factor has yet been determined for ferric chelate, it was assumed to be the same as ferrous sulphate—that is, 14% (Witts, 1936).

Haemoglobin, packed cell volume, and mean corpuscular haemoglobin concentration values were determined before, at the end of, and four weeks after the trial period. Additional haemoglobin readings were taken at weekly intervals to obtain the rate of response. It was not possible to perform estimations eight weeks after the finish of the trial, because maintenance iron therapy was started before this interval had elapsed.

The presence of E.D.T.A. in the sytron elixir, though in small quantities, raised the question of its action upon the blood coagulation mechanisms. In order to assess the possible effect of minimal absorption of versene,

prothrombin activities were carried out on this group in the middle and at the end of the trial period, and four weeks after, using the other groups as controls.

Results

Haematological Response.—Table II shows in detail the response of individual patients. It will be seen that all had a satisfactory response, as shown by a rise in the

M.C.H.C. The average weekly haemoglobin rise and the total increase of haemoglobin in each patient over the period of the trial are also shown. These last values have been averaged for each group, and are shown in the Figure. From this it will be seen that the mean weekly haemoglobin rise is as follows: ferric chelate, 0.57 g./100 ml./week; ferrous succinate, 0.40 g./100 ml./week; and ferrous gluconate, 0.35 g./100 ml./week. There is a signifi-

cantly greater rise in the patients taking ferric chelate than in the other two groups (0.05 > P > 0.02). The difference between the other two groups is not significant.

Prothrombin Times.—In the group of patients taking the ferric chelate there was a prolongation of prothrombin time (as estimated by Quick's one-stage method) of 0.5 second after three weeks of treatment in three patients, and of 0.5 to 1 second after six weeks in five patients. All of the patients had returned to normal values four weeks after cessation of treatment. None of the patients taking ferrous succinate or gluconate showed any such alteration of prothrombin time.

Side-effects.—Diarrhoea or vomiting, or both, appeared in three patients taking ferric chelate. Cases 1 and 10 had moderate diarrhoea during the first week of the trial, but this cleared spontaneously without treatment or withdrawal of the drug. Case 2 developed severe diarrhoea and vomiting during the second week of the trial, necessitating withdrawal of the drug and vigorous rehydration therapy. Pathogens were never isolated, but in view of the severity and the timing of the attack it may be that it was not due entirely to the drug. It was not thought justifiable to reintroduce the drug after this patient's recovery. Case 28, receiving ferrous gluconate, had mild diarrhoea during the first week. Side-effects were not observed in the patients taking ferrous succinate, but in Case 18 death occurred from pneumonia during the fourth week of the trial.

Discussion

The group of patients receiving ferric chelate showed a significantly greater response to treatment than did the other two groups. They were, however, receiving very much larger quantities of elemental iron (Table I), because the utilization factor used to calculate the dose was an assumed one only. It seems likely that this assumed 14% utilization was too low, and that this accounts for the superior response. That an organic ferric salt should have such a good utilization factor is of interest, and is in marked contrast with inorganic ferric salts. It will also be noted that the dose of ferrous succinate administered was half of that normally recommended (Gillhespy, 1955), yet had as good a therapeutic effect as ferrous gluconate given in standard dosage (Hein and Keibl, 1950). The choice of iron preparation for a given patient would appear to be governed less by pharmacological considerations than by such factors as gastric tolerance, and, especially in children, palatability, together with the comparative cost of dispensing.

The slight prolongation of the prothrombin time observed in half of those taking ferric chelate is difficult to explain. Prolonged hypocalcaemia has been observed in rabbits following intravenous E.D.T.A. (Watson and Blackburn 1956), but serum calcium levels cannot be affected in man by very large oral doses of the drug (Spencer *et al.*, 1956). Although the small alteration in prothrombin time seen in this group is apparently of no clinical significance, its cause has yet to be determined.

The higher incidence of diarrhoea and vomiting in the group taking ferric chelate must also be noted. This is no isolated occurrence, since it was found in preliminary trials with the drug; large doses were taken by my colleagues and myself over several weeks, and all noted some diarrhoea. Prothrombin times were not reduced by more than the one second reported in this trial. The diarrhoea may in part be explained by the relatively large amounts of iron in the doses given, and it would seem reasonable to suggest that doses of ferric chelate lower than those used in this trial would produce an adequate haematinic response, with a reduction in side-effects.

Summary and Conclusions

A group of 30 children and young adults with iron deficiency were treated with elixirs of ferric chelate, ferrous gluconate, and ferrous succinate. Those receiving the ferric chelate showed a significantly greater re-

sponse in haemoglobin rise compared with the other two groups, but this was probably due to the larger amount of utilizable iron given. Diarrhoea was more prominent, and there was some lowering of the prothrombin activity in half of this group, though not of sufficient degree to be of clinical importance. The dose of ferric chelate could probably be reduced below that given in this trial and still give an adequate haematological response but with a lessened likelihood of side-effects.

I am grateful to Dr. L. T. Hilliard, superintendent of the Fountain Hospital, Tooting, for permission to treat patients under his care, and to Professor T. Crawford and Dr. J. L. Stafford for advice and criticism. The work could not have been carried out but for the co-operation of the dispensary and nursing staff of the Fountain Hospital. The sytron was kindly supplied by Parke, Davis & Co., the ferromyn by Calmic Ltd., and the ferlucon by Evans Medical Supplies Ltd.

TREATMENT OF ANTICHLINESTERASE POISONING

BY

W. S. S. LADELL, M.B., B.Ch.

Chemical Defence Experimental Establishment, Porton Down, Salisbury, Wiltshire

The recent work in this Establishment (Childs *et al.*, 1955; Askew, 1956, 1957) which has been concentrated upon the search for a practical chemotherapy in organophosphate poisoning has resulted in the development of a combined treatment with 2-hydroxyimino-methyl-N-methyl pyridinium iodide (P.A.M.) and atropine. This has been shown to be effective in all the common laboratory species and against several times the LD₅₀ of the more toxic organophosphates and to eliminate the necessity for artificial respiration. Recent reports from Japan (Namba and Hiraki, 1958) indicate that this treatment has now been used in organophosphate insecticide poisoning in man, in some cases with marked success.

Experiments with P2S

The latest development in these laboratories has been the use of the methane sulphonate equivalent of P.A.M., which is much more soluble than the iodide but is no less effective. We have given this the code name of P2S. Animal experiments have shown that P2S may be expected to be effective therapeutically against the common insecticides such as parathion, malathion, etc., and also against amiton when accidental poisoning has occurred in manufacture or actual use. Human tests have therefore been carried out (G. D. Wedd, H. W. Whitcher, and A. Taylor, unpublished work) in which P2S has been given by intramuscular injection of the 15% aqueous solution in doses up to 20 mg./kg. At this dosage reasonable therapeutic results have been obtained in animals. P2S has also been administered orally in capsules in doses up to 75 mg./kg. In no case have there been any deleterious effects following the administration as exemplified by clinical manifestations, by changes in E.C.G., pulse rate, or arterial blood pressure, or by alterations in the blood picture. The maximum dose of P2S so far given experimentally to one man has been 4.5 g. by mouth followed by 1 g. intramuscularly three hours later.

Further work is required before a standardized treatment can be recommended, and in any case atropine is still essential. Some of the common organophosphate insecticides, however, which themselves are relatively non-toxic to man are slowly converted in the body to very toxic substances—for example, parathion is converted into the very poisonous paraoxon. Repeated dosing with P2S and atropine may therefore be necessary to counteract the effects of successive amounts of, for example, paraoxon, as this is synthesized *in vivo* from the reservoir of parathion.

P2S tends to produce small quantities of cyanide when heated in aqueous solution, the cyanide formation being greater in neutral (pH 7) than in acid (pH 4) solution. Solid P2S decomposes when heated at 150° C. It cannot, therefore, be sterilized by heat either as the solid or in solution. However, Seitz filtration has proved satisfactory. At room temperature aqueous solutions are stable for three months provided that the pH is kept at 4. The solid appears to be stable indefinitely.

P2S plus atropine is unlikely to be effective against poisoning by phosphates in which a diaminoalkyl group is directly connected with the phosphorus atom as in O.M.P.A. or mipafox (Kewitz *et al.*, 1956).

TWO CASES OF SUBCLAVIAN ANEURYSM ASSOCIATED WITH CERVICAL RIB

BY

A. NAYLOR, Ch.M., M.Sc., F.R.C.S.

Consultant in Orthopaedic Surgery, Bradford (A) Group Hospitals and Keighley Hospital

The vascular phenomena associated with a cervical rib, though less frequently observed than the neurological complications, are sufficiently well known that considerable discussion concerning their aetiology has arisen. Coote (1861) first described a vascular complication of a cervical rib which was treated by surgery, an aneurysm of the subclavian artery being present. The infrequency of vascular symptoms was shown in a review of 716 cases of cervical rib by Halsted (1918)—only 19 (5.3%) cases exhibited purely vascular symptoms, whilst 106 had a combination of neurological and vascular phenomena. An aneurysm was present in only 27 of the 716 cases. Eden (1939), in a review of 46 published cases, noted aneurysmal dilatation in nine, while Stammers (1950) stated that such a complication was, in his experience, very rare.

Todd (1911, 1913) postulated that the vascular changes associated with a cervical rib were trophic in nature, induced by irritation of the sympathetic fibres passing in the brachial plexus. Telford and Stopford (1931) enlarged on this theory, but suggested that irritation of the sympathetic fibres produced vasospasm, the infrequency of vascular symptoms being said to result from the distribution of the sympathetic fibres in the plexus. It was suggested that vascular phenomena developed only if there was a concentration of the sympathetic fibres in the lower trunk in its inferior part, the fibres thus being more prone to irritation than in a normal plexus. Their theory was supported by the demonstration of such an arrangement in one of nine subjects studied. The majority of evidence, however,

supports the theory evolved by Lewis and Pickering (1934), who suggested that the vascular symptoms associated with a cervical rib are most probably due to local thrombosis occurring in the subclavian artery, with subsequent ejection of multiple small emboli. Such a view of the aetiology is supported by the two cases reported in this paper.

Case 1

A married woman aged 56 was admitted to hospital and was seen by me on June 17, 1949. She gave a history of sudden onset of pain in the right arm when combing her hair three months previously. The pain was followed by paraesthesia, and since that time she had had periodic attacks of pain and paraesthesia in the right arm and hand, associated with weakness of grip. She had noted some swelling at the right side of the root of the neck for the past five years.

Examination revealed a marked pallor of the distal two-thirds of all the fingers of the right hand. There was full active movement of the digits, and no muscular wasting was apparent. Immersion of the hand in warm water caused the pallor to change to a cyanotic colour. No radial pulse could be detected, but in the right side of the root of the neck a pulsatile swelling could be detected, the pulsation coinciding with the apex beat. X-ray examination revealed the presence of bilateral complete cervical rib. The Wassermann reaction was negative.

A diagnosis of subclavian aneurysm associated with a cervical rib was made, the peripheral vascular changes being thought to be due to multiple emboli, the pain and paraesthesia being ischaemic phenomena.

Operation.—On June 17 a right collar incision was made, the clavicular portion of the sterno-mastoid being partly divided and the brachial plexus exposed. The latter was found to be adherent to an aneurysm of the third part of the subclavian artery, the upper trunk passing anterior to the swelling. The plexus was mobilized and freed and the aneurysm resected, an abnormal vessel arising from its superior aspect being ligated prior to removal of the aneurysm. The anterior two-thirds of the cervical rib was excised and the wound closed. Section of the aneurysm revealed a thrombus adherent to its posterior and inferior walls.

On June 18 the hand was still cyanotic but the pain was relieved; normal colour was present on June 20. The patient was discharged home on June 29, when hand and shoulder movements were normal in range and power. No untoward symptoms were present on examination two months later.

When reviewed on April 13, 1955, the patient stated that she had not experienced any symptoms since the operation. There was no detectable difference in the temperature, colour, and muscle power of the upper limbs, but the right radial pulse was absent.

Case 2

A man aged 39 was admitted to hospital with a history of dull throbbing pain in the left forearm which began suddenly three months previously. The pain gradually extended up the arm and was accompanied by a feeling of coldness in the fingers. When the fingers were cold they were seen to be blue at their tips. Warmth relieved his symptoms, while cold had the opposite effect.

On examination the left hand was cold, clammy, and blue. While there was no wasting, the grip of the left hand was markedly impaired as compared with that of the right. Sensation to touch, pain, and temperature was normal. A pulsatile swelling was present in the left side of the root of the neck. The Wassermann reaction was negative. X-ray examination revealed the presence of a bilateral complete cervical rib.

A diagnosis of subclavian aneurysm with embolic phenomena associated with a cervical rib was made and operation advised.

Operation.—On May 19, 1954, a left collar incision was made and the brachial plexus exposed. An aneurysm of the third part of the subclavian artery was present, the upper trunk passing anterior and lateral and the middle trunk lying also anterior to the swelling, both trunks being adherent to the aneurysm. The plexus was mobilized and the aneurysm resected after division of the clavicle to remove the distal portion; the anterior two-thirds of the cervical rib was excised and the wound closed. No fixation of the clavicle was provided, the arm being retained in a sling.

On May 24 the finger movements were normal, the left hand still colder than the right, but pain had been abolished. The radial pulse was absent. Shoulder movements were begun on the fourteenth post-operative day and the patient was discharged home. When seen one month after operation there were full movements of all the joints of the left upper limb, whilst the clavicle was firmly united and the grip of the left hand was equal to that of the right. He returned to his work of dyer's operative on June 30. In February, 1955, his left hand was slightly colder and paler than the right, but function was normal and no further symptoms had been experienced.

The pathological report by Dr. I. Stewart on the sections of the aneurysm was: "The inner wall of the vessel is deformed by a flattened excrescence coated by a thin layer of laminated fibrin. Its substance is of fibrillae in which cells of the type seen in cartilage lie in pockets singly or in pairs. There are three distinct zones: in one the cells are ranged in columns with small vessels and few fibrillae; in the second and third the structure resembles cartilage but the cells differ in number. The appearances indicate repeated intravascular thrombosis with subsequent organization and cartilage deposition."

Discussion

Both cases described above exhibited purely vascular symptoms, the common initial symptoms of pallor and dull diffuse pain due to ischaemia being well demonstrated. It was thought that the release of emboli from the subclavian aneurysm accompanied by vasospasm produced the vascular symptoms, and section of both specimens reported showed intra-arterial thrombosis. It is evident, however, that there was also a vasospastic element in the development of their symptoms, as shown by their amelioration and improvement in the circulation of the limb after operation. It is feasible to suggest that the vasospasm is due to irritation of the sympathetic fibres in all the trunks, as these were adherent and stretched over the aneurysm. But complete recovery occurred after only a few days, indicating that the vasospastic element was merely a factor in the production of symptoms.

In treatment, excision of the rib alone or scalenotomy without any attack on the aneurysm has often been advocated. It is suggested that excision of the aneurysm is essential to eliminate further vascular symptoms. In Eden's (1939) case excision of the rib alone proved insufficient to prevent further embolic phenomena, and it is for this very reason that excision of the aneurysm should be undertaken.

Summary

Theories of aetiology of the vascular symptoms associated with cervical rib are reviewed.

Two cases of subclavian aneurysm associated with cervical rib are described.

Complete excision of the aneurysm and rib is advised to prevent recurrence of symptoms.

SPLINTER HAEMORRHAGES

BY

MARGARET M. PLATTS,* M.D., B.Sc., M.R.C.P.

AND

MAVIS S. GREAVES, B.Sc.

From the Department of Medicine, Sheffield University

Splinter haemorrhages are recognized as a characteristic physical sign in patients with subacute bacterial endocarditis. They were first described in this condition by Horder (1920), who thought they were due either to "toxic" damage to capillary walls or to minute emboli. In their textbooks on cardiology Lewis (1942), White (1947), and Wood (1950) state that capillary fragility is increased in bacterial endocarditis and that the splinter haemorrhages and petechiae found in this condition are due to the abnormality in the capillaries. However, Bramwell and King (1942) consider that the white centres which are often seen in the petechiae in bacterial endocarditis indicate that they are embolic in origin.

McNaught (1939) and Sheldon (1941) described splinter haemorrhages seen in bacterial endocarditis in patients who had no other evidence of this disease, and this prompted us to investigate the incidence and significance of these lesions in more detail.

Present Investigation

We have examined the finger-nails of 429 patients and normal individuals and 35 cadavers. The lesions classified as splinter haemorrhages were all beneath the finger-nails; the toes were not examined. The lesions were usually brown or black in colour, but when fresh they were red, and changed in colour during the next few days; they did not blanch on pressure. They were 1 to 3 mm. long, linear, and longitudinally situated beneath the distal third of the nail. They did not fade or disappear spontaneously, but grew out with the nails and could eventually be cut off. As

TABLE 1.—Incidence of Splinter Haemorrhages in Different Types of Disease

Type of Disease	Patients with Splinter Haemorrhages		No. of Patients Without Splinter Haemorrhages
	No.	%	
Systemic arterial embolus (5 had mitral stenosis)	6	86	1
Probable bacterial endocarditis (mitral stenosis, negative blood cultures)	2	67	1
Uncomplicated mitral stenosis	10	44	13
Rheumatic fever (no evidence of mitral stenosis)	3	27	8
Proved bacterial endocarditis (mitral stenosis, positive blood culture) partially treated	1	25	3
Patients with marked purpura at time of examination	1	25	3
Arthritis other than rheumatic fever	1	20	4
Renal disease	4	20	16
Blood diseases not exhibiting purpura	6	19	25
Hypertension	3	18	14

Nervous disease	3	11	24
Endocrine disease	2	11	17
Normal individuals	0	0	35

a rule the patient was unaware of their existence, but occasionally mild discomfort had been experienced. When the "haemorrhages" were associated with a history of recent trauma to the finger-nails they were ignored, as were blemishes which could conceivably have been due to dirt or

*J. G. Graves Research Fellow in receipt of a grant from the Medical Research Council.

ridges on the nail. Each patient was examined once only, and therefore the actual incidence of the haemorrhages is probably higher than we report.

We found splinter haemorrhages in 77 of the persons examined; in 60 cases there was more than one lesion. The highest incidence (86%) was in seven persons who had suffered recent major arterial emboli (Table I). Five of these patients had mitral stenosis, one was suffering from partially treated bacterial endocarditis, and one had had a recent coronary thrombosis. Of the other patients with mitral stenosis, 44% exhibited splinter haemorrhages, but they were no more common in those patients who were also thought to have bacterial endocarditis. However, we did not have the opportunity to examine any untreated patients with this disease, and the incidence may be higher in such individuals. Splinter haemorrhages did not occur more often in persons with auricular fibrillation than in those with sinus rhythm. In all other diseases the incidence of these lesions was about 15%.

We did not find any splinter haemorrhages in our unselected series of 35 normal persons. However, since we have been interested in this subject about a dozen acquaintances in normal health have shown us their nails, demonstrating lesions which we classify as splinter haemorrhages. We have gained the impression that they are particularly liable to occur after repeated jarring of the hand, unassociated with direct trauma to the nail. For instance,

Splinter haemorrhages under the finger-nail of a man suffering from diabetes and emphysema.

4 out of 12 healthy young women who had played hockey during the preceding week had splinter haemorrhages under their finger-nails. The photograph shows splinter haemorrhages under the nail of an emphysematous diabetic patient with no cardiac disease who was employed in making packing-cases. Five of his finger-nails showed splinter haemorrhages, but he had no recollection of injuring his fingers recently. None of the seven persons with splinter haemorrhages who were examined after death had any demonstrable ante-mortem intracardiac thrombus. However, two had had recent major systemic arterial emboli and two had had pulmonary emboli. One of the latter had a valve-type foramen ovale, and one of the remaining three patients had gross atheroma with ulceration of the aorta. None of the 28 patients without splinter haemorrhages who were examined after death had had systemic emboli, and only two had had pulmonary emboli.

We estimated the capillary fragility of 139 of our patients by means of Hess's test, performed in the following manner. A sphygmomanometer cuff was placed on the upper arm and inflated to midway between the systolic and diastolic arterial blood pressures for five minutes. A count was made of the petechiae which were produced in a circle 1 in. (2.5 cm.) in diameter drawn on the skin of the antecubital fossa. Ten or more petechiae were regarded as indicating excessive capillary fragility.

The capillary fragility was no greater in the patients who had splinter haemorrhages than in other persons (Table II). We did not find that the capillary fragility was increased in our partially treated patients with subacute bacterial endocarditis. Only one out of four grossly purpuric patients had any splinter haemorrhages.

Nail parings containing splinter haemorrhages which had grown out were treated with benzidine and barium peroxide. The lesions gave the green coloration characteristic of altered blood. Nail parings were stained with eosin and examined histologically. The splinter haemorrhages appeared to consist of a homogeneous mass of altered blood embedded in a layer of squamous cells adherent to the under surface of the cut nail.

TABLE II.—Capillary Fragility in Patients With and Without Splinter Haemorrhages

Type of Disease (Same Classification as in Table I)	Patients with Splinter Haemorrhages		Patients with no Splinter Haemorrhages	
	Total No. of Patients Examined	No. with more than 10 Petechiae after Hess Test	Total No. of Patients Examined	No. with more than 10 Petechiae after Hess Test
Systemic arterial embolus	3	1	0	—
Probable bacterial endocarditis	0	—	2	1
Uncomplicated mitral stenosis	7	1	5	1
Rheumatic fever	0	—	3	2
Proved bacterial endocarditis	0	—	2	1
Patients with marked purpura at time of examination	1	0	3	1
Arthritis	0	—	2	1
Renal disease	1	0	6	2
Blood diseases not exhibiting purpura	4	1	13	5
Hypertension	0	—	6	5
Heart disease other than mitral stenosis	0	—	15	4
Miscellaneous	4	0	13	2
Pulmonary disease	6	1	13	5
Peptic ulcer	2	1	4	1
Nervous disease	2	0	2	2
Endocrine disease	1	0	6	2
Normal individuals	0	—	13	2

The difference in incidence of the splinter haemorrhages in normal persons, patients with mitral stenosis, and patients with other diseases confirms our belief that the lesions are neither artifacts nor due to direct trauma to the nails. We do not think they are analogous to petechiae produced by haemorrhages from capillaries, for the following reasons. Splinter haemorrhages are linear, longitudinally placed under the nails, and do not fade as they age, characteristics which would not be expected of capillary haemorrhages. The frequency of these lesions in patients with uninfected mitral stenosis and with no signs of active rheumatic disease makes it unlikely that they are due to a toxic process acting on the capillaries, and the normal capillary fragility in these people confirms this. On the other hand, patients with mitral stenosis frequently have thrombus in the left auricle and are liable to arterial emboli. The high incidence of splinter haemorrhages in these people, and especially in those who had had recent large emboli, supports the other clinical evidence, which suggests that these lesions are embolic in origin.

However, if splinter haemorrhages are emboli in terminal digital vessels it is difficult to explain how they grow out with the nails and become embedded in the avascular squamous epithelium on the under surface of the nail. The histological appearance of splinter haemorrhages and their relation to the other tissues in the finger-tip is to be investigated further.

Summary

Examination of the finger-nails of 464 persons has shown that splinter haemorrhages occur in many patients who are not suffering from bacterial endocarditis. They occurred in 44% of patients with uninfected mitral stenosis and also in about 15% of persons with other diseases. Our evidence suggests that these lesions are usually due to emboli in the terminal vessels of the nail-bed.

We are indebted to Professor C. H. Stuart-Harris, in whose department this work was carried out, for his helpful advice and criticism. We also thank Mr. J. T. Chesterman and Dr. E. K. Blackburn for allowing us to examine their patients, and Mr. J. F. V. Larway for the photograph.

Medical Memorandum

Perforated Duodenal Ulcer During Pregnancy

Perforation of a duodenal ulcer during pregnancy is a rare and serious condition which requires urgent treatment to obtain a successful outcome for both mother and foetus.

The following case is reported on account of the rarity and importance of the condition, and also because some interesting points occurred during treatment.

CASE REPORT

A primipara aged 30 first attended hospital for routine antenatal care at the 14th and 30th weeks of pregnancy. One week after the last attendance she was admitted with epigastric pain associated with vomiting. A tentative diagnosis of hyperemesis was made, and as the trouble rapidly subsided she was discharged after a stay of three days. She was readmitted that same evening with severe abdominal pain of 12 hours' duration. She had also vomited half a pint (284 ml.) of blood. Her previous history revealed that she had experienced indigestion for three and a half years before she became pregnant, but had never sought medical advice. For the first 30 weeks of the pregnancy she had noticed complete freedom from indigestion.

Examination revealed a young woman of slight build. She was obviously in severe pain and there was a moderate degree of shock. Her temperature was 98.4° (36.9° C.), pulse rate 140, respirations 20, and blood pressure 120/80 mm. Hg. Abdominal examination showed the uterus was 32 weeks by size and obscured most of the abdomen, but there was tenderness with guarding, mainly in the epigastrium. The foetal heart sounds were heard. There were no signs of toxæmia of pregnancy.

A tentative diagnosis of perforated duodenal ulcer was made, and in the circumstances it was decided to treat the condition conservatively by continuous gastric suction; intravenous glucose and saline solution; pethidine, 100 mg. six-hourly; injection of penicillin, 1 mega unit twice daily; and injection of streptomycin, 1 g. twice daily. For the ensuing 24 hours her general condition remained unchanged and the foetal heart sounds were still present.

The serum electrolytes were then within normal limits: Na 126 mEq/l., K 4.87 mEq/l., Cl 84 mEq/l. White blood cells, 17,000/c.mm.; haemoglobin, 84%.

However, after a further 18 hours the membranes ruptured spontaneously and after a further three hours she miscarried and delivered a stillbirth.

The abdomen was diffusely tender, with moderate rigidity, and was silent on auscultation. As her general condition was still satisfactory it was decided that laparotomy would be the safest course, and this was performed. It was by now 60 hours after the onset of pain.

Under general anaesthesia the abdomen was opened through a right upper paramedian incision. There was much odourless bile-stained fluid in the peritoneal cavity. A large perforated duodenal ulcer about 19 mm. in diameter was found on the anterior aspect of the first part of the duodenum. The edges of the perforation were clean-cut, with little surrounding oedema. The perforation was closed with five catgut sutures and the wound closed with a small suprapubic drain to the pelvis.

Gastric suction with intravenous glucose and saline solution, and antibiotics, were continued as before the operation.

Her convalescence was satisfactory, although prolonged, owing to suspicion of a formation of a subphrenic abscess, which, indeed, she never had. She was discharged from hospital two months after admission and has remained well on diet since then, with no recurrence of indigestion. A

barium-meal examination performed three months after discharge showed the "duodenal cap deformed but not tender; appearances probably cicatricial."

COMMENT

During pregnancy activity of a peptic ulcer is infrequent and perforation of a peptic ulcer rare. Mussey (1927) reported only two cases of peptic ulceration in 370 operations during pregnancy at the Mayo Clinic in a period of 10 years.

In a search of the world literature Sandweiss *et al.* (1943) found 13 cases of complications of peptic ulceration during pregnancy; nine were cases of perforation and four were of haemorrhage. He found only one case of perforated duodenal ulcer in 70,310 pregnancies in Detroit in the period 1928-37, and also one case of perforated gastric ulcer in 348,310 pregnancies over a period of three years in New York. Both patients died. Avery Jones (1947) stated that no case of proved peptic ulcer was discovered among 10,000 pregnancies and 2,000 abortions that he reviewed. James (1948) reported one case of perforated duodenal ulcer at the 36th week of pregnancy in a patient with a known duodenal ulcer. Operation for suture of the perforation was performed and four days later spontaneous delivery of a living child occurred. The patient survived and six weeks afterwards a barium-meal examination showed an active duodenal ulcer.

Howkins (1950) quoted Professor Grey Turner's statement that he "has never seen undue activity of a peptic ulcer during pregnancy, but is very familiar with the opposite state of affairs where ulcer symptoms disappear during pregnancy"; also Sir Gordon Gordon-Taylor's statement that he "cannot remember a perforated gastric or duodenal ulcer during pregnancy."

Way (1945) attempted to explain the rarity of peptic ulcer and complications in pregnancy by correlating the hypochlorhydria found in these patients with the increased secretion of the anterior-pituitary-like hormones in the urine. He concluded that the greater the secretion of these latter the more marked the hypochlorhydria. This endocrine explanation appears to be the most likely reason for the rarity of peptic ulcer activity during pregnancy.

Hurst and Stewart (1929) stated that there was no doubt that pregnancy exerts a favourable influence on the symptoms of an ulcer and in some cases appears to lead to actual healing apart from any specific treatment. This they attributed to the mechanical effects of support of the stomach by the rising uterus. This is supposed to relieve the strain on the lesser curvature and improve the local circulation, which promotes healing of any ulcer.

It is noteworthy that most cases of perforated ulcers during pregnancy have a definite history or radiological proof of an ulcer prior to pregnancy. The case here reported occurred in an undiagnosed ulcer case. Treatment was at first by the conservative method, but, after miscarriage, operation revealed a large unsealed perforation, and this was closed and convalescence was uninterrupted. When the patient was seen six months later progress had been quite satisfactory.

I thank Mr. R. A. C. Owen, consultant surgeon at Walton Hospital, for his help and advice in the preparation of this paper.

MARTIN HORWICH, M.B., F.R.C.S.,
Senior Surgical Registrar, Walton Hospital, Liverpool.

Reviews

CHRONIC SCHIZOPHRENIA

Chronic Schizophrenia. By Thomas Freeman, M.D., D.P.M., John L. Cameron, M.B., Ch.B., D.P.M., and Andrew McGhie, M.A. Preface by Anna Freud. Foreword by T. Ferguson Rodger. (Pp. 158+x. 21s.) London: Tavistock Publications, Ltd. 1958.

In this book two psychiatrists and a psychologist discuss the causation, symptomatology, and treatment of chronic schizophrenia, in part based on a study of a group of patients admitted to hospital with this illness. Dr. Anna Freud has written an appreciative preface. A psycho-analytic viewpoint on schizophrenia is put forward, and a good account is given of all the varying psycho-analytic theories about this disease that have been propounded in the last 50 years.

Of special interest is a report on the treatment of 17 chronic patients in a mental hospital, the average duration of whose illness was already eight years. A much more "permissive" regimen was used than is general in ordinary mental hospitals; other nurses in the hospital, in fact, referred to the ward used in this experiment as the rumpus room. Every encouragement was also given to nurses to try to foster as stable a personal relationship with each of their patients as possible, and this was considered by the authors to be the most important aspect of their special psycho-analytically orientated treatment. It is unfortunate that Freeman and his colleagues can as yet give no statistical details of the results achieved by the interesting regimen they devised; and this absence of figures is a weakness of much of the recent writings on the use of psycho-analytic concepts in the treatment of schizophrenia.

It is difficult, really, to compare the effects of the therapeutic methods used in this study with those that could be obtained with the skilled employment of more established methods. For instance, only one of these tragic patients had even been given the benefit of a full or modified leucotomy, though some had already spent up to 12 years of agitated misery in the back wards of the hospital concerned; only some of them seem to have had insulin, and none seems to have had the advantages of the new tranquillizing drugs in large doses. But this is a stimulating and interesting book, and certainly every method that helps even a small number of schizophrenic patients is to be welcomed. The book should be read especially by those who feel that sympathy and respect for the suffering of the individual patient need to be constantly emphasized in the psychiatric treatment of to-day.

WILLIAM SARGANT.

ANALYTICAL PSYCHOLOGY

New Developments in Analytical Psychology. By Michael Fordham, M.D., M.R.C.P., F.B.P.S. Foreword by C. G. Jung. (Pp. 214+xiv; illustrated. 25s.) London: Routledge and Kegan Paul. 1957.

The assembly in book form of nine papers, delivered for the most part to special audiences, is almost bound to give the effect of many targets. Yet the method has advantages for those who prefer the written to the spoken word. The appeal of this book is mainly to the psychotherapist versed in Jung's writings, but it has much to offer to the larger body of psychiatrists who make no claim to be Jungians or Freudians. Both groups will find the first essay, on "Biological Theory and the Concept of the Archetypes," worthy of their attention. It is a careful attempt to open new ground by linking the theory of the collective unconscious with accepted biological theory. The discussion centres on such themes as the possible relation between archetypes and the action of the organic nervous system; the function of the unconscious in the process of discoveries in science; the pitfalls in the attempt to make comparisons between ontological and phylogenetic development in biology or psychology.

The justification for claiming "New Developments" in the title lies, first, in the author's views on child psychology and on the analysis and ego development of children; and, secondly, in his evaluation of transference and counter-transference. In the section "Notes on the Transference," Fordham traces the expansion of Jung's teaching on the transference and adds his personal observations and opinions. Those in touch with the outlook of the C. G. Jung-Institut in Zurich may not go all the way with him, but, while stating his convictions frankly and clearly, he never slips over the border into dogmatism.

The foreword by Jung is a personal tribute to the author, special commendation being given to his presentation of the difficult subject of synchronicity as a principle of explanation, additional to causality. As Jung was the first to use the concept of synchronicity in psychology and in psychopathology his observations are of particular significance.

E. A. BENNET.

CLINICAL ENDOCRINOLOGY

Atlas of Clinical Endocrinology: Including Text of Diagnosis and Treatment. By H. Lissner, A.B., M.D., and Roberto F. Escamilla, A.B., M.D. (Pp. 476; 148 plates, 3 in colour. £7.) London: Henry Kimpton. 1957.

As is stated in a foreword, this is a clinical endocrinology for clinicians. The authors' aim is to present their large experience of clinical endocrine problems. Inclusion of the fundamentals of endocrine physiology, pathology, and chemistry was thought by the authors neither appropriate nor necessary. Emphasis is on the visual presentation, and in this volume the written word takes second place. The illustrations are excellent and most are original, with a few which are classics, such as Cushing's giant and Gilford's progenia. They are offered in profusion, and succeed in giving a vivid impression of the many visible features of the whole range of endocrine disorders. The text is brief and concise, but adequate and well up to date. Symptoms, signs, and diagnostic tests are each divided up into important, less important, and incidental—an excellent feature. The discussion is very sensible, and advice on treatment, though brief, is practical. A few relevant references are given for each section.

Many well-illustrated volumes on endocrinology have been produced, but this is very different from the majority. It contains much interesting and unusual information. There are given, for instance, good details of 30 famous giants together with the present location of skeletons of nine of these. There is an excellent table of the milestones to 2 years of life. The mode of presentation may be illustrated by the chapter on diabetes insipidus, a disorder not well suited to visual handling. Here is shown a very clear diagram of the anatomy of the supraoptic nucleus and some photomicrographs of nerve cells in a normal and a diseased supraoptic nucleus. There is an extremely vivid photograph of a man with severe diabetes insipidus, an excretory urogram showing dilatation of the urinary tract, and a cystogram of the enlarged bladder. There is a remarkable genealogical chart of a family of 679 persons, 88 of whom had the disease through seven generations. A clear chart well illustrates the difference in response of diabetes insipidus, normals, and psychogenic polydipsia in the intravenous hypertonic saline test of Carter and Robbins, and a small table compares the costs of treatment of the patients in different ways.

All other fields are handled with equal thoroughness, and the highly unusual is frequently found. There is, for instance, a page of interesting illustrations of true eunuchs from the Imperial Palace, Peking, from Zanzibar, and from Russia, showing the variety of types. Illustrations of this high quality will not date as must inevitably much of the text in any textbook. The relatively high cost of the book, inevitable in one so well produced, can be justified by the very long period of use to which such a work can be put. It will be found fascinating by all interested in endocrinology and a most valuable work of reference.

C. L. COPE.

CLINICAL ORTHOPAEDICS

Clinical Orthopaedics, No. 10. Editor-in-Chief: Anthony F. DePalma. (Pp. 367+x; illustrated. Single copy 60s., subscription copy 48s.) Philadelphia and Montreal: J. B. Lippincott Company. London: Pitman Medical Publishing Co., Ltd. 1958.

The biographical notice in this volume of Phemister, for over 20 years professor of surgery at Chicago, is welcome, for his work on the growth of bone and on some aspects of abdominal surgery is respected in this country and he had carried out a year's research work in London. The greater part of the book is concerned with affections of epiphyses and apophyses; there is a symposium on metabolic bone disorders, and the chapters on general orthopaedics include spinal conditions and fractures around the femoral neck. As Phemister studied avascular necrosis it is fitting to find many references to this in the contribution on the epiphyses and carpal lunate. During the last 30 years much study has been made of pathological conditions of epiphyses, so that it is not surprising to find the publication of many illustrations and statistics of their origin and subsequent changes which are now familiar. The reader will welcome the chapter on treatment of avulsion of the ischial tuberosity; it includes two most striking illustrations, one being a graphic record of athletic stress on the tubers, depicting high hurdling—a pity one hurdle is falling—and the other of avulsion fracture of all four tubers in mother and daughter in an automobile accident.

Although our knowledge of general metabolism when bone changes exist is still immature, there is evidence of much research work being carried out, and the book under review includes comprehensive reports with many statistical tables, one on calcium metabolism in relation to metastatic malignancy coming from Boston, and another on the relationship of steroid hormones to the development and management of osteoporosis in ageing people from New York. Interspersed between mechanical aids for the injured femoral neck will be found a "spectator letter" on the problem of the physically handicapped children of India, where help is badly needed. Many doctors as well as most of its population are ignorant of what can be done for the deformed and injured child, and it was only 20 years ago that the first orthopaedic department was set up. The book is full of interest, and the collection of essays are of the standard found in previous volumes.

ST. J. D. BUXTON.

FANCIES IN DIET

Fat Consumption and Coronary Disease: An Evolutionary Answer to this Problem. Basic Approach to the Prevention and Arrest of Coronary Disease. By T. L. Cleave, M.R.C.P.(Lond.). Foreword by Percy Stocks, C.M.G., M.A., M.D.(Camb.), F.R.C.P.(Lond.), F.S.S. (Pp. 40. 5s.) Bristol: John Wright and Sons Ltd. 1957.

The author's thesis is that man can rely with confidence on the instinct of appetite to tell him what he should or should not eat, but only so long as his instinct is being exercised on natural substances, not necessarily in their raw state but also cooked in a simple form. In passing, the author deplores the unnatural increase in concentrating and refining processes such as those used in commercial sugar and white flour production.

According to the author, fats existing in their natural environment, even though concentrated and isolated as in butter, can be eaten in strict proportion to appetite and are harmless. On the basis that coronary disease is commonest in the wealthy sections of the community, where least margarine is eaten, he is prepared to discount any great harm from hydrogenation. But he considers that through the agency of arbitrary meals and arbitrary food mixtures—designed or prepared by others without the consumer exercising his preference—there occurs unnatural interference with the exercise of instinct for fats. This may result in over-consumption of fat as in fried foods, pastries, batter puddings, etc. Unnatural fat consumption is likely then to give rise to a higher total fat consumption. The

author considers that consumption of unnatural fat is the only causal agent of coronary disease which best fits all the facts. He considers that this disease is one of the penalties of industrialization, as are possibly many other diseases.

This essay is in essence a plea for the simpler, less sophisticated life—"A little of what you fancy does you good." It is rather a mixture of fact and considerable speculation.

D. P. CUTHBERTSON.

RHEUMATOID ARTHRITIS

La Polyarthrite Chronique Evolutive. By L. Isemein and A. M. Fournier with three collaborators. Preface by Professor F. Coste. (Pp. 315; illustrated. 3,200 frs.) Paris: Masson et Cie. 1956.

This is an exhaustive study of rheumatoid arthritis in all its aspects. It is the product of many years of fruitful collaboration between a physician and a radiologist. Although it is divided into the usual sections, these contain more than routine information, as the personal views of the writers are of considerable interest and should provoke new thought on many aspects of the multifarious problems associated with this disease. It is a useful book, more particularly for the specialist, for whom it is no doubt primarily written. It is well produced on good paper, but is deserving of a more permanent cover. It has an extensive bibliography, a few of the references being to the British literature.

SEX PERVERSIONS AND CRIMES

Sex Perversions and Sex Crimes. By James Melvin Reinhardt, M.A.; Ph.D. (Pp. 340+x. 43s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1957.

This is an exasperating book on an important subject. Written primarily for law-enforcement officers, judges, and prosecutors, it nevertheless casts a hopeful eye on medical men and social workers. But it has four main faults. To begin with, it is written in much too journalistic a style, using such chapter headings as "Transvestism: Nature's Cruel Paradox." This is quite out of place in a scientific work, and in any case is not particularly accurate. Secondly, the author is only with difficulty able to restrain his repugnance at some of the more morbid sadistic perversions and crimes of violence. Thirdly, his case histories are not much more illuminating than those that appear in the sensational Sunday Press. The fourth objection may not be generally agreed among psychiatrists—namely, that Mr. Reinhardt's concepts of aetiology are confused and, from the psychodynamic point of view, somewhat superficial. He veers from hereditary to environmental factors, noting on the way some developmental influences of the usual familial type. But he rarely or never looks behind the conscious surface, being content to maintain that the significance behaviour has for society reacts on the behaviour—a generalization which the clinician will not find very helpful. In spite of these faults, it must be conceded that the author, who is Professor of Criminology at the University of Nebraska, has had a great deal of experience of the more regressive sexual perversions, and to those medical men who are unfamiliar with the subject the book may serve as an eye-opener. It may even put them on the *qui vive* to recognize among their adolescent patients such traits as may later take a dangerous antisocial form. This is the best that can be said of a disappointing book.

EDWARD GLOVER.

A Textbook of Histology, by A. A. Maximow and W. Bloom, has been an authoritative work on the subject for nearly 30 years. The seventh edition (W. B. Saunders Company Ltd., Philadelphia and London; 628 pages; 77s.) has been revised throughout to incorporate advances made in the last few years, and some new electron photomicrographs have been added to the many fine illustrations in the book.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JULY 19 1958

HUMAN BEHAVIOUR AND SOCIETY

"The proper study of mankind is man." This poetic dictum of Alexander Pope was the theme of Professor A. P. Thomson's presidential address at Birmingham on Monday of this week. His purpose, he said, was "to direct attention to the increasing responsibilities that society imposes upon its doctors and to examine some of the consequences that may flow from a wider range of medical activity." With this as his starting point Professor Thomson ranged far and wide in the brief but engaging compass of his talk. The doctor to-day is indeed caught up at almost every intersection of the web of human society. As a man struggling, like other men, to earn a living for himself and his family, he nevertheless enters into the lives of other workers in a way that is unique, intimate, and individual, yet with social consequences which are compelling and of growing complexity. The medical man, as Professor Thomson points out, belongs to a profession bred in a long tradition of individual freedom. It is in the conditions set by this freedom that a long line of discoveries have been made which to-day give mankind a control over his physical destiny that was scarcely dreamed of a hundred or even fifty years ago. The check imposed on bacterial infections has liberated for other purposes beds in tuberculosis sanatoria and fever hospitals. The tightening net cast over malaria is creating problems for societies in tropical countries which are almost frightening in their implications. The once comfortably solid and seemingly indivisible atom is now, to man its discoverer, a source of unlimited power for good or evil. The medical man has to get to grips with the medical and biological problems posed by nuclear energy. Inventions and new techniques pour out thick and fast. To keep abreast with modern knowledge is a hard enough task for even the toughest-minded man with leisure into the bargain. Is it surprising, therefore, that the hard-pressed practising doctor finds it difficult to keep his head above the swirling waters of modern medical science, and feels too that all this somehow conveys

a threat to his individual freedom of choice and action?

Professor Thomson, however, does not hesitate to lay down a new task for the practising doctor. There is, he says, "a clamant need for the branches of social science to make dispassionate studies of what actually happens in human societies." The medical man—especially the family doctor—has, he believes, a contribution to make in such studies. He refers to Canon Raven's suggestion "that between sociology and medicine there might well be established the same sort of unity which has been established between psychology and medicine." The family doctor is the one intimate objective witness of the stresses and strains of relationships in the fundamental unit of human society—the family. Professor Thomson therefore suggests that a team of family doctors might be linked with a university department of sociology in a joint piece of research, and proposes that some such experiment as this should be promoted jointly by the B.M.A. and the College of General Practitioners. "Adventure of this kind, a study of human behaviour in society," he finely says, "would surely restore interest in another problem of fundamental importance which we share with the whole company of thinkers, and which medicine, absorbed in the application of its new therapeutic resources, has neglected of late. What is the nature of man? How should we regard the individuals who consult us?" Here is a challenge to be taken up. Human genetics and human ecology are proper disciplines for the proper study of mankind. Modern medicine is emptying the wards of the fever hospitals and sanatoria. But the wards of the mental hospitals are full to overflowing. The study of human behaviour in society might afford at least part of the explanation of this, and of the other problems to which the new President of the B.M.A. so profitably directs the attention of his colleagues.

UNSATURATED FATS IN TREATMENT OF CORONARY DISEASE

Much has been written and spoken about dietary fats and coronary disease. An excessive intake of fat from early childhood has been incriminated by some as the cause of coronary disease, whereas others, while regarding dietary fat with suspicion, believe that there are many other aetiological facets to this disease. All would agree that coronary disease is in some way associated with a disturbance of fat metabolism, although both the aetiological and therapeutic implications of this association have yet to be determined. In experimental animals the extent and

severity of cholesterol deposition on the arterial wall and of atheromatous lesions can be directly correlated with the height and duration of hypercholesterolaemia induced by a diet high in cholesterol; moreover, reduction of hypercholesterolaemia is followed by a proportional regression of the arterial lesions. From this evidence it has been argued for the human, in whom atherosclerosis develops spontaneously by early adult life, that control of the serum cholesterol may be desirable and that reduction of hypercholesterolaemia in patients with coronary disease is beneficial. But some of the difficulties of gathering clear-cut data and of analysing them are evident from the careful study reported recently by Drs. H. Keen and G. A. Rose.¹

Reduction of dietary cholesterol alone does not decrease the serum cholesterol significantly in man.² Reduction or total avoidance of dietary fat does,^{3,4} but a diet sufficiently low in fat to produce lasting and significant reduction of the serum cholesterol is not tolerable to many people. Until recently, animal or saturated fats and vegetable or unsaturated fats were regarded as interchangeable so far as their effect on serum cholesterol was concerned,⁵ but now evidence has accumulated that most animal fats raise the serum cholesterol and most vegetable fats lower it.⁶⁻¹¹ There is, however, no general agreement on the nature of the cholesterol-lowering action of unsaturated fats. From carefully controlled studies E. H. Ahrens and his colleagues¹² conclude that the more unsaturated the fat the greater the depression of serum cholesterol. On the other hand L. Horlick and B. M. Craig¹³ have shown that a derivative (ethyl linoleate) of one of the unsaturated essential fatty acids, linoleic acid, lowers the serum cholesterol. L. W. Kinsell and his colleagues¹⁴ obtained the same result with ethyl linoleate and with a derivative of another unsaturated essential fatty acid, arachidonic acid, and suggest that the cholesterol-lowering property of vegetable oils may be related more to their content of essential fatty acid than to their lack of saturation. However, the speculation that coronary disease might be due to a deficiency of essential fatty acids¹⁵ has not been substantiated by finding a reduction in their concentration in the serum of patients with coronary disease.¹⁶ Alternatively, corn oil, which is generally acknowledged as the most effective unsaturated vegetable oil, may have some cholesterol-lowering property not explained entirely by its fatty acid composition¹⁷; and J. M. R. Beveridge, W. F. Connell, and G. A. Mayer¹⁸ think that its sterol content may partly be responsible.

Though the mechanism whereby unsaturated vegetable fats lower the plasma cholesterol is uncertain, their substitution for saturated fats is an effective

dietetic treatment for the short-term reduction of serum cholesterol. This effect of unsaturated fats may, however, depend partly on simultaneous restriction of the intake of animal fats. For example, the use of safflower oil, the most unsaturated fat available to-day, as a supplement to a normal and unrestricted diet did not result in reduction of the serum cholesterol in normal subjects.¹⁹ It has not yet been established whether reduction of the serum cholesterol can be maintained for years, though H. Malmros and G. Wigand²⁰ have obtained promising results during one year's substitution of corn oil for animal fats in hypercholesterolaemic patients.

What, then, is the place of unsaturated fats in the treatment of coronary disease? At present there is no evidence in man either that reduction of the serum cholesterol causes regression of atherosclerosis or that the prognosis of hypercholesterolaemic patients with coronary disease is improved by reduction of their high circulating cholesterol. Nevertheless it is probably justifiable to act on an unproved hypothesis and substitute corn oil for animal fats in the hypercholesterolaemic patient with a bad family history of coronary disease. In contrast to this experimental approach, much more basic information is required before the public can be advised either to eat less of saturated fats or more of unsaturated fats. Even so, there are already several types of milk, cheese, and margarine containing unsaturated oils available in retail stores. Some industrial firms, believing that these preparations will be commercially profitable, have launched publicity campaigns. Many people would hold, however, that some of the claims made for these foods, which can cause dyspepsia and diarrhoea and may be expensive, are unsubstantiated and premature. We are still passing through an experi-

mental phase in the understanding of coronary artery disease, and no specific dietary recommendations, apart from reduction of obesity, can reasonably be made.

ACCIDENT INSURANCE FOR B.M.A. MEMBERS

A new and most valuable practical benefit of membership of the B.M.A. was announced at the Representative Meeting in Birmingham last week. Full members of the British Medical Association have now the opportunity to effect a personal accident insurance on terms so highly favourable as would appear to be unobtainable anywhere else. The matter was introduced at the A.R.M. on a motion by Dr. I. M. Jones as chairman of the Private Practice Committee. The details of an unusually attractive scheme submitted by the Medical Insurance Agency were put before the Representatives and are repeated in an advertisement at pp. 7-8. The scheme provides full cover for death, loss of limbs or sight, and permanent disablement that may result from accident. Any B.M.A. member may take from one to ten units of benefit, each unit costing 10s. per annum. The maximum of ten units, then, can be taken for an annual payment of £5—of which £3 10s. is subject to tax relief within the usual statutory limitations—and for this modest outlay a cover of £10,000 is provided. As Dr. Jones explained to the R.B., the cover is world-wide in scope; there is no barrier of colour, race, or creed to acceptance in the scheme; and it is open to women doctors as well as to their male colleagues. No prior medical examination is necessary. The one essential requirement is full membership of the B.M.A. That is to say, for exactly the same premium the Australian and New Zealand member of the B.M.A. can get exactly the same cover as his fellow member in the United Kingdom.

The welcome announcement last week was the happy culmination of discussions at the last two Annual Representative Meetings. Members were becoming worried about the hazardous position of the young doctor and of those with limited years of service in the N.H.S. Last year the R.B. resolved "that Council be requested to arrange with the Medical Insurance Agency an appropriate insurance policy covering injury or loss of life incurred by doctors carrying out their practice." But the scheme now available is not restricted to accidents incurred only while at work. Any member, say, motoring abroad on holiday is as fully covered as when he is going on his rounds at home. The B.M.A. has added a novel kind of benefit for its members, and one which should go a long way to relieving an anxiety which any practising doctor must experience.

ALLERGIC GRANULOMA

About two years ago, in the United States, a new man-made dermatosis with unique features was seen, which has an important bearing on the understanding of certain problems in general pathology, and perhaps also on the pathology of berylliosis. L. F. Weber and his colleagues¹ in Chicago were the first to report cases of an unusual papular eruption of the axillae in patients who had used deodorant sticks. They were soon followed by others, and more than 70 cases have been recorded. These have now been summarized by W. B. Shelley and H. J. Hurley,² who have also described their researches to elucidate the pathogenesis of the disorder. Shelley gave a first-hand account of the detective trail followed when he delivered the Prosser White Oration to the St. John's Hospital Dermatological Society in London last year.³ The clinical picture consisted of an eruption of flesh-coloured or brownish dome-shaped papules of varying sizes aggregated in the vault of the axillae. Symptoms were minimal or absent. In all cases the axillae had been shaved and a stick type of deodorant used as opposed to a liquid or cream preparation. Histologically the papules showed a sarcoidal granuloma in the dermis. No treatment had any effect on the condition, but it tended to resolve spontaneously over one or two years.

The recognition of this axillary granuloma followed very soon after the introduction of a new type of stick deodorant containing a zirconium salt. The stick was a soap-alcohol gel of sodium stearate, ethyl alcohol, carbitol, and water, to which was added about 10% of a 45% solution of sodium zirconium lactate. Zirconium is a metallic element close to titanium and hafnium in the periodic table. It has been used in medicine in various forms previously without any ill effects—for brain clips and bone screws in surgery, as an ointment for contact dermatitis, and as an intravenous solution for pyodermas. It has been administered to animals by various routes, and no adverse reactions were encountered. Hence it appeared perfectly safe to use as an anti-perspirant and deodorant in place of the standard aluminium salts.

Shelley and Hurley injected each of the constituents of the deodorant stick into control subjects. Only the sodium stearate produced a granuloma, but it occurred in every patient and resolved in a few weeks. Since the incidence of deodorant axillary granulomas was small in proportion to the large number of persons exposed, the sodium stearate could not be the cause. In an attempt to produce this condition experimentally, thirty men were asked to rub a zirconium stick into one shaved axilla and a non-zirconium stick into the other. The chances of success were not great, but one man developed the characteristic zirconium granuloma after a month, and it was confirmed by biopsy. It followed the natural history of the previously described granu-

lomas. Intradermal injections showed that these patients were allergically sensitive to zirconium itself and reacted to minute amounts.

About thirty American deodorant products were said to contain zirconium salts at one time. It was introduced into stick deodorants in Britain in 1956, but was stopped after a period of only a few months, as soon as the possible harmful effects were brought to the notice of the manufacturers. As a result it is unlikely that the deodorant granuloma will be seen in Britain, though one patient has been reported in this country by C. D. Calnan and I. Sarkany.⁴

Allergic granulomatosis is not an entirely new concept in medicine. It has been used to designate the processes described by F. Wegener⁵ and by F. G. Zak and colleagues,⁶ but in neither of these has there been any clue to the identity of an allergen. The closest similarity to the zirconium granuloma is beryllium disease.⁷ Apart from pulmonary lesions, patients are seen in whom a minute amount of the metal may painlessly penetrate the epidermis and give rise to a sarcoidal granuloma in the dermis. It is always associated with allergic hypersensitivity which can be demonstrated by a positive patch test. The sites of some of these positive patch tests later show a granuloma of the same type.⁸ It is known that an epithelioid granuloma can be produced by many infective agents and different foreign materials. The work of Shelley and Hurley suggests the possibility that small amounts of trace metals other than beryllium and zirconium may be pathogenic as a result of hypersensitivity. They have also proved that a pure sarcoid reaction can be a manifestation of allergy.

HORMONE IN THE PINEAL GLAND

The pineal gland remains till now an unexploited organ. However, extracts of it have long been known to cause a change in skin colour when injected into frogs, toads, and fish. Whereas a hormone in the posterior lobe of the pituitary turns light-coloured frogs dark or indeed black, extracts of pineal gland have the opposite effect, and turn dark skin light. A. B. Lerner and his colleagues¹ at Yale have now isolated the active substance which has this action, and they propose to call it melatonin, though they do not say why they have chosen this name. Their original material was ox pineal gland, and they purified it by testing the effect of fractions on isolated skin of the frog *Rana pipiens* which they made dark with caffeine. Their work was done in the department of dermatology, and they used the most modern chemical methods (including counter-current distribution) such as are rarely seen used in departments of dermatology in Britain.

In preventing darkening of frog skin by the melanocyte-stimulating hormone, their new substance was found to be 100 times as active as adrenaline, 200 times as active as triiodothyronine, and 5,000 times as active as hydroxytryptamine. The new substance had no adrenaline-like activity on the rat uterus and no activity like that of hydroxytryptamine on the clam heart. It

¹ Lerner, A. B., Case, J. D., Takahashi, Y., Lee, T. H., and Mori, W., *J. Amer. Chem. Soc.*, 1958, **80**, 2587.

was not present in ox pituitary, or in the hypothalamus, or in any of the endocrine organs. Nor was it present in the eye. As to its chemistry, these authors confine themselves to the remark that the fluorescence and ultraviolet absorption were characteristic of hydroxyindoles.

PROTECTIVE OINTMENT AGAINST BILHARZIA

Rhodesia is developing fast. New and large irrigation projects and dams are being constructed and more farms are being opened up daily. With all these projects the risks of contracting bilharzia are increasing. It is often necessary in farming to use water from dams and streams. One source of infection is the watering of tobacco seed beds. As the water is usually pumped from the river under pressure, some of the cercariae might be killed by it, but they can withstand a pressure of 200 lb. per square inch (14 kg. per square cm.), which is higher than obtained by the ordinary farmer's pump. The infection is still more likely to occur from handling pumps suffering from mechanical breakdowns.

Dr. William Alves, director of the Bilharzia Research Laboratory in Southern Rhodesia, has therefore recently recommended the use of a repellent ointment to prevent cercarial penetration of the skin and so bilharziasis. The Commission on Schistosomiasis and Tropical Diseases of the United States Army devised this method of protecting soldiers exposed to the disease in the Far East.¹ Alves has made it clear that the ointment is not intended to protect swimmers but only those running an occupational risk. No doubt anglers may be tempted to use it, but as yet they have not been encouraged to try. The ointment is rubbed on the part of the body to be exposed to infection, such as the hands, forearms, ankles, and feet. Half an ounce (14 g.) is sufficient to cover all these parts. Alves's trials were not as extensive as those carried out by the Commission in the Philippine Islands, where a large number of compounds were incorporated into ointments applied to the shaved skin of the tails of mice. This was done in order to ascertain whether any of the ingredients protected the skin against penetration by cercariae during prolonged exposure to water. The mouse was placed in a brass cylinder with its tail exposed to water containing *Schistosoma japonicum* in a Wassermann tube so that the cercariae were more concentrated. Alves exposed his mice to water containing the cercariae of either *S. bovis* or *S. matthei*, and confirmed that the best protection was given by the following ointment, which he is now recommending:

Castor oil	...	...	...	...	40 parts
Lanolin	...	...	...	...	15 parts
Diglycol stearate	...	...	...	...	10 parts
Dibutyl phthalate	...	...	...	...	25 parts
Paraffin wax	...	...	...	...	10 parts

It is difficult to predict how efficacious this method of protection will be, but it is unlikely to be used with the constancy it might deserve. Farmers, miners, and even engineers will probably not cover their hands consistently with the ointment. Anglers may perhaps become infected through exposure of the hands to water

¹ Wright, W. H., Baumen, P. N., and Fry, N., *Amer. J. Hyg.*, 1948, **47**, 44.

harbouring cercariae, yet it is rare to see bilharzia in a person who has only fished and not swum in the water. There is unfortunately little evidence on the extent of this hazard. It is commonly assumed that cercariae can penetrate the skin of any part of the body with equal facility, but this may not be so. The skin of the hands and fingers is thicker and tougher than that of some other parts, and the cercariae may not be able to penetrate it, in which case there would be little indication for the ointment. The second variable factor in assessing the value of the ointment perhaps is that the risk of contracting the disease is greater when exposed to water at a dam or recently constructed project than to swiftly flowing water, to water at an altitude of over 6,000 ft. (1,800 m.) above sea level, or to rivers and lakes which have remained undisturbed for centuries. Men seem to be able to swim off the shores of Lake Nyasa with safety, but not in the smaller side streams entering it, on the banks of which refuse is strewn.

DISSOCIATION IN DEVELOPMENT

It is always easier to appreciate the vagaries of physical development in infancy than to recognize the aberrations of mental development, yet the latter may be of even greater importance. The outstanding "milestones," such as the age at which the head is held up and when sounds and persons are recognized, and the standard of performance with cubes and similar manipulations, are usually noted, and, since A. L. Gesell¹ and his associates brought this subject to the fore in 1925, most doctors have included some simple estimate of mental development when examining infants. With the increasing interest in such conditions as cerebral palsy and behaviour disorders in early childhood the assessment of the mental status and the likely prognosis of affected children are clearly urgent requirements, and any method of examination which will assist in providing this information is to be welcomed wholeheartedly.

Recently R. S. Illingworth² has drawn attention to the significance of dissociation in the different processes of growing up—as in an infant, for example, whose speech acquisition is notably in advance of, or behind, his motor development—and to the ways in which dissociation may be of diagnostic and prognostic value. He considers in particular motor development, which may be related to hypo- or hypertonia, sphincter control, development of speech, and social behaviour. As a result of his studies Illingworth concludes, for example, that isolated delay in motor development is not a sign of mental deficiency, and conversely isolated advanced motor development is not a sign of superior intelligence and may, indeed, occur in mentally defective children. Isolated delay in speech—another common and worrying problem—is likewise not a sign of mental defect and may be present in children of normal or superior intelligence. This is significantly different from delay in speech associated with other signs of retardation, in which the prognosis is bad. As to the age at which infants develop sphincter control, a matter equally

worrying to parents, isolated delay is usually unimportant as a sign of mental development. To appreciate the signs of dissociation adds scope to the methods of assessing child health and represents an advance in technique which is well worthy of study.

ADENOVIRUS VACCINE

The discovery of what are now known as adenoviruses,¹ and the realization that some of these agents are important causes of acute respiratory illnesses in military recruits² while others are responsible for outbreaks of acute pharyngitis and conjunctivitis in civilians,³ gave rise to the hope that a great advance had been made towards identifying the cause of many respiratory infections of otherwise unknown aetiology which bulk so largely as a cause of human incapacity. Vaccines composed of two⁴⁻⁶ or three⁷ antigenic types of adenovirus inactivated by formaldehyde proved effective in preventing the acute infections by adenovirus types 3, 4, and 7, which cause much illness among newly recruited Service men in North America.

The possible value of adenovirus vaccines to civilians, and especially to children, in whom many of these infections occur, has been discussed in recent American papers by M. R. Hilleman⁸ and W. S. Jordan.⁹ Though the distribution of antibodies suggests that adenoviral infections are common in early life,^{3 9-12} relatively few such infections have been detected in general surveys of sick persons.¹¹⁻¹⁷ In various reports reviewed by Jordan⁹ evidence of adenovirus infection had been found in only 0.5 to 3% of civilian patients with various respiratory illnesses. Adenoviruses were uncommon causes of illness in a group of London families¹⁴; and in the U.S.A. they gave rise to only 4% of the respiratory illnesses observed in families in Cleveland¹² and not more than 10% of such illnesses seen in a group of families in Fort Leavenworth, Kansas.¹⁰ In Great Britain, as in other countries, adenoviruses have been incriminated as the cause of outbreaks of generally brief, non-fatal

respiratory illness, such as febrile catarrh in the Army¹⁵ and Air Force,¹⁶ pharyngo-conjunctival fever in children,^{14 15 18 20} and epidemic keratoconjunctivitis^{21 22}; they have also been associated with sporadic infections of the respiratory tract or eyes.^{11 20 23-25}

Adenovirus vaccines may prove useful for preventing outbreaks of illness in special groups such as newly recruited Service men, but on present indications it seems doubtful whether yet another series of injections would be worth while for the prevention of generally minor infections constituting only a small proportion of all the respiratory illnesses suffered by the general civilian population. Among children, however, adenovirus infections may be of greater importance, and it remains to be established whether significantly deleterious effects may result from chronic carriage of adenoviruses in lymphadenoid tissues of the body.

UNEXPLAINED MYOCARDIAL HYPERTROPHY

When the common causes of myocardial hypertrophy have been excluded there still remain a few patients whose cardiac enlargement has no apparent explanation. Asymmetrical hypertrophy of the interventricular septum or part of the wall of the left ventricle has been found in young adults, and Donald Teare¹ has recently described eight cases; three were known to have had auricular fibrillation, and there was some electrocardiographic evidence of conduction defects or myocardial damage. All but one of these eight patients collapsed and died suddenly and unexpectedly. In one family three siblings appeared to have the same condition, and two have died with unexplained asymmetrical myocardial hypertrophy. It is interesting to compare this localized hypertrophy of heart muscle with the diffuse cardiomegaly of familial type^{2 3 4} and with congenital glycogenic "tumours" of the heart.^{5 6} The patients with familial cardiomegaly are usually young adults, who may have heart block and may die suddenly; their hearts show a diffuse myocardial hypertrophy chiefly affecting the whole of the left ventricle. In several cases the myocardial fibres have been found to be vacuolated and contain glycogen. This raises the possibility that familial cardiomegaly may represent von Gierke's glycogen storage disease solely affecting the heart, but W. Evans² did not consider this to be a correct interpretation. Congenital glycogenic "tumours" of the heart are multiple myocardial nodules which are usually found in young children with tuberosus sclerosis,^{5 7} and the muscle fibres show vacuolated "spider" cells with demonstrable glycogen. Although these are often described as rhabdomyomata, they are believed to be of developmental origin^{7 8} or to be related to a glycogen storage disturbance.^{9 10}

The histological structure of asymmetrical hypertrophy appears to differ from that of familial cardio-

megaly and the congenital glycogenic nodules: there is irregular overgrowth of the myocardium with bizarre arrangement of the muscle bundles, and the fibres are not vacuolated. Teare prefers to regard the asymmetrical hypertrophies as hamartomata—developmental tumour-like malformations—rather than true rhabdomyomata. It is not easy to decide if these different myocardial abnormalities are interrelated; the anatomical differences between hearts with a developmental abnormality, a metabolic defect, or a true tumour of the myocardium are not always characteristic. The families of patients with unexplained myocardial hypertrophy should be investigated. When more information is forthcoming it should be possible to decide if the localized, as well as the diffuse, forms of hypertrophy have a genetic basis.

GOLD MEDAL OF THE B.M.A.

Last Monday the new President of the B.M.A., Professor A. P. Thomson, had the pleasant task of presenting the Association's Gold Medal for Distinguished Merit to Lord Adrian, O.M., F.R.S. It was awarded by the Council "in recognition of his distinguished services to medicine, particularly his research in the physiology of the nervous system." Like Sir Henry Dale, the previous recipient of the Medal, Lord Adrian has been conspicuously successful in advancing medicine by devoting his life to experiment in the laboratory. Much of the earlier work of this great physiologist was on the transmission of the nervous impulse, to the study of which he began to apply the electronic equipment, with its relatively crude thermionic valves, of the 1920's. A natural development of this interest was the study of the electric rhythms of the brain, first reported by Berger, and Lord Adrian and his colleagues were pioneers in making a rational basis for electroencephalography. Later he devoted his attention to the transmission of sensory impulses, chiefly for smell and sight. As President of the Royal Society in 1950-5 and Master of Trinity College, Cambridge, since 1951, as well as Vice-Chancellor of the University since 1957, Lord Adrian has shown his guidance outside the laboratory to be as illuminating as it was and still is within it. Another side is touched on in the citation which accompanied the presentation of the Medal: "Yet generations of medical students at Cambridge must have had a picture of you that is probably different from that conjured up by these almost overwhelming distinctions of mind and office, borne with a modesty of corresponding dimensions. It is a picture of a man bicycling from the Great Gate of Trinity to the laboratory and the lecture theatre, where the complexities of the central nervous system were made to seem even attractive by your skilful use of clinical neurology as an aid to understanding: a picture of a man for whom a host of students have felt affection as well as veneration."

Sir James Paterson Ross was re-elected President of the Royal College of Surgeons of England on July 10. Mr. A. Dickson Wright was elected, and Sir Archibald McIndoe re-elected, Vice-President.

British Medical Association

ANNUAL MEETING, BIRMINGHAM, 1958

SUMMARY OF PROCEEDINGS

THE SECTIONS

SECTION OF THORACIC MEDICINE AND SURGERY

Monday, July 14

Cortisone in Lung Disease

With the president, Mr. A. L. D'ABREU (Birmingham), in the chair, Dr. W. BROCKBANK (Manchester) described the use of cortisone in the treatment of asthma. He said that since the introduction of corticotrophin for the treatment of status asthmaticus its place had been established as a valuable remedy. The results of treatment with cortisone in chronic asthma were less definite, and the use of "blind trial" methods, with an inert control, had been necessary to assess results. Although initial improvement was good, deterioration took place after several months of treatment. Seven patients had died unexpectedly, possibly as a result of adrenal atrophy. Disturbing side-effects sometimes followed withdrawal. Accidents, operations, and infections were particular hazards at this stage. There had been an increased mortality from asthma in older patients in recent years. Steroid therapy might be partially responsible for this. Increase in weight was troublesome during treatment, but increase in blood pressure seldom occurred. Antibiotics were often helpful when infection was present. Cortisone was a habit-forming drug, even in patients deriving no benefit from its exhibition. On the whole, long-term treatment had been disappointing.

Steroid treatment was most valuable in the acute phase, not only in status asthmaticus but in patients given to spontaneous remissions. Prednisolone and cortisone were equally effective, though cortisone was preferred because it was cheaper and because complications occurred more slowly. Treatment aimed at starting with a big dose: 300 mg. of cortisone was given on the first day, the dosage reduced by 25 mg. each day, the course lasting 12 days. If patients relapsed a second course could be given safely. Other blind trials had shown that aerosol inhalations of hydrocortisone failed to bring relief, but inhalation of powdered hydrocortisone was helpful. The dose of hydrocortisone by this method was very small: presumably the drug acted by a local effect on the bronchial tree. The inhalation method was most applicable to less severe cases of asthma, but brisk systemic administration over limited periods was the treatment of choice.

Cortisone in Tuberculosis

Dr. N. W. HORNE (Edinburgh) spoke on the use of cortisone in pulmonary tuberculosis. Early work had suggested that cortisone was helpful in tuberculosis, but it was now apparent that it was not only safe but, sometimes, beneficial. In theory, cortisone was used for its pharmacological action in suppressing inflammatory tissue response. This allowed active multiplication of the tubercle bacilli, a stage at which anti-tuberculous drugs were most active. At the same time the harmful development of allergic reactions and fibrosis was suppressed. Cortisone should only be used at the same time as adequate anti-tuberculous drugs, and was often useful in suppressing hypersensitivity to these drugs. Cortisone was definitely valuable in the treatment of tuberculous pleural and pericardial effusions, the duration of the effusion being halved. It was necessary to continue the treatment for three weeks after the effusion had absorbed to

prevent relapses. The value of cortisone in primary tuberculosis had not been established.

Chemotherapy was so effective in the treatment of pulmonary tuberculosis that the place of added cortisone was difficult to assess. Evidence suggested that cortisone was effective in controlling the systemic symptoms in acute cases. It was not effective in hastening sputum conversion or cavity closure. The radiological changes during cortisone treatment were more difficult to assess. Pulmonary function was probably better maintained in patients receiving cortisone. The physiological action of the drug was sometimes helpful in patients with chronic tuberculosis and impaired renal function.

Sarcoidosis

Dr. HUGH SMELLIE (London) reported on the use of cortisone in 45 patients with sarcoidosis who had been under the care of Dr. Clifford Hoyle at King's College Hospital. Cortisone was imperative in patients showing hypercalcaemia or uveitis. Four patients with hypercalcaemia and uraemia had been treated by a low-calcium diet and cortisone with excellent results. Cortisone reversed the increased calcium absorption produced by calciferol. Eleven patients with uveitis had responded swiftly, but seven had relapsed after cortisone had been withdrawn. Treatment should be continued for at least a year. The indications for treating patients with pulmonary infiltration were less definite. Thirty-nine patients had been treated and the results assessed by serial radiographs. Anti-tuberculous drugs were not used. Those treated before infiltration had been present for less than two years did best; but early treatment had to be weighed against the chance of spontaneous recovery. A defect in pulmonary diffusion capacity was an added indication for treatment. Usually the optimum time for treatment was between 18 months and 2 years from the onset. There was a liability to relapse even after a year's treatment: clearly cortisone controlled the sarcoid reaction but did not eliminate the underlying cause.

AIR COMMODORE C. A. RUMBALL (London) confined his comments to the acute form of sarcoidosis as seen in Service patients. The main clinical features of the disorder were arthralgia, erythema nodosum, fever, and sweating. Radiographs showed hilar adenopathy, the sedimentation rate was raised, and proof of the diagnosis could usually be obtained from liver biopsy or the Kveim skin reaction. At a time when cortisone was in short supply the patients had been treated by daily intravenous corticotrophin, treatment being limited to one month. Although patients with this disease showed spontaneous improvement, response to treatment was rapid, symptoms being controlled in two days. Sections from serial liver-biopsy specimens were shown to demonstrate the histological improvement.

Pulmonary Fibrosis

In describing the use of cortisone in pulmonary fibrosis Dr. A. G. W. WHITFIELD (Birmingham) showed the effect of the drug on radiation fibrosis, interstitial fibrosis (the Hamman-Rich syndrome) and collagen diseases. Radiation fibrosis, after treatment for breast carcinoma, responded well. Treatment had to be maintained for at least three months. Even in the late stages cortisone was of some value, although spontaneous improvement sometimes occurred. Anticoagulants had been used in an attempt to prevent irradiation fibrosis: cortisone had also proved an effective prophylactic. Four patients with the Hamman-Rich syndrome had been treated, but there had been no response. Of the collagen disorders, systemic lupus erythematosus responded best. In polyarthritis nodosa, pulmonary infiltration responded to cortisone. The results in scleroderma were disappointing.

Complications of Cortisone Treatment

Dr. STEPHEN GOLD (London) reviewed the indications for cortisone in dermatological practice, and analysed the complications occurring during treatment of 210 patients.

Gastro-intestinal complications included four patients who sustained perforation or haemorrhage. Glycosuria was usually transient and soon recurred when treatment stopped. Two patients had, however, succumbed to diabetic coma. Mental symptoms developed in five patients, one of whom had a previous history of psychotic disturbance. Cardiac failure developed in four patients and was associated with water retention. One patient developed active tuberculosis while on treatment. Purpura, venous thrombosis, and osteoporosis were rare complications. Complications peculiar to corticotrophin therapy were rigors when the drug was given intravenously and abscess after intramuscular injection. It was concluded that complications were rarely severe enough to merit withholding treatment.

In the discussion which followed Dr. W. S. HAYNES (Kenya) described his experiences in treating with prednisolone 40 Africans suffering from tuberculosis. He drew attention to the recurrence of fever and the appearance of a rash when the drugs were withdrawn. Dr. C. M. FLETCHER (London), Dr. K. ROBSON (London), and Dr. G. W. HEARN (Birmingham) also took part in the discussion.

SECTIONS OF OBSTETRICS AND GYNAECOLOGY AND GENERAL PRACTICE

Monday, July 14

Looking at the Cervix

Dr. H. W. DONOVAN (Birmingham), president of the Section of General Practice, took the chair at the joint meeting with the Section of Obstetrics and Gynaecology, when Professor H. C. McLAREN (Birmingham) spoke on the use of the vaginal speculum, without examination by which he regarded no gynaecological examination as complete. In Britain the left lateral or Sims position was generally used, and one lubricated finger was passed into the vagina in order to assess the size of speculum to be inserted. In a tense, nervous patient a satisfactory examination by speculum might be impossible, in which case, if abnormality was suspected, the patient should be admitted for examination under anaesthesia. However, as Professor McLaren demonstrated by lantern slides, the interpretation of the clinical appearance of the cervix was not always easy. The cervix should be regarded as guilty until proved innocent, for now the cytological examination of smears made the diagnosis of pre-invasive cancer possible. General practitioners should therefore be encouraged to screen normal patients by cervical smears at regular intervals, sending the slides to a special centre for reading. If 10,000 fit women were examined in this way there would be discovered 60 women with pre-cancer of the cervix, 20 with early cancer of the cervix, and 10 with cancer of the body of the uterus.

In the subsequent discussion Professor ALEC AGNEW (Vancouver) said that cytological screening was the greatest recent advance in the diagnosis of gynaecological cancer, and described how in his area the general practitioners played the main part in carrying out these examinations. Dr. E. VON KUENSSBERG (Edinburgh) added that in Edinburgh, under the aegis of the College of General Practitioners, family doctors had carried out such a campaign with very encouraging results, especially in the diagnosis of pre-invasive cancer in women under 40 years of age.

Episiotomy

Mr. J. D. S. FLEW (London) read a paper on episiotomy and methods of perineal repair. He said that the indications for episiotomy were to forestall a spontaneous tear; for ease of vaginal manipulations—e.g., in forceps delivery; for all breech and all premature deliveries; to give more room when the subpubic angle was narrow; to help shorten the second stage in the interests of mother or baby; and as a long-term policy to prevent future prolapse. Except when undertaken immediately preceding vaginal manipulations, episiotomy was performed when the presenting part was well on the perineum, so that the consequent relief of ten-

sion would result in immediate delivery. In cases of foetal distress with the head on the perineum, episiotomy would lead to a quicker delivery than would forceps. In forceps extraction the instrument could usually be applied and the head brought down on to the perineum before performing the perineal incision. The anatomy of the area made a median episiotomy ideal, but to prevent extension into the rectum a J-shaped incision was preferred; but in every case the incision must start in the midline at the fourchette and extend throughout the depth of tissue and not merely cut the skin.

If episiotomy were urgent it could be done at the height of a pain with no anaesthetic at all, but local infiltration or pudendal block afforded excellent analgesia for the operation. Mr. Flew thought that about 70% of primigravidae and 20% of multigravidae required episiotomy, but it might not need to be repeated in subsequent labours. In conclusion, he emphasized the necessity for careful apposition of the incised tissues at repair, not only because it made for good surgical practice, but also because it was important for the future marital happiness of the patient.

In the subsequent discussion Dr. MERVYN GOODMAN (Liverpool) stressed the importance of having a good light and adequate exposure in the lithotomy position for repair of the perineum in domiciliary practice. Dr. A. S. VALENTINE (Sierra Leone) and Mr. S. BENDER (Chester) also spoke.

Use of Pessaries in General Practice

Dr. R. H. D. LAVERTY (Coventry), a vice-president of the Section of General Practice, then took over the chair, and Mr. W. G. MILLS (Birmingham) traced the history of the use of pessaries in the vagina from early times. In the first part of the nineteenth century it was said that there were two fortunes to be made out of gynaecology—by those who inserted pessaries and by those who removed them. To-day, although a prolapse or a retroversion causing symptoms could usually be easily cured by surgery, indications for pessary treatment still existed. Thus a pessary might be used as a temporary expedient for postnatal retroversion or pelvic floor relaxation as well as in patients awaiting operation. A pessary could also be used diagnostically to ascertain whether symptoms were or were not due to an associated displacement. The permanent use of a pessary might be indicated in the aged or infirm, but was not satisfactory in certain circumstances, such as when it was easily extruded or caused pressure symptoms or excited a local reaction. The pessary of choice for prolapse was nearly always either round or oval in shape; the fitting of other types (such as the Simpson shelf pessary for procidentia) fell in the field of the specialist. The traditional type of instrument made of compressible material covered with rubber commonly caused a vaginitis with offensive discharge. This could be avoided by using the modern plastic type, which was particularly easy to insert and remove if made of soft polythene.

The patient with a permanent pessary should be re-examined within three months to ensure that the instrument fitted properly and relieved the symptoms. Douching was unnecessary in most cases with plastic rings, but the doctor should inspect the vaginal walls regularly and change the ring for a different size as necessary. In exceptional cases an early prolapse in a post-menopausal woman appeared to be cured by the use of successively smaller rings. Mr. Mills concluded by summarizing that, while the gynaecologist was responsible for deciding that a pessary was indicated and for the initial fitting, subsequent care belonged to the general practitioner.

Dr. G. I. WATSON (Peaslake, Surrey) and Mr. J. D. LLEWELLYN-JONES (Malaya) contributed to the discussion on Mr. Mills's paper.

Brandt-Andrews Technique for Delivery of Placenta

Mr. NORMAN KIMBELL (Peterborough) described the technique for delivery of the placenta which had been described independently by Brandt in 1933 and Andrews in 1940. This method reduced blood loss in the third stage, the

average duration of which was only 8-9 minutes. The most important signs of placental separation were the onset of bleeding from the placental site and a change in the shape of the fundus from discoid to globular. A hand was placed on the patient's abdomen, so that the thumb was parallel to the symphysis and the palm and fingers were on the front of the uterus just above the pubes. Holding the umbilical cord taut, a gentle upward push was made on the uterus without trying to grasp the organ. If separation of the placenta had not taken place, the cord would be drawn upwards. If separation had occurred, the cord would not rise and the uterus could be pushed upwards while gentle cord traction was made to deliver the placenta.

The routine use of ergometrine intravenously, or intramuscularly combined with hyaluronidase, at the close of the second stage increased uterine tone and enabled the placenta to be delivered by the Brandt-Andrews technique within 5 minutes in most cases. The method, the technique of which Mr. Kimbell illustrated by a film, had been used in over 5,000 cases in the Peterborough area since July, 1954, by both midwives and doctors. Sometimes it had obviated the need for manual removal of the placenta from a woman admitted from the district for that purpose. It had saved many hours of midwives' time, but had not increased either the postpartum haemorrhage rate or the number of cases requiring manual removal of the placenta, nor had inversion of the uterus followed in any case.

Mr. Kimbell replied to questions from Dr. MERVYN GOODMAN (Liverpool), Dr. K. G. DICKINSON (Birmingham), Dr. A. FULLERTON (Batley), Miss JEAN HALLUM (Birmingham), Mr. W. G. MILLS (Birmingham), Miss ELSIE WARREN (London), Dr. H. C. W. BAKER (Birkenhead), Dr. H. W. DONOVAN (Birmingham), Dr. G. I. WATSON (Peaslake, Surrey), and Dr. ROSITA RIVERA-RAMIREZ (Philippines).

SEVENTH INTERNATIONAL CANCER CONGRESS

LONDON, JULY 6-12

The Seventh International Cancer Congress was held at the Festival Hall, London, from July 6 to 12, under the auspices of the International Union against Cancer. It was opened by the DUKE OF GLOUCESTER and attended by 2,500 delegates from 64 countries. The president of the Congress was Sir STANFORD CADE, senior surgeon of the Westminster Hospital. The chairman of the British Organizing Committee was Dr. RALSTON PATERSON, and the secretary-general of the Congress Professor R. W. SCARFF.

The main part of our report consists of dispatches from five special correspondents each of whom reviews a principal subject of discussion. The programme included plenary sessions on cancer control, hormones and cancer, carcinogenesis, and the chemotherapy of cancer; lectures by Professor L. BUGNARD (Paris), Dr. CHARLES HUGGINS (Chicago), Professor V. R. KHANOLKAR (Bombay), and Professor L. KREYBERG (Oslo); experimental and clinical group and sectional meetings; sessions arranged by the International Union; and many proffered papers.

Presidential Address

At the opening ceremony on July 7, Professor J. H. MAISIN (Louvain), president of the International Union, installed Sir STANFORD CADE as president.

The purpose of the Congress, said Sir STANFORD in his presidential address, was to take stock of present knowledge on cancer, analyse the accumulated facts, and critically review the different opinions on debatable points. The Organizing Committee had chosen for consideration what he would term "the front-line advance in cancer research" and the most urgent, important, and promising clinical subjects. Picking out certain of these for comment, Sir Stanford noted the ever-increasing role of biochemistry in cancer research; the reasoned thought which was result-

ing in sounder surgical judgment—"the concept of cancer as a biological disturbance and not merely as a tumour has resulted in surgery being more selective, more discriminating, and serving perhaps a fewer number of patients but to a better purpose"; radiotherapy, which had achieved broader, safer, and more effective reaches of usefulness; and the development of chemotherapy, which alone, or in combination with surgery, or even as an umbrella against implantation of cancer cells during operation had widened the group of medicinal remedies against cancer. Hormonal regulation of cancer of the breast and prostate had made no longer tenable the belief that cancer is autonomous, uncontrollable, and independent of the normal physiological processes. There was a crescendo of progress from the cruder methods of surgical ablation, once the only weapon, to the more selective action of radiation, applicable to an increasing number of patients, the specific effect of chemical substances useful in a limited group, and the physiological methods of hormonal control in two sites.

Progress in early diagnosis was slow; it depended upon the doctor's awareness of cancer and the patients' belief that early advice was always to their benefit. Even prevention of cancer was not beyond the hope of achievement. To-day cancer was indeed "captain of the men of death." It was the universal enemy of mankind. It called for a united international effort.

At the close of the Congress it was announced that the Eighth International Cancer Congress will be held in Russia in 1962. Professor ALEXANDER HADDOW has been nominated president-elect.

I.—CARCINOGENESIS

In the field of non-viral carcinogenesis it is fair to say that no startling new advances were reported. After listening to a number of individual reports, and several general lectures and discussions, one was left with the impression that the various groups of workers in this field are less rigidly divided in their outlook than formerly. The point was made on several occasions that cancer may arise in many ways and that the common factor, if there is one, is to be looked for not in the properties of the agents, exogenous or endogenous, which produce it, but in the type of disturbance which they produce. This disturbance was variously described: a continually stimulated proliferation without the inhibition which normally follows seems its most general property. This may result simply from separation of tissue from its normal contacts, as in the connective-tissue tumours which develop close to plastic or metal sheets implanted subcutaneously in rats by Dr. and Mrs. E. T. OPPENHEIMER and their colleagues (New York), and others, or in pituitary glands implanted subcutaneously in normal mice by Professor O. MÜHLBOCK (Amsterdam), or merely by long-continued culture of tissues *in vitro*. Interference with one of the normal feed-back systems has a similar effect, as in the various cases of tumour development in endocrine glands produced by diversion of their secretions or removal of their target organs, as described by Dr. J. FURTH (Boston) and Professor F. BIELSCHOWSKY (Dunedin).

Mode of Action

That carcinogens often act not directly upon the cells which become neoplastic but on some other tissue or tissues was the conclusion to be drawn from a number of different observations. Dr. H. S. KAPLAN (San Francisco) developed this general theme. Of the examples of such action perhaps the most striking is one which he himself has described—namely, the development of lymphomas in normal thymus glands transplanted to thymectomized, totally irradiated mice. These tumours are sometimes of host, sometimes of donor, origin; in the latter case carcinogenesis is certainly indirect, since the graft has not been irradiated. Some observations of Professor J. W. ORR (Birmingham) brought further support for the hypothesis of indirect action.

In order to bring chemical carcinogenesis into line with this general scheme various theories were put forward. That

of the Madison, Wisconsin, school was represented by Dr. C. HEIDELBERGER and Dr. V. R. POTTER. It assumes that carcinogens combine specifically with certain essential cell proteins, which are then eliminated from the cell. The loss is permanent, and results in uncontrolled growth. Exactly how is not stated. Dr. POTTER suggested a possible mechanism—namely, that a biosynthetic pathway might be stimulated by the deletion of a competing catabolic pathway. He and Dr. S. WEINHOUSE (Philadelphia) agreed that Warburg's theory that the carcinogenic change consists of an irreversible damage to the respiratory mechanism of the cell is no longer tenable. This is a highly speculative field; moreover, the main evidence on which the theory of specific protein deletion is based has been severely criticized, notably at this congress by Dr. D. L. WOODHOUSE (Birmingham), who showed that the case for specific union between carcinogens and cell proteins is not as firmly established as was claimed. Another criticism of a theoretical kind is that since the cellular change produced is heritable it must involve nucleic acid, and, whereas it is known that transmissible "information" can pass from nucleic acid to protein, there is no evidence that the reverse procedure ever occurs. Those that use this argument conclude that the essential attack of a carcinogenic agent is on the nucleic acids, and that alteration or loss of proteins must be secondary or incidental, although quantitatively greater.

Another view, which is constantly reappearing in new forms, is that carcinogens increase the frequency of mutations, assumed to be occurring at a low rate in normal somatic tissues, which confer on the mutant cells a selective advantage in resisting normal growth controls. Sir MACFARLANE BURNET (Melbourne) developed this theory, and expressed the opinion that the study of cancer as a problem in population genetics is likely to be fruitful.

The two-stage theory of carcinogenesis received rather less attention than in recent years. Professor K. SETÄLÄ (Helsinki), who has previously reported a tumour-promoting action on mouse-skin of very large doses of certain commercial surface-active substances, described similar effects by specially synthesized substances of this class where the presence of impurities could be virtually excluded. These observations have caused concern for some years because of the increasing use of surface-active substances as detergents and as food additives. This concern is likely to be increased by Dr. P. SHUBIK's (Chicago) demonstration that one of these substances ("Tween 60") is weakly carcinogenic as well as tumour-promoting on mouse-skin.

Cancer of the Bladder

The debt which experimental research in this field owes to clinical observation, especially in industrial medicine, was freely acknowledged. The remarkable series of researches on bladder carcinogenesis by Dr. G. BONSER and her colleagues in Leeds and Dr. W. C. HUEPER in Bethesda, U.S.A., all derive from observations of the high rate of bladder cancer in dye workers. Dr. BONSER and Professor E. BOYLAND (London) emphasized that we now know enough about bladder carcinogens to make it reasonable to hope that we may be able to eliminate most of the potentially dangerous substances of this class from our environment, or to antagonize their action.

Aetiology of Lung Cancer

Professor L. M. SHABAD (Moscow) described the great reduction in benzpyrene content of the atmosphere of a new industrial town in Russia (Angarsk) by improved methods of fuel combustion and smoke control.

Contributions to the tobacco-lung-cancer problem were numerous. Those who spoke on this subject appeared more willing than formerly to accept the possibility of multiple factors in the causation of lung cancers. Professor L. KREYBERG (Oslo) stressed the importance, and also the difficulty, of accurate histological typing of lung tumours. His careful surveys provide a firm basis for detailed correlation between the frequencies of different kinds of lung

cancer and exposure to tobacco, dusts, and other environmental conditions. The conclusion, previously suspected but now firmly established, is that only squamous and undifferentiated (oat-cell) tumours can be associated with smoking habits. Many puzzles remain: for instance, Dr. E. V. COWDRY (St. Louis) pointed out that histological changes often regarded as precancerous, such as squamous metaplasia, were at least as common in the trachea as in the bronchi, yet cancer is uncommon in the former, common in the latter. Some light relief from these serious, sometimes sombre, deliberations was provided by Professor P. R. PEACOCK's (Glasgow) film showing the gradual conditioning of fowls and other creatures to the practice, and apparent enjoyment, of cigarette smoking: no lung tumours have so far resulted. The application of tobacco tars to various animal tissues still gives widely differing results in different hands. While tumours have been produced with whole tar, and certain crude fractions, in several laboratories, no single constituent has so far been incriminated. The view that a combination of several constituents of tar are involved, possibly in conjunction with atmospheric pollutants, is gaining ground.

Dr. R. DOLL (London) dealt with the criticisms which have been made of the statistical evidence, and concluded that a causal connexion with smoking was still the most probable explanation of the observed facts. Professor W. C. HUEPER (Bethesda) stressed the possible role of metal dusts, not only in industrial workers but also in the general population. Dr. E. L. WYNDER (New York) has been trying to modify methods of cigarette manufacture so as to reduce the hydrocarbon yield on burning. This is an approach of considerable practical interest.

Radiation Hazards

The role of radiation in the aetiology of human cancer also received attention. Dr. R. DOLL pointed out that, although acute leukaemia, monocytic leukaemia, and chronic myeloid leukaemia are positively associated with previous exposure to irradiation, a similar association in the case of chronic lymphatic leukaemia is uncertain. Both this speaker and Dr. R. H. MOLE (Harwell) were of the opinion that there is no threshold dose below which irradiation is safe. Others were inclined to believe that a threshold exists in some cases, but all were agreed that it is hard to conceive an experiment or survey likely to establish this point with certainty. An interesting contribution in this field was that of Professor N. PETROV and his colleagues from Leningrad, who reported the production of a significant number of bone tumours in monkeys by intramedullary implantation of radioactive substances, though these animals are highly refractive to the action of chemical carcinogens applied by this as well as other routes.

II.—VIRUS-INDUCED TUMOURS

In the few years since the Sixth Cancer Congress in São Paulo both the scope and the amount of research into virus-induced tumours have increased tremendously. Dr. L. GROSS (Bronx, New York) has very recently discussed the viral aetiology of mouse cancer in this *Journal* (July 5, p. 1), and it was unfortunate that illness prevented his participation at the last moment in this Congress. For the centre of greatest interest in the viral field was undoubtedly mouse leukaemia and the other tumours produced by this virus or virus-complex.

Mouse Leukaemia

Dr. GROSS has now found that 50% of young, adult C3H mice—of his "low leukaemia" strain—develop leukaemia after irradiation with 150-200 r per week for four or five weeks. Filtered extracts from such tumours were inoculated into newborn C3H mice: 11% developed leukaemia (at 13 months average age) and 5% parotid tumours (at 10 months). Cell-free extracts of normal organs of healthy adult C3H mice inoculated under the same conditions gave rise to only 0.5% leukaemia (at 17 months),

but also, paradoxically, 7.5% parotid gland tumours (at 4½ months)—which therefore arose faster than in the treated group. Serial passage of the leukaemia agents in newborn hosts was found to increase the potency to such an extent that older, suckling mice could be infected.

Since Gross's first reports in this field a number of similar observations have been made. Professor A. GRAFFI (Berlin-Buch) and his colleagues are working with a mouse myeloid (chloro-) leukaemia. The same agent was derived from a number of different, spontaneous mouse carcinomas and sarcomas—but carcinogen-induced sarcomas gave negative results. The tumour yield from the filtrates was dependent upon the age of the hosts at the time of inoculation; it fell from some 40–50% between 1 day and 11 days to 22% at 3–4 months. Splenectomy before injection of the filtrate reduced the number from 72% in the controls to 8%, but if the splenectomy was delayed for one to two months after inoculation the tumour yield rose to 54%. The filtrate appeared to contain a particulate agent with the properties of a nucleoprotein. It was not highly antigenic for mice, as hyperimmune mouse serum did not fully inactivate it, but normal rabbit serum and rabbit anti-mouse bone-marrow antiserum gave no inactivation. Attempts to culture the agent on chorio-allantoic membrane appeared to be unsuccessful during the first ten passages, but at the eleventh passage tumours were produced in 78% of the inoculated mice.

A leukaemia, serially transmissible by cell-free filtrates to adult mice, was described by Dr. C. FRIEND (New York). This disease, unlike those of Dr. Gross and Professor Graffi, is characterized by a very short incubation period of about two weeks. The agent is immunologically distinguishable from normal mouse spleen and serum proteins. Immune sera from rabbits and mice neutralize the agent's infectivity, but sera from mice with other types of transplantable or "cell-free filtrate"-induced leukaemias, and sera from man, both normal and leukaemic, do not contain neutralizing antibody. It is possible to immunize mice with a formalin-treated virus vaccine: 80% of the animals given three intraperitoneal vaccinations resisted challenge with either virus or leukaemic cells and remained completely free of the disease. A similar cell-free agent derived from the brain of a C3HeB mouse bearing a spontaneous leukaemia, and inoculated intracerebrally or intraperitoneally into adult mice of the same strain, was reported by Drs. H. M. SCHOOLMAN, S. O. SCHWARTZ, W. SPURRIER, and P. B. SZANTO (Chicago) to give a 70% yield of leukaemia.

Tissue Culture of Mouse Leukaemia Agent

These agents are intriguing enough, but Drs. S. E. STEWART, B. E. EDDY, and M. F. STANTON (Bethesda) were able to culture a mouse leukaemia agent on trypsinized mouse-embryo mince. The supernatant fluids from such cultures contained an agent which produced multiple types of tumours in 60–100% of newborn mice of two different strains. All tumour-bearing mice had pleomorphic tumours of the salivary glands, and many had up to eight other types of unusual primary tumours and lesions. The latent period between inoculation and tumour production varied from a few days to several months. Further, and yet more remarkable, this mouse-derived agent was not species specific. Tumours have also been produced in rats, rabbits, and hamsters. In the hamster—and for this animal it was not even necessary to use newborn animals—sarcomas of the heart, kidneys, and subcutaneous tissues were the commonest tumours, but many had also haemangio-endotheliomas of the liver and lungs. The agent was highly antigenic, and tumour induction in mice was completely inhibited by passive immunization with rabbit antiserum.

Two other, distinctive, approaches to the subject were described by Dr. R. LATARJET (Paris) and by Dr. J. RYGARD (Copenhagen). The former has tested extracts of leukaemic Ak mouse tissues in newborn isologous mice. The appearance of spontaneous leukaemias in this strain was accelerated, and in a few cases various multiple malignant tumours

appeared. The agent was resistant to enzyme digestion with proteases and nucleases, and preliminary results with inoculated purified nucleic acids from leukaemic tissue suggest that these acids may have some influence on the tumour incidence. Dr. RYGARD has found that some treatments which induce leukaemia in mice also lower their resistance to infections, and has correlated this with a depression of phagocytosis as judged by the rate of clearance of colloidal radiogold from the blood. Furthermore, he found that 2–4-day-old mice also show a low blood-clearance.

In electron micrographs Drs. L. DMOCHOWSKI and C. E. GREY (Houston) and L. GROSS (Bronx, New York) claim to be able to identify the agent in the induced parotid tumours. While Professor A. D. TIMOFEEVSKY (Moscow) reported that he and his colleagues have observed particles 40–80 millimicrons in diameter in a large proportion of human tumours. Fewer particles were present in normal tissues. There was some evidence that these globular virus-like bodies could be cultivated, together with living tissue, on chorio-allantoic membrane, and they had a distinctive antigenic composition.

Mouse Mammary-tumour Agent

The mouse mammary-tumour agent was the subject of four communications. Dr. D. H. MOORE (New York) correlated its physical and biological properties, and in an attempt to fit in all the evidence from filtration, irradiation, diffusion, and biochemistry was forced to postulate the presence in the milk of a particulate inhibitor intermediate in size between two different active forms of the virus. Dr. H. B. ANDERVONT (Bethesda) has observed, within the past few years, the disappearance of the tumour agent from two female mice of the RIII strain—i.e., mammary cancer was absent from their descendants. Current experiments are being directed to finding out whether the disappearance is a result of a change in the agent, in the mice, or in both.

Dr. M. K. DERINGER (Bethesda) produced a substrain (C3He) of strain C3H mice by transfer of fertilized ova from a C3H female to the uterus of a mated C57BL female. The young were nursed by their "foster-mother" until weaned. The new agent-free strain showed a very high incidence of hepatomas—59% in virgin females, 27% in breeding females, 38% in force-bred females, 54% in stilboestrol-treated males, and 91% in breeding males. Recent studies on the mouse mammary-tumour agent were also reviewed by Dr. J. J. BITTNER (Minneapolis).

Viral Tumour of Monkeys

A new virus producing benign fibromatous lesions in rhesus monkeys was described by Dr. C. H. ANDREWES (London) and his colleagues. A year ago at the West African Institute for Medical Research in Nigeria a rhesus monkey in an outdoor cage developed a rapidly growing nodule on the eyebrow. Within the next few months similar growths appeared on the face or limbs of 20 other rhesus monkeys and a baboon. Serial transmission studies showed that the pox-like virus produces large growths which spontaneously regress after about a month. The virus passed a 0.65 μ gradocol membrane, and smears from the growths showed abundant D.N.A.-containing elementary bodies resembling those of vaccinia. Tissue cultures of monkey kidney could be infected and the virus multiplied giving cytoplasmic inclusions and elementary bodies similar to those in the growth themselves.

Benign fibromas in Virginian white-tailed deer also have been investigated by Drs. K. R. DUMBELL (Liverpool), R. MANGOLD and L. G. MACNAMARA (New Jersey), and R. E. SHOPE (New York). This filterable agent was transmitted experimentally to other deer. The incubation period was prolonged and the regression rate high. The few experimental growths that did persist eventually approached, in size and appearance, the naturally occurring ones.

Drs. P. ROUS, S. ROGERS, and J. G. KIDD (New York) transplanted metastatic tissue from the Shope rabbit carci-

noma into newborn rabbits. Many tumours could be propagated serially, and extracts of some 50% of them, inoculated into the hyperplastic skin of adult rabbits, gave a few typical papillomas but no carcinomas. Papilloma virus antigen appeared, however, to be present in the transplanted tumours. A similar phenomenon was discussed by Mrs. M. L. DURAN-REYNALDS (New Haven) and her colleagues. Cortisone treatment of rabbits with regressing methylcholanthrene-induced skin tumours brought about a reactivation, which reversed when the daily cortisone was discontinued. During the stage of active cortisone-induced growth, a filterable agent could be recovered which induced, both grossly and histologically, a papilloma-like lesion.

A number of interesting studies on filterable chicken sarcomas and leukoses—where a viral aetiology is unquestioned—were also reported, but there is no space to summarize them here.

Future Research

In brief, one's immediate impression is that two main factors account for the great advances reported on the viral aetiology of mouse cancers. The first is the use of newborn test animals. The second is the successful propagation of the virus in tissue culture. The latter procedure may result in a considerable augmentation of both virulence and titre. The former has an obvious corollary: that together with a search for new agents—and it may not be long before cell-free filtrates from human tumours will be shown to produce tumours in mice and hamsters—a close study should be made of the reactions of newborn animals to antigenic "insults" of this kind, and, in particular, to the possibility of the animal having acquired an immunological tolerance to a "latent" agent.

III.—IMMUNOLOGY AND IMMUNOGENETICS

Present attempts to discover immunological differences between malignant and normal cells may be expected to shed light on the aetiology of cancer and perhaps also, in the future, on its treatment. Much experimental work in this field involves of necessity the study of tumours that can be serially transplanted, which in turn demands the use of pure lines of animals. Members of such inbred strains, like identical twins, have the same genetic and antigenic constitution. Until very recent times it was only from the mouse that such stocks had been raised, and this is why such extensive use has been made of this species.

Antigenic Changes in Cancer Cells

Recent hypotheses relate malignancy to the loss of cellular components which, it is postulated, are essential to the normal control of cell multiplication. On the other hand, the finding of additional antigenic components in virus-induced tumours is hardly unexpected. Their appearance in other tumours, whether indicative of virus action or not, raises distant therapeutic possibilities. For it is clear that tumours, unlike normal tissues, may survive and grow despite certain degrees of antigenic disparity between them and their hosts. In such experimental situations passive and active immunization have been effected. In fact Dr. G. D. SNELL (Bar Harbor) described such a procedure in his further analysis of the genetic factors influencing the transplantability of tissues in the mouse. He used paired inbred strains whose selected genetic (and hence antigenic) differences were too slight to cause the mutual rejection of grafted tumours. But prior immunization of one strain with the normal tissues of the other protected the host from the otherwise fatal tumour grafts from the partner strain. He has used this method to investigate minor antigenic differences which would cause rejection of a skin graft for example, but which do not suffice to destroy genetically comparable tumour tissue.

Several investigators have attempted the production of antibody fractions directed specifically against tumour antigens. Dr. I. L. SPAR and his colleagues (Rochester, U.S.A.),

using a radioactive label, showed that such preparations when injected into tumour-bearing animals may be selectively taken up by tumour tissue. However, it was by no means certain that this occurs as a result of the simple immunological reaction originally proposed. Be that as it may, the suggestion that such preparations may serve as carriers of radioactive or chemotherapeutic agents and bring about their concentration in the target cells is a hopeful one.

The acquisition of new antigens is not of course incompatible with loss of others. Dr. E. WEILER (Pasadena) demonstrated the disappearance of organ-specific antigen (antigen common to the species but peculiar to a particular tissue) from the liver of rats during the evolution of chemically induced hepatomas and, similarly, from the kidney during the development of stilboestrol-induced renal carcinoma in the hamster. He has recently shown that this latter antigen is apparently lost within a very short time in tissue culture, probably after only a few cycles of cell division. He finds that these antigens are confined to normal liver parenchymal cells and normal renal tubular epithelial cells respectively—that is, to the cells from which these tumours arise. There is as yet no evidence that this loss is in any sense a causal rather than a secondary event, nor that it has any bearing on the changes, possibly allied to malignancy, which accompany the derivation of continuously propagated lines of cells from normal tissue in culture.

Serological Test for Tumour Antigens

Professor L. A. ZILBER and his associates (Moscow) have used an ingenious and sensitive technique for the detection of additional antigens in human and animal tumours (including a chemically induced hepatoma of an inbred strain of mice). Guinea-pigs are sensitized to fractions of tumour tissue and later desensitized with comparable fractions of normal tissue. They are then challenged with the tumour fractions. Anaphylactic reactions denote residual sensitivity to antigen(s) absent from the desensitizing preparations. Their results with this and other methods lead them to recognize that the appearance of these new antigens may be accompanied by some loss of normal tissue antigen, but they at present differ from Dr. Weiler in their views on the extent to which organ-specific antigens are affected.

Reports by Professor G. KLEIN and Drs. E. KLEIN and K. BAYREUTHER (Stockholm) indicate that other kinds of antigens may be suppressed. Their methods enabled them to detect variants from among the cell populations of sarcomas arising in hybrid mice. By transplantation and other tests they showed that, in some tumour-cell lines so derived, iso-antigens (cellular antigens present in some but not all strains of the species) are either lost or suppressed. This is in keeping with extensive previous work on the apparent loss of iso-antigens by tumours in the course of serial transplantation. It also draws attention to the heterogeneous nature of tumour cell populations and the influence of intercellular variation and selection in the successive stages of their evolution towards increased autonomy. These workers made the striking observation that each new sarcoma displayed individual characteristics in the production of variants, although all were histologically similar and had been induced by the same dose of carcinoma in the same tissue of genetically identical mice. By contrast Drs. L. SACHS and M. FELDMAN (Rehovoth, Israel) support the view that in some instances tumours can acquire increased "antigenicity" in response to immune reactions, enabling them to neutralize the host's output of cytotoxic antibodies.

Interpretation Must be Cautious

Some account of current misgivings is perhaps as important as accounts of current research. Dr. P. GRABAR (France) pointed out the need, particularly important to aetiological concepts, to distinguish between absolute and merely quantitative changes in tumour tissue. Dr. T. S. HAUSCHKA (U.S.A.) and Dr. P. A. GORER (London) both

Motoring News

DEPRECIATION

The eternal problem of counteracting wear and tear on motor-cars confronts us all at some stage or another, and there comes a time when decisions have to be made on whether the car should be done up or exchanged for a later model. Car dealers have never been the most popular members of the community, for they are often accused of making large sums of money out of the simplest of business transactions. But they have to live, and, though a few do make big money, trade is seasonal and they sometimes have to cover their losses on narrow profits. The wise car-owner can therefore take advantage of this if he chooses the right time of year to trade-in his used model.

The owner of a small popular model has little to fear from the dealer, because the resale value of modern cars of low horse-power is very high. Demand is great because of their economy and low insurance rates, and they can still be sold easily third- or fourth-hand.

The financially economical period of use for a small car such as a Morris Minor is, in theory, about two years. After this time its basic value begins to drop off, depreciation figures on tax accounts begin to level off, and repair charges loom ahead. The more expensive car, say one costing just over £1,000, retains its value only if it is a popular model which is reasonably economical for its size and is not likely to be superseded by a new model in the near future. A typical example of a car in this group which is selling well at present is the Austin A90. Care is needed when buying the more expensive type of car, since the greater the initial cost the more will the price drop when selling time comes round.

As to the medium-priced luxury models, of which the Rover range are among the best sellers, five years would be an economical period of ownership for a car of this sort if the user is to recover the considerable initial outlay by way of lower repair charges on a quality model which will last well for a number of years. In fact, by careful buying and selling, cars in this class can sometimes be sold after five years for very substantial sums if they have been carefully looked after, often for as much as would be realized on the sale of two cheaper smaller cars used over the same period. But this may be exceptional; it happens to apply to Rovers, while the less popular luxury models often lose value quickly. Buyers of this type of car can afford to buy them new, and second-hand prices have to be slashed to attract the small minority of purchasers who just cannot afford the new price. Though petrol consumption has to be taken into account, many G.P.s find it no more of a financial burden to run a large car and claim considerable tax relief on heavy garage bills than to suffer the relative discomfort of an economy car with the correspondingly small tax allowance on fuel and repairs.

In most cases favourable part-exchange terms are obtained by disposing of a car in favour of a similar new model, preferably through the same dealer as supplied the old one. In this way the trade-in loss covers the running costs for, say, two years, and one starts off with a new model again. This process has to be kept up, however, for if the gap between new and old is allowed to grow then the price gap becomes too great. Many country doctors doing large annual mileages adopt this scheme; the cars are supplied and serviced by the dealer concerned and exchanged at a pre-arranged price.

Car Radios

There are no hard-and-fast rules about which radio sets perform best in which cars, and, unless the makers them-

(Continued at foot of next column)

To-day's Drugs

In this column we publish from time to time authoritative notes on a selection of drugs in current use.

Sandosten+Calcium (Sandoz Products Ltd.).—Sandosten is the proprietary name of the antihistamine drug thenalidine (or thenophenopiperidine) tartrate, and it is recommended that it should be given in conjunction with calcium. Tablets are available each containing thenalidine tartrate 25 mg., calcium lactate 579 mg., and calcium gluconate 794 mg. This antihistamine drug is also marketed in ampoules for intravenous injection, in an ointment, a syrup, and a nasal spray.

This combination does not seem to have been tried extensively in Great Britain and the reports of clinical trials emanate from the U.S.A. Internal treatment, with or without local application of the same substance, is reported to have given the best results in allergic rhinitis, but good results also in allergic skin conditions, notably contact eczema, atopic eczema, and urticaria. The duration of action is four to six hours, so that treatment should presumably be given three or four times daily. The few published clinical trials report a very effective action combined with the minimum of side-effects and toxicity.

N.H.S. basic price: 100 tabs., 19s. 8d.

Debendox (Riker Laboratories Ltd.).—Each tablet contains dicyclomine hydrochloride 10 mg., doxylamine succinate 10 mg., and pyridoxine hydrochloride 10 mg.

Since the exact pathogenesis of pregnancy sickness is still unknown, a variety of drugs is being used to counter or prevent it and to reinforce dietary and other advice. The drugs fall largely into three groups—sedatives and antispasmodics, antihistamines, and B vitamins—and there are several proprietary preparations which contain a combination of different drugs from the three groups, as does debendox. Dicyclomine hydrochloride is an antispasmodic, weaker than atropine and having some local anaesthetic action. Its value in the treatment of peptic ulceration and for conditions of increased gastro-intestinal mobility has been reported on favourably. Doxylamine succinate is one of the less active but longer lasting antihistamines. Pyridoxine is vitamin B₆. The tablets are coated so that absorption is delayed and the anti-emetic action takes effect four to six hours after ingestion. The recommended dose is therefore two tablets at bedtime so as to counter the early morning attack which is the usual, but not constant, feature of pregnancy sickness.

N.H.S. basic price: 100 tabs., 38s.

(Continued from preceding column)

selves specify a particular set, trial and error is really the best method of finding them, particularly portables. The small battery-mains portable or transistor models are ideal for use in the car, and they can be taken out for picnics or home use. Battery-mains models will give better reception in a car than battery-only examples. Built-in sets are now available with push-button controls even in the cheap cars. They are a much better buy than manual-tuning sets because there is little difference in the price and the cheapest push-button ones give very good reception. Those fitted in Rover and Humber cars are really good and are well worth the money asked. The Ekco radios on Fords give good reception, though most have manual tuning. Aerials, like the sets, vary too, and their positioning for best results depends largely on where the car is being used (since certain parts of the country have better radio reception than others) and on the set fitted.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Ectopic Pregnancy after Pelvic Tuberculosis

SIR.—Tuberculosis of the female genital tract is a comparatively frequent cause of infertility, and, although the incidence may not be increasing, modern diagnostic methods have allowed the condition to be discovered more often. The finding of an active tuberculous lesion in the endometrium may be associated with gross pathology in the Fallopian tubes and there may be corresponding symptoms of pain and heavy periods. In many cases, however, there is no complaint beyond the infertile marriage. Treatment has been completely altered by modern chemotherapy. Surgical removal of the pelvic organs was formerly practised with some success, but conservative surgery frequently led to fistulous complications, while radical removal could on occasion prove extraordinarily difficult. The patient with quiescent disease would often remain untreated. It was natural that streptomycin and allied drugs should be adopted as an alternative to surgery, and this conservative medical treatment is now widely used.

It is the purpose of this letter to draw attention to a complication of this medical treatment that has not received sufficient notice. I refer to the increased incidence of ectopic pregnancy among these patients, and I attribute this directly to the resolution of the active tuberculous salpingitis that accompanies many (if not all) cases of endometrial tuberculosis. Unfortunately the tube seems often to be left patent but inert, so that the active spermatozoa can migrate but the passive fertilized ovum cannot be propelled into the uterus. Among 29 patients seen personally with pelvic tuberculosis there have been six tubal pregnancies. The two most recent are described briefly below.

* Mrs. R. S. complained of infertility after only a year of married life and had an ovarian cyst impacted in the pelvis. Her husband's seminal analysis was normal. At laparotomy (September 9, 1957) the dermoid was removed, but chronic interstitial salpingitis suggested tuberculosis, which was confirmed by culture and sub-curettage. Treatment with streptomycin and P.A.S. and subsequently isoniazid was given and she was awaiting curettage of the uterus. Pregnancy continued on March 20, 1958.

Mrs. M. B., aged 26, complained of infertility and vague pelvic pain. Two salpingograms showed abnormal results with inadequate tubal spill, and a diagnosis was made of chronic pelvic adhesions, probably associated with appendicitis in the past. At laparotomy on October 8, 1956, chronic interstitial salpingitis was discovered and tuberculosis confirmed on examination of curettings. Chemotherapy with streptomycin and P.A.S. was given for three months, after which curettings were proved negative. A baby was adopted, intercourse became relatively infrequent, and the tubal pregnancy ruptured on June 30, 1958.

There are patients in whom it may be right to foster the tiny hope of successful pregnancy following medical treatment for pelvic tuberculosis, but the disease will surely exact a toll of ruptured ectopics. The day may yet dawn when patients will be asked to accept the almost inevitable infertility of pelvic tuberculosis, and after adequate chemotherapy the diseased tubes at least will be removed. In the case of each patient reported above, *both* tubes were excised at operation, for which the husbands as well as their wives were demonstrably grateful.—I am, etc.,

WILFRED MILLS.

WILFRID MILLS.

Ring Pessaries

SIR,—Dr. D. N. S. Robertson and Dr. F. D. Stott, in their admirable memorandum on "polythene" ring pessaries (*Journal*, July 5, p. 30), mention that they are suitable for those women for whom an operative cure would be an unwarranted risk, for those who refuse to undergo surgical repair, and for women in the midst of their childbearing.

though they do state that surgical repair is the ideal method of treating this common disability. They then proceed to state the advantages of polythene over rubber and vulcanite. They make no mention of celluloid rings, which have been available from Allen and Hanburys Ltd. for many years. I have used them in a great many cases for about 12 years, and have found them most satisfactory. They are inert, produce no tissue reaction and no vaginal discharge, so that douching is not necessary. They do not compress for insertion in the introitus, but when immersed in boiling water for a few seconds they soften and can be bent to any shape, hardening immediately on cooling.

It is my experience that few women need a circular ring, that indeed a circular shape keeps the vaginal walls stretched and does not encourage them to regain their tone, while a pear-shaped support, somewhat like an Albert Smith pessary and wide enough at the base to ensure that it remains *in situ*, is easily inserted. It is always possible to make the patient completely comfortable by altering the shape—for example, to take pressure off the rectum, or give more support to the bladder. I believe that operative measures are often unnecessary where such a pessary is worn for long enough in cases of prolapse after childbirth and combined with exercises to improve muscle tone. It is usual to find that gradually a smaller size becomes necessary as the muscle tone improves, until no further support is required. I well remember one patient, a farm labourer's wife, who presented with a procidentia after her thirteenth confinement: she needed a 95 mm. ring to begin with, but gradually improved and needed narrower and smaller pessaries (she ended up with a 65 mm.), until after four years she was restored to normal and the pessary removed. It is, of course, likely that there will be a recurrence of the prolapse when such patients are much older, but at such a stage it is usually much easier for patients to submit to operation, which can create so many problems for a mother with a young family.—I am, etc.,

London, N.W.1.

ELEANOR MEARS.

Cardiac Arrest

SIR,—I am interested to see in the article on cardiac arrest by Dr. D. W. Blair and his colleagues (*Journal*, June 28, p. 1521) a statement of the need for a visual pulse monitor. I have been using a simple instrument of this type for some eight years and have found it extremely useful. It was described in the *British Medical Journal* (1952, 1, 1188), but the circuit given there has since been improved. No "electronic" parts are used in the electrical circuit, and it is cheap, portable, and easily constructed. As it does not depend on the electrical activity of the heart but on pulsation in the arterioles of the finger pulp, a severe fall in blood pressure or an ineffective peripheral circulation is shown at once and so too are cardiac arrhythmias or variations in output.

I have not been able to interest British instrument manufacturers in the device, but it is made by several firms in the United States.—I am, etc.,

Stow on the Wold.

V. J. KEATING.

SIR,—Dr. D. W. Blair and his colleagues (*Journal*, June 28, p. 1521) are surely right to re-emphasize the need for vigilance in the use of neostigmine, and to attribute their case of cardiac arrest to its too-rapid injection after what might seem a possibly inadequate dose of atropine. Correctly used, neostigmine is a very safe antidote to curare or gallamine, but a sound "drill" should be adopted, such as the following:

Having decided that neostigmine is needed, atropine is given intravenously, the dose (commonly up to 1/50 of a grain—1.3 mg.) depending largely on the anticipated total dose of neostigmine which is to follow. In abdominal cases the atropine is best given just before starting peritoneal closure. Once the peritoneum is securely closed and atropine-induced tachycardia established, the pulse is timed and the state of respiratory activity (or lack of it) noted. The anticipated necessary total dose of neostigmine (usually between 1 and 3 mg. in adults) is then drawn up

and one-third of it injected intravenously. Two minutes later the pulse and respiration are again observed and the second third injected. The last fraction is similarly given two minutes later again, but each injection is preceded by observation of the respiratory activity to make sure that it is necessary, and of the pulse rate to make sure that it is safe, the aim being to have the patient leave the theatre with full respiratory activity and a slightly rapid pulse, for the slowing effect of neostigmine may outlast the accelerating effect of atropine.

The fractional technique enables one to adjust the anticipated dosage up or down to meet the exact requirement, and to give extra atropine in good time should bradycardia threaten. Most textbooks of anaesthesia are seriously deficient in detail on this point. The above procedure is very reliable and convenient in practice and soon becomes second nature.—I am, etc.,

Bristol.

T. R. STEEN.

SIR,—In their account of a case of cardiac arrest (*Journal*, June 28, p. 1521) Dr. D. W. Blair, Mr. W. T. Irvine, and Dr. R. C. Taylor rightly emphasize the value of a means of continuously monitoring the patient's pulse during anaesthesia. Since, however, they appear to imply that such an instrument is not available it should be pointed out that a number of cardiachometers have been designed.

While it is a comparatively simple matter to monitor the heart beat under optimal conditions, reliable operation is much more difficult to obtain under conditions of diminished cardiac output and when friction of towels against skin is present. One of the most useful and reliable instruments for the anaesthetist is that described by Molyneux.^{1,2} This possesses no unnecessary refinements (unless one includes under this heading an audible, as well as visual, signal synchronized with the pulse) and utilizes nine transistors and four crystal diodes. The subject has recently been well reviewed.³—I am, etc.,

Southend-on-Sea.

Neurological Reactions with Phenothiazine Derivatives

SIR,—The publication of Dr. E. H. Hare's memorandum (*Journal*, June 21, p. 1462) describing an unusual dystonic syndrome in a patient on chlorpromazine (3-chloro-10-(3-dimethylamino-*n*-propyl)phenothiazine) prompts me to report the following case.

On December 5, 1957, at the urgent request of a London teaching hospital, a man aged 65 who had been attending the outpatient department and "had been seen over a long period by a succession of doctors" was admitted here as an emergency case. On examination he was found to be an emaciated and very ill man. Facial tics (bilateral) caused him to grimace continually and "make faces." Involuntary twitching of the muscles of the mouth, throat, and neck caused great difficulty in articulation (spastic dysarthria) and his speech was indistinct. Every few minutes severe spasm of the left sternomastoid caused the face to be turned to the right side and the head to the ipsilateral side (spasmodic torticollis). The muscles of all the four limbs were in a state of general rigidity, more marked in the legs, while tremors and jerky contractions were more marked in the arms. He was unable to sit still, nor could he dress himself or tie his shoe-laces.

Nothing abnormal was detected in his central nervous system. The knee-jerks were very brisk, the abdominal reflex was present, and the plantar reflexes were flexor. The clinical picture was a combination of pseudo-bulbar palsy and Parkinsonism, although the facial tics and some of the gross tremor were hysterical in nature. Mentally he was quite conscious but obviously very apprehensive.

With rest in bed the acute symptoms and the dysarthria cleared up. The tics and gross tremor responded to the usual method—i.e., suggestion—leaving generalized rigidity of the limbs. He was therefore given benzhexol hydrochloride, 1 mg. once daily for three days and then 2 mg. daily for 10 days, which afforded him great relief. He was free of symptoms for several weeks and expressed a desire to return to work. As the aetiology of his acute symptoms and dysarthria was not apparent on May 1, he was given 50 mg. of chlorpromazine hydrochloride three times a day, and this dose was kept up for four days, when he felt "very well

indeed." On May 5 he was given 25 mg. of promazine hydrochloride (10-(3-dimethylaminopropyl)phenothiazine hydrochloride), thrice daily, and this was continued for some days. On May 10 he went to London by train, but in the evening noticed spasm of the muscles and was unable to walk or talk clearly. He was brought back by car. Next day he could not get out of his bed at all and had a recurrence of the rigidity of the muscles of all the four limbs. He suffered from severe spastic dysarthria and could not articulate at all. Attempts to speak caused severe spasm of the neck muscles with gasping for breath. He had also difficulty in swallowing. The alarming nature of his symptoms caused much concern not only to the nursing staff but also to the other patients on the ward. Promazine hydrochloride was therefore discontinued. Within 30 hours he showed marked improvement, was able to leave his bed unaided and talk normally. He had no more symptoms until his discharge on June 6, 1958. He was an intelligent man who seems to have suffered from chorea at the age of 13 but had been passed fit for the Forces and had also served at Gallipoli.

It is only fair to add that up to 300 mg. of promazine hydrochloride daily has been given here to a large number of patients with great benefit, and no untoward reactions have been noted even after sudden withdrawal of the drug. From a single case it would not be fair to draw the conclusion that chorea in childhood was responsible for the symptoms described above. To enable doctors and nurses to recognize this condition and differentiate it from acute hysterical aphonia, a film has been prepared at this hospital.—I am, etc.,

Belmont Hospital Neurosis Centre,
Sutton, Surrey.

M. N. PAI.

Burns in Sterilizing Rooms

SIR,—The incidence of burns among members of the nursing staff who work in sterilizing rooms is very high. I do not think that this is due to such staff being particularly accident-prone. An examination of the conditions of work in a number of sterilizing rooms reveals a state of affairs that no inspector appointed under the Factories Act would ever tolerate. Ventilation is almost always inadequate, the humidity is appalling, and the sterilizing apparatus is of poor design and badly installed. Steam pipes are often quite unlagged, taps and handles inadequately insulated, and bowl and instrument sterilizers are capable of discharging jets of steam upon the bare arms of the passer-by.

One may wonder, also, for how much longer our surgeons, who have the use of some of the world's best surgical instruments, will continue to allow them to be ruined by boiling in hard water, instead of using hot-air sterilization as has been the practice on the Continent for very many years.

I would suggest that this is a problem that should be attacked by hospital boards with a determination and resolution equal to that devoted to the elimination of static electricity in operating theatres.—I am, etc.,

Hove, Sussex.

REX BINNING.

Wrong Connexions

SIR,—One evening recently I went to anaesthetize for an emergency operation. The Boyle machine had been used since the orderly had gone off duty, so that the labels on the cylinders did not necessarily reflect their state. On opening the valves in turn, it was seen that the "wrong" rotameters registered; the connexions were checked and it was found that the two oxygen cylinders delivered to the nitrous oxide rotameter and vice versa.

The machine is of a "safe" type, with non-interchangeable Schrader connexions to the reducing valves, non-interchangeable threaded unions to the flow-meter block. Certain parts had been renewed the previous day, when presumably wrong union nuts had been fitted to the ends of the tubes. (The latter, of anti-static rubber, bore the correct identifying colours.) Two anaesthetists had used the machine in this state without remarking anything amiss. Calculation shows that when the oxygen meter showed a flow of 2 litres/minute and the nitrous oxide meter showed 6 l./min., which is a common setting, the resultant mixture would be 77% oxygen and total flow 9.2 l./min.

To check everything oneself seems pedantic, and many anaesthetists using familiar equipment in well-staffed theatres take correct function for granted, with a confidence matching that with which they drive off in their cars each morning without investigating oil and water levels. The mistake described did not have dangerous consequences but shows how careful it is necessary to be. If there had been an accident the anaesthetist would have faced H.M. Coroner.—I am, etc.,

Bramhall.

R. N. SIDEBOTHAM.

Pseudo-medical Advertising

SIR,—As medical adviser to an advertising agency, I was very interested to read Dr. R. E. Dawson's comments in your correspondence columns on "pseudo-medical advertisements" (*Journal*, June 21, p. 1482). I think that he is being unnecessarily harsh on advertisers. Most large advertising agencies employ a medical adviser, who is consulted whenever the question of claims in the medical field for any product arises in connexion with advertising. Most manufacturers of medical or semi-medical products also have their own scientific advisers, and, very frequently, also have qualified medical advisers as well. Moreover, there are bodies whose job it is to examine claims made by advertisers, and these bodies have laid down strict rules and codes of standards which are accepted by the majority of newspapers, magazines, and other publications, as well as television interests and by far the majority of service advertising agencies. It is therefore practically impossible for exaggerated benefits to be claimed in normal advertising channels for "useless products." In addition, in the highly competitive commercial conditions applying to-day, such products would not be handled by reputable advertising agents nor would responsible retail outlets accept them for sale.

In my opinion, the public will always buy tonics, vitamins, pain-killers, and indigestion remedies because they would rather pay for them than queue in their doctors' over-crowded surgeries. If they were not aware of the availability of these products, I would hate to think what number of extra patients would waste their G.P.'s time for minor ailments. It is of course quite natural and surely not unreasonable that a manufacturer should, in his advertisement, seek to bring before the public the advantages which his product enjoys over those manufactured by his competitors.—I am, etc.,

Guildford.

DICK GLOVER.

Calcium and Phosphorus Metabolism

SIR,—There are several points in the article by Dr. G. L. Mouzas (*Journal*, June 14, p. 1385) which conflict with my experience of calcium and phosphorus metabolism in 230 patients with renal calculi.¹

Dr. Mouzas states that only four of his patients had parathyroid dysplasia. He apparently requires to have both an elevated serum calcium and a low serum phosphorus, and hypercalciuria, to make the diagnosis of hyperparathyroidism. I have found no single test which is a satisfactory test of parathyroid function, but this does not mean that hyperparathyroidism cannot be present unless all these abnormalities are found, as Dr. Mouzas seems to imply. I have observed patients with hyperparathyroidism in whom only one of these abnormalities was present. Hypercalciuria disappears and the serum phosphorus rises again with the onset of renal failure, and in these patients a raised serum calcium may be the only biochemical sign of hyperparathyroidism. In almost all patients with hyperparathyroidism who are followed up for a sufficiently long period before operation both the serum calcium and serum phosphorus values fluctuate, the lower values often falling within the normal range. Dr. Mouzas regards a raised serum calcium alone as being of no significance. An elevated serum calcium is always pathological and deserves the most careful investigation to discover its cause. Quite apart

from the tendency for these patients to form calculi again, the hypercalcaemia causes renal damage. I also have noticed the frequency with which a low serum phosphorus occurs amongst calculus patients. Occasionally a low serum phosphorus may be the only sign of hyperparathyroidism, although there are other causes of disturbed phosphate metabolism.

It is difficult to interpret Dr. Mouzas' figures for phosphate/creatinine and calcium/creatinine ratios, because the headings of his Table III appear to be transposed. He has shown by 24-hour calcium excretion studies that all patients with a calcium/creatinine ratio above 0.3 had hypercalciuria. It cannot be claimed that this ratio is an effective screening test unless it can also be shown that values below this figure were not associated with hypercalciuria. I note that in seven of his patients the value of the serum alkaline phosphatase is above the upper 1% range, although he states in the text that all were within normal limits.

I think that his interesting group of patients merit further study.—I am, etc.,

Belfast.

Rheumatology as a Whole-time Specialty

SIR,—Dr. L. Mandel (*Journal*, June 21, p. 1482), referring to the treatment of the rheumatic diseases, stresses that the doctor must be trained "to treat the patient as a whole, and not the disease or local disability." His conclusion that treatment should be organized by a system of dual control seems, however, unlikely to achieve this object.

This approach to the problem is absurd, in this country at any rate. Consultants in physical medicine are now required to hold a higher medical degree in addition to the specialist diploma. A long training in both general medicine and physical medicine is necessary before senior status is attained. In fact, whether Dr. Mandel likes it or not, physical medicine is the specialty best suited to deal with the rheumatic diseases under the N.H.S., and, in view of the magnitude of the problem, it is hoped that the establishment of physical medicine specialists will soon be increased in order to provide adequate cover for the whole country.—I am, etc.,

Broadstairs, Kent.

R. W. BARTER.

Undescended Testicles

SIR,—I was extremely interested in the paper on the results of hormonal treatment of the undescended testis by Drs. J. Brunet, R. R. de Mowbray, and P. M. F. Bishop (*Journal*, June 14, p. 1367). At the time of passage of the testis through the inguinal canal in normal descent a marked lengthening takes place in the cord without which the vas deferens would be too short to permit such a movement. The remaining testicular descent process—i.e., from the neck of the scrotum to its floor—is brought about by lengthening of the cord, particularly of the vas deferens and cauda epididymis, and of the pars vaginalis gubernaculi (which includes the cremaster muscle). These changes would appear to be under the influence of gonadotrophic hormones, either directly, or indirectly through the testis due to its androsteroid production, and the clinical results published in this paper are essentially in agreement with these views. So long as the mesenchyme of the gubernaculum testis has not been involved by fibrous tissue, which would prevent normal growth changes and anchor the testis or its covering in an abnormal manner, there seems no anatomical reason why hormone treatment should not produce the results quoted.

Mr. Denis Browne's objections to hormone treatment (*Journal*, June 28, p. 1541) do not appear to be based on the anatomy of normal testicular descent. It is unfortunate,

therefore, that he should accuse the endocrinologists of just such a lack of knowledge. As I commented last year on certain of Mr. Browne's anatomical views (*Journal*, June 15, 1957, p. 1420) I do not propose to repeat myself needlessly. I would, however, in all fairness to Mr. Browne, agree that the anatomical criteria put forward by Dr. Brunet and his co-workers would sometimes be difficult to substantiate, as they themselves admit. I would suggest that the important criteria for hormonal treatment of testicular maldescent are that the testis should be somewhere on the track of normal descent and not anchored peripherally. A testis found in Browne's "superficial inguinal pouch" is off the normal course of descent and therefore not likely to descend under the influence of hormones. The difficulty, however, appears to be that of diagnosing accurately when a testis is or is not on the correct line of testicular descent when in the external inguinal region.—I am, etc.,

London, W.C.2.

K. M. BACKHOUSE.

Fatal Haemorrhage from Superficial Varix

SIR,—In our local newspaper recently a 30-year-old mother of five children was reported to have bled to death from a varicose vein in her leg. This recalled a similar death of which I had heard years ago. A tourniquet in that instance had been applied by a lay person between the heart and the hole in the vein. On hearing of another fatality, I wondered if the same mistake had again been made. By courtesy of Dr. L. Manoin, the coroner's pathologist, I was able to see the necropsy.

The body was that of a young woman about seven months' pregnant. The pale skin, pale mucous membranes, and pale organs made plain that blood loss had been severe. Her left leg was swollen. Both her lower limbs showed varicose veins, and many of these varicosities were particularly superficial, even protuberant. About 8 in. (20 cm.) above the left lateral malleolus there was a small opening into one of these extremely superficial varicosities. This opening was only of about one-tenth of an inch (2.5 mm.) in diameter. From a vein above and below it the pathologist expressed blood on to the skin through the hole. Microscopy gave evidence of ulceration at this site.

Her husband and her friends had said that through this small venous opening she had bled to death. They had applied some home-found tourniquets, towels, handkerchiefs, even bed sheeting around the leg above the hole in the vein. They thought this was the correct site for tourniquets, but, no matter how hard they had tried to compress the leg with their tourniquets, the bleeding had continued until she died.

To return to the consulting-room, patients sometimes ask if their varicosities will bleed. The chance of this is usually so small that mostly the medical attendant will be justified in giving an assurance: but, while operation is being arranged for those who require it, any who have particularly vulnerable veins can be told what to do if bleeding should occur. They should apply pressure directly to the bleeding point. The danger of ignorance in this matter is shown by the fate of two persons. To each a tourniquet had been applied between the heart and the hole in the vein. Such "first-aid" measures by part-trained or untrained persons are understandable, but so are the fatal results.—I am, etc.,

Launceston, Tasmania.

W. W. WOODWARD.

Male Homosexuality

SIR,—I was most interested in the excellent article entitled "A Factual Study of Male Homosexuality" by Dr. R. E. Hemphill, Dr. A. Leitch, and Dr. J. R. Stuart (*Journal*, June 7, p. 1317). It was encouraging to find that others had quite independently come to almost the same conclusions as I had myself. As the authors state that "there is surprisingly little factual literature dealing with homosexuality," it would seem that my paper,¹ which would come into this category, has escaped the notice of those interested in psychological and social medicine, no doubt owing to its title, "Venereal Disease and the Homosexual," and to the fact that it was published in a journal mainly concerned with venereal diseases. In it, among other things, I analysed

the life histories and sexual mores of 54 male homosexuals attending a V.D. clinic. My patients differed from those of Dr. Hemphill and his colleagues in that they were free young men-about-town who were contented with their mode of life and were not in any legal or psychiatric trouble.² The only significant difference between their findings and mine seems to be that my patients were attracted to adult or adolescent consorts and were not interested in having sexual relations with small boys.—I am, etc.,

London, W.2.

F. J. G. JEFFERISS.

REFER SUE

¹ Jefferiss, F. J. G., *Brit. J. Vener. Dis.*, 1956, 32, 17.

Occupational Diseases of Musicians

SIR,—In reply to the letter by Dr. M. Anderson (*Journal*, July 5, p. 51) and for the information of others who may be interested, there is a good deal of literature on the occupational diseases of musicians. There is indeed a monograph by Kurt Singer, who was both a specialist in neurology and the music critic for the *Berlin Vorwärts* and who lectured regularly at the Academy of Music in Berlin on the diseases of professional musicians. This was translated from the German by Vladimir Lakond and published by Greenberg in New York in 1932 with the title "Diseases of the Musical Profession: A Systematic Presentation of Their Causes, Symptoms, and Methods of Treatment." There are also numerous articles, the references for which can be obtained from the *Index-Catalogue of the Surgeon-General's Library* and from the *Quarterly Cumulative Index Medicus*.—I am, etc.,

London, N.W.1.

F. N. L. POYNTER.

Iatrogenic Disease

SIR,—Your issue of June 21 opens with an article by Dr. John W. Dundee entitled "Iatrogenic Disease and Anaesthesia" (*Journal*, June 21, p. 1433). I supposed that I was to read of asthma, say, or rheumatoid arthritis or some other disease that by its length and refractoriness provides sustenance for honest doctors, for iatrogenic means "doctor-sustenance," just as carcinogenic means "cancer-begetting," and erogenic "love-begetting." But the learned author defines his word as a malady or an abnormal state produced by physicians. A similar mistake, for such I suppose it to be, is made with the word psychogenic, which means "soul-begetting," not "soul-begotten," as usually intended. I suggest that the word γεννητός (gennētos) is the right suffix, meaning "begotten of"—for example, "Among those born of women (ἐν γεννητοῖς γυναικῶν) there hath not risen a greater than John the Baptist."

For a disease, then, born of a doctor we may write iatrogennete, but we should not write iatrogenic nor yet iatrogenetic.—I am, etc.,

Orpington, Kent.

H. ST. H. VERLUE.

Mortality and Morbidity of Steroid Therapy

SIR,—Dr. Michael Kelly in his letter to you (*Journal*, July 5, p. 50) condemns steroid therapy for arthritis, and to prove his case quotes a number of references, including one from myself. I am misquoted as reporting 6 deaths in 90 patients as due to steroid therapy, whereas I commented that one death followed a car accident and two were from carcinoma. One wonders whether his other references are equally inaccurate.—I am, etc.,

London, S.W.1.

OSWALD SAVAGE.

Alfred Russel Wallace

SIR,—Dr. F. N. L. Poynter's article on the centenary of the Darwin Wallace paper on natural selection (*Journal*, June 28, p. 1538) appeals to me, as I have always been an admirer of these two. The following is a note of a visit I made to Alfred Russel Wallace on March 1, 1905.

While doing a locum at Broadstone I was called to the house to see a servant. Asked Mrs. Wallace if they did not once live

Obituary

ANDRIJA STAMPAR, M.D.

Professor A. Stampar, professor of public health and social medicine at the University of Zagreb and President of the First World Health Assembly in 1948, died on June 26, aged 69.

Andrija Stampar was born on October 1, 1888, in Croatia. He studied medicine at the University of Vienna, graduating in 1911. During the first world war he was interned for four years during the occupation of Serbia, but by the time the new state of Yugoslavia had come into existence he had already made a name for himself in the field of public health and preventive medicine. He was only 31 when he was appointed director of public health in Yugoslavia. In the following years he created the public health services of his country, including a network of health centres covering the remoter areas. In 1931 he was elected professor of hygiene and social medicine in Zagreb University and later he became rector of the university and dean of the medical faculty.

For many years he had been one of the most forceful and effective teachers of public health and social medicine, and at the First World Conference on Medical Education, held under the auspices of the World Medical Association in London in 1953, Professor Stampar, as a vice-president of the Congress, took the chair at the meetings of the section which was concerned with preventive and social medicine. Thanks to his outstanding knowledge of the subject, the meetings of that section were particularly successful.

M. D. M. writes: The death of Professor Andrija Stampar will be a deep sorrow to his many friends all over the world. He will be remembered chiefly for the immense contributions he made to international preventive medicine. He began this work in 1924, and until the outbreak of the last war he was continually associated with the activities of the Health Section of the League of Nations, in the countries of Europe, the Americas, Asia, and the U.S.S.R. After the war Stampar again took up his post at Zagreb University, but devoted a steadily increasing part of his time to the development of international medicine, particularly to the creation and functions of the World Health Organization. In 1946 he was elected first vice-president of the Economic and Social Council of the United Nations. After contributing enthusiastically to the work of the Preparatory Committee for the creation of the World Health Organization he was elected as permanent chairman of the Interim Commission which was authorized to assume the responsibilities of the future World Health Organization. In 1948 he became president of the first World Health Assembly in Geneva. Subsequently, for nearly 10 years he headed the Yugoslav Delegation to W.H.O. Stampar's knowledge covered every branch of preventive and social medicine, but he was particularly interested in rural hygiene, the training of doctors and health workers both in their own countries and abroad, and schools of hygiene. Whilst his outstanding career and his wide knowledge called for the admiration of all who met him, it was his dynamic and lovable personality that made him friends everywhere. He was essentially human, and with a keen sense of humour always ready to help in health problems either national or personal. Stampar was twice

at Dorking, my native town. She said Yes, spoke to me of Dorking people, and said her husband would like to hear of them. Mrs. W. took me into the study and introduced me to the professor. He is a tall thin man with snow white hair and beard; stoops very much; wore a very loosely fitting brown suit, thick soled black shoes.

A. R. W. first asked me about people he had known at Dorking and then got on to the subject of his various residences. Dorking did not suit them, it is too much in a valley. He moved to Croydon, then to Godalming, where they lived nine years, then to Parkstone, now in Broadstone. He hunted all along the Downs from Sevenoaks to Guildford without finding a suitable site for a house, or a house with a proper garden. The present house bears the initials A. R. W.; it is on a slight elevation, looks over moorland to Poole and Poole harbour about three miles off. There is a large clump of fir trees in the garden with a small plot of grass; in front of the house is an acre or two of uncultivated moor. Tea was brought in at this stage (about 4 p.m.). Two cups in the ordinary style for Mrs. W. and myself with cake and bread and butter. A. R. W. had a brew to himself: a little tea and much water straight from a kettle over a spirit lamp, poured off almost directly, cup half-filled with milk, sugar two lumps in a small cup, soon disposed of; another cup, less tea this time, more milk, still sugar two lumps; then more cups with less tea each time, still sugar two lumps.

On my rising to go A. R. W. said he must first show me his blue water-lilies, which he said I had never seen before and probably never would again. We went through the greenhouse and here I had the misfortune to knock over a flowerpot and break it. Happily the plant did not appear injured nor the earth shaken from the roots. A. R. W. made light of it, but I was very much annoyed at my clumsiness and could not enjoy the rest of the interview. The blue lilies are very pretty and have an agreeable scent, they come from Port Elizabeth. He showed me a New Zealand plant grown from seed which had not got accustomed to the seasons and flowered in winter. A. R. W. was very chatty and communicative, and if it had not been for the flowerpot incident I should have enjoyed the whole interview very much.

—I am, etc.,

Bath.

CHARLES A. MARSH.

Alcohol and Driving

SIR,—Dr. R. P. W. Kup (*Journal*, July 5, p. 46) writes: "It would appear fairly logical that people [charged with driving under the influence] with a good defence should resort to such a tactic [electing trial by jury] and those without a reasonable answer to the charge should content themselves with a magistrates' court. . . ." In actual fact, it is the other way round. It speaks volumes that the Recorder of London, Sir Gerald Dodson, is reported in *The Times* of May 22 as having said in the Central Criminal Court on the previous day: "I think everyone would welcome a short Act of Parliament which would deprive drivers accused of being under the influence of drink of the right to be tried by a jury."—I am, etc.,

Isleworth, Middlesex.

H. PULLAR-STRECKER.

1959 Medical Directory

SIR,—The annual schedule, upon the return of which the accuracy of the *Medical Directory* depends, has recently been posted to all traceable members of the medical profession, and its speedy return would be appreciated.

A number of schedules, sent to a doctor's last known address, have been returned through the Post Office marked "Gone away." Although in such cases every effort is made to find a new address, I should like to remind practitioners that, if these efforts are not successful before the book goes to press, the names in question will be omitted from the next edition. Any doctor who has not received the annual schedule, or who has mislaid it and would like a duplicate, is requested to communicate as soon as possible with the Editor, *The Medical Directory*, 104, Gloucester Place, London, W.1. The full name and year of qualification of the doctor should be sent for identification, please.—I am, etc.,

B. STANTON,
Editor,
The Medical Directory.

London, W.1.

E

married. He had a large family, several of whom continued to live under his roof in the patriarchal system. His very happy family life was a fitting background to the great contribution he made to the progress of mankind, towards closer collaboration in medicine, and a better understanding between nations.

ISIDOR C. RUBIN, M.D., F.A.C.S., Hon.F.R.C.O.G.

Dr. Isidor Rubin, who had an international reputation in gynaecology, died in London on July 10 during a visit from the U.S.A. He was a pioneer in the invention and development of apparatus for insufflation of the Fallopian tubes.

Isidor Clinton Rubin was born on January 8, 1883, and received his early education in New York. After taking the M.D. of Columbia University in 1905, he became an intern at the Mount Sinai Hospital, New York, remaining there until 1909, where he spent a year visiting Vienna, Berlin, and Paris. On his return to the U.S.A., in 1910, he obtained appointments at the Beth Israel Hospital, and subsequently also at the Mount Sinai and Montefiore Hospitals in New York. From 1937 to 1947 Rubin was clinical professor of obstetrics and gynaecology at Columbia University. Not only was Rubin the author of many papers and several books on his specialty, but he undertook many editorial tasks also; these included membership of the editorial board of the *American Journal of Obstetrics and Gynecology*. Among the honours bestowed on him is the French Legion of Honour and, in Great Britain, the honorary fellowship of the Royal College of Obstetricians and Gynaecologists.

Mr. V. B. GREEN-ARMYTAGE writes: Thirty-three years ago in America those on higher gynaecological study leave were attracted by three outstanding men—Whitbridge Williams, John Sampson, and Isidor Rubin, though hardly less so perhaps by Graves of Boston, Curtis of Chicago, and Masson of the Mayo's. Although hysterosalpingography was already on the map, first in Buenos Aires, and later in Paris, Rubin came straight into the limelight when, after many experiments, he discovered that CO₂ was the ideal gas and method for demonstrating tubal patency, and more particularly when he was able to prove that, in the case of the hitherto long-infertile woman, 18% of those insufflated for the first time conceived within the next few weeks. In 1925 this was indeed hot news. In those days his instrument was not his latest minute compact aluminium one, with a graph rotated by electricity and CO₂ activated by a tablet of "alka seltzer," but a heavy, cumbersome, temperamental affair of cylinders, drums, and tubing run by whirring clockwork. Nevertheless it worked, showing normal oscillations or the rises in pressure due to treatable spasm or organic obstruction.

He was generosity itself to postgraduates, and I recall many a visit to his multi-cubed office in Park Avenue, where we would listen to him, surrounded by nurses, practitioners, and stenographers, as he passed from patient to patient. In those days he was rosy cheeked with rippling auburn hair. He never got rattled; he was always quiet and efficient as he taught us how to work his beloved machine. So impressed was I that, on return to London after many months in the States, I sought out my old friend Clifford White, who was then secretary of the Obstetric Section of the Royal Society of Medicine, and begged him to obtain the ukase to invite Dr. Rubin to give us a paper, whilst I would make myself responsible for his entertainment at the old East India United Services Club. He came, he conquered. His address that October night in 1925 was a triumph. Indeed, with his Heath-Robinson-like apparatus sprawling over the table, he gave us the very first exposition of this technique in Europe. Everything went perfectly, and no one was more thankful than he and I that in a packed Barnes Hall he was even able to convince some of the old diehards of our specialty who were present. This test, by virtue of its proved diagnostic and therapeutic value, made

him a benefactor to all mankind. What wonder then that his own great country and every civilized land has praised and honoured him. France at once made him a Chevalier, and then a few years ago promoted him to be an Officer of the Legion of Honour. In Great Britain our own Royal College made him an Honorary Fellow. But though the flame of his fame burned brightly, and his apparatus was acclaimed the world over, the man himself, the real scientific Rubin, remained ever the same, whether on hospital rounds, in operating theatre, or as a friend met casually of by intent in many of the great cities of the world—calm, humble, humorous, and helpful. Indeed, for him and his charming family life was lovely and pleasant. He had friends in every capital. The younger generation never looked in vain to him for help and guidance: I recall him quoting to a group of them at a clinical meeting those words from Masfield's "Adventurer":

Adventure on, for from the littlest cue

The next to lighten all men, may be you.

Rubin was always welcomed wherever he went. No better living evidence of the high regard in which he and his work was held can be given than the fact that in 1947 111 of his friends, associates, and pupils presented him with a *Festschrift* to which each of them had contributed a special article. If the measure of any man's greatness is the number of disciples he has gained, or the number of persons of all nations he has helped along the ladder of life to greater happiness, then assuredly Isidor Rubin is among the blessed.

Mr. ELLIOT PHILIPP writes: When six weeks or so ago the University of Mexico City awarded several honorary doctorates, it was for one man alone that the whole audience rose to give a warm spontaneous standing ovation. That man was Isidor Clinton Rubin; and the ovation was a measure of the honour, esteem, and affection felt for him in academic and medical circles throughout both the Americas.

It is not given to many men to make even one worthwhile advance in the knowledge of their specialty, but Rubin made several. His first paper was published in 1910 and shows that already, half a century ago, he was concerned with the early diagnosis of cervical carcinoma and the condition we now call carcinoma in situ. It is worth while quoting the last sentence of this first paper: "The important criteria of malignancy in these early cases lie not so much in the relation of the cell nests to the stroma, the depth or extent of epithelial invasion, or evidences of surrounding inflammatory changes, as in the intrinsic morphology of the epithelial cells."

The young man in his twenties had laid a stone in the foundations of the increasingly exact science of early cancer detection. More than that he would himself not claim, although repeatedly his early and his late papers deal with cancer cell detection.

Yet although Rubin had the gifts of a scientific research worker he also had great dexterity as an operator, and a wonderful gentleness and warmth of character that drew people to him. So inevitably he was taken from the laboratory to the clinical field and there became acutely aware of the misery of sterility. With determination and with a band of faithful collaborators at the Beth Israel and Mount Sinai Hospitals in New York he set to work to unravel one problem after another. He did not casually stumble on his discovery that the ovum was conveyed to the uterus by the peristaltic waves of the Fallopian tube. Originally he injected radio-opaque substances into port-mortem specimens, then into a live dog, and in 1914 he carried out the first hysterosalpingography on a patient. In 1919 he was the first person bravely and against the advice of his colleagues (who feared the patient would die of peritonitis) to insufflate the tubes with a gas. He used oxygen and, very soon after, carbon dioxide, which he rightly judged to be safer. This first patient became pregnant shortly afterwards.

He had a severely logical mind and he deduced from his observation of his early insufflation patients that shoulder

pain was diagnostic of stretching the ligaments on the under surface of the diaphragm. Thus he was the first to describe shoulder pain as being of diagnostic value in ruptured ectopic pregnancy.

In his more than fifty years of practice Rubin approached each patient as a human and a scientific problem. He was quiet, gentle, wise, and immensely generous. Above all he was inspiring, yet he detested bombast, hypocrisy and lack of truth, and would not hesitate to criticize a work that he judged prematurely published or inadequately proved.

His consulting-room was adorned by honorary diplomas and fellowships from universities and colleges throughout the world, and two he valued highly were from the University of Paris and from our own Royal College of Obstetricians and Gynaecologists. His high rank in the French Legion of Honour he, too, wore proudly when in France.

His aristocratic and noble patients who came from all over the world to see him adored him, but much more touching was the attention he gave the poor. I took him out to Romford on his only free time—a Sunday morning—last year to see the wards and one or two patients who were either particularly interesting or worrying, but it was at the bed of a woman dying of inoperable carcinoma that he stopped longest to speak words of encouragement. As he left the ward the orderly who had brought him tea said, "That is the finest gentleman I have ever met." And so he was.

To his wife Sylvia, who for so many long years so devotedly encouraged, protected, and helped him, both in his beautifully traditionally orthodox Jewish home and on his world-wide travels, and to his daughters and son, our deepest sympathy goes out. For their love is ours too.

E. L. ELLIOTT, M.B.E., M.B., B.S.

Dr. E. L. Elliott died suddenly after a long illness at his home at Stokenchurch on June 4. He had been in general practice in the district for nearly forty years.

Edgar Lionel (Jack) Elliott, the son of a doctor, was born at Bromsgrove on October 24, 1885. Educated at Marlborough and Guy's Hospital, he graduated M.B., B.S. in 1910, and for a time afterwards was house-physician to Sir William Hale-White. From 1914–19 he served as surgeon lieutenant in the Royal Navy, mainly in the Mediterranean theatre in H.M.S. *Somali* and *Karapara*. After the war he entered general practice at Stokenchurch, joining, and later succeeding, his father. In his younger days he had been a keen sportsman, playing Rugby football and cricket with some success at Guy's; after the war riding and hunting became his main hobbies, and he was a familiar figure visiting remote parts of his practice on horseback. A serious accident in 1931 in which he fractured his spine curtailed his riding, and afterwards he became interested in dinghy sailing. He bought a small cottage on the Dorset coast at Ringstead Bay and spent most of his holidays there. During the second world war he was area medical officer to the Home Guard and was awarded the M.B.E. for his services. He continued in active practice after the war in spite of gradually increasing cardiac failure, resulting from valvular disease and aggravated by Paget's disease. Although the prolonged inactivity of his first long illness was irksome to him, he bore it with great patience and good humour.

Dr. Elliott married Miss Mabel Drew Hobley at Sevenoaks in 1912, and she survives him with one son, one daughter, and one adopted son. Both his sons had joined him in his practice.

C. S. writes: E. L. Elliott had been "The Doctor" at Stokenchurch since 1919. In the tradition of his calling he was much more than just a medical practitioner: the parish council, the village sports clubs, the British Legion, the schools, and many other local organizations had known and valued his wisdom and support. To the ordinary people of the villages and hamlets around Stokenchurch he was "their doctor," a man of vigorous habits and cheerful

countenance, a wise and humane man, a man who would be very gentle with children and very kind to those in distress. His main interests were in his home and family, in his practice, and, of course, in the fortunes of Marlborough and Guy's.

When he succeeded his father in Stokenchurch he was single-handed, but he had a dynamic personality, and in time his practice grew and he was able to found a group practice. As senior partner and "elder statesman" of the firm for twenty years he was an unfailing source of help and encouragement to those who came to work with him. He believed profoundly in the continuing education of general practitioners, and in breaking down the isolation which had often been the lot of the country doctor in the past. A small local society, known as the XX Club and composed of G.P.s from neighbouring practices, owes much to his influence. All those who have attended the XX Club meetings, whether as members or guests, will know how well worth-while such societies are, and will remember Jack Elliott with deep gratitude. They will also wish to extend their deep sympathy to his wife and family.

H. H. BAYLEY, M.D.

Dr. Harry Bayley died suddenly from a heart attack on June 14, at his clinic in Barbados. He was 49 years of age.

Harold Haynes Bayley was born in Barbados and educated at Harrison College, Barbados, and New York. At the age of 16 he went to Columbia University, where he studied natural sciences, and at 18 went up to Sydney Sussex, Cambridge, where he achieved the feat of passing his second M.B. and getting an athletic blue in his first year. From Cambridge he went to King's College Hospital, being awarded the Burney Yeo scholarship. He qualified in 1934 and graduated M.B., B.Chir. in 1935. In the same year he returned to Barbados, where he started in general practice. His main interests lay in laboratory work, and at an early stage he established his own laboratory. His practice grew steadily until by 1948 he had been joined in partnership by Dr. A. L. Goddard and had built a finely equipped laboratory and a private clinic of 23 beds, with a good x-ray department, operating theatre, and all the facilities of a small hospital.

Harry Bayley had great ability and exceptional energy, and while at Cambridge and at King's College Hospital, where his teachers included Professor R. A. McCance and Dr. R. D. Lawrence, he developed an absorbing interest in biochemistry and clinical pathology. These he felt to be the foundation of scientific medicine, and they were to be his special concern throughout his career. General practice in a small West Indian island seemed to offer little scope at first, but by unremitting hard work and determination he was able to give his patients the type of service one associates with the medical department of an English hospital. In 1948 there was an epidemic in Barbados of severe jaundice, which was believed to be a special form of infectious jaundice peculiar to the island. This stimulated Bayley's love of research, and in an exhaustive investigation he proved the disease to be leptospirosis. For a thesis based on this work he was awarded the degree of M.D. in 1942. Other subjects which interested him and on which he published papers were the "bush-teas" of Barbados, larva migrans, the poisonous scorpion fish, and the Galli-Mainini test, using the local *Bufo marinus* toad. His wide scientific training and keen interest in recent developments in medicine helped him to develop a considerable consulting practice. His colleagues found his opinion always sensible and valuable.

Harry Bayley's enthusiasms were not confined to medicine. Astronomy, music, modern languages, and horticulture filled his brief leisure hours, and he had recently completed a remarkably successful hydroponic garden. His gaiety, high spirits, and warm sympathy for his patients made him much beloved in Barbados and the neighbouring

The following degrees were conferred on July 2:

M.D.—T. H. Bewley, F. O. Dosekun, Edna La C. Murphy.
M.A.O.—C. J. B. Orr.
M.B., B.Ch., B.A.O.—Sara R. Abels, Bridget M. Acheson, H. B. Allen,
J. Bennett, P. J. Blackburn, J. S. Brown, R. J. M. Collis, Edith M. Cross.

SCARLET FEVER

Number of Cases vs. Weeks

52	600	2400

**Week Ending July 5**

The largest variations in the trends of the notifications of infectious diseases in England and Wales during the week ending July 5 were increases of 412 for measles, from 6,026 to 6,438, 81 for food-poisoning, from 261 to 342, 46 for dysentery, from 873 to 919, and 37 for whooping-cough, from 783 to 820.

The largest rises in the incidence of measles were 188 in Lancashire, from 758 to 946 (Liverpool C.B. 263, Blackburn C.B. 117, Manchester C.B. 99), 71 in Warwickshire, from 191 to 262 (Birmingham C.B. 176), 70 in Cornwall, from 156 to 226 (Falmouth M.B. 85), and 54 in Shropshire, from 88 to 142 (Oakengates U.D. 75); the largest falls were 72 in Derbyshire, from 224 to 152, 59 in Gloucestershire, from 220 to 161, and 52 in Denbighshire, from 102 to 50. The notifications of scarlet fever numbered 663, being 1 more than in the preceding week, and there were no large fluctuations in the local returns. The largest rises in the number of notifications of whooping-cough were 25 in Yorkshire West Riding, from 53 to 78, and 20 in Durham, from 35 to 55. Three cases of diphtheria were notified, being 2 fewer than in the preceding week.

The notifications of acute poliomyelitis numbered 48, and there were 1 more for paralytic and 4 more for non-paralytic cases than in the preceding week. The largest returns were Yorkshire West Riding 12 (Halifax C.B. 3, Leeds C.B. 2), Essex 6 (Hornchurch U.D. 2, Rochford R.D. 2), Lancashire 4, Staffordshire 4 (Cheadle R.D. 4), Surrey 4 (Woking U.D. 3).

The chief centres of dysentery were Yorkshire West Riding 202 (Thorne R.D. 54, Barnsley C.B. 23, Leeds C.B. 23, York C.B. 15, Rotherham C.B. 13, Sheffield C.B. 13, Bradford C.B. 10); Lancashire 130 (Liverpool C.B. 22, Manchester C.B. 21, Burnley R.D. 13, Rawtenstall M.B. 10), London 119 (Islington 31, Bermondsey, 14, Finsbury 10), Durham 44 (Whickham U.D. 11, Easington R.D. 11), Berkshire 42 (Easthampstead R.D. 40), Essex 37 (Walthamstow M.B. 24), Staffordshire 37 (Rugeley U.D. 14), Middlesex 36 (Willesden M.B. 12), Gloucestershire 29 (Bristol C.B. 19, Gloucester C.B. 10), Warwickshire 25 (Bedworth U.D. 10), Yorkshire North Riding 25 (Middlesbrough C.B. 22), Hampshire 24 (Droxford R.D. 12, Havant and Waterloo U.D. 11), Surrey 21 (Banstead U.D. 10), and Cambridgeshire 20 (Cambridge M.B. 19).

The largest outbreak of food-poisoning notified during the week was 138 cases in Birmingham C.B.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending **June 28** (No. 26)
and corresponding week 1957.

Figures of *cases* are for the countries shown and London administrative county. Figures of *deaths* and *births* are for the whole of England and Wales (London included). London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenzal pneumonia

§ Includes puerperal pyrexia.

Medical News

Buckston Browne Dinner.—Sir JAMES PATERSON ROSS, P.R.C.S., presided at the Buckston Browne dinner, held at the Royal College of Surgeons on July 9. The toast to "The College" was proposed by Mr. DEREK WALKER-SMITH, who in some light-hearted remarks described after-dinner speaking as "all part of our puritan doctrine of after pleasure—pain." Mentioning the interest shown in the work of the College by the business world, Mr. Walker-Smith said that, in its broadest sense, the industrial future of the country depended on the health of the people, and that depended on the progress of medicine and surgery, which in its turn depended on research. In reply, Sir JAMES PATERSON ROSS said that the College was indebted to Sir George Buckston Browne for enabling it to undertake some of the most important work that had to be done to-day. Only a small number of people realized what research work was being done by the College: all of it had a practical application to medicine and surgery. It was of the utmost importance that research should be fruitful, so that its results might bring healing to all mankind. Proposing the health of the guests, among whom were many leaders of industry, Sir ARCHIBALD MCINDOE mentioned that, besides the President, three past-presidents of the College were present—Sir Harry Platt, Sir Cecil Wakeley, and Sir Hugh Lett, who was the son-in-law of Sir George Buckston Browne and one of the greatest friends the College had ever had. Replying to the toast Sir HARRY JEPHcott described the great influence the College had in building up medical schools overseas: its work was of great public as well as of medical importance.

Royal College of Surgeons.—At the council meeting on July 10 (see also p. 153) Dr. WARREN H. COLE, of Chicago, and Dr. CHARLES W. MAYO, of Minnesota, were admitted as honorary fellows. Dr. G. S. W. ORGANE was co-opted to the council as representing anaesthetics. Dr. I. W. MAGILL, Dr. R. J. MINNITT, Dr. E. S. ROWBOTHAM, Sir HENRY SOUTTAR, and Dr. R. M. WATERS were elected honorary fellows of the Faculty of Anaesthetists. Dr. H. J. WINDSOR, of Brisbane, was admitted to the fellowship as a member of 20 years' standing. The following professors, lecturers, and demonstrators were appointed for the ensuing year:

Hunterian Professors.—W. E. Tucker, R. A. Mogg, E. M. Nanson, J. B. Curtis, C. J. Kaplan, P. H. Jones, G. J. Hadfield, A. G. Parks, T. J. S. Patterson, J. W. Dickson, C. Harvard, A. J. Davies, G. S. M. Botha, and J. S. Calnan.

Arris and Gale Lecturers.—E. R. Smith, G. L. Bourne, and K. M. Backhouse.

Erasmus Wilson Demonstrators.—R. Goodbody, K. M. Laurence, L. W. Proger, R. C. B. Pugh, H. A. Sissons, and M. O. Skelton.

Arnott Demonstrators.—J. Dobson, A. A. Barton, A. Howe, R. J. Last, R. M. Livingston, and B. Cohen.

King Edward's Hospital Fund.—At the Fund's 61st annual meeting in London on July 11, the DUKE OF GLOUCESTER, the president, reviewed some of the improvements the Fund had effected in hospitals during recent years. Grants had been used to provide amenities for patients and better living conditions for nurses; meals had been improved through the Catering Advisory Service and the School of Catering; much money had been spent on mental hospitals; and the influence of the three staff colleges—for ward sisters, future matrons, and hospital administrators—was leading to no less real results. Lord McCORQUODALE, chairman of the management committee, drew attention to the inquiry into means of reducing unnecessary noise in hospitals. The treasurer, Lord ASHBURTON, said the Fund's capital was still £7m., in spite of the fact that since its inception 60 years ago the Fund had distributed over £16m. to the hospitals of London.

Birmingham Cancer Laboratories.—On July 4 Professor A. LACASSAGNE, of the Pasteur Radium Institute, Paris,

opened new clinical research laboratories for the University Medical School in Birmingham. These laboratories, which have cost £50,000, were provided by the Birmingham Branch of the British Empire Cancer Campaign. They are situated on the site reserved for clinical research near to the Queen Elizabeth Hospital and the Medical School at Edgbaston, and will permit all research work on cancer carried on in Birmingham to be centred in one place. Professor JOHN ORR, professor of pathology in the University and director of cancer research, has been intimately concerned with this project. After the opening ceremony Professor L. SEVERI, of Perugia University, unveiled a plaque commemorating the work of Sir Gilbert Barling, the first chairman of the Birmingham Branch of the British Empire Cancer Campaign. A second plaque commemorating a gift from Alfred and Ruth Bullock towards the cost of the laboratories was then unveiled by Dr. O. MÜHLBOCK, of the Dutch Cancer Institute, Amsterdam.

Chair of Parasitology at Liverpool.—At a meeting of the University council on July 8 Dr. W. E. KERSHAW was appointed to the Walter Myers and Everett Dutton chair of parasitology and entomology upon the retirement of Professor R. M. GORDON. Dr. Kershaw graduated in medicine at Manchester University in 1935, proceeding M.D. in 1949 and D.Sc. in 1956. During the war he served in the R.N.V.R., first at sea and later as pathologist to the Royal Naval Auxiliary Hospital in Ceylon. In 1946 he was appointed lecturer in medical parasitology in the Liverpool School of Tropical Medicine, and Leverhulme senior lecturer in parasitology in 1957. He was awarded the Chalmers memorial gold medal of the Royal Society of Tropical Medicine and Hygiene in 1955, and was appointed to the council of that body in 1956. Dr. Kershaw will take up his new appointment on October 1.

New D.C.M.O. at Ministry.—Dr. D. THOMSON is to become a Deputy Chief Medical Officer at the Ministry of Health on October 1, on the retirement of Dr. G. A. CLARK. The other D.C.M.O. is Dr. G. E. GODBER. Before going to the Ministry of Health in 1946 Dr. Clark was professor of physiology and dean of the faculty of medicine at Sheffield University.

Monash University.—At its inaugural meeting on June 19 the interim council of the proposed Monash University in Victoria, Australia, decided that the new university should include a medical faculty. The Government of Victoria promulgated an Act in April to provide for the establishment of a second university in the State, to be named Monash University (after a former Chancellor of Melbourne University), and one of its purposes is to relieve those faculties at Melbourne University which already have to limit their intake of students. The medical members on the interim council are Professor MAURICE EWING, professor of surgery at Melbourne, and Dr. R. R. ANDREW, dean of the Alfred Hospital Clinical School.

Royal Society of Medicine.—Sir GEOFFREY MARSHALL has been elected president for the 1958-9 session. Other changes among the society's officers are that Professor R. H. S. THOMPSON succeeds Dr. G. W. S. ORGANE as an honorary secretary, and Mr. MYLES FORMBY and Dr. F. C. KELLY become honorary directors of photography in place of Professor K. J. FRANKLIN and Dr. D. A. McDONALD. Sir CLEMENT PRICE THOMAS is the immediate past president.

Seventh International Congress of Leprology.—Arrangements to hold this quinquennial congress in New Delhi in November have unfortunately had to be cancelled at short notice. The Japanese Leprosy Foundation has offered, however, to hold it in Tokyo on November 12 under joint sponsorship with the International Leprosy Association. The secretary of the International Leprosy Association (8, Portman Street, London, W.1) urgently requests all who would be able to attend the congress in its new location to inform him at once.

"Biochemical Pharmacology."—This new quarterly from the Pergamon Press Ltd. is described as an international journal for research on the development of biologically active substances—particularly in the field of cancer chemotherapy—and their mode of action at the biochemical and sub-cellular level. Professor ALEXANDER HADDOW, F.R.S., is chairman of the editorial board, and the regional editors include Dr. P. ALEXANDER (executive editor) and Sir RUDOLPH PETERS, F.R.S. The first issue, dated July, 1958, contains original papers, short communications, and book reviews. Annual subscription (including postage) is £6 per volume (£5 5s. if for personal use). The publishing offices are at 425, Fitzroy Square, London, W.1.

Light Diets.—The Hospital Catering Advisory Service of King Edward's Hospital Fund has issued a memorandum on "Light Diets." It is designed to help catering officers or housekeeping sisters fulfil prescriptions for light diets. Copies of the memorandum are obtainable (price 1s., post free) from the Fund's officers, 34, King Street, London, E.C.2.

Bristol University.—Dr. J. CLUTTON-BROCK has been appointed lecturer in anaesthetics and head of the department of anaesthesia. Dr. SUZANNE CLARKE has been appointed lecturer in bacteriology.

Aberdeen University.—At the graduation ceremony on July 4 the University's honorary D.D. was conferred on the Reverend Dr. A. C. IRVINE, senior missionary of the Church of Scotland Mission in Kenya.

Film Award.—A film on congenital obstruction of the bladder neck, made by Mr. D. I. WILLIAMS, Dr. D. EDWARDS, and the film unit of the Institute of Urology, London, was awarded a silver medal at the International Congress of Urological Films in Brussels last month.

COMING EVENTS

Royal Microscopical Society.—Exhibition of photomicrographs, July 23–30, at the Polytechnic School of Photography, 309, Regent Street, London, W.1. Open to non-fellows of the society (admission free) after opening day (July 24 and 29, 10 a.m. to 10 p.m.; other days, 10 a.m. to 4 p.m.).

Cambridge University Postgraduate Medical School.—Course on "Progress in the Biological Sciences in Relation to Dermatology," September 22–27, at Cambridge. The course is intended primarily for practising dermatologists. Details from the Secretary, the Medical School, Tennis Court Road, Cambridge.

NEW ISSUES

The journals listed below are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Annals of the Rheumatic Diseases.—Issued quarterly (£3 annually). The new issue, Vol. 17, No. 2, includes:

PREDNISONE IN RHEUMATOID ARTHRITIS: METABOLIC AND CLINICAL EFFECTS. L. Emmerson Ward, Howard F. Polley, Marschelle H. Power, Harold L. Mason, Charles H. Slocumb, and Philip S. Hench.

GENETIC STUDIES ON RHEUMATOID ARTHRITIS. J. S. Lawrence and J. Ball.

ARTHRITIS ASSOCIATED WITH ULCERATIVE COLITIS. E. G. L. Bywaters and B. M. Ansell.

EFFECT OF LONG-TERM TREATMENT WITH CORTICOSTEROIDS ON ADRENOCORTICAL FUNCTION. F.-E. Krusius and Matti Oka.

RADIOIODINE CLEARANCE FROM THE KNEE JOINT IN RHEUMATOID ARTHRITIS. R. Harris, J. B. Millard, and S. K. Banerjee.

OBSERVATIONS ON THE SHRINK TEMPERATURE OF COLLAGEN AND ITS VARIATIONS WITH AGE AND DISEASE. Patricia C. Brown, R. Consden, and L. E. Glynn.

CLINICAL FEATURES AND COURSE OF ANKYLOSING SPONDYLITIS. M. Wilkinson and E. G. L. Bywaters.

MEASUREMENT AND INTERPRETATION OF SYNOVIAL FLUID VISCOSITIES. C. H. Barnett.

ESTIMATION OF THE ERYTHROCYTE SEDIMENTATION RATE OF CAPILLARY BLOOD. H. E. D. Lloyd.

RELATION BETWEEN THE AFFINITY FOR CONGO RED AND THE GLYCOPROTEIN CONTENT OF SERUM IN RHEUMATOID ARTHRITIS AND RELATED DISEASES. Børge Larsen.

Abstracts of World Medicine.—Issued in the first week of each month, this journal contains abstracts of important papers selected from the current medical literature of the world. Annual subscription £4 4s.

British Journal of Ophthalmology.—Issued monthly (£6 annually). The new issue, Vol. 42, No. 7, includes:

EFFECT OF CERVICAL SYMPATHOTOMY ON AN OCULAR RESPONSE TO HYPOTHALAMIC STIMULATION. J. Gloster and D. P. Greaves.

OPHTHALMIC DISEASE IN HONG KONG. G. C. Dansey-Browning.

PROTECTION OF THE GRAFT WITH CONDOM IN KERATOPLASTY. A. Miklós and L. Masovszky.

REPLACEMENT OF TRAUMATIC IRIS PROLAPSE. R. Stein.

DOMINANTLY INHERITED OPTIC ATROPHY. Ruby Joseph and J. B. Davey.

INCOMITANT STRABISMUS OF UNUSUAL ORIGIN. M. S. Niranjan and M. C. Maudgal.

INFECTION WITH MICROCOCCUS TETRAGENUS AS A COMPLICATION OF PENETRATING KERATOPLASTY. G. J. Romanos.

"AMYLOID TUMOUR" OF THE EYELIDS. S. Agarwal and J. B. Shrivastav.

TWO CASES FROM MALAYA. B. M. McOWAN.

OCULAR CASES OF MEDICAL INTEREST. J. Horton Young.

REFRACTION IN MARKED PTOSIS AND BLEPHAROPTHALSIS. J. D. Marot Cardell.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Tuesday, July 22

SOCIETY FOR THE STUDY OF ADDICTION.—At Medical Society of London, 8 p.m., 6th Kelynaek Memorial Lecture by Dr. M. H. J. Krauwel (Amsterdam): Incidence and Treatment of Alcoholism in the Netherlands.

Wednesday, July 23

● INSTITUTE OF CHILD HEALTH.—5 p.m., Simpson Smith Memorial Lecture by Dr. Willis J. Potts (Chicago): Congenital Atresia of the Oesophagus.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. Janet S. F. Niven: Cytopathological Aspects of Latent Infection.

Thursday, July 24

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—At Hospital for Tropical Diseases, 7.30 p.m., clinical meeting.

WEST LONDON HOSPITAL MEDICAL SCHOOL.—5 p.m., Alex Simpson Smith Memorial Lecture by Mr. Harold Burge: Problems in Gastric Surgery.

Friday, July 25

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Mr. W. P. Cleland: clinical demonstration.

● ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.—5 p.m., William Meredith Fletcher Shaw Memorial Lecture by Professor James Black: Reminiscences of Fifty Years' Medical Practice—Forty-seven of Them in South Africa.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—4.30 p.m., Moynihan Lecture by Dr. Willis Potts: Respiratory Emergencies in the Newborn.

APPOINTMENTS

NORTH-WEST METROPOLITAN REGIONAL HOSPITAL BOARD.—D. E. Savage, M.B., F.R.C.S., M.R.C.O.G., Gynaecologist, Highlands General Hospital; A. Knudsen, M.D., M.R.C.P., Pathologist, West Middlesex Hospital; R. C. Fuller, M.B., F.R.C.S., Surgeon, Acton Hospital; J. C. MacKillop, M.B., F.F.Hom., Homoeopathic Physician, Royal London Homoeopathic Hospital; Margaret D. W. Hamilton, M.B., F.F.A. R.C.S., Anaesthetist, Willesden General Hospital.

WRIGHT, J. T., D.M., M.R.C.P., Part-time Consultant Physician to the London Hospital, Whitechapel, E.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Carrick.—On July 4, 1958, to Muriel and David Carrick, M.R.C.S., L.R.C.P., of Feering House, Kelvedon, Essex, a daughter—Eugénie Sarah Anne.

Dhanji.—On June 20, 1958, at 27, Belle Vue Terrace, Sandbach, Cheshire, to Iris (formerly Lewis), wife of Dr. Noor Ali Dhanji, a daughter—Judith Soraya.

Dunn.—On July 5, 1958, at home at Bridgnorth, to Sylvia (formerly Matheson), M.B., B.S., and Andrew Dunn, L.D.S., a son—Conal Matheson.

DEATHS

Bell.—On July 4, 1958, Henry Cooke Bell, M.M., L.R.C.P.S.I. & L.M., of The Paddock, Weston-on-Trent, near Derby, aged 64.

Crichton.—On June 27, 1958, James Smith Crichton, M.B., Ch.B., of 9, Addison Crescent, Kensington, London, W.

Dunn.—On June 27, 1958, at his home, Fern Hill, Manchester Road, Burnley, Lancs, William James Dunn, M.D.

Dyson.—On June 28, 1958, Harold Edward Dyson, M.D., of Stoneacre, Hoxey Hill, Westerham, Kent, formerly of Wembley, Middlesex.

Hudson.—On July 11, 1958, Major-General Corrie Hudson, C.B., C.I.E., D.S.O., F.R.C.S. Ed., of Garth Knowle Drive, Sidmouth, Devon, aged 84.

Jackson.—On June 21, 1958, at his home, 96, Lowther Road, Bourne-mouth, Hants, Thomas Sparks Jackson, M.R.C.S., L.R.C.P., aged 95.

Jordan.—On June 27, 1958, at her home, near Lechlade, Glos., Helen Rosalind Jordan (formerly Ashton), M.B., B.S., aged 66.

Macdonald.—On July 2, 1958, at Feltwell, Norfolk, Alexander Lamont Macdonald, M.B., Ch.B.

Smith.—On June 25, 1958, Edward Archibald Smith, M.B., Ch.M., F.R.C.S., of Eastfield House, Wells, Somerset, late of Vancouver, British Columbia, aged 83.

Smith.—On June 26, 1958, at Monmouth, Herbert Smith, M.R.C.S., L.R.C.P., D.T.M., aged 68.

Smith.—On June 21, 1958, at Bromley, Kent, Fleet Floyd Strother Smith, M.D., Colonel, I.M.S. (retired), aged 74.

Stratfield.—On July 2, 1958, in hospital, London, William Hugh Raymond Stratfield, M.R.C.S., L.R.C.P., of 18a, Thurlow Place, London, S.W., aged 79.

Swan.—On June 22, 1958, James Douglas Carnon Swan, M.B., Ch.B., of 370, Dorchester Road, Weymouth, Dorset.

Tuohy.—On June 29, 1958, at a nursing-home, Patrick Gerald Tuohy, M.B., Ch.B., of Shornbrook, Crowborough, Sussex, aged 70.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Chemotherapy for Pulmonary Tuberculosis

Q.—What is the optimum dosage of streptomycin and isoniazid for patients suffering from pulmonary tuberculosis with positive sputum and high E.S.R.?

A.—The optimum dosage for patients under the age of 40 is streptomycin sulphate 1 g. in one injection daily together with isoniazid 100 mg. twice daily. This should be continued at least until three sputum cultures are known to be negative, when P.A.S. with isoniazid can be substituted. It is safer still to initiate treatment with all three drugs until the patient's organisms are known, by laboratory testing, to have been initially sensitive to all three drugs. Otherwise isoniazid resistance may emerge in the occasional patient who has had the misfortune to be infected with streptomycin-resistant organisms, or vice versa. In any case chemotherapy should continue for at least a year after sputum conversion. Streptomycin should not be given every three days with daily isoniazid: with this regime resistant tubercle bacilli will emerge in 10 to 15% of cases.¹ In patients over the age of 40 daily streptomycin is apt to give rise to vestibular upset. These patients can be given streptomycin three times weekly, but then in that event both streptomycin and P.A.S. (5 g. of the sodium salt twice daily by mouth) must be given if drug resistance is to be avoided. Streptomycin is more likely to give rise to vestibular upset, dihydrostreptomycin to deafness. Dihydrostreptomycin may be permanent. At least partial recovery from vestibular upset is usual, especially if streptomycin is stopped as soon as the patient complains of giddiness. Streptomycin is therefore preferable to dihydrostreptomycin. For details of chemotherapy the *Textbook of Medical Treatment*, edited by Dunlop and his colleagues,² may be consulted.

Antibiotic Antagonism

Q.—Since tetracyclines may antagonize the action of penicillin, is it inadvisable to give systemic penicillin at the same time as local tetracycline therapy?

A.—Antagonism between penicillin and tetracyclines is a reality, but strictly conditioned by the concentrations of the two antibiotics. Thus it is demonstrable in the treatment of acute infections in mice only when the dose of each antibiotic is near the minimum effective level, and the only clear illustration of it on record in the clinical field was in the treatment of meningitis, when neither antibiotic was administered intrathecally, and the concentration attained by each in the cerebrospinal fluid must have been at a critically low level.

The mechanism of this effect, when it occurs, is interference with the bactericidal action of penicillin—which is exerted only on multiplying bacteria—by an antibiotic which is bacteriostatic—i.e., prevents multiplication. It is a purely one-way effect: penicillin does not interfere with the action of a tetracycline when the latter is present in a concentration in excess of that necessary for independent effect. There is thus no objection to the treatment specified in the question: the high concentration of tetracycline produced by local application—say, to the eye—would be unaffected by any penicillin in the lacrimal secretion. On the other hand, so little tetracycline would be absorbed that any antagonistic combined effect in the body generally would be most unlikely.

Determining Immunity to Poliomyelitis

Q.—May the usual serum tests—precipitation, complement fixation, or virus neutralization—be used to determine immunity to poliomyelitis?

A.—Antibodies to the three types of poliomyelitis virus may be detected by either neutralization, complement fixation, or flocculation. The last method is experimental and has not been accepted as a routine method.¹ Following infection, specific complement fixing and neutralizing antibodies can easily be detected, but the former fall off much quicker than the latter and will not be found in the absence of neutralizing antibodies.² The neutralization test is therefore the best method of detecting whether a person is immune to poliomyelitis or not. Subjects without antibody must be considered susceptible, although a small proportion of these may in fact be immune as their antibody may be below the detectable level. Detectable antibody to any given type indicates prior infection with, and therefore immunity to, that type but not to the other two, although heterologous antibody may reduce the incidence of clinical disease in some instances. The routine tests in use for detecting neutralizing antibodies are time-consuming and expensive, and attempts have been made to introduce simpler techniques.³ Unfortunately a reliable skin test is not yet available.

N-acetyl-p-aminophenol

Q.—N-acetyl-p-aminophenol is being advertised now as a substitute for aspirin. Is this, like most aniline derivatives, a substance likely to cause agranulocytosis?

A.—N-acetyl-p-aminophenol may also be called p-hydroxy-acetanilide, which shows that it is closely related to p-ethoxyacetanilide or phenacetin. It may be regarded as a variant of phenacetin. While acetanilide has some reputation for causing agranulocytosis, though much less than has aminopyrine, phenacetin has rarely been known to do so.¹ The substances which cause agranulocytosis include the sulphonamides and thiouracil; it is very difficult to indicate what chemical groups are responsible. All probably act because they resemble compounds occurring in the body whose place they usurp.

Simple Retroversion

Q.—What is the treatment for a simple symptomless retroversion of the uterus found at post-natal examination?

A.—A symptomless, simple (i.e., mobile) retroversion found post-natally needs no treatment unless it is associated with obvious subinvolution—in which case correction and the insertion of a pessary to maintain the new position for six weeks are advisable. In nearly all women with simple post-natal retroversion the uterus was in that position before pregnancy. A patient who has been told she has a retroversion should be assured that it is normal for her.

X-ray Sterilization of Bone Grafts

Q.—Is it possible to use x rays for sterilizing bone for storage and subsequent grafting?

A.—A good deal of experimental work is being done on the use of x rays for sterilization, particularly in the canning industry. No definitive conclusions have yet been reached which would lead one to expect x rays to be used for a like purpose in medicine. In any case radiation is no respecter of cells, and if a dose lethal to an organism is applied it will also presumably ensure the death of the cells in the tissue upon which the organisms lie. In the case of homografts, which, unlike autogenous grafts, are not, in fact, grafts but implants, their contained cells apparently

EXPECTATION OF LIFE AND MORTALITY FROM CANCER
AMONG BRITISH RADIOLOGISTS

BY

W. M. COURT BROWN, M.B., B.Sc., F.F.R.

Director of the Medical Research Council's Group for Research on the General Effects of Radiation, Western General Hospital, Edinburgh

AND

R. DOLL, M.D., D.Sc., F.R.C.P.

Deputy Director of the Medical Research Council's Statistical Research Unit, London School of Hygiene and Tropical Medicine

It has been stated, in a report on "The Biological Effects of Atomic Radiation" by the United States National Academy of Sciences (1956), that the average age at death of American radiologists was about 5 years less than the average age at death of American physicians having no known professional contact with radiation. It was inferred from this finding that exposure to the levels of radiation dose which are received under occupational conditions would result in a reduction in the expectation of life, in the same way as the longevity of animals is reduced by large doses of whole-body radiation given at a high dose rate. Others have claimed that, in this respect, the action of radiation is non-specific and that exposure to even very low doses confers some degree of general unfitness to survive. In explanation, it has been suggested that radiation leads to an accelerated rate of senescence due to the accumulation of genetic damage in the somatic tissues (Failla, 1957; Henshaw, 1957).

The present report stems, in its inception, from the various studies that have been made on American radiologists, and gives the causes of death among a similar group of British radiologists during a 60-year period from 1897 to 1956. The investigation had two objects: firstly, to see whether there was evidence for a decrease in the expectation of life as the result of a non-specific ageing effect, and, secondly, to examine the mortality of British radiologists from cancer.

The Study Population

Through the co-operation of the Council of the British Institute of Radiology and the Council of the Faculty of Radiologists, lists were compiled of the members of each society who had a medical or a dental qualification. In subsequent descriptions members with dental qualifications have been classed with the medical members, whether or not they also had a medical qualification.

For the British Institute of Radiology, the lists were made retrospective to 1897, which was the foundation year of its precursor the X-ray Society, the first radiological society in the world. Soon after its foundation the name of the X-ray Society was changed to the

Röntgen Society, and in 1927 this society amalgamated with the British Institute of Radiology, which had been founded separately in 1922, to form the present institute. For the Faculty of Radiologists, lists of members were obtained from the date of its foundation in 1939 and also from the records of its antecedent societies, the British Association of Radiologists and the Society of Radiotherapists of Great Britain and Ireland, which were founded respectively in 1934 and 1935.

The period over which the data were collected includes the period of the early development of medical radiology, and consequently the persons studied include a large proportion, and probably the great majority, of the pioneer British radiologists, many of whom unwittingly exposed themselves to excessive amounts of radiation.

The lists contained the names of all who joined the societies up to December 31, 1954, and altogether records were obtained of 2,035 medical and dental members; 1,461 of these, on the basis of initial addresses in Britain or Eire or of belonging to the Colonial or Armed Services, were regarded as constituting the "Home" population. For simplicity of analysis, the few women in the population (80) were excluded and the study was limited to an analysis of the mortality among the 1,381 men in the "Home" population.

For each member of the population the following data were recorded:

Name and qualifications; address on entry and last known address; sex; date of birth; date of joining one of the societies; status on January 1, 1957; and (if dead) the date and cause of death.

The information required had to be obtained from a number of sources. It was sought primarily from the records of the societies, but when these were inadequate it was sought in the records of the General Register Office, the General Medical Council, the British Medical Association, other professional organizations, or the hospitals in which the members worked. In a few instances information was obtained direct from the member himself, or from other members or relatives. Whenever a member was known to have died, a copy was obtained of the cause of death entered on the death

5090

play no part in the incorporation into the host, and any simple and non-specific form of sterilization would be suitable.

Notification of Industrial Dermatitis

Q.—Are there any regulations for reporting industrial dermatitis?

A.—H.M. Factory Inspectorate of the Ministry of Labour and National Service is concerned with the prevention of dermatitis in establishments under the Factories Acts, and expert advice, including that from the medical branch, is available to any employer.¹ Dermatitis is not a notifiable industrial disease under the Factories Acts, but, with certain qualifications, occupational dermatitis is prescribed for injury benefit under the National Insurance (Industrial Injuries) Act.²

Thermometer Hygiene

Q.—What is a proper technique for thermometer hygiene when recording a number of temperatures in the course of a round of visits?

A.—When temperatures are taken in the axilla, which is perhaps preferable in the circumstances, there is little risk of transmitting infection unless from a patient with an infective dermatitis in that area. Oral use clearly demands that a reliable process of disinfection be regularly employed. The most comprehensive study of this problem was made by Frobisher, Sommermeyer, and Blackwell.¹ They considered several classes of germicide unsuitable for various reasons, and found others, which are credited with high activity in other types of use, to be ineffectual. Their best results in disinfecting glass rods or actual thermometers contaminated with tubercle and diphtheria bacilli, staphylococci, and streptococci were obtained with 70% ethyl or isopropyl alcohol, the latter being rather more effective. The results were improved by preliminary wiping on cotton-wool wet with a mixture of equal parts of tincture of green soap and 95% ethyl alcohol. If this is done, carrying a thermometer in a case containing spirit of the right concentration should evidently be safe, but it would be advisable to renew the contents frequently.

A.I.H. in "Normal" Partners

Q.—What part can artificial insemination, using the husband as donor, play in the treatment of infertility when both husband and wife are apparently normal? Is the chance of conception increased when the semen is placed in the uterus instead of in the vagina?

A.—A.I.H. has no place in the treatment of infertility when both husband and wife are apparently normal and when coital effectiveness has been demonstrated by a satisfactory post-coital test. However, since this important test is so often omitted in the so-called investigation of infertility as generally practised outside special fertility clinics, it is possible that the apparently normal husband and wife referred to do not have mechanically effective intercourse. If appropriate investigation shows this to be the case, and advice intended to improve coital technique still fails to produce a satisfactory post-coital test, then clearly A.I.H. would be a logical procedure to recommend. Nevertheless, early conception after resorting to A.I.H. in cases of this kind is the exception rather than the rule.

Adequate data on which to base an answer to the second part of the question are not available. Such as exist do not suggest that superior results from A.I. necessarily follow intrauterine insemination, except, of course, when cervical hostility is the reason for using A.I. By cervical

hostility is meant the condition in which the cervical secretions, by reasons of their quality, quantity, or both, do not permit the passage of spermatozoa through them. This is a commonly encountered finding in subfertile couples and frequently defies attempts at treatment. In such cases the object is to place some spermatozoa above the cervical block in the hope that they will then be able to proceed through the uterus and tubes.

NOTES AND COMMENTS

Toxicity of "Albamycin."—Dr. A. R. H. HICKS (medical adviser, Upjohn of England Ltd., Crawley, Sussex) writes: I have read with some concern the answer of your expert to the question, "Does albamycin (calcium salt of novobiocin) have a toxic effect on the liver?" ("Any Questions?" June 21, p. 1493). The occurrence of diffuse hepatic necrosis in the case cited by Bridges *et al.*¹ is possibly attributable to novobiocin, but it must be considered in relation to the dose of novobiocin which the patient received. The boy, aged 14 years, received 2 g. novobiocin 12 hourly, orally for eight days. The weight of the boy is not given but is unlikely to be more than 50 kg. He received, therefore, about 80 mg. per kg. of body weight daily for eight days—more than five times the recommended dose (15 mg. per kg. of body weight daily). A report from the Upjohn Company (presumably Larson *et al.*²) is quoted as describing the occurrence of severe degenerative changes in the liver and kidneys in dogs receiving 300 mg. albamycin per kg. of body weight daily. These changes were only noted when doses of 300 mg. were given intravenously for five days. When the same dose was given orally no degenerative changes in the liver or kidneys were observed at necropsy. Welch *et al.*³ report on a series of 208 adult males who were given 10 g. novobiocin over a 12-day period. Only one of these exhibited a drug rash and three of them showed a yellow discoloration of the sclerae which faded gradually on discontinuation of the drug. By now many thousands of patients have received albamycin and the many reports which have been published demonstrate conclusively that it is an effective drug and that its use, in the recommended dosage, is accompanied by but few side-effects—most of these being insignificant clinically. To my knowledge there has been no further reference to any toxic effect on the liver. If potent drugs are given in doses greatly in excess of those recommended by the manufacturers it is not unlikely that disasters will occur from time to time, and it is not unreasonable to assume that novobiocin could have been responsible for the pathological changes described earlier. However, the omission of details concerning the unprecedented high dosage employed must have given a very false impression of albamycin, a drug which wide usage has shown to be extremely useful and safe in the normally accepted dose range.

certificate. This last information was omitted in a few cases in which the member was reported to have died abroad and there was little doubt about the cause of death—e.g., accidental death or death through enemy action. It proved possible to trace all but four members of the male population, and the subsequent analyses are therefore based on the 1,377 males whose status was known on January 1, 1957. The fact that those whose deaths had not been recorded were alive after this date was confirmed by (1) personal contact or (2) discovering that they had subsequently paid a subscription to one or other medical society.* The majority (probably the great majority) of these men were or are engaged in the practice of diagnostic radiology, and the group as a whole may be regarded as a group of radiologists.

It seems likely that most full-time radiologists in Britain and Eire are, or have been, members of one or other society. The survey is, however, deficient in that it does not include a number of radiologists—mostly perhaps part-time—who have not been members of either society. It is also possible that in the past such people may have been those least protected from radiation. Some indication that such workers have been overlooked arose when, during the course of the survey, the records were brought to our notice of a part-time diagnostic radiologist who recently died from aplastic anaemia and who had never been a member of either of the two societies.

The Extent of Radiation Exposure

It is only recently that active steps have been taken to record the amounts of exposure received by the staffs of radiological departments. Available evidence suggests that exposure, under modern conditions, is almost always well below the weekly maximum permissible dose of 0.3 r (Godfrey, Osborn, and Templeton, 1957). This, however, has not always been the case, and during its formative years medical radiology was often practised without any protective measures being taken. In the earliest days it was common practice for a radiologist to test the condition of his x-ray tube by the deliberate exposure of his hands, and he assessed the state of the tube by the density of the shadows of his hand bones cast on a fluorescent screen.

Hunter (1955) states that protective clothing was introduced in 1903, and Cuthbert Andrews (personal communication) says that by 1909 the wearing of such clothing was a fairly general practice. The clothing was clumsy and bulky to wear, and to obviate this steps were taken, during the first world war, to incorporate protective shielding into the x-ray equipment. In spite of this, radiation damage continued to occur, and in 1921 the British X-ray and Radium Protection Committee was formed as the result of co-operative action between the Royal Society of Medicine, the Röntgen Society, and a number of other interested bodies. This committee issued its first recommendations in July, 1921. There is reason to believe that the action of the committee was fairly quickly effective in arresting the sequence of casualties to x-ray and radium workers. In this survey, therefore, the study population has been divided into those members entering before 1921 and those joining one or other society in 1921 or afterwards. It is assumed that those joining after 1920 would on the whole commence the practice of radiology under recognized conditions of protection, and the comparison of these two sections of the population should be of value in ascertaining whether any significant radiation effects had occurred.

There is little point in attempting to assess the total exposure to radiation of individual members. No data exist

*Except in one instance, when the only evidence that the member was alive later than 1954 was that his address was given in the British and Canadian Medical Directories. He joined the institute in 1949, when aged 30 years.

which permit such estimates to be made with any confidence. It seems reasonable, however, to proceed on the assumption that the average exposure of the pre-1921 members was excessively high, and that the average exposure of the post-1920 members has been within the various permissible limits that have been recommended.

Calculation of the Expected Mortality

To calculate the mortality expected among the members of the societies it is necessary to know the population at risk at each age and in each year from the date when the first members joined the first society (1897) until the end of the period of observation (December 31, 1956). Members were regarded as being at risk from the year in which they first entered a society until either their year of death or the end of 1956, whichever was the earlier, irrespective of the actual length of time membership may have continued. Each member was considered as being at risk for half a year in the year in which he first entered, and, in the event of death, for a similar period in the year in which he died. Members entered the population and deaths occurred more or less equally in each month, so that both events may be regarded as having occurred, on average, at mid-year. The population at risk was then obtained by counting the members at risk at each year of age and for each year from 1897 to 1956, and then adding in each five-year age group the numbers of "man-years" at risk for the period 1897 to 1915, for the quinquennia from 1916 to 1950, and lastly for the period 1951 to 1956.† Separate counts were made for the members who first entered the population before January 1, 1921, and for those joining on or after that date. The numbers of man-years at risk in each five-year age period and for each period studied are shown separately in Table I.

The expected numbers of deaths were estimated, as a first approximation, by assuming that the mortality should be the same as that recorded for all men in England and Wales in the same age groups and over the same periods of time. The numbers of man-years at risk were therefore multiplied by the corresponding age-specific male death rates (McKenzie, Case, and Pearson, 1957), and the total numbers of deaths expected were obtained by adding together the results for all the age groups.

These figures are, however, not the best estimates which can be made, as over the years there has been an appreciable difference between the mortality experience of different socio-economic classes and of different occupational classes. These differences can be allowed for by utilizing the data published in the Registrar-General's Occupational Mortality Supplements. Data have been published for the periods 1910-12, 1921-3, 1930-2, and 1949-53 (Registrar-General, 1923, 1927, 1938, 1958), and they are given separately for different social and occupational classes (including the medical profession). The data are also published in each instance for various age groups up to and including those 75 years of age and over. Some slight variations were made in the definition of the first socio-economic class in the different reports, but in general the class has corresponded to the members of the major professions, senior business executives, etc.

It is reasonable to suppose that the mortality of radiologists would most closely correspond to that of the first social class, which includes all members of the medical profession. The mortality of doctors as a whole has, however, differed appreciably from that of this class. To some extent this may be the result of specific risks associated with general practice, and it is possible that the conditions of life of men in social class I provide a better indication of the conditions of life of radiologists (apart from the latter's specific radiation exposure) than the conditions for the medical profession as a whole. Separate estimates have therefore been made of the total numbers of deaths which

†These periods were chosen for convenience, since age-specific death rates have been published by McKenzie, Case, and Pearson (1957) for cancer of various sites for quinquennia from the period 1911-15.

would have been expected if the mortality of the members of the radiological societies had corresponded on the one hand to that of doctors and on the other to that of men in social class I.

To make the necessary corrections the mortality rates at each Census period were calculated for male doctors and for men in social class I for each age group for which data were given. These were expressed as percentages of the corresponding rates for all men during the same period, and the estimates of the correcting factors required for each of the periods studied were obtained by interpolation. Thus in 1921-3 the mortality of men in social class I aged 55 to 64 years was 88% of the general male population; in the period of 1930-2 it was 95%. Therefore in the quinquennium 1926-30 the correcting factor for social class at ages 55 to 64 years was taken to be $\{88 + 6/9(95 - 88)\}/100$ or 93%. The numbers of deaths expected in each age group calculated on the mortality rates for England and Wales were multiplied by the corresponding correcting factors, and the results summed for all ages and periods to give the corrected estimates of the total mortality (estimates B in Tables II, III, and IV).

These corrections are, however, less satisfactory than might be thought. The reason lies in the fact that above the age of 65 years the Registrar-General's occupational mortality rates are increasingly biased, because a proportion of retired

men fail to give their last occupation on the Census schedule, whereas this is nearly always obtained by the Registrar on the registration of a death. As a result the mortality of all occupations (and of all social classes) is artificially increased in the older age groups, while a very low mortality is recorded for men classified as being unoccupied. This factor cannot be ignored, though it is perhaps less likely to affect the recorded mortality for doctors and for men in social class I generally than for men in most other occupations. It has therefore been thought wise to make a second estimate of the corrected mortality (for both social class and occupation) on the assumption that the mortality at ages over 65 years bears the same relationship to that for all men as does the mortality at ages 55 to 64 years—the oldest age group for which the data can be relied on with confidence (estimates A in Tables II, III, and IV).

The total numbers of deaths expected to be attributed to all types of cancer, and the appropriate corrections for occupation and social class, were calculated by the same method. Data are not available in the same detail to enable similar estimates to be made for expected cancer mortality at specific sites, and a more approximate method was used for this purpose. The numbers of expected deaths were calculated from the national mortality rates in the same way, but in deriving correction factors for social class age was ignored, and the appropriate factors for each

* Estimates made on different assumptions about the relative mortality of men in these social groups aged 65 years and over: see section on "Calculation of the expected mortality."

period were obtained by interpolation from the standardized mortality ratios for ages 20 to 64 years published by the Registrar-General.* For example, the standardized mortality ratio for cancer of the stomach was 60% for social class I in 1921-3 and 55% in 1930-2; the correcting factor for the quinquennium 1926-30 was therefore calculated to be $\{60 + 6/9 (55-60)\}/100$ or 57%. No figures are available for the years prior to 1921, and the standardized ratios for 1921-3 have been taken as the correcting factors for all the preceding years. In the case of leukaemia the earliest available figure was 163% in 1930-2.

The Expectation of Life

Results

The numbers of deaths reported among those members who entered the population before January 1, 1921 (the "pre-1921 population"), and among those who entered in 1921 or later (the "post-1920 population") are shown in Table II separately for nine periods between 1897-1915 and 1951-56. The numbers of deaths in each group are compared with the numbers which it is estimated would have occurred among comparable groups representative of (1) all men in England and Wales, (2) men in social class I, and (3) male doctors. For reasons which have been stated previously two sets of figures are given for the expected numbers of deaths for men in the last two categories, and it is likely that the best estimate lies somewhere between them. The total numbers of deaths for each of the two populations are shown in Table III, subdivided according

TABLE III.—Number of Deaths from Cancer and Other Causes: Observed and Expected, All Periods

	All causes	463	525	499 - 522	514 - 516

* See footnote to Table II.

† Including two deaths attributed to aplastic anaemia and one death for which information about the cause was not obtained.

to whether the deaths were attributed to cancer or to other causes. It is clear that the total of observed deaths (463) is less than would have been expected if the members had suffered a mortality similar to that experienced by all men in England and Wales over the same period (525). It is also less than expected for men either of the same social class (499 to 522) or of the same profession (514 to 516). If the deaths attributed to cancer are excluded the relative differences between the observed and expected numbers of deaths are more marked, and the difference from the smallest number which could reasonably be expected approaches statistical significance (observed 384, expected 421; $P=0.07$).

When the radiologists who joined before and after January 1, 1921, are examined separately it is found that the actual number of deaths was less than the expected number in both groups and that the deficiency was more marked among those who joined later. In the pre-1921 group, however, there was a small excess of deaths due to cancer, and if these are excluded the deficiency of deaths due to other causes is of the same order in both the groups.

*The standardized mortality ratios published for 1930-2 are for the age group 35 to 64 years and these ratios have been used for this period.

These findings should not be interpreted to mean that radiologists have an increased life expectancy as a result of their occupation. A large part of the deficiency is contributed by the experience of the first few years, and much of this is likely to be an artifact due to the exclusion of men who were particularly unhealthy. It is common actuarial experience that men who voluntarily join some organization have a healthier record than average for a few years, because those who know they are seriously ill tend not to undertake new responsibilities. In the course of time the effect of this type of selection must be expected to disappear, and it is unlikely to be appreciable after five years (Jordan, 1952). Whether it has contributed to the present results can be tested by calculating separately the number of deaths expected to occur within the first five years of joining one or other society. When this is done it appears that the deaths observed during this period were markedly fewer than those expected (24 against 42 expected on the basis of the national rates); it would therefore seem reasonable to exclude this part of each individual's membership from the study. The results obtained by so doing are shown in Table IV. The total mortality is still lower

TABLE IV.—Numbers of Deaths from Cancer and Other Causes: Observed and Expected, First Five Years at Risk Excluded

* See footnote to Table II. † See footnote to Table III.

than that expected from the experience of comparable social and professional groups (439 deaths against the lowest estimate of the expected number of 463), and the mortality from causes other than cancer is also lower than that expected—though now clearly not significantly lower (observed deaths 363, least number of expected deaths 390; $P=0.17$).

The slight deficiency of deaths due to causes other than cancer could have arisen because of an inadequate correction for social class and occupation. The correction for class and occupation could not be very accurate, as so many of the deaths occurred at ages 65 years and over and the occupational mortality data available for these ages are known to be unreliable. There has, however, been little change in life expectancy at these older ages over the last half-century, and it seems unlikely that social factors can have had a greater effect on mortality in this age group than at ages 55 to 64 years. It is believed, therefore, that the alternative method which has been used for correcting for social factors will have over-corrected rather than under-corrected the expected mortality. That the deficiency is not due to an error of this type is, moreover, suggested by examination of the mortality among men aged 45 to 64 years. Men in this age group will have had the maximum exposure to occupational radiation, and the corresponding correcting factors for social class and occupation are believed to be reliable. The results for this age group, after exclusion of the deaths which occurred during the first five years of membership, are shown in Table V. It is clear that in this group also there is no evidence of any excess mortality from causes other than cancer among either the pre-1921 or the post-1920 radiologists.

TABLE V.—Number of Deaths from Cancer and Other Causes, Men Aged 45-64 Years: Observed and Expected, First Five Years at Risk Excluded

Group of Radiologists	Cause of Death	No. of Deaths Observed	No. of Deaths Expected from Mortality of		
			General Population	Men in Social Class I	Doctors
Pre-1921	Cancer	22	18	16	14
	Other cause	69	82	76	88

	Other cause	63	67	65	70
All members	Cancer	35	37	33	26
	Other cause	132	149	141	158
All causes		167	186	174	184

Another explanation for the difference could be that the standard chosen for comparison was unsuitable. It is conceivable that, apart from the radiation to which they are exposed, radiologists may constitute a particularly sheltered group with a favourable expectation of life. It is, however, difficult to believe that any such added advantage over other doctors and other men of the same social class could be so great as to outweigh a substantial occupational hazard due to radiation.

Discussion

Experimentally it has been shown by several workers that a single sublethal dose of whole-body radiation shortens the average expectation of life of exposed animals. Experiments on rats and mice have shown that for such doses the reduction in life-expectancy is of the order of 25 to 50% per 1,000 r. Furthermore, it has been considered that the amount of shortening is proportional to the dose received. Mole (1957) has reviewed the existing experimental data on the effect of chronic irradiation on animals—that is, daily exposure, five, six, or seven days a week at dose levels permitting survival for at least six months. With doses of γ -rays, or their equivalent in fast neutrons, of 10 r per week or more there is a demonstrable and significantly reduced expectation of life. For doses of less than 10 r per week the position is equivocal, and in none of the nine reported studies at such low dose rates do the life-expectancies of the experimental groups differ significantly from the controls.

There has, however, been a tendency to draw conclusions about the possible effects of really low radiation doses from the effects observed to follow either single sublethal doses or chronic exposure at comparatively high dose rates. To effect such extrapolations Blair (1956), in particular, has developed a general mathematical theory of the effect of radiation on life expectancy, and, using this theory, Hursh (1956) has calculated that a man exposed to 0.3 r per week—the maximal permissible dose—for 20 years would suffer, in an expected life-span of 65 years, a reduction of life expectancy of two years. Jones (1957) has stated that he considers that in man a whole-body dose of 1 r will reduce the expectation of life by about five days. Failla and McClement (1957) have re-examined the theoretical background of the deductions from animal studies about the possible effects of low-dose exposure in man, and they have suggested that, so long as the exposure rate does not exceed 0.5 r per day, the reduction in life-expectancy per r of whole-body dose is likely to be one day.

There can, however, be no substitute for observations made directly on man. Warren (1956) studied the average age at death of American radiologists and claimed that the finding of a reduction of about five years in comparison with physicians not practising radiology was evidence of an ageing effect of radiation. He thought also that, as the average age at death was reduced for each of the several

causes of death studied, the effect was non-specific. The use of the average age at death as a biological indicator can, however, be justified only if the contrasted populations (1) have a similar distribution of ages at entry, (2) have a similar rate of loss from all causes other than death, and (3) are studied over the same period. In the comparison which has been made between radiologists and non-radiological physicians these conditions have not been met. Since radiology requires postgraduate study the age at entry is raised and the proportion of radiologists in the youngest medical age group is small. Since radiology is a young and growing specialty, the proportion of radiologists in the oldest age group is also small. Hence the test used by Warren—a comparison of their average ages—suggested that the groups were comparable when in fact, as Seltzer and Sartwell (1958) have shown, there is a difference in the age distribution of the groups which is sufficient to account for the whole of the reported difference in the average age at death. It must be concluded, therefore, that Warren's data are not evidence of a reduction in longevity consequent upon occupational exposure to radiation.

Dublin and Spiegelman (1948) reported that the mortality of American specialists in radiology was less than that for all physicians—that is, 90%—but slightly more than that for all specialists (which was 78% of the rate for all physicians). Only 95 deaths were, however, recorded among the radiologists, and the differences are not large enough to be significant.

The mortality data for British radiologists, published by the Registrar-General for England and Wales (1958), relate to even smaller numbers. It may be noted, however, that only eight deaths were recorded among radiologists aged 20-64 years between 1949 and 1953, when the number expected from the rate for all occupied and retired men was 12. The standardized mortality ratio of approximately 70% compares with ratios of 89% for all doctors and 98% for all men in social class I.

The most reasonable interpretation of the results of the present study is that the expectation of life of British radiologists is similar to that of other men of comparable status and has not been substantially altered by their occupational exposure to radiation. This negative finding is all the more striking when the analysis is confined to those radiologists entering the population before 1921. This group of men contains the pioneer radiologists, and an analysis of the deaths from skin cancer (see below) provides good evidence that these men suffered excessive exposure, at least to their limbs.

It may be argued on theoretical grounds that an analysis of the deaths from all causes does not necessarily provide a true indication of whether a group of men is ageing at an accelerated rate. Certainly the process of ageing and the fact of death may be dissociated, and it is possible to visualize circumstances—for example, the outbreak of a severe epidemic causing a high proportion of deaths—in which the total number of deaths would provide a very inadequate measure of the ageing process. Under modern conditions, however, and in the absence of a direct measure, it is reasonable to accept the mortality rate from all causes as a first approximation to the rate of ageing. It can be held, therefore, that the present study provides no evidence of an ageing effect in man under the circumstances of radiation exposure examined. If such an effect does exist, it is apparent that in the case of radiologists it must be very small.

The Mortality from Cancer

Results

The numbers of deaths attributed to cancers of all types and the corresponding expected numbers are shown in Table III. The total cancer mortality is close to that which would have occurred among men of similar social class (79 deaths against an estimate of between 78 and 84), but it is slightly more than would have been expected from

comparison with the cancer mortality of doctors—that is, between 61 and 71. When, however, the population is divided according to the date of joining one or other society, it is seen that there is no reason to suppose that there has been any excess among those joining after 1920; there may, however, have been an appreciable excess among those joining in the earlier years. Among this group 55 deaths were attributed to cancer, and the lowest estimate of the mortality expected among a comparable group of doctors is 35 ($P<0.01$). Exclusion of the first five years at risk makes no appreciable difference to the results (Table IV).

TABLE VI.—Numbers of Deaths from Cancer of Different Types: Observed and Expected, All Periods

Type of Primary Cancer	Pre-1921 Radiologists			Post-1920 Radiologists			All Members

Other	19	21.0	18.4	7	12.9	13.5	26	33.9	31.9
All types	55	47.7	40.9	24	38.3	34.9	79	86.0	75.8

The numbers of deaths attributed to cancer of different primary sites are shown in Table VI, in comparison with the numbers expected from (1) the mortality of all men in England and Wales, and (2) the mortality of men in social class I. As has been stated previously, it was not possible to make separate estimates of the mortalities to be expected specifically among doctors, and the estimates of the deaths which would have occurred among men in social class I have been made with a less detailed method than that used to derive the figures in the previous Tables. The estimates for the total numbers of cancers of all sites shown in Table VI had also to be made by the same methods and the figures for total cancers are therefore slightly different from those in Table III. The numbers of cases of each type of cancer are so small that it would be possible to recognize only gross differences in mortality, and small inaccuracies in the estimates of the expected numbers are unimportant.

No appreciable difference is made to the results by omitting the experience of the first five years' membership. One cancer death (due to cancer of the stomach) occurred in this period among the pre-1921 members, and the expected number of deaths for each site is reduced by about 4%. Two deaths (due to cancer of the pancreas and to a cerebral tumour) occurred among the post-1920 group, and the expected numbers of deaths are each reduced by about 10%.

From the data in Table VI there is no reason to believe that there has been any excess of cancer of any particular type among the post-1920 population; it should, however, be noted that the one death attributed to skin cancer was due to a typical radiation cancer of the fingers. Among the pre-1921 members the number of deaths from cancer of the skin was significantly greater than the expected social class mortality ($P<0.001$), and there is also evidence of an excess of deaths from cancer of the pancreas ($P<0.01$). Only two deaths were attributed to leukaemia; the disease, however, was seldom recognized in the early part of this century, and less than one case would have been expected (expected number 0.5, $P=0.09$). For other types of cancer, considered either as a group or individually, the numbers are close to those which it is estimated would have occurred among comparable non-radiological populations.

Other data for cancer in radiologists are few. Cases of skin cancer among the early radiologists have been reported by many authors, and there can be no doubt that the incidence was increased in several countries. There are good

grounds for believing that there was also an excessive incidence of leukaemia among radiologists in the U.S.A. (Dublin and Spiegelman, 1948; March, 1950). The mortality from types of cancer other than leukaemia was also slightly raised in Dublin and Spiegelman's study (133% for radiologists and 98% for all specialists against a standard of 100% for all doctors). The number of deaths from cancer other than leukaemia was, however, very small (13), and data were not given separately for the different types of the disease. Of the eight deaths among British radiologists reported by the Registrar-General (1958), one was attributed to cancer of the lung and one to leukaemia.

That ionizing radiations are an aetiological factor in certain forms of human cancer is well established. There is no doubt that radiations can induce tumours of the skin, bone, bone marrow, thyroid, and pharynx. There is reason to believe that tumours of other sites can also be induced, although the human evidence for this is not so strong. Animal studies, however, provide evidence that radiations can induce tumours in many deeply seated organs. It is of some importance, therefore, to find no evidence of an excess of cancer at any site in the post-1920 population. This presumably reflects the adequacy of the protective measures that have been recommended, but it is too early to be certain that they are wholly adequate, since half the members of this group have been observed for less than 15 years, and induction periods of 15 to 20 years and longer have been recorded for many radiation-induced tumours.

The study of the pre-1921 population reveals that the excess of cancers can be ascribed to an increased mortality from tumours of three particular sites: the skin, the bone marrow, and the pancreas.

The excess mortality from skin cancer is in keeping with the numerous reports of the development of tumours in skin showing evidence of radiation damage. In addition to the six cases in which death was ascribed to skin cancer, there are two in which this tumour is recorded as an associated cause. Records were also obtained, during the course of the survey, of a further 15 cases of severe damage to the skin of the hands, face, and legs. Many of these will have had associated tumours, and it is reasonable to assume that even this number is not comprehensive.

The increase in the mortality from leukaemia is appreciably less than might have been expected on the basis of the data for American radiologists. This is perhaps not so surprising as might appear at first sight. There seems little doubt that in Britain protective measures were introduced at a very early stage in the development of radiology: firstly, the use of heavy protective clothing, and, secondly, the combination of lighter apparel with shielding incorporated into the x-ray apparatus. These measures, coupled with the fact that x-ray beams of low penetrability were used and that only a small number of persons were at risk in the very early days, may explain the failure to find any large excess of deaths attributed to leukaemia. It has, however, already been pointed out that leukaemia was comparatively seldom diagnosed during the early part of the century, and it is worth noting that in two cases death was ascribed to aplastic anaemia. Both individuals concerned entered the population before 1921, and the deaths occurred in 1921 and in 1941. In the first case the illness is described as being of only a few weeks' duration; in neither case has it proved possible to check the validity of the death-certificate diagnosis. From previous experience (Court Brown and Doll, 1957) it appears that many cases in people suffering considerable radiation exposure may be examples of acute aleukaemic leukaemia, and it is possible that one or both cases may fall into this category.

There remains the unexpected finding of a significantly increased mortality from cancer of the pancreas. The fact that this occurs in the heavily exposed section of the population suggests that it may be related to radiation exposure. The pancreas is, however, a deeply seated organ and would of necessity have received proportionately smaller doses than the bone marrow. It would therefore have to be

postulated that the pancreas possessed a most unusual degree of sensitivity to radiation carcinogenesis. In the absence of supporting data it would be unwise to conclude that this increased mortality is a specific radiation effect. If confirmatory data are not forthcoming it may be presumed that the present findings are due to the operation of chance.

Applicability of the Findings

It is clear that under modern working conditions—that is, the provision of and adherence to adequate protective measures—the personnel of medical radiological departments have not run any substantial risk of (1) a reduction in the expectation of life from a non-specific ageing effect, or (2) an increased mortality from the common forms of cancer. These conclusions, however, are based on the study of fewer than 1,400 men, and in a group this size a very small risk would not have been easy to detect. Much larger numbers of persons are employed in industrial plants associated with the use of radiation sources of various kinds, and there can be no doubt that these numbers will increase considerably in the ensuing decades. These men are, on the whole, exposed to more energetic sources of radiation, and in some cases to types of radiations—for example, fast neutrons—for which the relative biological efficiency for the induction of delayed radiation effects may have a value greater than that of γ rays or medium voltage x rays. It is therefore necessary to be cautious in generalizing from the present experience.

The findings do, however, suggest that, so long as care is taken to introduce and observe the recommended measures of protection, the long-term somatic risks of radiation will be very small.

Summary and Conclusions

A study has been made of the causes of death of 1,377 male British radiologists during a 60-year period from 1897 to 1957.

A comparison of the observed and expected numbers of deaths from all causes provides no evidence that occupational exposure to ionizing radiations has caused a detectable non-specific shortening of the expectation of life. This is particularly striking, since the population includes most of the pioneer British radiologists, many of whom are known to have suffered from specific effects of over-exposure—that is, radiation dermatitis and skin cancer.

A significant excess of cancer deaths was found among those men entering the practice of radiology before 1921, the year in which the first committee to advise on protection was formed. The excess was confined to tumours of the skin and pancreas and (possibly) leukaemia.

No excess mortality from cancer was found in those men entering radiology subsequent to 1920; but it is as yet too early to be sure that the cancer hazard has been eliminated.

The suggestion that this survey should be undertaken was made by the External Radiation Subcommittee of the Medical Research Council's Committee on Protection against Ionizing Radiations, and we should like to record our indebtedness to the chairman, Dr. J. F. Loutit, and the other members of the subcommittee. We would like to thank the Council of the British Institute of Radiology and the Faculty of Radiologists for permission to make use of their records, and the members of their staffs for their ready assistance. We would like also to thank the General Medical Council, the British Medical Association, and the many persons who helped us to obtain information about the individual radiologists, and particularly Mrs. Tana Lloyd, Miss Flora Callaby, and Mrs. Marie Kidd, of the staff of the Medical Research Council, who collected the greatest part of the data.

H. KOPROWSKI, M.D.

Director, the Wistar Institute, Philadelphia, Pa., U.S.A.; previously Assistant Director, Virus and Rickettsial Research Lederle Laboratories, Pearl River, N.Y., U.S.A.

AND

G. NINANE, M.D.

Laboratoire Médical, Stanleyville, Belgian Congo

Vaccination of man by oral administration of live attenuated poliomyelitis virus has been employed in clinical trials in the United States of America (Koprowski, 1955; Koprowski *et al.*, 1952, 1956a, 1956b). Several attenuated strains representing the three types of poliovirus were investigated, and the number of persons vaccinated in each trial was kept purposely small until a strain could be found which would satisfy laboratory and clinical criteria of safety. Such strains finally became available (Koprowski, 1957), and therefore it was decided to organize a clinical trial on a larger scale than had been previously attempted.

While participating in a rabies course organized by the World Health Organization in 1955 in Muguga, Kenya, one of the authors (H. K.) had the opportunity, through

*Part of the work mentioned in this paper was supported by a research grant (E-1799) from the National Institutes of Health, U.S. Public Health Service.

the kindness of Dr. T. J. Wiktor, Veterinary Service, Belgian Congo, to contact one of the other authors (G. C.) and to propose a programme of experiments for the evaluation of attenuated strains of poliovirus in chimpanzees. Following the successful outcome of preliminary negotiations, a chimpanzee colony was established in Lindi (Stanleyville, Belgian Congo) and experiments were initiated after necessary permission and financial support had been obtained from the Government of the Belgian Congo.

In the course of this work, results of which will be published elsewhere (Courtois *et al.*, 1958), caretakers of the animal colony were vaccinated with attenuated virus in order to protect them against possible exposure to the virulent poliomyelitis used for challenge of vaccinated chimpanzees. The successful outcome of the programme for immunization of the caretakers prompted us to undertake clinical trials in the Belgian Congo on a much larger scale than had been attempted so far. Authorization to conduct such trials was obtained in the second half of 1957 from Dr. Charles Dricot, Physician-in-Chief, Government of Belgian Congo, to whom we express gratitude.

Material and Methods

Virus Strains.—The Chat strain of type 1 poliovirus and the Fox III strain of type 3 poliovirus were chosen for vaccination purposes (Koprowski, 1957). The large pools representing each strain were prepared in the Laboratories of the Wistar Institute, Philadelphia, Pa., and tested for lack of virulence in rhesus monkeys injected intracerebrally and intraspinaly and in chimpanzees injected intracerebrally (the latter tests were done in Lindi Camp, Belgian Congo). None of the intracerebrally injected monkeys and intraspinaly injected chimpanzees (five animals were injected with aliquots of undiluted material representing each pool) showed signs of illness, and histological examination of the central nervous system showed only one chimpanzee with mild lesions of the spinal cord suggestive of poliomyelitis infection (Fox III). Signs of polio infection were found in some of the rhesus monkeys injected intraspinaly with the undiluted material; this, however, has not deterred us from using these strains for mass vaccination purposes, as there is no strain of attenuated poliovirus available anywhere in the world completely devoid of pathogenic properties when injected intraspinaly into rhesus or cynomolgus monkeys (Sabin, 1957).

For additional testing, aliquots of each pool were injected into 20 rabbits, 14 infant mice, 5 guinea-pigs, and 12 adult mice in order to rule out the presence of other viral agents, such as B virus, lymphocytic choriomeningitis, and Coxsackie viruses. Although the material was filtered through bacteria-retaining filters, rigid tests for bacterial sterility were completed before the virus pools were used in man.

The efficiency of each virus preparation was finally checked by feeding the virus to a small group of infants and adults in the United States of America. These indi-

viduals had no antibodies against the type of virus administered, and in no instance was there a reaction of any kind. This procedure also made it possible to determine the minimum immunizing dose of the virus, which was found to be $10^{3.7}$ TCD₅₀ (tissue culture doses) for non-immune children and adults and $10^{5.0}$ TCD₅₀ for infants less than 1 month old.

Method of Administration of Virus to Man.—The virus preparation was administered either in capsule (Koprowski *et al.*, 1956b) or in liquid form. Administration of the liquid was accomplished either by immersing an automatic pipette into a large container of virus preparation and squirting 1 ml. direct into the mouth of the recipient or by simply using a tablespoon. The approximate minimum dose fed to each individual was $10^{5.3}$ TCD₅₀ of each strain. Throughout the above period the container of virus suspension was kept at 4° C.

Determination of Neutralizing Antibodies.—In localities where prophylactic vaccination was contemplated a certain number of individuals chosen at random were bled and the presence of neutralizing antibodies against all three types of poliovirus was determined by means of the immuno-inactivation test described by Gard (1957). Immunization of the total population of the community was decided upon only if 12% or more of the sera collected were found to have no antibodies against a given type of virus.

Since type 1 virus was incriminated in most outbreaks of paralytic poliomyelitis, including those in the Belgian Congo (see below), it was decided to give priority to vaccination with attenuated type 1 virus wherever it was statistically feasible.

Vaccination of Populations in the Absence of a Poliomyelitis Epidemic

Localities where trials took place are shown on the accompanying map of the Belgian Congo, and the total number of persons vaccinated is given in Table I.

Map showing locations in the Belgian Congo and Ruanda-Urundi (Aketi, Stanleyville, Ruzizi Valley, Banalia, Gombari, Watsa, and Bambesa) where mass vaccination trials with live attenuated poliovirus were conducted. The small insert map shows the same region (cross-hatched) in relation to the surrounding geographical area.

TABLE I.—Number of Persons Vaccinated with Live Attenuated Poliovirus* in Various Communities in the Belgian Congo and Ruanda-Urundi

Town	Adults		Children Under 15 Years	Total
	Males	Females		
Stanleyville	1,651	1,005	1,572	4,228
Aketi	1,371	1,028	1,978	3,482
Gombari	3,136	4,753	4,900	12,789
Watsa	219	946	1,268	2,433
Bambesa and Kule-Ponge	62,140	62,200	91,164	215,504
Ruzizi Valley	1,267	1,343	1,572	4,182
Banalia				
Total	69,784	71,275	103,537	244,596

* Chat strain type 1 poliovirus. In addition, 2,511 persons were vaccinated with type 3 poliovirus, Fox III strain; 134 men, 130 women, and 2,247 children.

Aketi.—Here 1,978 school-children, most of them between 5 and 15 years old, were chosen for vaccination. One hundred serum specimens obtained by random bleeding of future recipients of the vaccine were examined by means of neutralization tests; 15% were found to have no antibodies against type 1 and 43% no antibodies against type 3 virus. The Chat strain virus preparation was administered in capsules to 1,978 recipients (see Table I), and those who showed no antibodies against this type were bled again two months after vaccination. During that period rigid clinical observations failed to show any signs of illness which could be attributed to the vaccine. All but two of the vaccinated children who had no antibodies to type 1 virus before vaccination developed determinable serum antibodies against type 1 poliovirus following vaccination. Six months after vaccination with type 1 virus, the Fox III strain of type 3 virus was administered to the same population. Again no signs of illness were observed, and all but two who had no antibodies to type 3 virus before vaccination developed type 3 antibodies following vaccination.

Stanleyville.—During the 12 months preceding the mass trial at Ruzizi Valley (see below) infants, children, and adults of European and native origin living in Stanleyville were vaccinated with Chat and Fox III virus strains. A large group of school-children, mostly of European origin, were vaccinated with living virus every week during that period of time. The total number was 4,228 (see Table I), and careful clinical observations failed again to reveal any detrimental effects of the vaccines.

Ruzizi Valley.—A mass vaccination trial was decided upon after preliminary testing of 84 serum specimens collected at random from inhabitants of Ruzizi Valley revealed that 12% had no neutralizing antibodies against type 1 virus and 15% had no antibodies against type 3 virus. The trial began on February 24, 1958, and was completed by April 10. The native population were informed by their chiefs about the vaccination project and assembled daily at previously fixed rally points. From 3,000 to 11,000 persons were vaccinated daily by members of one or two vaccination teams. The vaccine used was a preparation of Chat type 1 poliovirus, given orally as a liquid. Included in the trial were two missionary schools whose pupils were divided into two groups, one receiving the vaccine and the other a placebo. Medical authorities were asked to report any occurrence of illness which could be attributed to vaccination, but none was reported. For evaluation purposes 450 blood specimens were obtained at random before vaccination from individuals who were less than 15 years old. The total number of children and adults vaccinated in the Ruzizi Valley was 215,504, as indicated in Table I.

Vaccination Against Poliomyelitis in Face of an Epidemic

Banalia.—Between the end of November, 1957, and the first days of January, 1958, eight cases of paralytic poliomyelitis in native infants and children less than 5 years old were observed in Banalia. Signs of paralysis in the latest two cases were observed five days before vaccination was started. The total population of Banalia was 4,182, and the number of children less than 5 years old was 674 (Table II). Since all cases of paralytic poliomyelitis

TABLE II.—Age and Sex Distribution of Inhabitants of Banalia Vaccinated with Live Attenuated Poliovirus

Age	Males	Females	Total
<5 years	312	362	674
5-14	497	401	898
Adults (over 14 years)	1,267	1,343	2,610
Total	2,076	2,106	4,182

occurred in children less than 5 years old, the actual incidence for that age group was 1.2%.

Following the recommendation of the Expert Committee on Poliomyelitis of the World Health Organization (Report of the Expert Committee, 1957) and upon the request of the Médecin Provincial of Province Orientale, Chat type 1 virus was administered to every inhabitant of Banalia. Blood specimens were obtained before vaccination, including samples from three of the persons who had contracted paralytic poliomyelitis most recently. Sera from these three patients were examined by means of a complement-fixation test for the presence of antibodies against antigens representing each of the three types of virus. No antibodies were discovered against type 2 and type 3 viruses, but sera in dilutions 1:16, 1:16, and 1:32 were found to fix complement in the presence of type 1 antigen; the outbreak would therefore seem to have been caused by type 1 virus. Not a single case of paralytic poliomyelitis was observed in Banalia following oral vaccination with the Chat type 1 strain of virus.

Gombari, Watsa, and Bambesa.—Within three weeks of the occurrence of the last paralytic case in Banalia, outbreaks of paralytic poliomyelitis were reported in Gombari, Watsa, and Bambesa. In Gombari, a village of 3,482 inhabitants, 12 cases of paralysis were reported. In Watsa, out of 12,789 inhabitants, two cases were observed. In Bambesa seven cases were noted among 2,350 inhabitants. Live attenuated Chat type 1 virus was administered within five days of the occurrence of the last reported case of paralysis. Again, as in Banalia, every inhabitant of Gombari, Watsa, and Bambesa received the vaccine. After the fourth post-vaccination day no new cases of paralysis were observed in these localities.

Summary and Conclusions

A total of 244,596 inhabitants of the Belgian Congo and Ruanda-Urundi of both sexes and all ages were vaccinated with live attenuated Chat strain type 1 poliovirus by the oral route. Of these, 2,511 also received the Fox III strain of attenuated type 3 virus. No sickness was reported following administration of the virus.

Figures based on a preliminary survey of neutralizing antibodies in the population who were later vaccinated indicated that 12% had no antibodies against the type 1 virus which was used as vaccine. More exact data on the proportion of polio-susceptible individuals will be obtained when laboratory tests on the large number of sera collected during the actual trial are completed.

Following recommendation of the Expert Committee on Poliomyelitis of the World Health Organization, the live Chat type 1 virus was administered during four epidemic outbreaks of paralytic poliomyelitis in the Belgian Congo. After vaccination no more cases of paralysis were reported in the four localities involved in the outbreaks.

We thank all the officials who gave us permission to carry out the mass vaccinations: Dr. Dricot, Physician-in-Chief, Government of the Belgian Congo; Dr. Gillet, Chief of the Hygiene Service at Bukavu, under whose control the Belgian Government has placed the experiments; Dr. Claessens, Dr. Gillart, and Dr. Van Daele, Provincial Physicians. We especially thank Mr. Brakel, who took part in the vaccination campaign during the epidemics. We likewise thank all those who contributed directly to the vaccination programme: Dr. Meyus, Dr. Dewolf, Dr.

(Case 24), admitted in 1943, was, according to her doctor, "of sufficient nuisance value for me to remember her. After leaving hospital she went downhill and died at home a few months later. She simply died of inanition, and there was no question of secondary infection."

One patient (Case 26), admitted in 1938, was still alive in 1953. Then her doctor wrote, "She is at present grossly emaciated, with severe chilblains of both hands and feet." She herself replied that she was fairly well, but that she dreaded the winters because of her chilblains. On January 28, 1954, she was admitted to hospital, having been found unconscious on the floor by her sister. She died within eight hours, and at necropsy death was attributed to myocardial degeneration. No other abnormality was found apart from extreme wasting of all tissues.

One patient (Case 30), who was intubated during her admission in 1953, died four years later. Her weight gradually fell to 4 st. 11 lb. (30.4 kg.) three weeks before she died, and she was finally admitted to hospital elsewhere in coma, with a blood-sugar level of 34 mg. per 100 ml. There had been at least two previous episodes of hypoglycaemic coma. Necropsy was not performed.

Follow-up of Surviving Patients

Of the 49 patients admitted up to 1953, 32 remain, and 15 of them have attended for interview and examination. Eleven others, mostly living out of London, have replied to questionnaires, and further information about them has been obtained when possible from their doctors. The relatives of one patient (Case 40) wished not to disclose her subsequent progress; one (Case 1) refused to be seen by an almoner who visited her home. Of the remaining four (Cases 22, 25, 32, and 42) adequate information has been obtained from their relatives and doctors and from other hospitals.

Twenty-three patients have recovered completely, the period of follow-up ranging from 3 to 21 years, with an average of 13 years. All are well nourished, happy, and fully employed; 12 have married and 6 of these have borne children. One patient (Case 36) was cured by leucotomy, performed elsewhere.

Six other patients reviewed 5 to 13 years after admission (average nine years) have improved. Thus five are at regular work, but are still underweight, with neurotic symptoms. These are unlikely to improve further, whereas one (Case 22), still only 17 years of age, has recently regained her normal weight, and may eventually also recover her normal mental outlook.

Three patients, on the other hand, have not improved. One (Case 1) is still poorly nourished and confined indoors, another (Case 25) is a gross hysteric, and another (Case 40), presumed from the attitude taken by her relatives not to have recovered, may have died.

Summary of Progress.—Thus out of a series of 53 patients with anorexia nervosa 10 have died, 3 have not improved, 6 have improved, and 23 have recovered. Seven are unaccounted for. The four admitted since 1953 have not as yet relapsed. These are among the seven treated with intubation; two others admitted earlier who were intubated are in the recovered group, and one who was not kept under surveillance has died.

Comment

The outcome in this as in most other reported series was largely unaffected by hospital treatment. Those patients who recovered did so of their own volition and in the fullness of time, mostly after their environment had deliberately or accidentally been changed. Only a few when questioned in retrospect could give a precise reason for recovery, and in these it was often as whimsical as the circumstance which had first precipitated the illness.

Thus one patient had been grossly underweight for six years until she developed bronchitis. It then occurred to her that if she did not eat she would die, whereupon her appetite returned and she recovered. Another, in the beginning, had tried repeatedly to diet, but had been defeated by hunger. At the age of 18 years she lost her appetite during an attack of influenza; she then succeeded in suppressing it further until her weight fell from 11 st. to 5 st. 9 lb. (69.9 to 35.8 kg.), and it remained at this level despite hospital treatment followed by four months at a convalescent home. Her eventual recovery she attributes to leaving home for domestic service; and now, at the age of 39, she frankly admits that the whole illness "was due to my own silliness in trying to starve myself."

It should not be inferred, however, that anorexia nervosa is best left to its own devices, for the mortality rate alone demands a most vigorous approach to treatment. Of the 53 patients under review, 10 died, and, although this is the highest death rate so far recorded, it has also been substantial in many other published series. The lowest weight recorded in the present series, 3 st. 8 lb. (22.7 kg.), was in a patient who recovered completely. Even so, the most emaciated patients are in greatest immediate danger, especially if their deterioration has been rapid (Emanuel, 1957).

Treatment by Psychiatric Methods

Psychiatrists almost without exception consider psychotherapy the appropriate treatment. Thus Du Bois (1949) claimed, "It is the neurosis and not the appetite that must be the prime focus of attack by the physician. Therefore psychotherapy is the major remedial agent. Little reference should be made to diet, and the family and nursing personnel are instructed to avoid talking about food or the patient's dietary habits. During the early weeks of treat-

ment psychotherapy consists of reassurance and explanation . . . and at the end of approximately three weeks it proceeds gradually to a deeper level." Yet of his 10 patients none was cured. Five remained thin and unhappy, two defaulted, and three were still under treatment. Similarly in Nemiah's (1950) series, although one patient gained 10 lb. (4.5 kg.) while in hospital, and another 20 lb. (9 kg.), there was no response from the remaining 12. Rahman *et al.* (1939) were forced to conclude, after treating 12 patients in this way, that much time and patience was required, and that the under-cover hostility met with made it difficult or impossible to establish a satisfactory therapeutic rapport.

Waller *et al.* (1940) have claimed a specific psychopathology for the illness, based on fantasies of oral impregnation which both their patients had experienced. Yet even psychiatrists are now sceptical of Waller's Freudian hypotheses (Kay, 1953), and are discouraged by the results of treatment based upon them. Kay and Leigh (1954) believe that psychotherapy is not the treatment of choice unless (1) there is no urgency, (2) a good relationship can be quickly established, and (3) the patient is able to formulate a complaint which could be used as a basis for therapy.

Whereas recent views on treatment have largely ignored its "somatic" aspect, it cannot be overemphasized that the danger to life is entirely from malnutrition or its consequences, and that the patient who succumbs does so only from starvation. But in endeavouring to reclaim anorexia nervosa it must first be established why it has strayed from the realm of somatic medicine to the borderlands of psychiatry (Cobb, 1943). The discouraging results of treatment based on general medical principles is one of the more obvious causes of its defection. Yet probably the most important is its tendency sometimes to simulate the psychoses, particularly schizophrenia, thus suggesting to physicians that it is a disease outside their competence to treat.

Neurotic symptoms and depression are common (Kay, 1953) and easy to understand. They may, in fact, be the direct outcome of inanition (Schiele and Brozek, 1948). Peculiarities of behaviour or "the perverse conceits and strange notions" described by Gee (1907), on the other hand, are more disconcerting. "One of these girls," he observed, "when she was alone in the drawing-room, was overheard to tell her parrot that she was not much longer for this world. Lost in her museful moping, she takes delight in nothing and loves to be alone, though solitude does her more harm. . . . Sometimes she will think that exercise is very necessary and will take long walks far beyond her strength, or she will try the ecoprotic powers of leaping and dancing in her bedroom before daybreak until the awakened household protest against the continuance of such preposterous therapeutics." Despite this and similar instances, Kay and Leigh (1954) have reassuringly concluded that schizophrenia and anorexia nervosa are in no way allied. Furthermore, none of the patients in the present series has developed schizophrenia or any other psychosis requiring prolonged institutional care.

Hurst's Method of Treatment

The best results of treatment have been claimed by Ryle (1936), Ross (1936), and Hurst (1939), based on almost identical principles. These principles were most clearly enunciated by Hurst, who said that with explanation, firmness, and good temper the most resistant patient could be persuaded to consume a full meal, her progress thereafter being uninterrupted. Hurst, however, gave no details of the results he obtained, and Ryle, while stating that in the majority of well-handled cases recovery is complete, did not deal specifically with the immediate outcome. Many of his cases were in fact mild. Thus in 11 of his 46 female patients, who did not have amenorrhoea, the criteria for diagnosis were not fulfilled; and having traced 37 patients, 17 of the 21 who had recovered had not required institutional treatment. All 19 of Ross's patients, on the other

hand, increased weight by at least 14 lb. (6.4 kg.) during admission.

But the ineffectiveness of Hurst's method in the hands of others and the difficulties entailed have never been adequately stressed. It was doubtless employed in many of the patients in the present series with results which were almost wholly discouraging.

Treatment with Intubation

All seven patients who were intubated gained weight, an average of 22 lb. (10 kg.) per patient, and their condition on discharge from hospital was good. Forty-four patients, on the other hand, not treated in this way gained an average of only 9 lb. (4.1 kg.) per patient, only seven gaining more than 14 lb. (6.4 kg.). Berkman *et al.* (1947) cautioned against intubation on the premise that the aggressive treatment of patients who are extremely emaciated might prove disastrous, and it has been used only inconsistently and in extreme cases by others (Rahman *et al.*, 1939; McCullagh and Tupper, 1940; Farquharson, 1941).

The method, however, has obvious advantages. Because little active co-operation is sought the initial resistance is never as great as to normal feeding, and at this stage the more enfeebled the patient the easier it is in any case to overcome (Lasègue, 1873). Furthermore, the protracted ordeal of each meal is avoided, and because calorie intake can readily be made to exceed requirements the rate of recovery is always maximal. The patient should still be encouraged to eat at meal-times despite the postprandial discomfort and superadded anorexia of prolonged starvation (Fenwick, 1880; Carlson, 1916). Meanwhile as weight inevitably increases so may depression and other nervous symptoms disappear (Schiele and Brozek, 1948; Keys *et al.*, 1950).

One patient in the present series, who was successfully intubated, died four years later, thus emphasizing the need for close liaison with the family doctor and all others concerned in the patient's care. In this way intubation may have to be employed repeatedly on patients who will eventually recover, but meanwhile the more recalcitrant are saved from dying of inanition.

Treatment with Leucotomy

A few patients resist medical treatment in any form. They constitute Ryle's (1936) psychotic group with inadequate personalities, but who at first are indistinguishable from their fellows. Anorexia in these, if they survive, persists indefinitely, and their treatment presents the greatest problem. In some the response to leucotomy has been excellent (Sargent, 1951; Sifneos, 1952; Mallinson, 1953; Sands, 1953), although Carmody and Vibber (1952) stressed that it should be considered only in refractory cases and in those who are frankly psychotic or of the obsessive compulsive group. Two patients in the present series recovered spontaneously after having been refractory for 8 and 11 years, and the selection of cases needing leucotomy is therefore still difficult.

Summary

The progress of 53 patients with anorexia nervosa has been studied, during and after their stay in a general hospital.

In-patient treatment was ineffective except in those who were intubated. Follow-up shows that 10 patients have died, 8 of them solely of malnutrition, others of the same severity recovering spontaneously after a varying number of years. Twenty-three patients have recovered completely.

The importance of the nutritional aspect of treatment should be stressed, and, whereas leucotomy may rarely be required, specialized psychotherapy is not indicated.

I am grateful to the physicians of the London Hospital for permission to study and publish their cases, and I am particularly

indebted to Dr. Donald Hunter and Dr. Kenneth Perry for their advice and criticism. I also thank Mrs. E. Scott, chief dietitian to the hospital, for her help, as well as the many general practitioners who co-operated in this investigation.

TWO CASES OF COW'S-MILK ALLERGY

BY

B. D. BOWER, M.D., M.R.C.P., D.C.H.
Lecturer

D. G. STANLEY-ROOSE, M.B., B.S.
Formerly Resident Medical Officer

AND

O. H. WOLFF, M.D., M.R.C.P., D.C.H.
Senior Lecturer

From the Children's Hospital, Birmingham, and the
Department of Paediatrics and Child Health,
University of Birmingham

Acute allergic reactions to cow's milk in infancy are uncommon enough to justify a description of two cases that presented problems in diagnosis and management. In particular, the occurrence of ascites in one case deserves mention as a sign not previously reported.

Case 1

The patient, a female infant, was delivered by caesarean section after a 38-weeks' pregnancy. She was the first child of healthy parents and there was no family history of allergy. The neonatal period was uneventful. She was fully breast-fed until 3 weeks of age, when she was given a bottle feed of dried milk ("ostermilk No. 2"). Immediately after this feed she vomited, and the next day developed diarrhoea with much mucus but no blood in the stools. Rapid deterioration with fever, intense irritability, and further vomiting led to her admission to the Children's Hospital, Birmingham, on July 26, 1956, within 48 hours of the first feed of cow's milk.

On admission she was shocked with peripheral cyanosis, a fever of 103° F. (39.4° C.), pulse rate of 160, and respiration rate of 50. Her cry suggested pain. The abdomen was distended and tympanitic, but no other signs were found.

Investigations.—Cerebrospinal fluid, normal. X-ray examination (Dr. R. Astley) of chest, normal; of abdomen: "The small and large intestines are fairly full of gas, with

a few small fluid levels. In addition there is some diffuse opacity, and the abdominal distension is not entirely due to intestinal gas. Consistent with peritonitis." Paracentesis abdominis: clear straw-coloured fluid obtained without difficulty; microscopy showed some red cells, a few endothelial cells, and lymphocytes; no organisms were seen or cultured. Blood count: haemoglobin, 100% (14.8 g. per 100 ml.); W.B.C., 6,600 per c.mm. (metamyelocytes 1%, myelocytes 3%, polymorphonuclears 35%, eosinophils 1%, lymphocytes 54%, monocytes 6%). Urine, normal. Blood urea, 19 mg. per 100 ml. Stool: many fat globules, no pathogens isolated. Blood culture: *Staphylococcus albus* (contaminant).

Before paracentesis a diagnosis of primary peritonitis had seemed likely, but the nature of the ascitic fluid ruled this out. In the absence of a diagnosis the patient, who presented the picture of an overwhelming infection with intense toxæmia, was treated with oxygen, subcutaneous fluids, penicillin, and streptomycin. Her condition improved quickly and within a few hours of admission she tolerated oral feeds of 5% dextrose in 0.18% saline. The following day the fever had settled and she had gained 11 oz. (340 g.), but was still passing loose green motions with much mucus. The improvement continued and on the second day after admission quarter-strength feeds of dried milk (half-cream national dried milk) were started. Within a few hours she became ill once more; bile-stained vomits and frequent watery stools led to a weight loss of 6 oz. (170 g.). The pyrexia recurred, the abdominal distension increased, and a fine erythema appeared on the trunk and face. At this point the diagnosis of cow's milk allergy was first suggested. Consequently streptomycin and penicillin were discontinued and the feed was changed to expressed breast milk. The resulting improvement was dramatic; the fever settled, vomiting ceased, the motions became normal, abdominal distension subsided, and she started to gain weight.

Tests were undertaken to confirm the diagnosis of cow's milk allergy and, if possible, find a substitute for cow's milk: (1) *Scratch tests* on Infant*: breast milk, negative; half-cream national dried milk, positive; evaporated milk, positive; goat's milk, positive; "soyolk" (soya-bean milk), negative; "nutramigen" (a synthetic food in which amino-acids and simple peptides have been obtained by enzymic hydrolysis of casein), negative; "allergilac" (dried milk from which most of the lactalbumin has been removed and acid added), negative. (2) *Passive transfer test* (Prausnitz-Küstner reaction)*: Serum taken from the infant was injected intradermally into the mother's forearm; 24 hours later a drop of milk to be tested was placed on the skin areas thus treated and a scratch made through each drop. Control tests were carried out in untreated areas on the opposite forearm:

	"Treated" Areas	Control Areas
Breast milk	Negative	Negative
Half-cream national dried	Positive	"
Evaporated milk	"	"
Soyolk	"	"

These tests confirmed the diagnosis of cow's milk allergy, but, as will be seen, were of no help in choosing a substitute.

During the next three weeks she was fed on expressed breast milk and gained over a pound (450 g.) in weight; the stools remained normal and she did not vomit. Four weeks after admission she was given a 6-oz. (170-ml.) feed of breast milk containing approximately 0.5 g. of soyolk powder. Within an hour of the feed she vomited copiously. The following day a similar feed had the same effect. The next day she tolerated a feed containing nutramigen in the

* "Positive" signifies appearance within 10 minutes of a weal and surrounding area of erythema greater than 2 cm. in diameter. "Negative" signifies absence of weal and little or no erythema. (Separation of test results into these two categories presented no difficulty.)

same dilution; during the ensuing five days the amount of nutramigen was gradually increased, but when the concentration reached eight times the original one vomiting recurred. On returning to pure breast-milk feeds vomiting ceased. Our third, and successful, choice was allergilac, which was added to breast milk at first in a dilution of 1 fl. dr. (3.5 ml.) of full-strength milk to 6 oz. (170 ml.) of breast milk; during the next nine days the amount of allergilac was increased up to full strength. She made uneventful progress and was discharged at the age of 10 weeks in excellent condition, but with a small patch of eczema on the forehead.

When she was four months old one drop of boiled cow's milk was added to each allergilac feed without ill effect, and thereafter the quantity was slowly increased, until two months later she was on full-strength cow's milk. No vomiting occurred during this period. Solids were then introduced, and she tolerated a normal toddler's diet, including cereals, eggs, meat, fish, etc. At 6 months the scratch test with cow's milk was negative and the passive transfer test gave only a slightly positive reaction.

Further progress has been uneventful, though the small patch of eczema on the forehead persisted to the age of 7 months.

Case 2

The patient, the fourth child in the family, was born normally at term. Birth weight, 8 lb. (3,630 g.). During the pregnancy, which had been complicated by excessive vomiting, the mother took between 1 and 2 pints (570 and 1,140 ml.) of milk daily. The three siblings were healthy, but the mother had always had eczema of the hands, and a paternal uncle suffered from asthma.

During the first few days of life two complementary feeds of cow's milk were given. A rash with "blisters" appeared on the buttocks at this time and took some weeks to fade. From the end of the first week until the age of 4½ months she was entirely breast-fed and thrived. Introduction of cow's milk was then tried, but each attempt led to pronounced resistance, the baby spitting out the milk vigorously; "blisters" appeared wherever milk touched the skin, and an erythematous rash occurred on face, neck, and trunk. Boiled cow's milk, three different popular dried milks and allergilac produced the same result whether given by bottle, cup, or spoon. Though there was no vomiting, she lost weight during out-patient observation. At the age of 6 months the mother's milk was failing and the infant had to be admitted to hospital to find a substitute for breast milk or, if the search proved unsuccessful, to desensitize her to cow's milk.

On admission she was contented and not obviously wasted, though her weight was only 12 lb. 8 oz. (5,585 g.). The following sensitivity tests were carried out: (1) *Scratch Tests on infant*: Breast milk, negative; cow's milk, positive; half-cream national dried milk, positive; full-cream national dried milk, positive; allergilac, positive; goat's milk, positive; soyolk, negative. (2) *Prausnitz-Küstner reaction* (intradermal injection of patient's serum into her father's forearm and scratch testing 24 hours later): No reaction to half-cream national dried milk, full-cream national dried milk, unmodified cow's milk, allergilac, soyolk, breast milk.

Soyolk therefore seemed suitable for trial. For three days this feed was given with no ill effect, although her resistance to feeding by bottle, cup, or spoon was such that it had to be given by intragastric tube. Then vomiting started and, far from being relieved by chlorpromazine, was apparently aggravated by it. Consequently, after a short period of dextrose feeding, a slow intragastric drip of breast milk was started, and vomiting ceased. At this point a barium-meal x-ray examination showed no anatomical abnormality of the oesophagus, stomach, or duodenum, but the stomach emptied slowly.

Three weeks after admission we tried goat's milk, despite the positive skin test, as an adequate supply of breast milk

could not be guaranteed. A feed of 1 fl. oz. (28 ml.) of goat's milk and 5½ fl. oz. (156 ml.) of expressed breast milk was given, but was immediately vomited. For the next 10 days her feed consisted of breast milk alone, with two notable exceptions: one feed contained a small amount of soyolk and the other consisted of a full-strength dried milk feed given in error. These two feeds were the only ones to cause vomiting. As all these feeds were given by intragastric tube, it seems unlikely that a different taste or smell was responsible for the vomiting.

A desensitization course of cow's milk was started at the end of the fifth hospital week, when she was 7½ months old. A feed containing one drop of cow's milk in 8 oz. (230 ml.) of breast milk was given without incident, but when on the following day two drops were added to the feed she vomited. On this, as on the five subsequent occasions when an increase led to vomiting, no further increase was made for two or three days. After five weeks she was tolerating full-strength cow's milk.

When, during the period of desensitization, occasional feeds were offered by bottle or spoon she still refused them; and after desensitization it took five weeks of patient persistence on the part of the nursing staff before she accepted feeds from cup or spoon. Chlorpromazine was given for part of the time and seemed to help. Mixed feeding was then introduced without difficulty.

At 10 months she was discharged home, where good progress continued. Her mother had no difficulty in feeding her with solids, but at 16 months she still resented milk if it was not disguised.

Incidence

In British paediatric practice cow's-milk allergy is regarded as uncommon and in many of our standard textbooks is not mentioned, but Sheldon (1951) and Holzel (1955) give full descriptions. In other countries estimates of its incidence vary widely. Vest (1953) discovered only nine cases among 1,500 infants seen in a 25-year period (incidence 0.06%), and Collins-Williams (1956) found an incidence of only 0.3% in 3,000 infants and children. On the other hand, De Toni and Mitolo (1955), basing their opinion on the finding of positive intracutaneous skin tests in 14% of 132 healthy infants, regard cow's milk allergy as a very common condition during the first months of life, and stress its importance in the causation of many allergic conditions. Similarly, Clein (1951) found the high incidence of 1 in 15 infants (6.7%), but he attributes to cow's milk allergy such common symptoms as colic, "always chesty and snuffly," or "very unhappy all the time."

Loveless (1950) obtained information from a poll of specialists in allergy and paediatrics and estimated the incidence to be 1.5%. In our experience the condition is rare. One of us (O. H. W.) has seen approximately 2,000 infants and children during the period in which these two cases came under our care. All would agree that severe anaphylactoid reactions, such as were described by Cumming (1928) and Ashby (1929), are rare. In 1955 Collins-Williams reported another such case and stated that it was the 30th case of acute allergic shock due to milk in the English literature. In the milder reactions the diagnosis must often remain in doubt, at least to the sceptical observer.

Symptoms and Signs

Onset of Symptoms.—Symptoms may occur, as in our first case, immediately after the first feed of cow's milk. Vest (1953) suggested that placental transfer of antigen may then be responsible for sensitization. Collins-Williams (1955) stressed that a high milk intake during the pregnancy may be dangerous, but Clein (1951) could find no connexion between maternal milk intake during the pregnancy and subsequent development of allergy in the infant. More commonly the first symptoms occur one to five weeks after starting cow's milk or when cow's milk is reintroduced after a period of breast-milk feeding. Symptoms usually appear during the first four months except when introduc-

tion of cow's milk has been delayed until the second six months, as it was in Cumming's (1928) and Ashby's (1929) cases.

Typical symptoms are acute shock with peripheral failure, wheezing, vomiting, diarrhoea, abdominal distension, fever, and the appearance of a rash where milk touches the skin. Ashby (1929) and Rubin (1940) described the presence of blood in the stools. Some writers attribute many common symptoms in infancy to milk allergy; but we, in agreement with Bachman and Dees (1957), regard as unconvincing the evidence for milk allergy being a cause of such conditions as colic, a constant runny nose, a cough, or persistent crying. Warren (1957) described a case which presented with marasmus. Ascites, a prominent feature in our first case, has to our knowledge not been previously reported and led to much diagnostic difficulty; another unusual feature was the high fever, so that the picture at first suggested a severe infection rather than allergy. The symptoms and signs in our second case were more typical; spikes of fever again accompanied reactions.

Diagnosis

The diagnosis is usually made on clinical grounds and without inquiry into the diet is apt to be missed. Sometimes, as in our first case, the diagnosis is not made until the second attempt at introducing cow's milk has led to relapse. The diagnosis is confirmed by the rapid improvement that occurs when cow's milk is replaced by breast milk and the recurrence of symptoms when cow's milk is reintroduced. We agree with Vest (1953) that further tests are often unnecessary and at times their results are difficult to interpret.

Direct Skin Test.—Most writers (Hill, 1939; Loveless, 1950; Miller, 1950; Rosenblum and Rosenblum, 1952; Collins-Williams, 1955; Tudor, 1956; Bachman and Dees, 1957) find this test of little value; positive results are not conclusive, and negative results do not rule out the diagnosis. If the test is of limited value in diagnosis, it gives even less help in choosing a substitute for cow's milk. Despite negative skin tests, both our patients were unable to tolerate soyolk, and Case 1 reacted similarly to nutramigen.

Passive Transfer Test (Prausnitz-Küstner Reaction).—This test is useful and when positive is proof of allergy (Miller, 1950), but a negative reaction does not rule out the diagnosis. Positive reactions may be commoner in patients with acute allergy. Thus in our first case the reaction was positive, while in our second case, with less severe manifestations, it was negative.

Eosinophils in Stools.—Rosenblum and Rosenblum (1952) and Bigler (1955) stressed the value of this test, but Bachman and Dees (1957) found it disappointing.

Progress

Death from milk allergy undoubtedly occurs (Holzel, 1955), and possibly is not quite as rare as a search of the literature would suggest. The clinical picture in our first case made us realize how easily we might have arrived at a mistaken diagnosis of "overwhelming infection with intense toxæmia," and if the infant had died not even the necropsy examination would have given the correct diagnosis.

In the survivors the condition is commonly self-limited and cow's milk is tolerated during the second six months of the first year (Clein, 1951; Rosenblum and Rosenblum, 1952; Vest, 1953), but according to Clein 15% of cases remain sensitive to cow's milk. As both our cases were given desensitization courses we cannot comment on this point.

Sequelae.—Eczema and other allergic manifestations were regarded as common by Rubin (1940), but as uncommon by Vest (1953) and Collins-Williams (1955). Except for a small patch of eczema in our first case we noted no such manifestations, not even when during the later

months of infancy food substances other than milk were introduced into the diet. Cumming (1928) mentioned that in his case of extreme hypersensitivity, weaning was very troublesome; in our second case we had the greatest difficulty in persuading the infant to take feeds from the bottle and for long periods had to resort to feeding by oesophageal tube. Even some time after desensitization an intense distaste for cow's milk persisted and presented a real problem in management.

Treatment

Immediate treatment consists of withdrawal of cow's milk and, in cases of acute reactions, treatment for shock. Breast milk is the feed of choice, but if it is not immediately available a clear fluid mixture—for example, 5% sugar in one-fifth normal saline—can be used to tide the infant over the immediate emergency. A breast-milk bank provides an invaluable service for these infants, but as they may remain intolerant of cow's milk for several months it is unwise to rely entirely on this service; therefore the search for a substitute should start as soon as possible. In this search, which may be difficult and at times, as in our second case, fruitless, one has little to guide one but trial and error.

1. *Evaporated Milk.*—Ratner and Gruehl (1935) and Collins-Williams (1955) suggested that evaporated milk is somewhat less allergenic than boiled, dried, pasteurized, or unmodified cow's milk, but Collins-Williams's (1955) case of allergic shock occurred after evaporated milk.

2. *Goat's Milk.*—According to the literature on severe cow's milk allergy, goat's milk is a valuable substitute (Hill, 1939). However, our patients gave strongly positive skin reactions with goat's milk and, more significant, the second patient vomited immediately after the first trial feed.

3. *Soya-bean Milk.*—Most writers have had good results with this preparation (Clein, 1951; Rosenblum and Rosenblum, 1952; Vest, 1953; Ratner *et al.*, 1955; Collins-Williams, 1956; Tudor, 1956); but cases of sensitivity to it are on record (Vest, 1953), and our two cases were sensitive.

4. *Nutramigen.*—Unlike Rosenblum and Rosenblum (1952) we found nutramigen of no value in the patient on whom it was tried.

5. *Allergilac* is prepared specially for use in infantile eczema; we have not seen a mention of its use in severe cow's milk allergy, and were surprised to find it so successful in our first case.

6. *Other Substitutes.*—Vest (1953) suggested the flour of various nuts or 10% oatmeal porridge and wheat germs, and Holzel (1955) described a pudding made with "farex" and eggs.

Desensitization.—Vest (1953) stated that cow's milk is best avoided until cure has occurred—that is, until the infant can tolerate cow's milk without desensitization. Collins-Williams (1955) described a case in which desensitization was not started until the age of 7½ months, and even at 2½ years only four teaspoonfuls of cow's milk could be given in a day. When, as in our second case, the infant has to be reared on expressed breast milk, desensitization is urgent, as supplies of breast milk are not inexhaustible. Even when a substitute has been found, it would still seem preferable to start desensitization early, because the nutritional adequacy of the substitute food will often be in doubt (Fries, 1957) and because weaning on to solid foods will be easier if the patient can already tolerate cow's milk. We suggest that desensitization is started when the infant has fully recovered from the acute allergic illness and is making a satisfactory gain in weight. In the first case this was three months after admission, at the age of 4 months, and in the second case five weeks after admission, at the age of 7½ months.

Summary

Two cases of severe cow's-milk allergy are described. In one patient, in addition to the severe collapse produced by the first feed of cow's milk, ascites was a

presenting feature and caused diagnostic difficulty. In the second patient gastro-intestinal symptoms and urticaria after feeding with cow's milk were followed by refusal of milk which persisted for some weeks after desensitization.

Diagnosis of cow's-milk allergy is mainly clinical. The passive transfer test is a useful aid, but the direct skin test is of little value. Treatment consists in withdrawal of cow's milk and substitution of a suitable alternative, the choice of which is a matter of trial and error. Alternatively, desensitization to the milk is carried out.

DIABETIC COMA IN INFANCY*

BY

D. W. BEAVEN, M.B., M.R.C.P., M.R.C.P.Ed.
M.R.A.C.P.

Christchurch Hospital, New Zealand

During infancy diabetes mellitus presents as an acute metabolic disturbance.

Both Gaisford and Lightwood (1954) and Paterson (1956) state that diabetes is very rarely seen under the age of 1 year, but Schwartzman *et al.* (1947) collected details of 57 cases in this age group, and Keidan (1955), reviewing the literature, added 22 cases, six of these being transient in the first month of life.

Since that time sporadic cases only have been reported, but details of the following two cases are presented "to augment the knowledge of this group" (Schwartzman *et al.*, 1947). As guidance on the management of diabetic coma in small babies is difficult to obtain, certain aspects of treatment have been discussed. These comments are based on experience in these two cases, on a further two cases in patients under the age of 2 years (not reported here), and on the available literature. Recent experience in the treatment of problems in adult diabetic coma has been utilized and adapted.

Case 1

A full-term female baby born on October 30, 1954 (Birth weight 2.6 kg.), progressed normally until she was first admitted to hospital on July 10, 1955, with irritability, cough, loose bowel motions, and temperature suggesting an infection of the upper respiratory tract. Various investigations were carried out with negative results, and the temperature slowly settled on penicillin therapy. At this time the urine showed a trace of reducing substance on

one occasion, but not on four other occasions. The C.S.F. sugar was 80 mg./100 ml. She was discharged home five weeks later with a diagnosis of recurrent bronchitis.

She was readmitted on October 18, at the age of 11½ months, with a cough and rapid respiration and dehydration, the diagnosis being pneumonia. By next morning drowsiness had increased and a diagnosis of probable diabetic acidosis was made. Blood sugar was 400 mg./100 ml. and serum electrolytes showed a severe primary metabolic acidosis with pH 7.18; CO₂ tension, 22 mm. Hg; blood buffer base, 26 mEq/l.; bicarbonate 7.8 mEq/l.; sodium, 146 mEq/l.; potassium, 3.6 mEq/l.; chlorides, 120 mEq/l. Serum keto-acids were 180 mg./100 ml. Her weight was 18 lb. (8.1 kg.).

FIG. 1.—Details of treatment, showing blood-sugar levels, serum potassium levels, and improvement in acidosis in Case 1.

Soluble insulin was started at 1 p.m., and Fig. 1 shows that an initial insulin dosage of 80 units was required before some control of the blood sugar was obtained. The blood buffer base rose steadily with the correction of the acidosis and with 150 ml. of 1/6 molar sodium lactate solution given intravenously.

The initially rather low potassium fell to 1.7 mEq/l. within 24 hours of starting treatment. During this period calcium gluconate was given intravenously on two occasions for fits of a decerebrate nature with relief of twitchings. On these two occasions the blood sugar was 350 mg. and 110 mg. respectively. (The low serum potassium may have played some part in her slow recovery from drowsiness, but the irritability may have been related to the relative increase in alkalinity.) After the first 24 hours soluble insulin was given according to urine tests three times daily, the total daily dosage being 20–30 units.

Insulin zinc suspension was begun on the fourth day, when solid foods were again taken. The dosage was steadily increased, and she was finally discharged after a respiratory infection on 20 units of I.Z.S. and a 1,200 calorie diet. Before discharge the chest x-ray picture was clear and the ocular fundi were reported normal by the ophthalmologist.

Over the next year she was on a diet averaging 1,200 calories (distributed as protein 40 g., carbohydrate 160 g., and fat 40 g.) and gained 11 lb. (5 kg.), to weigh 29 lb. (13.2 kg.) and measure 34 in. (86 cm.). The height and weight are at the upper limit of normal for her age.

The insulin dosage for this age and weight was 16 units of I.Z.S., and the blood sugars two and a half and two hours after meals were 95 and 105 mg./100 ml.

Case 2

A female baby born on December 25, 1954—birth weight 8 lb. 6 oz. (3.8 kg.)—was quite well until the morning of her admission to hospital on December 10, 1955, when she was noticed to be drowsy and "off-colour," with sunken eyes. She became increasingly breathless during the day and was admitted to hospital at 6.30 p.m. with a diagnosis of pneumonia.

On admission she was a dehydrated semiconscious infant with cold extremities, rapid grunting respirations, and a few moist sounds in the left chest; respirations 64 a minute, and pulse 170 a minute. A tentative diagnosis of diabetic coma with respiratory infection was made and an intravenous drip inserted. Blood-sugar results were 1,000 and 950 mg./100 ml., and the serum electrolytes were as follows: blood pH 7.08; CO₂ tension, 19.5 mm. Hg; blood buffer base 24 mEq/l.; plasma bicarbonate, 5.6 mEq/l., which was in keeping with the marked respiratory compensation. Her plasma sodium was 140 mEq/l.; potassium, 4.6 mEq/l.; chlorides, 102 mEq/l.; proteins, 8.7 g./100 ml.; P.C.V., 43%; serum keto-acids, 100 mg./100 ml.

Soluble insulin, 10 units intravenously and 20 units intramuscularly, was given at 8 p.m., and two and a half hours later a further 50 units was given intramuscularly, when there was no fall in the blood sugar. By 4 a.m., with a falling blood sugar (700 mg.), only a further 20 units of insulin was given, and this total of 100 units was sufficient to keep the blood sugar below 200 mg. for the next 30 hours.

Fluids in the first 24 hours for this 20-lb. (9.1-kg.) baby are shown in Table I. At 18 hours these fluids had resulted in a hyponatraemia of 157 mEq/l., and the drip was discontinued at 20 hours, when adequate fluids were being taken by mouth.

TABLE I.—Fluids Given During First 24 Hours of Diabetic Coma

Case	Weight	Fluids
Case 1	8.1 kg.	255 ml. per kg. body weight
Case 2	9.1 kg.	229 " " " " "
Case not reported	10.2 kg.	250 " " " " "

Details of Fluids in Case 2 during First 24 Hours		
Type of Solution	Route	Vol. in ml.
1/6 molar sodium lactate	Intravenous	150
Isotonic saline	"	160
5% glucose solution	"	400
5% glucose with 1/5 N saline	"	250
1/2 normal saline	Subcutaneous	220
Glucose solutions	Oral	420
Total all routes		1,600

For the next week soluble insulin was given six hourly, according to urine tests, and on the eighth day I.Z.S. and a 1,100-calorie diet were started. This dosage was later reduced to 16 units, but the baby was kept in hospital for a further three months on account of a throat infection, an attack of rubella, and also home circumstances, but was finally discharged on March 22, 1956 on 30 units of I.Z.S. daily and a fairly free diet of about 1,250 calories. Capillary blood sugars morning and evening on this gave figures of 200–250 and 85–150 mg./100 ml.

At home this dosage has gradually been reduced over the past year to 24 units of I.Z.S. daily. At 22 months her weight was 28 lb. (12.9 kg.) and blood sugar 105 mg./100 ml. two and a half hours after dinner.

Discussion

Mortality.—Between 1925 and 1946 the mortality averaged 45–50% for collected cases of diabetes in infants under the age of 1 year, but in more recent series reported by Brodribb *et al.* (1952) and by Keidan (1955) the mortality is nearer 25%.

Presentation.—These two cases and our other young diabetics illustrate a point stressed in the literature—namely, that an erroneous diagnosis of respiratory infection or meningitis is often made. Where there is a relative hypo-

kalaemia with a low blood pH depression of the respiratory centre may result and the typical Kussmaul respiration may be reduced or absent. This finding has recently been reported in a number of adults by Murray (1958), and infants are particularly liable to develop a severe metabolic disturbance. The admission diagnoses in the 12 most recently reported cases of diabetes mellitus under 1 year of age were pneumonia in 4, meningitis in 4, dehydration and infection in 1, "shock" in 1, and diabetes in 1. Newcomb (1951) reported that symptoms pointing to the respiratory system (tachypnoea and fever) were present in all of their six cases in diabetic coma, and signs in the chest were found on auscultation in four of his cases.

The diagnosis may easily be missed, and diabetic acidosis should be considered in any baby with respiratory signs and symptoms and dehydration who does not improve on treatment.

Age of Onset (Table II).—Keidan (1955) has commented on the age distribution at the beginning and end of the first year of life. This may be due to selection of cases, because

TABLE II.—Age Distribution of 79 Reported Cases of Diabetic Coma Under the Age of 1 Year

0–3 Months	4–6 Months	7–9 Months	10–12 Months
29	12	10	28

of greater interest in the neonatal group or because of inclusion in the first three months of all the cases of transient diabetes.

Sex Incidence.—Of the 80-odd reported cases male babies predominate 2:1.

Influence of Heredity.—In Schwartzman's series of 57 cases and Keidan's additional collected 22 cases a positive family history of diabetes mellitus was given in 43% of cases. A history on both sides of the family may be helpful in diagnosis, but in New Zealand and Australia it is often difficult to obtain relevant data about grandparents. Fig. 2 shows the family history in Case 2, with the birth weights where known. The mothers of both these infants had a flattened type of curve on glucose-tolerance testing, suggesting an increased tolerance for glucose, but the significance of this finding is not clear.

FIG. 2.—Family history of Case 2, with birth weights where known.

The mothers of both these infants had a flattened type of curve on glucose-tolerance testing, suggesting an increased tolerance for glucose, but the significance of this finding is not clear.

Management of Coma

Both in these cases and in the older children adequate biochemical control during the first 24 hours is essential. For some time it has been the practice in this hospital for blood to be withdrawn in the casualty or admitting department in all cases of diabetic coma, and also in cases of acidosis in babies.

Correction of Acidosis.—In those cases with a severe keto-naemia the pH, even with adequate respiratory compensation, may fall below 7.2. It appears likely from the work of Kety *et al.* (1948), and also from work on anaesthetic cases by Murray (1958), that depression of medullary centres takes place with low pH figures. Murray has reported three cases in severe diabetic acidosis with absence of Kussmaul respiration because of respiratory centre depression at low pH figures. It has been our practice to use 1/6 molar sodium lactate solution or bicarbonate solution as the initial intravenous fluid whenever severe acidosis is present. Lactate

*Based on papers read before the Annual Meeting of the New Zealand Paediatric Association in 1956 and 1957.

solution offers some advantage over sodium bicarbonate solution in being more stable and also in providing a glucogenic effect (60 ml. of 1/6 molar sodium lactate per kg. body weight possesses a glucose potential of 0.9 g./kg.). Hartmann and Erganian (1947) recommend 30 ml. of sodium lactate per kg. body weight initially, but in these two cases the average figure was 20 ml./kg. In two other patients between the ages of 1 and 2 years about 15 ml./kg. body weight has been used in the initial 12-hour period. Hartmann and Erganian have also shown that, in comparison with the use of isotonic saline and insulin, sodium lactate solutions will produce a more rapid improvement and so lessen the danger to the cerebral cells of an unduly prolonged low serum pH.

Insulin Requirements.—Reports on the dosage of insulin given to infants in diabetic coma vary from the successfully treated patient of Gans (1954)—5½ lb. (2.5 kg.)—who was given 250 units of insulin in the first 24 hours, to that of Hartmann and Erganian, who recommended 1½ units/lb. (3.3 units/kg.) body weight initially to be repeated in six hours as necessary. Nelson (1954) recommends an initial dosage of 20–30 units at the age of 1 year, and thereafter about half the amount in one to two hours. The insulin dosage used in babies in diabetic coma with severe acidosis is shown in Table III. Thus on body weight an initial

Diabetic Coma			
100 units	8.1 kg.	Case 1	11 months
100 "	9.1 "	" 2	11 "
175 "	10.2 "	"	19 "
110 "	16.0 "	"	29 "

dosage of about 3 units/kg. (or 1½ units/lb.) is advisable, with an additional dosage of 2 units/kg. (or 1 unit/lb.) where the plasma keto-acid level is over 150 mg./100 ml. (Dumm and Shipley, 1946). A gradation of this dosage should be repeated in three to four hours, when the report on further blood-sugar and keto-acid estimations come to hand. There seems to be no advantage in the common practice of hourly injection of insulin. Better control is achieved when insulin is given on the results of these four-hourly blood-sugar and keto-acid estimations.

Hypoglycaemia.—There are many references to hypoglycaemia occurring towards the end of the first 24 hours in the treatment of diabetic coma. We have noticed repeatedly that soluble insulin may have a duration of action up to 36 hours where ketonaemia persists. Even with intra-

FIG. 3.—Showing prolonged action of insulin as observed in Case 2.

muscular instead of subcutaneous injections its action may still last for 24 hours. Fig. 3 shows the prolonged action of insulin in Case 2. Heberden and Friedlander (1955) have mentioned the use of cortisone, sedation, and hypothermia in the treatment of prolonged hypoglycaemic attacks unresponsive to intravenous glucose solutions. They also re-emphasize the cerebral damage which can occur with hypoglycaemic attacks in infants.

Fluids.—The intravenous fluid given initially will largely depend upon the degree of acidosis and the plasma sodium level. The use of 1/6 molar sodium lactate solutions has already been discussed in those cases where severe and dangerous acidosis is present. In one of our recent cases (10.2 kg., 19 months) hypernatraemia was present before treatment, and Case 2 became hypernatraemic during minimal sodium therapy. We believe that this hypernatraemia which occasionally occurs is due to loss of a greater amount of water than sodium and may prejudice the chances of survival in patients in severe diabetic coma. Murray and Beaven (1958) have reported 16 cases of hypernatraemia occurring in diabetic coma, and we suggest that this produces a very severe intracellular dehydration on account of the extreme plasma osmolarity. Where hypernatraemia exists only glucose-containing solutions should be given in the first few hours or until the serum sodium falls. Where initial serum sodium levels are not low, caution is necessary with sodium-containing solutions. The amount of fluid administered in the first 24 hours in three of our cases is shown in Table I, but we are guided by clinical signs of dehydration and serial estimations of packed cell volume, total N.P.N., and plasma proteins. In the treatment of one of these infants and in bigger babies we have used 1/5 or 1/2 normal saline solution with hyalase subcutaneously where the taking of oral fluids has been slow after removal of the intravenous infusion. Plasma can be used as in adults on a body-weight basis where shock does not improve with the correction of the acidosis.

Hypokalaemia.—An initially low serum potassium or an abrupt fall at the four-hour electrolyte estimation should give warning of impending hypokalaemia. In Case 1 intravenous potassium was not given early enough, and fits of a decerebrate nature occurred when the potassium level was 1.7 mEq/l. Low serum potassium levels are particularly dangerous in association with persisting acidosis, as it may further aggravate the depression of the cerebral cells.

Stabilization.—On recovery from coma, stabilization is achieved by means of a fixed calorie diet with soluble insulin given three times daily and I.Z.S. started some time in the first week. At home we have encouraged the parents to try to maintain a low-fat diet which must of necessity be fairly free in other respects. The daily insulin dosage is adjusted according to the previous day's tests.

Follow-up.—One year after discharge both babies were fully re-examined and their diet was adjusted. At the same time several capillary blood-sugar levels were taken to estimate the degree of control. With the onset of diabetes in infancy or early childhood the ultimate prognosis will depend upon a number of factors, not least of which is the intelligence of the parents and how far they are prepared to co-operate with the enthusiasm of their family doctor. Arterial changes and eye complications may develop within a shorter period than in adults, but Wilson *et al.* (1951) present evidence to suggest that good control of urine sugar may possibly delay the onset of arterial complications.

Conclusion and Summary

Two cases of diabetic coma under the age of 1 year are reported.

The comparative rarity of reported cases in this age group is noted and it is suggested that cases may masquerade as meningitis or pneumonia.

The history of familial incidence may be over 40% where accurate information is available.

Some aspects of the management of diabetic coma in small babies have been discussed. These include: the value of 1/6 molar sodium lactate solution; some suggestions on insulin dosage; frequency of hypoglycaemia due to prolonged insulin action; hypernatraemia; and hypokalaemia.

The importance of parental intelligence and co-operation in subsequent management is stressed.

I thank Dr. J. F. Landreth, senior paediatrician to the Christchurch Hospital, for permission to report these cases and for his help and encouragement; and Mr. J. T. Murray, biochemist, for his enthusiasm for electrolyte estimations at all hours and for first drawing my attention to some of the problems of acidosis and of hypernatraemia in diabetic coma.

AETIOLOGY AND TREATMENT OF CONGENITAL DEAF-MUTISM

BY

J. MCKENZIE, M.D.

Lecturer in Embryology, Department of Anatomy,
University of Aberdeen

During an investigation into the problem of congenital abnormalities of the head it was noted that occasionally a child showing obvious maldevelopment of the first visceral arch was also deaf-mute, although the external ear and auditory meatus were normal. Attention was thereby drawn to the possibility of a close connexion between deaf-mutism and abnormal development of the first arch.

The cases described below show little or no obvious evidence of first-arch defect, and the above premise suggested the clinical experiment of determining whether their deaf-mutism was associated with middle-ear (first arch) defect.

Case 1

A boy aged 11 was suspected at the age of 2 years of having middle-ear deafness, "possibly from infection in the first few months of life." When he was first examined it was reported that he did hear—cochleo-palpebral reflex was present but weak. The surgeon had the impression when using tuning-forks that it was a conduction deafness, but was not at all certain. Although six months later (aged 2½) the child showed signs, with pure-tone bone-conduction audiometry, of a severe upper-tone loss in both ears, a tentative diagnosis of air-conduction deafness associated with mental deficiency was made.

At 3½ years co-operation was said to be non-existent during clinical examination; a muscular tic reported a year previously was more pronounced. No final diagnosis was reached, and special schooling was recommended. No other member of the family suffered from deafness or congenital

abnormality, and x-ray examination of the skull was normal. Fig. 1 shows the result of audiometry examination (May, 1957); deafness is shown to be profound, but the marked discrepancy between air-conduction and bone-conduction hearing indicates that at the lower frequencies the deafness is essentially of middle-ear origin, although the upper-tone loss suggests inner-ear deafness.

Case 2

A girl aged 9½ was found most difficult to examine at the age of 2, when the cochleo-palpebral reflex was elicited on very slight stimulus. At 5 years of age the only finding of note was a single islet of hearing at 1,024 cycles revealed by pure-tone audiometry. She was a pleasant, but very shy, timid, little girl, and of her relatives only an aunt of her mother's was reported to have been born deaf; no further information was available. The patient was consigned to a school for the deaf without further attempts to arrive at the cause or nature of the deafness. At school she was given and wore an air-conduction hearing-aid as a routine, but it was not regarded as being of much help to her. The skull was normal on x-ray examination. Audiometry (Fig. 2) revealed a deafness strikingly similar to that of Case 1.

FIG. 1.—Case 1. O = Right. X = Left.

FIG. 2.—Case 2.

Cases 3, 4, and 5

Three children aged 12, 9, and 9, respectively (the latter two being twins) were all members of one family suffering from a congenital deafness, which must be hereditary. The mother was born deaf, but the trait could not be traced further back on her side of the family. The father was one of five deaf-mute sons in a family of nine; one of his affected brothers died in a mental hospital, where another was still an inmate; the others and the father of the three patients were normal apart from the deafness. X-ray

FIG. 3.—Case 3.

examination of the skull was normal in all three cases. Audiometry examination (Figs. 3, 4, and 5) was very similar in each case to those of Cases 1 and 2. There had been no previous otological or audiometry examination of these children, and all have been wearing air-conduction hearing-aids at the school for the deaf.

FIG. 4.—Case 4.

FIG. 5.—Case 5.

Careful attention was given to the possibility of the child confusing hearing with vibration during bone conduction testing, and in each case we were satisfied that the patient was able to differentiate them clearly.

Discussion

No one has ever suggested that congenital deaf-mutism may be of middle-ear origin; in fact, the condition is generally regarded as an affliction of the internal ear. Wilson (1955) deals very briefly with congenital abnormalities of the internal

ear, merely saying, "This subject is inextricably mixed up with deaf-mutism, to the chapter on which the reader is referred"; in that chapter he mentions only once the involvement of the middle ear in cases of congenital deaf-mutism—namely, as an incidental finding when the cause is syphilis, and that, he says, is infrequent.

Recently there has been an awareness that few children are completely deaf. The majority of those recognized as deaf-mutes are classified as "profoundly deaf," and schools, unfortunately with different principles of teaching, have been established for these children. Speech-training at first meant finger-spelling, but very soon attempts to teach them to speak were begun. Lip-reading was encouraged, but efforts have more recently been directed towards making the children hear as much as possible in their training. All children attending these schools use hearing-aids, either individual or group models of the air-conducting type.

The results of this investigation are surprising and unexpected. Testing by air conduction showed profound deafness, while by bone conduction there was remarkably good hearing at the lower frequencies, with no response whatsoever to the higher. There is undoubtedly a marked internal-ear or perceptive deafness, but the picture is dominated by the degree of air-conduction deafness, a feature so far unsuspected by clinician or teacher.

The full significance of this discovery is, first, that congenital deaf-mutism is not due entirely to an internal-ear or perceptive deafness, and, second, that if these children are to be expected to hear as much as possible then bone-conduction hearing-aids should be used. One great objection to this type of aid is the size and weight of the batteries supplied for the instrument, but there appear to be no technical difficulties in producing more suitable batteries. The third point also concerns the treatment. From bone-conduction audiometry it is obvious that there is an appreciable cochlear defect—almost normal hearing at the lower tones

"tailing off" to give no response at the upper tones; the loss is neither irregular nor patchy. The difference between air- and bone-conduction readings points to gross middle-ear involvement and shows that it is the more serious, although, clinically, the middle ears of such patients had been regarded as normal.

The problem being one of deciding which is the primary defect, three reasons are offered for regarding the middle ear as being initially at fault. (1) Two congenitally deaf-mute children, unfortunately too young to co-operate in the examination, showed obvious deformities of the first visceral arch, and this arch contributes to the formation of the middle-ear structures. (2) The middle-ear deafness was greater in all those examined, and it is unlikely that a less degree of perceptive deafness could cause a major degree of conduction deafness. (3) While the cochlea and middle ear are closely associated functionally, the structural association between the cochlea and vestibular apparatus is even greater; yet in children with congenital deaf-mutism it is unknown to find lack of balance due to coincident involvement of the vestibular apparatus (except in cases of syphilitic infection). If the defect were primarily labyrinthine and secondarily middle ear, then surely signs of involvement of the vestibular part would be found in at least some of the cases, especially those who are absolutely deaf.

No morphological evidence of a defect of the middle ear in these cases is available; x-ray examination with various projections has been of no assistance in identifying the presence or absence of the ossicles, far less their normality, but the difficulties of radiodiagnosis in this region are well recognized (Hodgson, 1951).

Whether the congenital abnormality of the middle ear is minimal or gross, its effect is clearly that of interrupting the transmission of vibrations to the internal ear. A developmental defect such as this, arising in the early weeks of intra-uterine life, must have an effect on the associated parts of the hearing mechanism, and it may be best expressed as a loss of stimulation to further development of the inner ear. Whether this loss takes effect during the remainder of intra-uterine life, thereby leading to structural maldevelopment, or whether the effect occurs in the equally obscure and unknown period of the development of hearing—namely, in the first few months of life—is a matter for conjecture, but it is much more likely to be after birth, when the initial abnormal changes will be functional rather than structural. Thus the pathological processes are in the nature of a disuse atrophy of the cochlea. Accordingly, not only must the training of the deaf-mute comprise the use of a bone-conducting aid, but it must also start as early as possible, at a stage when it may still be possible to retrieve leeway lost in the first few months of life.

Even if all cases of deaf-mutism do not arise from primary defects of the middle ear, the disadvantage of fitting each child with an elaborate hearing-aid and awaiting the result of audiometry examination at the age of 7 or 8 is far outweighed by the advantages which are sure to accrue from the earliest stimulation of what hearing exists. By this means it is likely that little, if any, perceptive hearing loss (except perhaps in the highest tones) will be present by the time the child is old enough to be examined properly; and in the meantime it is likely that speech will have advanced to nearly normal standards.

The interrelationship of a wide field of congenital abnormalities of the head and neck will be described in a subsequent publication, but the findings in regard to congenital deaf-mutism were considered important enough to warrant this preliminary report and a discussion on its aetiology.

Summary

The results of audiometric examination in five deaf-mute children are presented. In each case the degree of hearing by bone conduction is much greater than that by air conduction, an indication that the primary defect is

the result of congenital maldevelopment of the middle ear and not of the inner ear, as is generally supposed. In order to stimulate and improve the residual hearing in these children treatment should therefore begin at the earliest possible age with the use of a bone-conducting hearing-aid.

I am greatly indebted to Professor R. D. Lockhart for his encouragement and advice during this investigation, to Mr. I. S. D. Thomson for allowing me access to his notes on Cases 1 and 2, and to Miss J. C. Macrae for carrying out all the audiometry examinations.

HYDATID COMPLEMENT-FIXATION TEST: INFLUENCE OF INTERMEDIATE HOST PROTEIN ON SPECIFICITY OF SHEEP HYDATID FLUID ANTIGEN

BY

H. J. BENSTED, O.B.E., M.C., M.R.C.P.*
Lieutenant-Colonel, R.A.M.C. (Ret.)

AND

J. D. ATKINSON, F.I.M.L.T.
From the Central Public Health Laboratory, Colindale, London

Kellaway and Fairley (1932) considered the hydatid complement-fixation test to be specific, and we (Bensted and Atkinson, 1953), reporting on the examination with standardized reagents of a small series of cases, fully supported this opinion. Since that time a further series of over 300 cases of suspected hydatid disease have been examined serologically by the same technique, and out of 70 cases, subsequently proved to be hydatid disease, significant complement-fixing antibody was demonstrated in the serum of 61 of the patients concerned. There were 240 patients in whom further investigation showed that their condition was due to some disease other than hydatid. Sera from all but one of these patients gave negative results in the hydatid complement-fixation test. It is this false-positive result—the first in our experience—that initiated the investigations recorded in this communication. The explanation proved to be simple, and once the facts were known the results of the investigations were in full accord with what was expected. Nevertheless some interesting observations were made which seemed worthy of record as they had not, so far as is known, previously been published.

During radiological examination the patient in question had been found to have a suspicious shadow in the lung, and blood serum had been forwarded for the C.F.T. to exclude hydatid disease. The Casoni test had been reported as negative, but the C.F.T. with the standardized sheep hydatid fluid antigen was positive to a titre of 1 in 16. Further clinical investigations, however, revealed that the patient had a carcinoma of the lung. The disease ended fatally in a short time and no evidence of a hydatid cyst was found.

*Now at the Lister Institute of Preventive Medicine, Chelsea Bridge Road, London, S.W.1.

It was at first thought that the complement fixation might have been due to the development of some non-specific reacting substance associated with the rapidly growing neoplasm, but our records showed that 12 similar cases of carcinoma of the lung had been examined serologically for the presence of hydatid complement-fixing antibody and in all the test had been completely negative. Further inquiries, however, revealed that the patient had recently returned to this country from the Middle East, where, a few weeks before sailing, he had been bitten by a rabid dog and had been given a "full course" of a sheep-brain anti-rabies vaccine.

Some time after this incident, and additional to the series referred to above, a similar case came to light. In this case, however, the anti-rabies vaccine had been given some years previously. Two Casoni tests gave atypical delayed reactions, and the C.F.T. performed after a short interval showed partial fixation at a titre of 1 in 2 only. The case subsequently proved to be carcinoma of the lung.

Without the history of the previous case these results would doubtless have been disregarded, but now the possibility of sheep-protein sensitization from the sheep-brain anti-rabies vaccine and the boosting effect of the intradermal injections of the sheep hydatid fluid (for the Casoni tests) seemed to warrant further investigation.

Although there was little doubt that individuals recently immunized with sheep-brain anti-rabies vaccine would have some sheep-protein antibodies in their sera it would be necessary to check this. There was considerable delay before we were able to obtain material for such tests, and in the meantime we decided to try to obtain the required evidence from animal experiments.

Experimental

Rabbits

Rabbits are not suitable for immunization experiments with sheep-tissue vaccines. Friedemann (1917) had shown that rabbits possess a natural haemolysin for sheep's red blood cells, and by the use of suitable antigens it was found that other sheep antibodies, such as complement-fixing antibodies for sheep protein, could be demonstrated in the sera of a high proportion of normal rabbits. The presence of this natural complement-fixing antibody in the serum of normal rabbits suggested that further examination of this point might yield information of interest.

Hiles (1926) had noted that the sera of normal rabbits gave positive complement fixation with sheep hydatid fluid and assumed that the reaction was due to some anti-hydatid substance in the sera. We confirmed Hiles's observations, but when we tested a representative number of sera against ovine and bovine hydatid fluids† and a suspension of normal sheep's brain in parallel, we found that practically all the sera showed some degree of fixation of complement with the sheep-brain antigen, but that only those sera with a relatively high anti-sheep titre gave fixation with an ovine hydatid fluid. Reactions with the bovine hydatid fluid were only occasionally seen. When complement fixation occurred with the sheep hydatid fluid the titre was significantly lower than that against the sheep-brain antigen; the occasional reactions with the bovine fluid were incomplete. Rabbit sera did not react with pure hydatid antigen, and absorption of a serum, giving fixation with both sheep-brain and sheep hydatid antigens, with massive doses of washed scolices from a fresh hydatid cyst failed to reduce the complement-fixation titre to either antigen. The titre of a serum containing true hydatid antibody was reduced to nearly zero in a parallel absorption test.

†Diluted in accordance with assay requirements.

It seemed clear, therefore, that the reactions observed by Hiles were due to the natural sheep antibody in the rabbits' sera fixing complement with the sheep protein in the ovine hydatid fluid and not to hydatid antibody. The reactions we obtained with the bovine fluid were not unexpected, since Schiff (1937) showed that there was a partial antigenic relationship between ovine and bovine tissue extracts. The explanation for the difference in the complement-fixation titres obtained with the two types of sheep antigens is discussed below.

Guinea-pigs

Natural sheep antibodies are not found in the sera of guinea-pigs, and our previous experience in the preparation of the standard hydatid antibody suggested that the animals would be suitable for immunization with a normal sheep-tissue vaccine. After pre-inoculation test-bleeds, two guinea-pigs were given weekly intraperitoneal injections of a 5% saline suspension of fresh sheep brain which had previously been well washed to remove as much blood as possible.

The antibody response was not so good as had been expected, and the final serum pool had a homologous titre of little more than 1 in 8, but the fixation was good and the end-point clear-cut. The serum, however, showed no complement fixation with sheep hydatid fluid. It would appear that the concentration of sheep protein in this fluid, as diluted for the hydatid C.F.T. by the standard method, was too low to detect the relatively low-titre sheep antibody. (We have found that when the titre of natural sheep antibody in rabbit sera had a level of 1 in 32 or more we obtained fixation with the hydatid fluid in a serum dilution of about 1 in 8.)

In order to test the possibility of multiple Casoni tests influencing antibody production in immune animals the following experiment was done. One month after bleeding the immunized guinea-pigs, when their sheep antibody level was beginning to fall, they were given spaced doses of 0.1 ml. of sheep hydatid fluid intradermally. There were no tissue reactions to the injections, but the anti-sheep titre increased by a full step to 1 in 16. This level was apparently still too low, because no reaction was obtained with the hydatid antigen. It was not feasible, unfortunately, to continue this experiment.

Human Volunteers

"Anti-rabies treatment" with the Semple type of vaccine involves a long course of daily injections of a phenolized suspension of infected sheep brain, and it seemed reasonable to expect a long-lasting "basal immunity" to sheep protein in individuals who had received this form of treatment. One of us (H.J.B.) and four colleagues, all of whom had received one or more courses of the Semple vaccine many years previously, were given intradermal injections of sheep hydatid fluid in doses of 0.1 ml. at intervals of 7-10 days to ascertain (1) if previous exposure to sheep protein influenced the response in the local reaction to the intradermal injections, and (2) whether these injections gave rise to sheep antibody response, as in the case of the guinea-pigs. The results of this experiment are summarized in Table I.

It will be noted that three of the five subjects developed significant complement-fixing antibody to sheep protein as a result of the intradermal injections of the sheep hydatid fluid.

The result of the final C.F.T. in subject P. with the hydatid antigen is of very doubtful significance. The test was twice repeated, and on each occasion there was merely delayed haemolysis in the lowest dilution (1 in 2); higher dilutions were completely negative. Further investigations of H.J.B.'s serum were made, and these are reported below.

With the exception of H.J.B. the only one showing any local reaction to the injections was W., in whom the first injection was followed by a delayed mild erythema while the second produced a slightly more severe reaction of the same type, but both were trivial in nature and quickly

TABLE I.—Effect of Multiple Casoni Tests with Sheep Fluid on the Complement-fixation Reaction in Individuals Previously Sensitized Against Sheep Protein

Volunteer and Date of Last Anti-rabies Injection	Reaction to Casoni Test	Time of Test Bleeds Related to Casoni Tests	Complement-fixation Reaction	
			Hydatid Antigen	Sheep-protein Antigen
W. (1927)	± +	Before After 1st dose " 2nd "	Negative " "	Negative ±(2) ++(4)

H.J.B.* (1939)	Negative ++ +++	Before After 1st dose " 2nd " " 3rd "	Not done " " ++(16)	Not done " " ++(16)

Figures in parentheses—reciprocals of complement-fixation antibody titres. Controls: Individuals not previously sensitized with sheep vaccine gave completely negative results after two weekly intradermal injections of sheep hydatid fluid.

*H.J.B. was not test-bled before he received his first intradermal injection, but the fact that his sheep protein and hydatid antibody levels both fell gradually to zero within the following 12 months indicated that, prior to the experiment, his serum also did not contain detectable antibodies to either antigen. The results have therefore been incorporated in a single table.

faded. H.J.B., on the other hand, was quite severely affected. He had a strong familial and personal history of allergic manifestations, but the reactions to the intradermal injections were much greater than had been anticipated. The first injection into the left forearm produced little or no reaction; but the second, after a week's interval, into the same forearm, although there was no immediate reaction, was followed after a delay of five to six hours by an intense erythema spreading from the site of the injection to an area of about 15 cm. across. After a week, when this reaction had almost faded, the third injection was given into the opposite forearm. The injection weal quickly spread to nearly 10 mm., but without pseudopodia. Within four hours an acute erythema was rapidly extending from the site of injection and soon covered the whole of the forearm, which became markedly oedematous and heavy. There were also mild general symptoms. At the same time the other arm flared up at the site of the second injection with a more intense reaction than previously noted. It was more than three weeks before the arms resumed their normal appearance. Blood taken shortly after this and examined with different antigens gave the following results in the C.F.T.:

Standardized sheep hydatid antigen	Positive (titre 1 in 16)
*Worm scolices antigen (specific hydatid)	Positive (titre 1 in 16)
†Beef hydatid fluid	Weak positive (titre 1 in 2)
Normal sheep-brain antigen	Positive (titre 1 in 16)

A mass of washed scolices was added to about 2 ml. of H.J.B.'s serum, and after one hour on the bench was allowed to act at 4° C. overnight. The complement-fixing antibody titre with sheep hydatid antigen was reduced by this procedure from 1 in 16 to just under 1 in 4, but the titre to the sheep-brain antigen remained unchanged at 1 in 16. The

*Fresh scolices from hydatid cyst fluid, after thorough washing to remove host protein, were ground up in saline and the supernatant assayed against standard antibody. In the optimal dilution this antigen gave standard fixation with standard antibody at the correct titre and failed to show any cross-reaction with sheep-protein antibody; it was assumed to be specific for hydatid antibody.

†This beef hydatid fluid, when examined in parallel with the standardized sheep hydatid antigen in a chessboard test against the standard hydatid antibody, proved to be a weak antigen; at its optimal dilution there was standard fixation (++) at 1 in 32 instead of 1 in 64, and, moreover, the optimal dilution was only 1 in 5, whereas the sheep hydatid antigen had an optimal dilution of 1 in 16, which gave standard fixation at a titre of 1 in 64. Weak antigens are notoriously unreliable in immunity reactions, and there seems to be little doubt that the titre recorded in the test is too low.

sheep-brain antibody level was not reduced by absorption with guinea-pig kidney tissue, and absorption with sheep brain or sheep or ox red blood cells made the serum markedly anticomplementary. In spite of these difficulties it seems clear that H.J.B.'s serum contained two distinct antibody fractions—one specific against the hydatid antigen and the other against sheep protein.

Inoculation of Individuals with Anti-rabies Vaccine

Many unsuccessful attempts had been made to obtain samples of serum before and shortly after the completion of a course of injections of sheep-brain anti-rabies vaccine, but we were eventually able to examine a number of sera from patients in Hong Kong who had just completed a course of injections of goat-brain anti-rabies vaccine. Unfortunately the majority of the sera proved to be anticomplementary, but three sera were free from this effect, and the results of the C.F.T.s with these sera and hydatid antigens of ovine origin and a normal sheep-brain antigen are set out in Table II.

TABLE II.—Effect of Recent Sheep-protein Immunization on Complement Fixation with Different Antigens

Complement-fixation Reaction—Serum Dilution Reciprocals														
Serum	Sheep Hydatid Antigen						Normal Sheep-brain Antigen							
	2	4	8	16	32	64	128	2	4	8	16	32	64	128
Anti-rabies HK 4	+	+	±	—	—	—	—	+++	+++	+++	++	+	±	—
“ HK 5	±	±	—	—	—	—	—	+	+	±	±	—	—	—
“ HK 7	+++	+++	+++	+	±	—	—	+++	+++	+++	+++	++	+	—
Standard hydatid antibody	+++	+++	+++	+++	+++	++	—	+++	+++	+++	+	—	—	—
“ sheep	—	—	—	—	—	—	—	—	—	—	—	—	—	—
Normal human serum	—	—	—	—	—	—	—	—	—	—	—	—	—	—

It is clear from this table that the sera of recently immunized individuals (with sheep- or goat-brain anti-rabies vaccines) may give positive complement-fixation reactions with a sheep hydatid antigen. Individual response to those with a sheep hydatid antigen, as judged by the results with the three speculations, appears to vary considerably, and, as in the mens available, appears to vary considerably, it seems that it is only cases of the rabbit natural antibody, it is high enough that when the sheep-protein antibody titre is high enough that there will be any demonstrable antibody titre with the sheep hydatid antigen.

Discussion

Although the hydatid C.F.T., employing sheep hydatid fluid as the antigen, has long been regarded as a specific test it is obvious that an antigen containing a factor derived from the host's tissues in addition to the specific component is liable to yield anomalous results under certain conditions. In view of the very large numbers of individuals (living in areas where rabies is endemic and hydatid disease not a great rarity) who have received the Semple type of anti-rabies vaccine it is surprising that results of the sort reported here have not been previously encountered. At least we have been unable to find any published records, although Kellaway and Fairley (1932) mentioned the possibility of previous sheep-protein sensitization interfering with the interpretation of the Casoni test but did not mention this complication in relation to the C.F.T. In spite of the fact that the test was introduced over 50 years ago (Ghedini, 1906) it seems likely that it is not employed very widely, otherwise the hazard would have been reported earlier.

From the limited evidence available induced sheep-protein antibody appears to fall to almost zero within 12 months, so that, provided no boosting injections are given in the interval, anti-rabies vaccine given a year or more previously would probably not complicate the interpretation of a hydatid C.F.T.

It is possible to prepare an almost completely specific hydatid antigen from fresh scolices as described briefly above, but the difficulty of obtaining suitable material in this country has restricted its use to experimental testing

only, and in common with most other workers in this field we have relied on sheep fluids. By examining fluids from separate cysts it has been possible to select those very rich in antigen which can be accurately standardized and give reproducible results over periods of years. Their working dilution is generally 1 in 16 or 1 in 32: these high dilutions greatly reduce the chances of non-specific reactions. In our experience bovine fluids have not been so rich in hydatid antigen, and the results of the C.F.T. employing this antigen have been much less satisfactory.

When a rabbit serum containing high-titre natural sheep antibody was tested against sheep hydatid fluid and normal sheep-brain suspension in parallel it was found that the titre with the former was much less than with the latter. The sheep hydatid fluid had been assayed against the standard hydatid antibody for the hydatid C.F.T., and because of its richness in hydatid antibody it required dilution well beyond the optimum for maximum sensitivity for the measurement of sheep-protein antibody. The hydatid fluid, therefore, will react only at higher concentrations of sheep-protein anti-

body and fail altogether when the total amount is below a certain level. This is well illustrated in the case of HK 4 (see Table II, top line) and of the guinea-pig anti-sheep serum.

The serological results in the case of H.J.B. are clearly in a different category. The very intense tissue reactions to the intradermal injections of the sheep hydatid fluid in a sensitized allergic subject resulted in the development of true antibodies to both the hydatid and sheep factors to approximately the same titre. It is possible that Graña's (1944) observation that the injection of hydatid fluid into patients with hydatid disease resulted in the development of sheep antibodies, if the injections gave rise to tissue reactions, is an example of the same order but with a reversal of the sensitizing agent.

Summary

The occurrence of false-positive reactions in the routine hydatid complement-fixation test is described as a rare event, and evidence is produced to show how the use of an antigen containing both the host protein and the specific hydatid fractions can confuse the issue in patients previously immunized with vaccines containing the same or related host protein.

We owe thanks to Dr. P. A. Clearkin and Mr. N. S. Schizas, of Cyprus, for their kindness in sending us generous supplies of hydatid fluids; to Dr. E. F. Duck and Mr. A. E. P. Grimmo, of the Pathological Institute, Caine Road, Hong Kong, for the sera from patients immunized with goat-brain anti-rabies vaccines; to our colleagues who volunteered for the human experiments; and to Dr. Naomi Datta for her help with the animal experiments, many of which have not been described here.

A RAPID TEST FOR THE PRESENCE OF INCREASED COLD AGGLUTININS

BY

D. H. GARROW, B.M., M.R.C.P.

Senior Paediatric Registrar, St. George's Hospital and Victoria Hospital for Children, Tite Street, London

Increased cold agglutinins are most commonly found in patients with virus pneumonia, but the usual method of estimating them, by titration, is time-consuming, and delay in obtaining the result limits the clinical value of the test. Since, however, cold haemagglutination is sometimes seen to occur almost immediately in the barrel of the syringe or along the side of the tube or pipette into which blood is drawn, it was thought possible that a test might be devised which would indicate rapidly whether or not cold agglutinins were present in excess. The purpose of this paper is to show that the rapid chilling of a simple mixture of whole blood and citrate provides a clinically reliable indication of the presence of increased cold agglutinins.

As long ago as 1903 Landsteiner made a study of the naturally occurring cold haemagglutinating antibodies which he had discovered to be present in various animals. He separated the serum of defibrinated blood from the red cells at 38° C. and added a small quantity of a suspension of autologous red cells in serum or saline to it on a slide, which was then placed in the refrigerator. He noted that, provided the proportion of plasma to red cell suspension was 10:1 or greater, the red cells formed large clumps, readily visible to the naked eye. When, however, the proportion of plasma to red-cell suspension was 5:1 or 5:2 no agglutination occurred.

My preliminary experiments were carried out with serum, plasma, and red blood cells, both undiluted and diluted in sodium chloride (0.9%) or sodium citrate (3.8%). These were mixed in different proportions and rapidly chilled. Undiluted specimens of serum or plasma from various children not suffering from virus pneumonia often produced agglutination of autologous cells provided that the suspensions were not too dense. When strong suspensions of red cells were used, however, agglutination regularly failed to appear. The serum or plasma from patients with virus pneumonia, in striking contrast, produced marked agglutination even of concentrated red-cell suspensions. Moreover, the stronger the concentration of red cells the more rapidly did they agglutinate and the larger were the clumps formed.

Dilutions of whole blood were then made in saline and citrate, and the effect of rapid chilling was observed. Sodium citrate was preferred to saline, since it prevented clotting and was incidentally found to enhance agglutination.

The most satisfactory and clear-cut results were obtained with a mixture of whole blood and citrate in equal amounts. Such a mixture constitutes approximately a 20% suspension of red cells in a 1:3 dilution of plasma. Under these circumstances the amount of cold antibody present in the blood of healthy persons produced no agglutination on chilling, whereas the red cells in the blood of patients with virus pneumonia rapidly formed coarse clumps. In whole blood, since in a given sample the ratio of red cells to antibody

is constant however it may subsequently be diluted, it might be expected that the relative amounts of blood and citrate could be varied considerably without affecting the result. This proved to be the case within wide limits, but a gross excess of citrate to blood produced a relatively finer pattern of agglutination; a similar excess of blood to citrate resulted in a sticky mixture difficult to read.

Dilutions were initially made on slides which were placed in the refrigerator for varying periods. Mixtures, however, are easier to handle in test-tubes, and tests showed that a small volume (0.4 ml.) of fluid in a Wassermann tube surrounded by ice crystals could be brought to a temperature of 0-4°C. within 15 seconds.

The Test

The following procedure has finally been adopted as a rapid test for the presence of increased cold agglutinins.

Approximately 0.2 ml. of blood, obtained from a finger or ear prick, is allowed to run into approximately 0.2 ml. of 3.8% trisodium citrate in a thin-walled glass Wassermann tube (60 by 7 mm.). The corked tube is rapidly chilled by rubbing it on the cold tray of a refrigerator so as to cover the outside of the tube with ice crystals and is left for about 15 seconds on its side in the tray. The tube is then removed, holding it at the corked end to avoid warming, and is slowly rotated so that the blood-citrate mixture runs gently over the chilled glass surface, to which ice crystals still adhere. The presence of coarse floccular agglutination is recorded as "positive." No agglutination, or the presence of a fine granularity, is recorded as "negative" (see Fig. 1).

FIG. 1.—Above, negative test. Below, positive test

The tube is then warmed in the hand for a few seconds and re-examined to confirm that all agglutination has disappeared. If a negative result is obtained there is no point in repeating refrigeration, since in no instance has the delayed development of agglutination been encountered. On the contrary, floccular agglutination either appears with remarkable rapidity or not at all.

Relation of Test to Cold Agglutinin Titre

A satisfactory correlation having been demonstrated between a positive rapid test and the subsequent detection of an increased titre of cold agglutinins in a number of patients with virus pneumonia, a systematic investigation was carried out on 92 specimens of serum to determine the range of titre associated with positive and negative results respectively.

Method of Titration.—Venous blood was obtained from the patient on the same day as the screening test was performed, and was allowed to clot at room temperature. Serum was separated after incubating the clotted blood for one hour at 37° C. Samples of serum were kept frozen solid until tested, within a fortnight of bleeding. Doubling dilutions were made in plastic trays, using 0.2-ml. volumes of serum in saline (isotonic sodium chloride). To each dilution was added 0.2 ml. of a 1% suspension of group O red cells freshly prepared and washed three times in saline. The same donor (D. H. G.) was used for all estimations. The results were read after overnight refrigeration. The tray was gently tapped to suspend the red cells, and the titre recorded as the reciprocal of the final dilution of serum showing definite agglutination readily visible to the naked eye, without special lighting. Agglutination which could be detected only with the hand lens or with difficulty was ignored. Although the impression had been formed that there was a positive correlation between the height of the

cold agglutinin titre and the size of the red-cell aggregates in the screening tests, no attempt was made to grade the latter, which were simply recorded as either positive or negative.

Usually the result was unequivocal, but borderline examples were occasionally encountered. As many as possible of these were included to determine the degree of overlap. The results are shown in Fig. 2. Screening tests

FIG. 2.—Results of rapid test compared with titre of serum obtained on the same day.

were usually negative at a titre of 32 and usually positive at a titre of 64. No negative result was recorded at a titre of 256 or higher, and no positive result at a titre of 16 or less.

Diagnostic Value of Test

This test has been found to be a convenient way of following the appearance and subsequent disappearance of increased cold agglutinins in children with virus pneumonia. With rare exceptions a positive result was found only in association with this condition. The accompanying Table

Diagnosis	Positive	Negative	Total
Virus pneumonia or bronchitis ..	56	3	59*
Bacterial or non-specific pneumonia or bronchitis ..	0	226	226†
Bronchiectasis or asthma ..	0	26	26
Pulmonary tuberculosis ..	0	17	17
Measles ..	1	19	20

Severe anaemia and leukaemia ..	0	9	9
Nephritis ..	0	15	15
Rheumatic fever ..	1	13	14
Other miscellaneous diseases ..	1	144	145
Healthy children and adults ..	0	45	45
Total ..	59	524	583

* Including 7 adults. † Including 59 adults.

shows the results of tests performed on 583 children and adults. Of the 59 children or adults positive on one or more occasions, 56 were considered to have virus pneumonia or bronchitis. In only three children was supporting evidence for a diagnosis of virus pneumonia not obtained—one convalescent from measles, one with rheumatic fever, and one infant admitted because of failure to thrive. In each of these the test was only weakly positive.

On the other hand, 524 children or adults failed to show a positive reaction when tested on one or more occasions. From the table it can be seen that a large proportion of these had pneumonia or bronchitis, usually of undetermined aetiology. Many acute infections of the upper respiratory tract have also been included under "other miscellaneous diseases," as have examples of other virus infections such as primary herpes simplex stomatitis, vaccinia, varicella, and infectious mononucleosis. Also included under this heading are examples of whooping-cough, fibrocystic disease of the pancreas, and gastro-enteritis.

These findings suggest that a positive rapid test is of value in the diagnosis of virus pneumonia.

Discussion

Clough and Richter (1918) noticed increased cold agglutinins when they attempted to perform a routine red-blood-cell count upon a patient almost certainly suffering from virus pneumonia. Upon drawing the blood into the diluting pipette it was found that the red blood cells became agglutinated so markedly that clumps were visible macroscopically as well as microscopically. They proceeded to carry out titrations of the patient's serum and to make a detailed study of cold agglutinins, but did not appreciate their clinical significance. The frequent association of the phenomenon with virus pneumonia was first recognized by Peterson, Ham, and Finland (1943) and by Turner (1943). These reports were soon confirmed and led to the adoption of cold-agglutinin titration as a routine laboratory procedure. The importance of a carefully standardized technique, however, was not at first appreciated. Each stage is a possible source of error. The temperature at which the serum is separated, the time it is stored, the strength of the red-cell suspension, the age of the cells, the donor from whom they are obtained, and the method of reading and expressing the end-point may all influence the result to a great extent. The rapid test avoids these sources of error, and has the additional advantages of being readily repeatable.

There is, however, another aspect of the problem to be considered. Even when accurately determined, titre as the sole measure of cold-haemagglutinating antibody has certain limitations. It takes no account of avidity, the term being used here as expressing the strength of red-cell adherence produced by a serum at a given dilution, as shown by the coarseness of the red-cell aggregates and their resistance to dispersal by agitation. Two sera may be defined as differing markedly in potency because of differences in avidity. Because of this, Crookston, Dacie, and Rossi (1956) used arbitrary "units" to compare the sensitivity to cold antibody of different red cells, allotting a score for the intensity of agglutination at each dilution and multiplying the sum of the scores by the number of tubes showing agglutination.

Turner, Nisnewitz, Jackson, and Berney (1943) observed that there was a definite correlation between high avidity (the formation of a solid disk of cells) at low dilutions of serum and the height of the cold agglutinin titre. Finland and Barnes (1951) observed that fine granular agglutination might sometimes be present in a variety of clinical conditions to quite high titre, but they regarded a lower titre of value in the diagnosis of virus pneumonia provided that floccular agglutination was present at a titre of 1:10 or higher. Whether or not estimation of avidity should take precedence over titre in the diagnosis of virus pneumonia, the rapid test (which is a measure of avidity) is a convenient way of obtaining an indication of the amount of cold antibody present in the blood of a particular patient.

Various methods have been used by different workers to simplify the estimation of cold agglutinins. Shone and Passmore (1943) observed in a number of patients with virus pneumonia that their blood rapidly formed clumps of red cells when a drop was left upon a slide at room temperature. They did not study the critical temperature at which this change occurred. Young (1946) used a presumptive test which, however, involved the separation of serum, the addition of a dilute suspension of red cells, and refrigeration in the usual way. Chang and Hou (1948) described a method whereby doubling dilutions of serum were made on a specially ground slide which could be examined directly under the microscope; agglutination was usually complete within two hours. Trönnberg (1950) described a simplified method of titration, using citrated plasma and a dilute suspension of patients' unwashed cells. None of these methods, however, is as simple and rapid as the test here described.

Summary

A simple and rapid screening test for the presence of increased cold agglutinins is described. A mixture of whole blood and sodium citrate in equal parts in a small

The drug was also tried in several cases of pemphigus and papular urticaria, but it did not produce any improvement. It has been used successfully in treating infective dermatitis, furunculosis, secondary infection in widespread eczemas, and in several cases of cystitis, cellulitis, and lymphangitis. For these, quite short courses were given with satisfactory results and no toxic symptoms were noted.

COMMENT

Twelve cases of dermatitis herpetiformis were treated with sulphamethoxypyridazine; one of them was of a severe bullous type and four were of the juvenile variety. Response in all these cases was most satisfactory. Several patients who had already received the usual controls for the disease declared spontaneously that the present treatment was the most pleasant and the most effective. One adult and three juvenile patients remained well after cessation of treatment.

In view of the variable course of the disease and the possibility of spontaneous remissions, it is extremely difficult to assess the results of treatment. All cases treated had an immediate response. In two cases treatment was interrupted when supplies were temporarily held up; in each case symptoms and rash promptly recurred and rapidly disappeared when treatment was restarted.

Local treatment consisted of mild soothing applications such as lotio plumbi and crem. calamin.; topical cortisone was not employed.

Toxic Symptoms.—Surprisingly, these were almost entirely absent. One patient developed what appeared to be genuine rubella and continued treatment without ill effect. Another patient developed a peculiar syndrome of dizziness and headache, but was able to continue the necessary dosage without further reactions. One patient has been taking four tablets daily for over one year without ill effect; blood counts and urinary tests reveal no abnormality.

I thank Dr. J. R. Wilson, of Messrs. Lederle Laboratories Ltd., for supplies of lederkyn, and Dr. Reginald Hall, my senior colleague at the hospital, for his constant interest and advice.

J. JEFFERSON, M.D.,
Dermatologist, Belfast City Hospital.

Culture of *Trichomonas Vaginalis*

Recently there has been an increased interest in the routine diagnosis of trichomonal vaginitis by culture rather than by direct examination. Media that are more easily prepared and are reliable have been described, giving bacteria-free cultures by the addition of antibiotics. American workers have claimed an increase up to 30% in positives by culture, and this method is often essential in diagnosis of the male carrier. Now that systemic treatments are being assessed, it is important that the most dependable methods should be used. The direct wet examination must be made shortly after collection, which precludes its use outside hospitals.

In the present investigation the value of Kupferberg's (1955) simplified "trypticase" serum (S.T.S.) medium (slightly modified) was explored (1) in increasing the number of positive results, and (2) as a transport medium.

MATERIALS AND METHODS

The patients were women with vulvovaginitis, and in some of them more than one specimen was taken during treatment. Swabs were collected by wooden applicators tipped with cotton-wool, or the discharge was pipetted off. In the hospital, specimens were brought straight to the laboratory, usually in warm saline. Swabs from outside were broken off into a bijou bottle of medium, and either reached the laboratory after some hours or were sent by post. On receipt specimens were examined in a warm preparation, and swabs in saline were transferred to S.T.S. medium. Drops were examined without coverslips, as these were found to force the organisms to the edges, thus delaying identification. Low power was used to pick up the motile trichomonads, and a higher power for checking. Cultures were made at 35 to 37° C., and were examined first after 24 hours and finally after five days, samples being taken from the bottom of the bottles, and, if negative, after centrifugation.

Kupferberg's S.T.S. Medium Modified.—Maltose, 1 g.; oxoid agar, 2 g.; trypticase (Baltimore Biological Laboratories), 20 g.; cysteine hydrochloride, 1.5 g.; distilled water to 1,000 ml. Autoclave at 10 lb. per sq. in. (0.7 kg./sq. cm.) for 10 minutes to dissolve. Adjust to pH 6 with N NaOH. Then add methylene blue 0.5%, 0.2 ml. Autoclave in 100-ml. bottles at 15 lb. per sq. in. (1 kg./sq. cm.) for 15 minutes. The medium is almost clear, is straw-coloured with a narrow blue zone at the top, and keeps three to four weeks. For use, tube in 5-ml. bijou bottles. Autoclave and add to each bottle 0.25 ml. of sterile serum containing 100,000 units of penicillin and 20 mg. of streptomycin per 5 ml. Discard after a week.

Minor modifications have been made from the original medium, as these facilitated its preparation and reduced the cost without decreasing its efficiency. pH adjustment of the serum was found to be unnecessary. The serum was taken from a pool of five bloods, as on two occasions when using individual sera from two patients no growth was obtained, even after pH adjustment. We can offer no explanation for this. Latterly tryptone ("oxoid") another pancreatic digest of casein, was used instead of trypticase, and the swabs were cultured in parallel.

RESULTS

The results of the examination of 405 specimens are shown in the Table. In no case was direct examination positive and culture negative. As an additional test of S.T.S. as a transport medium, duplicates of 20 of the swabs,

Results in 405 Specimens

	No. of Swabs	No. of Positive		% Positive	% Increase on Positive Direct by Culture
		Direct Examinations	Cultures		
Hospital ..	319	86	95	29.8	10.5
Outlying ..	86	14	23	28	

known by direct examination to be positive, were placed in it and sent by post. All gave positive cultures on arrival.

Tryptone seemed to be a satisfactory substitute for trypticase, but further investigation is being made.

COMMENT

S.T.S. appears to be a highly reliable medium for the culture of *T. vaginalis*, and, slightly modified from Kupferberg's medium, is simple to prepare. We have found culture rather superior to direct examination. Kean and Day (1954), using S.T.S., claim a 31% increase on culture, and Perl *et al.* (1956) a 10% increase. Our figure of 10.5% agrees closely with the latter. Some workers have reported no advantage on culturing (McVay *et al.*, 1951; Bernstine and Rakoff, 1953).

As a transport medium S.T.S. appears to be of considerable value. Positives sent by post survive, and from patients outside the hospital the improvement on direct examination by culture was from 14 to 23. We realize that these figures are small, but they suggest that general practitioners and outlying clinics need not forgo a satisfactory laboratory diagnosis.

We thank Messrs. Ortho Pharmaceutical Ltd. for their generous supply of trypticase.

Reviews

NEUROPATHOLOGY

Neuropathology. By J. G. Greenfield, M.D., F.R.C.P., LL.D., W. Blackwood, M.B., Ch.B., M.R.C.P.Ed., A. Meyer, M.D., W. H. McMenemey, M.A., D.M., F.R.C.P., and R. M. Norman, M.D., M.R.C.P., D.P.M. (Pp. 640+vi; illustrated. £5 5s.) London: Edward Arnold (Publishers) Ltd. 1958.

This handsome volume is a comprehensive and fully illustrated study of all aspects of neuropathology except neoplasms. Apart from his editorship Dr. Greenfield wrote seven of the 13 chapters. These deal with the various infective and demyelinating diseases; the system degenerations of the cerebellum, brain stem, and spinal cord; trauma; diseases of the peripheral nerves; lesions associated with diseases or malformations of the cranium and spinal column; as well as a more general and introductory chapter on the pathology of the nerve cells and neuroglia. In these important sections the mature experience of the author, based on a lifetime of routine work at the National Hospital, Queen Square, is crystallized. Posterity will be grateful for those more spacious years of his retirement that enabled Dr. Greenfield to undertake this labour, and our sole regret must be that he did not live to see and handle the product of his work.

Dr. Blackwood contributes a useful chapter on the vascular diseases in relation to the central nervous system. That by Dr. Norman deals with congenital malformations, the effects of birth injury, and neonatal diseases. This is an important and particularly well illustrated section, in which is most welcome, from an acknowledged expert in this field. Professor Meyer has written on anoxia, intoxications, and metabolic diseases. He and Dr. McMenemey are separately responsible, too, for different aspects of the field has been ably supported by his team, and the synthesis collectively reflects a high order of accuracy and scholarship in which the reader is brought up to date without loss of historical perspective. Each chapter has its own list of references and separate enumeration of the illustrations, but altogether there are about 500 of the latter. The text is laid out so readably and tersely that it is easy for reference as well as more extended study. It is safe to predict that the work will prove indispensable for all specialists in this field, whether pathologists or clinicians.

DOROTHY S. RUSSELL.

THE HISTORY OF PAIN

Anatomies of Pain. By J. D. Keele, M.D., F.R.C.P. (Pp. 260+x; illustrated. 27s. 6d.) Oxford: Blackwell Scientific Publications. 1957.

This is a valuable book whose title does not sufficiently indicate the wide field it covers. Pain has always been a serious problem, and in every age observers and thinkers have tried to locate the sensorium. Dr. Keele has read very widely and pondered deeply over the views held by the philosophers and scientists, and has produced a book which should appeal to the anatomist, the physiologist, the neurologist, the neurosurgeon, the psychologist, the medical historian, and even the metaphysician.

The first four chapters outline the views of Aristotle, Plato, Galen, Descartes, and others who sought for the sensorium commune. Chapter V gives an interesting account of the growth of knowledge of the spinothalamic tract. Then follows a masterpiece of compression (in places perhaps too compressed) in which, in 40 pages, the numerous discoveries made during the last 60 years are reviewed; in this the often conflicting experiments and theories have been, so far as is possible, reconciled. A reference to Jefferson's views on consciousness might well be added here. The last chapter, dealing with the structure of pain, will be of particular interest to the physician and psychologist. We cannot forbear one short quotation: "The witch-doctor who

knew how to choose the appropriately worded curse or spell was the current specialist in the manipulation of conditioned reflexes. It is doubtful whether his techniques have been improved upon even in the societies of to-day." Dr. Keele considers that "reinterpretation of the old ideas in terms of new knowledge constitutes a fruitful form of scientific thought." His book is an excellent demonstration of that thesis.

ZACHARY COPE.

LEGAL LIABILITY OF DOCTORS

Malpractice Liability of Doctors and Hospitals (Common Law and Quebec Law). By William C. J. Meredith, Q.C. (Pp. 300+xv. \$7.75.) Foreword by J. Gilbert Turner, M.D. Toronto: The Carswell Company Ltd. 1957.

I suppose reviewers may be forgiven if they sometimes skip. I did not skip this book. Mr. Meredith has not only achieved his aim of writing his law book on a special subject of general interest in language intelligible to laymen; he has written a law book which this lawyer found it difficult to put down.

After an opening chapter setting out the relation of doctor and patient as they still know it in Canada, unaffected by the impact of the National Health Service, Mr. Meredith deals chapter by chapter with those subjects which are of burning interest in principle as well as of daily practical importance: professional secrecy, with statutory privilege for the doctor in Quebec and some State jurisdictions in America in contrast to his nakedness at Common Law; the doctor as a witness, covering everything from what to do with a subpoena to how to set out a medical report in an accident case; malpractice in diagnosis and treatment, with a comforting reminder that the standard of care the law imposes is what his colleagues would expect of the ordinary competent practitioner in the circumstances; and the vicarious liability of hospitals, over which the Canadian courts have adopted the same approach as have the English courts since the decision in *Gold v. Essex County Council* in 1942.

Mr. Meredith includes chapters on civil courts and procedure, the assessment of damages, and criminal malpractice which afford interesting comparisons and contrasts with English practice. These chapters remind the English lawyer how fortunate he is to have one law only to deal with, and to be able to treat even Scots law as foreign. Apart from the statutory differences in the law in the "Common Law" provinces, the Quebec Civil Code does not stem from the Common Law at all.

"A BARRISTER."

TREATMENT OF ALCOHOLISM

Hospital Treatment of Alcoholism: A Comparative Experimental Study. By Robert S. Wallerstein, M.D., and Associates. Introduction by Karl A. Menninger, M.D. Menninger Clinic Monograph Series No. 11. (Pp. 212+xi. 42s.) London: Imago Publishing Company Ltd. 1957.

This book from the Menninger Clinic, U.S.A., examines the response of 178 persons treated in hospital for alcoholism. Three separate groups were given respectively "antabuse" (disulfiram), conditioned aversion treatment, and hypnotherapy, while a control group had only "a dynamically geared activities program in conjunction with group psychotherapy and with opportunities for individual psychotherapy." It was interesting to find that the patients given antabuse did by far the best of all four groups. Hypnosis came next, while both the conditioned aversion treatment and the control method helped only a quarter of the patients to whom they were applied.

In Britain a prerequisite of all treatments of alcoholism is thought to be the insistence on absolute teetotalism during and after treatment. But no attempt seems to have been made in this study to emphasize the dangers of taking "the first drink," which is considered so important here in the prevention of future relapses. It is significant, however, that the only group that did well was the one in which antabuse effectively stopped all drinking because of the severe physical

reactions that followed. The poor results reported with the conditioned aversion treatment were also probably due to the fact that the method was not used primarily as a means of indoctrinating and brain-washing the patient to a greater realization of the dangers of relapse whenever the first drink is again taken.

The book confirms what has been known for a long time—namely, that ordinary forms of psychotherapy and psycho-analytically orientated treatments work very poorly indeed in alcoholism. The only hopeful treatment seems to be to produce total abstinence by “fair means or foul.” It does not seem to matter much whether this happens following sudden conversion at a revival meeting, or by attending meetings of Alcoholics Anonymous, or by the regular taking of antabuse, or by using the increased suggestibility that occurs both during conditioned aversion treatment and hypnotherapy to drive home the absolute necessity for total future abstinence. Any treatment which permits a return to moderate drinking is practically always doomed to failure, and that is why the statistics of this study may not be indicative of the full possibilities of the same treatments in other hands.

WILLIAM SARGANT.

THINKING

Thinking: An Experimental and Social Study. By Sir Frederic Bartlett, C.B.E., F.R.S. (Pp. 203. 18s.) London: George Allen and Unwin, Ltd. 1958.

To the many admirers of Sir Frederic Bartlett's earlier work this slim volume will come as a distinct disappointment. Its subtitle, “An Experimental and Social Study,” suggests a type of content which is not in fact provided. The so-called “experimental” chapters can hardly be considered to be accounts of anything but the initial searchings which normally would precede a properly set-up and decisive experiment. All the author appears to have done has been to set up certain problems and to note what proportion of some ill-defined population, whose number is not even vouchsafed the reader, adopts one or other of several different alternative solutions. As regards the “social” side, this presumably refers to Sir Frederic's accounts of a number of historical instances of fruitful scientific thinking. These are in no way different from similar accounts written for similar purposes over the last 50 years, and it is difficult to see how they can be said to throw much light on the problem of thinking.

In his introductory chapter Sir Frederic gives his reasons for considering thinking to be similar in many ways to the type of skilled performance the experimental investigation of which has received so much attention in the Cambridge laboratories. Neither in this chapter nor in the following one is the case properly argued beyond noting a few superficial similarities; no decisive hypotheses are advanced and no deductions capable of being tested are derived. A further unsatisfactory feature of this book is its almost complete lack of any reference to the growing experimental literature on the subject, or even to recent American attempts at theory-making. In this book Sir Frederic has carried to its logical conclusion the well-known tendency of Cambridge psychologists to disregard contributions from outside the walls of their own laboratory; readers who are familiar with the experimental literature would not consider that the result has justified the effort. It is very much to be hoped that Sir Frederic will carry his researches to a more definitive conclusion and present them to us in a less restricted setting.

H. J. EYSENCK.

HORMONE RESEARCH

Recent Progress in Hormone Research. Volume XIII: Proceedings of the Laurentian Hormone Conference, 1956. Edited by Gregory Pincus. (Pp. 646+vi; illustrated. \$12.80.) London: Academic Books Limited. 1957.

In these volumes, which appear annually, are reprinted the papers presented at the Laurentian Hormone Conferences together with much relevant discussion. They have now

become an established part of endocrine literature. No attempt is made to cover the whole range of endocrinology, but certain significant fields have been selected for survey which are of general importance. Fourteen reviews are contained in the present volume, and each is a detailed study by an expert in his field.

Five main sections are included. The first covers aspects of neurohumoral and endocrine relationships. Under this head appear a valuable and concise review of present knowledge of serotonin; a detailed survey of the evidence for a mid-brain centre controlling hypothalamic and pituitary mechanisms; a study of the influence of the central nervous system on anterior pituitary function; and a detailed attempt to correlate rhythmic behaviour in psychiatric patients with hormonal rhythms, supported by experiments on rats. The second section is on transport of hormones in the circulation, and singles out for special study the interaction of thyroid hormones with protein in biological fluids and the binding of steroids and steroid conjugates to human plasma proteins. Both these are thorough and valuable reviews of their respective fields. The next section deals with some hormonal aspects of reproduction, including a study of implantation of ova in the rat and a review of the effects of three new synthetic progestins, such as 17- α -ethinyl-19-nortestosterone. Here also is a most interesting survey of the metabolism of progesterone as revealed by isotope labelling, with a review of the place of some long-acting steroids on reproduction. The fourth section, on hormones and metabolism, contains a review of the role of insulinase and insulinase inhibitors in diabetes mellitus and a very comprehensive survey of glucagon. In the final section, on hormones and stress, are discussed endocrine changes after anaesthesia, surgery, and trauma. There is also a study of the influence of the adrenal gland on gastric responses to stress.

It is clear, therefore, that a very wide range of subjects are discussed in some detail. The work is a most valuable reference volume for students of endocrinology, and should most certainly be present in the libraries they use.

C. L. COPE.

ENDOCRINOLOGY WITHOUT PICTURES

Introduction to Clinical Endocrinology. By A. Stuart Mason, M.A., M.D., B.Ch.(Cantab.), M.R.C.S.(Eng.), M.R.C.P. (Lond.) (Pp. 192+vi. 22s. 6d.) Oxford: Blackwell Scientific Publications. 1957.

This introduction to endocrinology gives information on the subject midway between the short accounts found in conventional textbooks of medicine and the voluminous descriptions contained in large reference books on endocrinology, of which latter there are quite a number. It is not entirely clear for whom such introductions are intended, but the student, practitioner, or physician who is interested in the subject but who cannot spare the time to read, or the money to buy, a fuller textbook will find in this comparatively small volume an admirably clear, accurate, and up-to-date account of clinical endocrinology in terms of applied physiology. The book is exceedingly readable and interesting and is written in excellent English. It is unusual for a work on this subject to contain no illustrations, which partly accounts for this book's very modest price. The author makes a virtue of necessity by claiming that the photographs of patients which usually illustrate such volumes show the end-point of disease, yet seldom portray early clinical signs and may actually give a visual bias against early diagnosis—an ingenious argument with some point to it. Less justifiable is the omission of any account of diabetes mellitus. It is odd that some pages should be devoted to the consideration of obesity and of spontaneous hypoglycaemia, and yet the most common and important endocrine disease in which so many ductless glands are involved should not be described. It is as though an author writing on what happens in *Hamlet* should omit all reference to the Prince of Denmark.

D. M. DUNLOP.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JULY 26 1958

THE BIRMINGHAM MEETING

Every visitor to the Annual Meeting must have been stimulated by the vigorous growth of Birmingham University. If Britain needs more scientists and doctors then the bulldozers churning through the red earth of Edgbaston were outward and visible signs of the University's intention to train them. The same sense of purposeful energy that was behind all the building activity must have inspired the organizers of the Annual Meeting. Every item on the programme was designed to give the visitor the best possible value for the time he or she was prepared to spend at the meeting: no organizational detail which helped to that end was overlooked. For this excellent result the President, Professor A. P. Thomson, and his three chief lieutenants, Dr. J. W. Brown, Dr. A. C. Houghton, and Mr. A. Gourevitch, must be given the lion's share of the credit, for it was plain that they had the complex mechanism of the meeting at their fingertips. From the reception given by the Midland Branch on July 9 to the final meetings of the Sections on July 18 everything ran on the smoothest of lines.

The whole-hearted co-operation of the University was of course invaluable. Not only was the meeting admirably sited in the university buildings but the generosity of the university staff, from Dr. Robert Aitken, the vice-chancellor, downwards, went far beyond the bounds of ordinary hospitality. Even the University Staff Club, in its charmingly rural surroundings—and with its tempting billiard table—was thrown open to the visitors. The reception given by the University on July 17 was a glittering climax to a series of memorable social occasions. The fact that the Town Clerk and other senior officials of the Corporation were active members of the local executive committee showed, too, that the City was not going to be neglectful of its medical visitors. The Lord Mayor, Alderman D. Johnstone, set the pace for the City's genial welcome, and he and the Lady Mayoress were the hosts at a civic reception in the Council House. Without the power to perform miracles the Chief Constable could hardly have unravelled the tangled skein of Birmingham's traffic specially for the meeting, but more than one B.M.A.

member, disconsolately pointing his car against the flow of swiftly moving vehicles in a one-way street, found the friendly advice of a Birmingham constable most tranquillizing in emergency. The special service of buses which was arranged for the meeting helped to overcome what might have been a minor disadvantage—the distance of the university from the centre of the city.

At the Scientific Sections there was a well-adjusted mixture of “easy” and “stiff” discussions, and Mr. A. Gourevitch, the science secretary, and his helpers had every reason to be satisfied with the results of their efforts. The plenary session on “Chemotherapy of Infections” was packed, and the speakers, responding to the occasion, instructed and entertained their audience with lively and informative papers and answers to questions. A less spectacular meeting, but one at which many thought-provoking ideas were discussed, was the symposium held by the Section of Medicine on “The Physician and Hospital Planning.” The Scientific Exhibition goes from strength to strength, and this year there was not a single exhibit which did not earn its place: because so many of the exhibits admirably succeeded in achieving their purpose, the judges had great difficulty in selecting the prize-winners.

The keenest visitor to an Annual Meeting cannot possibly find time to see and hear all that is going on. At Birmingham he had to go to at least one or two of the closed-circuit telecasts and, if not to all the medical centres in Birmingham which threw their doors open to visitors, at least to the overwhelmingly impressive Queen Elizabeth Hospital. Then again there was an attractively varied programme of films (arranged by the B.M.A.'s Film Library) to be seen every day, and, in addition to the usual bright display of surgical instruments, drugs, and books, a number of special exhibitions had been arranged, notably the historical exhibition of medical books. Right on the doorstep, too, was the Barber Institute of Fine Arts, where those bemused by science could take refuge among the productions of a different type of endeavour. While the medical visitor hurried from one lecture theatre to another, attuning his ear at one moment to remarks on “girth control” and focusing his eyes at another on the elimination of a haemorrhoid in full colour, his wife and other ladies were enjoying the agreeable surroundings of the Ladies' Club at Winterbourne, which the chairman of the Ladies' Committee, Mrs. L. S. Gathergood, had made a refuge from the bustle of the meeting. From Winterbourne expeditions sallied out to Stratford, Lichfield, and to other places of interest, including the works of the Austin Motor Company at

Longbridge and Cadbury's famous factory at Bournville. As if to emphasize that Birmingham was not an exclusively industrial city, flowers in great profusion and variety gave a colourful background to what was already a colourful meeting. Private hospitality, as would be expected from Birmingham, was most generously given, not only to house guests but also to many parties of visitors who, during tours of the district, descended from their buses at the homes of Birmingham members and were sent refreshed on their way. So another Annual Meeting has come to an end—a highly successful one, conducted with admirable vigour and efficiency. As the memory of it fades, so the work for the joint meeting with the Canadian Medical Association at Edinburgh in 1959 will go ahead with increased momentum.

THE R.B. AND THE N.H.S.

Some 500 Representatives from Divisions and Branches of the B.M.A. were certainly in no mood to look back at the past ten years of the N.H.S. with satisfaction. The present discontents were emphasized by three decisions announced at the Birmingham meeting. The first was the Representative Body's approval of the action of the Council to set up, in consultation with the Royal Colleges, the Scottish Royal Corporations, the College of General Practitioners, and the Society of Medical Officers of Health, a committee to review the health services of the country. The second was the statement of the Chairman of the General Medical Services Committee, Dr. A. B. Davies, that a "non-medical expert of eminence" was to advise a special sub-committee which was studying possible alternative schemes for providing medical services to the public. The third was the announcement by the Chairman of Council, Dr. S. Wand, that the contractual validity of the general practitioner Spens Report was to be tested by Scots law.

Those who take the trouble to read the full reports of the A.R.M. proceedings in the *Supplement* of last week and this will find more than enough evidence of the present disillusionment in the profession. All the more striking because of the studied moderation of his tone was the report of the Chairman of the Central Consultants and Specialists Committee, Mr. Holmes Sellors, on the hospital and consultant services. He brought out yet once again the sad and sorry plight of the time-expired senior registrar. Some 200 and more cannot be employed as consultants "although in nearly every case they were fully equipped for consultant work." Repeated attempts

¹ *Brit. med. J., Supplement*, 1958, 1, 352.

had been made to persuade the Ministry of Health to conduct a survey of hospital establishments; but the Ministry had persistently refused to do so. It had been hoped that during such a review the Ministry might give some of the time-expired registrars some security against the risk of dismissal, or a salary increase: but that had been refused. And the Minister of Health, in flat opposition to the C.C. and S. Committee and the Joint Consultants Committee, had created a special type of post—a subgraded consultant—to be filled by regional hospital boards. In the meanwhile a working party had been set up to study hospital staffing, and it was hoped that through this some solution might be found of the problems facing the senior registrars and the senior hospital medical officers. Mr. Holmes Sellors told the meeting that when the Staff Side of Whitley Committee B put before it the cases of some 500 S.H.M.O.s as coming up to consultant standard, "it appeared that the Management Side had had no idea that the problem was so extensive." Mr. Holmes Sellors moderately called this a "disconcerting feature." The appalling thing is that there is a crying need for more hospital beds and more consultants: and yet the men who have been trained to this end are denied the opportunity to complete their careers. Dr. E. A. Gerrard gave some alarming figures in this connexion. In surgery, he said, there were four people waiting for every bed in London's teaching hospitals, and five for every surgical bed in the provinces. In his own hospital in Manchester, with just over 100 beds, there was in December, 1957, a waiting-list of 2,676: non-urgent cases had to wait as long as three to four years before being admitted. Small wonder that he burst out thus: "This in a Health Service which is claimed to be the envy of the world. What complacency! What deception! What a scandal it all is!"

The Representative Meeting's principal concern is with medical politics and problems of medical organization. Dr. R. G. Gibson, Chairman of the Organization Committee, has, with his committee, been successful in rousing interest among younger members of the B.M.A. through the Junior Members' Forum, the first meeting of which was held two months ago.¹ He has, too, been looking into ways and means of rousing the average member from an apathy and inertia which are typical of all kinds of electorates. One such move towards this came in the shape of a motion from the Winchester Division that the Council should set up an intraprofessional information service "as a matter of urgency." Those who supported this motion certainly had different ideas on how to set about this. One speaker thought that "an efficient committee clerk could probably do

all that was necessary." Another envisaged "a full-time information officer," who would work in contact with all the Association's committees and "collect, correlate, and disseminate information." It was finally resolved that the Council should look into the arrangements for improving intraprofessional relationships and solidarity "in view of the approaching medico-political storm."

The R.B. gave its attention to a great many other matters, and in particular through the report by Dr. J. B. Tilley, Chairman of the Public Health Committee, showed its concern with the health of the community. Much of the discussion on several subjects was inaudible to many owing either to defective installation of microphones and loudspeakers or to the bad acoustics of an otherwise excellent hall. Dr. A. Beauchamp, the Chairman of the R.B., had his task made trebly difficult by this great acoustic disadvantage, and on occasion he had to repeat statements two or three times. All this undoubtedly added up to a considerable loss of time over the four days of the A.R.M., but in spite of this handicap the Chairman conducted the business with exemplary fairness and patience. Those Representatives who missed much of what was said from time to time will, it is hoped, be able to fill in the gaps by reading the account of the meeting in the *Supplement*. And if other members of the B.M.A. would read the account they would then be informed of the views on a variety of important subjects held by a representative cross-section of the medical profession.

RUSSIAN VACCINE FOR MULTIPLE SCLEROSIS

An important communication from Moscow appears in the correspondence columns this week (p. 245). It is on the Russian vaccine for multiple (or disseminated) sclerosis, and is signed by Professor George Dick, of the Queen's University, Belfast, who has recently visited the Soviet Union, and Professor A. K. Shubladze, Chief of Laboratory of the Ivanovsky Institute of Virology, Moscow. Professor Shubladze is in complete agreement with the findings of Dick and his colleagues, published recently in this *Journal*,¹ that the virus which is used to make the Russian multiple sclerosis vaccine of Shubladze and Margulis is similar to rabies virus. It is possible to go further than that, for the virus of the vaccine of Shubladze and Margulis is not only similar to rabies but is antigenically indistinguishable from it. This strain of

rabies virus (which is apparently the so-called *street* virus), came from a strain of virus claimed to have been isolated from the blood of a patient with a peculiar acute encephalomyelitis syndrome.² We understand that the original isolates of this virus are to be reinvestigated, but there is no evidence that it is causally related to multiple sclerosis; indeed, there is no satisfactory evidence that any virus is. As to the vaccine, there is no significant evidence of its clinical value either in the U.S.S.R. or in other countries of Europe where it has been tried. Furthermore, as was pointed out in these columns recently,³ the administration of it may possibly be harmful.

The marketing of this vaccine without any reliable evidence of its clinical value is unfortunate. Equally so is the publicity that must have raised the hopes of many sufferers from multiple sclerosis. Patients with this disease should be informed of the nature of the virus from which the vaccine is made, that the vaccine may be dangerous, and that it has not been shown to do any good. It is satisfactory that virologists in the U.S.S.R. and in Great Britain and Northern Ireland have reached such complete agreement on this vaccine and virus, an event that illustrates the great importance of personal exchanges of information between scientists of the two countries. It should also help to remove the vaccine from the political skirmishing that has been its lot in Britain.

TREATMENT OF CERVICAL SPONDYLOSIS

Cervical spondylosis is a term which is sometimes given a restricted meaning. But it is a useful term for all those chronic lesions of the cervical spine in which compression of the spinal cord or nerve roots is brought about by medial or lateral protrusions of the intervertebral disk, or by osteophytic outgrowths from the vertebral bodies and the neighbourhood of the joints of Luschka, where they may encroach on the intervertebral foramen and so compress the nerve roots. These outgrowths probably owe their origin primarily to disk degeneration, and have been found in 75% of a sample of hospital patients.¹ Cervical disk lesions are often associated with disk degeneration in the lumbar region, as might be expected, but the incidence of acute herniation of the nucleus pulposus is very much less in the neck. Not only is the disk much smaller, but the region is subject to very different strains and stresses. Acute herniation may be independent of cervical spondylosis. Because of the proximity of the spinal cord, the symp-

toms are severe and sudden in onset. There is no divergence of opinion about the need for surgical treatment in such cases. It is in the relief of chronic symptoms and signs that controversy has arisen.

The conditions of cord and root compression are best considered separately; one or other usually predominates. For the treatment of cord compression, E. A. Clarke and P. K. Robinson² concluded that conservative measures should be used at first, and continued if no further progression of symptoms has taken place. Failure to arrest the progress of the condition necessitates laminectomy and division of the dentate ligaments to allow the cord to ride freely over the protrusion. There is a large measure of agreement upon these principles, though some authors advocate traction,^{3,4} while others prefer immobilization.^{2,5} However, the socially unacceptable nature of most cervical collars limits their use to some extent. The most that should be hoped for from surgical treatment is that the progress of the disease may be arrested. W. R. Brain⁵ has pointed out that arrest is often spontaneous, but with surgery it is hoped to bring this about more rapidly and also to prevent extensive cord damage.⁶ He has also drawn attention to the danger of manipulation in these cases.

Many more operations are performed for cervical root compression in North America than in this country. Of 250 patients with cervical spondylosis operated upon by W. B. Scoville⁷ in a period of eight years, all but six had lateral protrusions and osteophytes. G. L. Odom, W. Finney, and B. Woodhall⁸ have just reported a similar number of patients treated over a period of 16 years, of which 72% were of this type. Though good or excellent results are claimed for 84% of lateral disk protrusion, and for 67% of those with foraminal spurs, the length of follow-up is not stated, and—as in some other papers advocating surgery⁹—it is not clear that a later return of symptoms has been excluded. There is a far from negligible risk of producing further damage to the cervical roots and cord when attempts are made to remove osteophytes. On this side of the Atlantic, operation is generally reserved for cases on whom conservative treatment has failed; spontaneous remission is quite common, and most surgeons are cautious in recommending operation. It is essential to differentiate other causes of pain in the upper limb, such as carpal tunnel compression of the median nerve, before concluding that the source is a cervical spondylosis, which may well be present, though unrelated to the symptoms. In the future more reliable operations may be devised, or, better still, means may be found of preventing the condition from developing.

TREATMENT OF IDIOPATHIC THROMBOCYTOPENIC PURPURA

The indications for splenectomy in the treatment of patients with idiopathic thrombocytopenic purpura have never been firmly established. Since the operation was first proposed by P. Kaznelson¹ in 1916, its frequent dramatic success in raising the platelet level and arresting haemorrhage made it the sheet anchor of treatment

for many years. Cure rates of over 90% were reported in some early series of cases, but it later became clear that post-operative improvement might be transient and that relapse might occur months or even years later. A more recent review of the effects of splenectomy in 303 patients with idiopathic thrombocytopenic purpura whose subsequent progress was followed for several years showed complete and lasting remissions in 61%, partial remissions in 17%, and failure in 22%.² Attempts to select patients more likely to benefit from the operation have been made, but neither the presence of eosinophilia and megakaryocytic hyperplasia in the bone marrow nor the existence of detectable circulating antibodies active against the platelets has proved of consistent value in forecasting response.²⁻⁴ Splenectomy has generally been avoided in purpura of acute onset, particularly in children and when there is any possibility that the condition might result from a recent infection or exposure to drugs, because spontaneous improvement is likely in these circumstances. In such cases transfusion with fresh, platelet-rich blood, preferably drawn into plastic or siliconized containers to improve platelet survival, and accompanied by administration of A.C.T.H., cortisone, or prednisone, provides the most satisfactory form of treatment. When purpura continues for several months, despite medical treatment, and in patients with a past history of bleeding episodes, splenectomy is commonly advised, since A.C.T.H. and cortisone, though improving capillary fragility, often fail to increase the platelet count and afford only temporary control of haemorrhage.⁵

Certain recent observations, however, strongly suggest that splenectomy should no longer be regarded as the treatment of choice in chronic idiopathic thrombocytopenia. Disseminated lupus erythematosus has been reported to develop after splenectomy in patients who before operation showed the clinical and haematological pictures of idiopathic thrombocytopenia or acquired haemolytic anaemia, with no manifest evidence of lupus,⁶ and W. Dameshek and his colleagues⁷ now claim that approximately 25% of all patients with apparently typical idiopathic thrombocytopenic purpura in whom the spleen is removed will eventually develop systemic lupus erythematosus. They think it possible that splenectomy in some way aids dissemination of the lupus process, which they believe to be present, in occult form, in many cases of thrombocytopenia. For this reason, and because the effects of splenectomy are in any case poorly predictable, he and his associates carried out a fresh assessment of medical treatment in thrombocytopenic purpura, with particular reference to the effects of prednisone on the bleeding tendency and the platelet count. Thirty consecutive patients, 11 with "acute" and 19 with "chronic" thrombocytopenia, were treated with prednisone in initial doses of 20 to 150 mg. daily. In 22 cases the platelet count rose to normal in 6 to 150

days, and remained well above haemorrhagic levels on maintenance doses ranging from 2.5 to 15 mg. daily. The dosage of prednisone was frequently altered to find the lowest effective dose in each case, and the drug was withdrawn entirely from eight patients without relapse. Prednisone appeared to be much more effective in raising the platelet count than either A.C.T.H. or cortisone in comparable dosage, and the authors now regard it as the treatment to be preferred in both acute and chronic forms of the disease, splenectomy being reserved for the occasional severe cases that fail to respond. The use of prednisone and of splenectomy in the treatment of idiopathic thrombocytopenic purpura offers a close parallel with their use in idiopathic acquired haemolytic anaemia. In both diseases splenectomy is variably and unpredictably successful and has possible concealed risks, and is therefore best postponed until prednisone has proved ineffective or effective only in doses too high to be tolerated for long periods. Provided control can be achieved and maintained with doses of prednisone small enough to avoid serious drug toxicity, this approach seems eminently sensible.

BYSSINOSIS

For nearly two hundred years Lancashire has been identified with cotton manufactures. While these brought wealth and industry, now unfortunately declining, to the population of the crowded mill towns, they also caused an inordinately high morbidity and mortality from chronic respiratory disease. The whole community suffered excessively from bronchitis, which was non-occupational but due to pollution of the atmosphere by the acrid smoke of house and factory chimneys.¹ Certain groups of workers, notably those employed in the processes of preparing the cotton and in the cardrooms and blow-rooms suffered additionally from "asthma," which was occupational and popularly attributed to the irritation of cotton dust. J. Leach,² a certifying surgeon of Heywood, Lancashire, described the disorder in 1863. Since then the disease, byssinosis, has continued to occur, causing chronic ill-health, disablement, and death. In recent years byssinosis has been the subject of extensive researches—clinical, pathological, and epidemiological—by R. S. F. Schilling and his co-workers,³ who have been admirably assisted by the mill owners and by the trade unions. In seeking ways of preventing this disease, or at least of minimizing its effects, occupational health workers must first estimate its prevalence and identify its cause or causes, and this entails a critical differentiation of occupational from non-occupational cases of chronic bronchitis. Schilling and his colleagues concluded that the symptom complex of chronic bronchitis is not the same as that of byssinosis, for whereas men with chronic bronchitis develop tightness of the chest whenever they are exposed to an irritating concentration

⁵ McKerrrow, C. B., McDermott, M., Gilson, J. C., and Schilling, R. S. F., *Brit. J. industr. Med.*, 1958, **15**, 75.

of any dust, in the early stages of byssinosis the workers are affected only by cotton dust and only on Mondays or on the day immediately following absence from work. They divided the disease into two stages—grade I in which chest tightness and/or breathlessness occur on Mondays only, and grade II in which chest tightness and/or breathlessness occur on Mondays and other days. But even in grade II the symptoms are worst on Mondays. This means that the occurrence of Monday symptoms,⁴ previously called "Monday feeling," is the specific characteristic in the diagnosis of byssinosis.

In 1956 the Industrial Injuries Advisory Council reported that although an experienced observer visiting the cotton mill on a Monday might be able to decide with some assurance whether a person was experiencing the symptoms of byssinosis (grade I), there was no simple objective test by which the disorder could be distinguished. C. B. McKerrrow and his colleagues⁵ have recently sought to discover such an objective test. In a carefully planned study, which is another example of the excellent scientific work initiated by Dr. R. S. F. Schilling and supplemented by the Medical Research Council's Pneumoconiosis Research Unit at Cardiff under the direction of Dr. J. C. Gilson, they measured respiratory functions by the accepted modern methods; these included indirect maximum breathing capacity (M.B.C.), maximum voluntary ventilation (M.V.V.), and peak inspiratory and expiratory flows coupled with an airways resistance (A.W.R.). The results showed distinctive specific patterns for both grades of byssinosis and for the controls. McKerrrow and his colleagues concluded that the mill dust—quantitatively as well as qualitatively—is the cause of the respiratory impairment and that it contains some pharmacologically active constituent. This work marks an important advance towards the establishment of a practical objective test for the detection of the earliest stage of the disease, especially as the specific changes in M.B.C. and A.W.R., but of less degree, were discovered among cotton workers without clinical byssinosis.

DIAGNOSIS OF ACUTE PANCREATITIS

The consensus of opinion at the present time is that operation should be avoided in acute pancreatitis.¹ Such a view presupposes a correct diagnosis. Unfortunately this is seldom easy, especially since the disease is uncommon compared with such conditions as perforated peptic ulcer, gall-bladder disease, intestinal obstruction, and myocardial infarction, from all of which it has to be differentiated. The most widely used laboratory aid in diagnosis is the level of the serum amylase, but this test has several disadvantages. Normal values do not necessarily imply the absence of acute pancreatitis, while levels above 200 Somogyi units, which can be regarded as the upper limit of normal, may occur in a variety of conditions, including those already mentioned.² Never-

theless a serum amylase concentration above 400 units is strongly suggestive, especially when accompanied by hyperglycaemia (which is seen in about half the cases) and by a leucocytosis with a relative lymphopenia. The rise, however, is short-lived and seldom lasts longer than 48 hours. An increase in blood lipase occurs later and is more persistent; this enzyme is relatively simple to estimate.³

Various other tests have been used. The serum calcium concentration is said to fall, presumably owing to combination of calcium with the fatty acids liberated by hydrolysis, but this usually implies a very poor prognosis. Some help may be obtained by radiography of the abdomen, especially if dilated loops of jejunum are seen round the area of the pancreas. A procedure which has recently been used with some success is to attempt to aspirate fluid from the peritoneal cavity.⁴ For this purpose a trocar and cannula are inserted into the flank, and a fine polythene tube is threaded through the cannula as far as possible in a cephalic direction.⁵ The cannula is then removed, so that the patient can be turned into various positions while an attempt is made to aspirate fluid. A positive diagnosis depends on the withdrawal of a haemorrhagic exudate with a very high content of amylase. This method too has its drawbacks, the main one being failure to obtain a sample, but it is at least simple and free from danger. It is worth considering in any patient in whom the question of acute pancreatitis arises, but it cannot yet be said that there is a reliable way of confirming the diagnosis of this serious disease.

HORMONE-INDUCED SEX CHANGES

The theory of sex determination by hormonal control is as old as Voronoff, but direct experimental evidence of this possibility is comparatively recent. Foetal intersex of various types can now be produced relatively easily in most laboratory animals by the administration of androgens to the mother, and there is accumulating evidence that similar effects may be reproduced inadvertently in the human female. G. Nellhaus¹ reports the case of a woman who had received a total dosage of 2 g. of methyltestosterone for habitual abortion, and who subsequently delivered a typical female pseudohermaphrodite, and he cites five other cases from the literature. Similar results are described following progesterone therapy for the same condition by other authors.^{2,3}

Up to the tenth week of gestation the two sexes share the common indifferent genitalia, differentiation into male and female appendages taking place within the next six weeks. A. Jost⁴ has shown that before this stage the genitalia are particularly susceptible to hormonal influence. The normal basic neutral structure is female, as in the ovum, future differentiation being directed by the testis, acting mainly through its testosterone secretion. Androgens administered to the mother at this

crucial stage pass easily through to the foetus in rather high concentration, and any excess may cause changes in its sensitive external organs. If the genetic sex is male, the added androgen will have little effect beyond reinforcing the natural testosterone and perhaps producing temporary genital hypertrophy. If, however, the sex chromosome addition is female, such treatment may easily simulate the hormonal effects of normal testicular development, with the production of a type of intersex such as pseudohermaphroditism. The same effect may be produced with progesterone (which is used much more widely than the androgens for threatened abortion) through its partial conversion into testosterone during normal metabolism. Here, however, the total amount of androgen released is relatively small, 1 mg. of progesterone being equivalent, according to J. K. Lamar,⁵ to 0.03 mg. of testosterone, so that its administration in the usual therapeutic dosage should be fairly safe. This cannot, however, be said for testosterone itself. Experimental and clinical observation shows that pregnant women taking large amounts of the hormone, particularly during the third and fourth months, may deliver a baby with abnormal external genitalia. Such treatment is anyway of doubtful therapeutic value, and in view of the inherent dangers it is probably unwise in any circumstances during early pregnancy.

MORE POLIO VACCINE

The Medical Research Council has produced compelling evidence^{1,2} that a third, or booster, dose of poliomyelitis vaccine is needed to maintain circulating antibody at levels likely to confer protection. Its results agreed with those of several American studies, which were discussed last year in these columns,³ where the suggestion was made that children who had had two doses should be offered a booster in the spring. Unfortunately this apparently was impossible. The Government's hope that supplies for this purpose will be available in the autumn, expressed by the Minister of Health last Monday, is therefore welcome. The offer of vaccination is also to be extended to people aged up to and including 25, and to a wider range of hospital staffs and their families. The Minister and the Secretary of State for Scotland are to consult with the B.M.A. and local authority associations on the details of continuing this elaborate campaign in preventive medicine.

Whether further doses beyond the third will be needed to maintain immunity has yet to be discovered, for much mystery still surrounds the nature of immunity and the relation between level of antibody and the protection it confers.⁴ The studies that are now being carried out may throw light on that within the next year or so. But, owing to the complex administrative arrangements that must of necessity be made to give these injections, it is a possibility worth keeping in mind. If the disease is to be reduced drastically, as diphtheria has been, for instance, very large numbers of inoculations may have to be performed, at least for some years.

British Medical Association

ANNUAL MEETING, BIRMINGHAM, 1958

SUMMARY OF PROCEEDINGS

FIRST PLENARY SESSION—REHABILITATION

Wednesday, July 16

The chairman, Dr. DONALD STEWART (Birmingham), emphasized that rehabilitation was a subject of importance to medical practitioners in every field, and hence the wide range of interests represented by the opening speakers, who were respectively a professor of medicine, an orthopaedic surgeon, a psychiatrist, a physical medicine consultant, and an industrial medical officer.

Professor R. E. TUNBRIDGE (Leeds) said that his purpose was to show the need for the profession to apply the lessons with which it was familiar. Rehabilitation was a professional responsibility, and as a profession we should press for the provision of a more complete service, particularly for all forms of planned convalescence. The changing practice of medicine and the changing structure of society had created both new problems and new opportunities. With an increased expectancy of life at birth more people were now living long enough to contract the chronic disabilities of the second half of life, particularly heart disease, cerebrovascular and peripheral vascular disorders, arthritis, chronic chest diseases, and mental disorders. This constituted a new problem, that of medicated survival. Rehabilitation was an attitude of mind, and much of value could therefore be achieved if the medical profession was alive to its responsibility. Many doctors considered it only as a problem after trauma, but in fact disability directly attributable to trauma constituted less than 25% of total disability at the present time, while 75–80% was due to the so-called internal diseases. Official sources tended to underestimate the size of the problem. The few detailed surveys carried out in this field showed that nearly one-sixth of the patients discharged from a general hospital were unsuitable for full employment, while about one-third were still at home three months after discharge. Social factors interfering with recovery seemed to assume greater prominence between the ages of 45 and 54 years. On reaching retiring age some 25% of men and 14% of women were chronically sick and a further 25% of men and 30% of women gave ill-health as their chief reason for retirement on reaching pensionable age. There was evidence to suggest that in the interest of health every year some 40,000 men between the ages of 55 and 64 years might with benefit change their job to a more suitable form of employment. Ministry of Labour industrial rehabilitation units had been concerned chiefly with industrial problems and with late results rather than with the early stages of disability, but the B.M.A. committee had suggested that there was an unnecessary amount of ill-health and unrelied disability in the period of one to six months after the onset of disability. The report of the Ministry of Health inquiry into the reason for prolonged ill-health of three to six months' duration would be studied with great interest.

Value of Customary Activities

Mr. L. W. PLEWES (Dunstable), speaking of rehabilitation as seen by the surgeon, said that during the war the need to salvage every possible pair of hands had reawakened interest in rehabilitation, and tremendous strides had been made in Britain, which still led the world in this field. It was, however, easier to convince the general public about the need for rehabilitation in a time of full employment than when times were bad. It should never be forgotten that the best form of rehabilitation was normal activity. We should pander more to a man's belief that he was important in his work. Most difficulties could be overcome if we took the

trouble to work out a solution and persuaded the employer to apply it. For example, the man with a Colles fracture did not get a stiff wrist, wasted muscles, or a frozen shoulder if he used his hand in a normal or near normal manner while in plaster. Furthermore, he lost no morale and maintained confidence in his own usefulness to the community as well as averting financial hardship. Finally he achieved a perfect functional result. A man kept at work through the period of his disability never risked the shattering of the illusion that he was indispensable in his job. Only two types of case required admission to a rehabilitation centre. First, those with a severe fracture, say of femur or of tibia and fibula, or with multiple injuries and considerable disability. In these cases the test of fitness to return to work was the ability to get on and off a bus. Secondly, there were patients with a severe and prolonged disability such as hemiplegia, paraplegia, crippling joint disease, or progressive neurological disorder, and these had to learn how to live with their disability.

Mr. Plewes found that to provide a comprehensive rehabilitation service for a population of 250,000 the requirements were a hospital rehabilitation centre designed to cater for 50–60 people, a similar centre located in the largest local industry, an occasional place for in-patient accommodation in a regional centre, an occasional place in a regional industrial rehabilitation unit and training centre, and a sheltered workshop for the employment of at least 50 people. Ideally there should also be a unit for helping the disabled housewife. There was in his opinion a strong case for introducing an industrial medical officer into the staff of the Accident Service and rehabilitation centre so that he could follow his cases right through treatment while working in his factory.

Psychiatric Rehabilitation

Dr. MAXWELL JONES (Sutton) indicated the importance of the modern tendency to treat mental illness in the community at home rather than in hospital, and he expressed his pleasure that similar trends were becoming apparent in the field of general medicine and surgery. In psychiatry, rehabilitation and prevention were part of the same process, and the primary need for rehabilitation in this sphere was the training of doctors in social medicine. The advent of the Welfare State had solved many of the patient's worries. However, too many patients now tended to wait for something to be done to them, and the social services had taken the place that the family used to hold in after-care. The artificial separation of treatment and aftercare services made the management of preventive psychiatry difficult. This difficulty had been overcome, however, in the few instances where integration had taken place between the local authority and local mental health services.

Most mental hospitals had a static pool of aged patients occupying beds. This could often be avoided if a request for admission was met by a visit to the patient at home by the psychiatrist and the psychiatric social worker. Under these conditions it could be indicated from the start that the family must assume responsibility. It could be made clear, for example, that the patient would only be staying in hospital for a short time while receiving some physical treatment. Often the patient could go to a 'day hospital' while the relatives attended to their jobs, and similar arrangements could be made for holidays. These methods of management led to a change in the family's attitude to their problem, and the patient could often play a useful part in the life of the family.

Importance of Team Work

Dr. F. S. COOKSEY (London) traced the evolution of rehabilitation in Britain through the present century. Now, in its sixth decade, we were trying to implement the legislation made in the fifth. When one considered in detail the number of doctors and ancillaries involved in the rehabilitation of a single patient one was led to question whether it would not be wise to broaden in each case the scope of the interests involved so that there was wittingly some overlap. Although it was necessary to implement the complicated statutory

¹ Report to the Medical Research Council, *Brit. med. J.*, 1957, 2, 1207.

² — *ibid.*, 1958, 1, 1206.

³ *Ibid.*, 1957, 2, 1229.

⁴ *Ibid.*, 1958, 1, 1227.

mechanism which made rehabilitation available to all who needed it, there was no need for restrictive practices in medicine. No one doctor was ever in absolute control of a case, not even the general practitioner, and team work was therefore essential. Procedure should be simplified wherever possible. Some overlapping of the responsibilities of the ancillary workers would also be of advantage, since this would tend to relieve the shortage of such invaluable people as physiotherapists, occupational therapists, almoners, and other social workers. These aims could largely be satisfied by the extension of the use of resettlement clinics, both industrial and social, where all interested parties met to discuss the problems concerned from the earliest stages of illness right up to the time of final resettlement.

Forward planning was essential. As soon as a long-term case, such as a severe fracture or hemiplegia, was seen to be safely through the emergency period an inspection should be made of the home conditions so that an accurate assessment could be made of the physical difficulties which would face the patient on returning home. The necessary team of workers could then be mobilized and effective plans made for the home-coming of the patient long before the event. This system of forward planning had the great advantage of suggesting at the earliest possible moment to both the patient and the relatives that return home was not only desirable but inevitable, and the patient was never allowed to acquire the idea of staying permanently in bed. Dr. Cooksey agreed with Dr. Maxwell Jones that day centres were necessary, not only for psychiatric cases but also for those with physical disabilities.

Back on the Job

Dr. A. A. WHITE (Birmingham), speaking of rehabilitation from the viewpoint of the industrial medical officer, said that sooner or later after the primary treatment of illness or injury had been completed the patient had to be advised on the effect any residual disability might have on his normal activities and particularly on his job. Even when full resumption of normal activities could be legitimately anticipated it was important that the patient should be made to understand this, because unjustifiable anxiety might handicap recovery and even lead to the seeking of modified employment which was not to his ultimate advantage. The problem of advising the incompletely recovered patient was far more difficult, particularly as recovery of working capacity did not automatically proceed in step with organic recovery from illness or injury. The industrial medical officer rarely found that employees returning to work after illness or injury had any good understanding of the effects of their illness, although the majority were well informed regarding the nature of their disability and the treatment they had received.

Clinical examination procedures, however carefully performed, were designed to detect disease and did not, except at the extremes of disablement, enable accurate conclusions to be drawn about working capacity or occupational prognosis. The experience of the past ten years had led Dr. White to conclude that, at the end of treatment and convalescence as we knew them at present, insufficient evidence about residual fitness existed to allow the making of an accurate occupational assessment of the partially fit. The disablement following illness or injury consisted of three components—organic, that due to disuse, and psychological. Under existing conditions of medical aftercare all these contributed to the reduction of the patient's occupational capacity when he returned to work. The three components could be separately influenced and disablement reduced by a planned rehabilitation programme. This included a direct study of the true effects of the organic component on occupational capacity, retraining by stages to eliminate fatigue and loss of particular skills, together with careful explanation, reassurance, and encouragement to allay anxieties. A positive rehabilitation policy gave to the patient an understanding of the true limits imposed by his disability, an optimum physical and psychological adjustment to residual disability,

ment, together with a knowledge of the safe range of future activity. In addition such a policy provided physical reconditioning and recovery of work habits with restoration of self-confidence. The doctor and the employer benefited by the acquisition of reliable information in terms of the actual working capacity of the patient, his level of skill, and his attitude and adjustment to his work. A serious criticism of objectives in treatment as they existed, particularly in hospitals, at the present time was that the total well-being of the patient tended to be lost sight of through too great a preoccupation with the actual disease and its treatment as an end in itself.

In expressing the appreciation of the audience Professor P. C. P. CLOAKE (Birmingham) reiterated the fact that rehabilitation had many aspects and many concepts depending entirely on the type of case to be dealt with. Adequate medicine consisted not only in treating acute episodes and then awaiting relapse but in active prophylaxis of future breakdown by careful rehabilitation from the earliest stages.

SECOND PLENARY SESSION—CHEMOTHERAPY OF INFECTIONS

Thursday, July 17

In his opening remarks the chairman, Professor D. M. DUNLOP (Edinburgh), briefly reviewed the successes and limitations of chemotherapy for infection. Its use had in two decades changed the face of medicine, with important social consequences. Many infectious diseases, however, were still beyond its influence, and superinfection with resistant organisms, especially *Staphylococcus aureus*, presented a growing problem in hospitals. The range of available agents was increasing, but thought and restraint were essential in using them.

How the Bacteriologist Can Help

Professor J. W. HOWIE (Glasgow) discussed three questions on which the bacteriologist could help the clinician in his application of chemotherapy. (1) *Which infections should be treated with antibiotics?* Penicillin was the drug of choice for erysipelas, scarlet fever, acute pharyngitis, and acute cellulitis, which were caused (or usually caused) by *Streptococcus pyogenes*; also for lobar pneumonia, gonorrhoea, syphilis, yaws, anthrax, and actinomycosis, and often for puerperal sepsis, meningitis, antral infections, bronchopneumonia, endocarditis, and septic fingers, which might be caused by *Str. pyogenes*. Sensitivity testing of bacteria isolated from the lesion was an important guide to treatment, though penicillin might reasonably be given before the results of bacteriological tests were known. Plague and tularaemia were best treated with streptomycin, typhoid and paratyphoid fever with chloramphenicol, typhus and undulant fever with chloramphenicol or tetracycline, meningococcal meningitis with sulphonamides, malaria with quinine, mepacrine, or proguanil, and trypanosomiasis with tryparsamide, suramin, and melarsen. (2) *Why antibiotics did not always succeed.* No drug, said Professor Howie, could succeed if the infecting organism was insensitive; into this group fell the viruses, and also resistant strains of bacteria, such as the staphylococci. The anatomy of the part and the pathological nature of the lesion could defeat chemotherapy even if the causal agent was sensitive; in necrotic bone, for example, or in urinary infection complicated by retention of urine. With certain exceptions—for example, bacterial endocarditis—these problems could not be solved by massive dosage or by combined therapy, and they were aggravated by the use of weak imitators of the major antibiotics. (3) *When antibiotics should not be used.* There was a place, said Professor Howie, for chemoprophylaxis in the surgery of infected tissue, for example, and in the control of rheumatic fever; but prophylaxis was out of place for clean operations or simple wounds and for normal labour. An antibiotic must not be used when a patient gives a history of sensitivity to it, and antibiotics

should never be used as a substitute for asepsis. Finally, it was important that the doctor should understand the pathology and bacteriology of the infection he was treating.

Non-tuberculous Pulmonary Infections

Professor C. H. STUART-HARRIS (Sheffield) spoke on the chemotherapy of non-tuberculous pulmonary infections. He said that the respiratory tract was probably subject to attack by a wider range of organisms than any other. Chemotherapy had achieved great successes in this field, but also suffered from defeats, and there were no rules of treatment which could replace diagnostic acumen and vigilance. The prognosis for pneumonia had been transformed by chemotherapy; mortality had fallen (though this fall began before the sulphonamides were introduced), and lobar pneumonia had also become less common in hospital practice. It was now the pneumonias of old age and of those with diseased lungs which were predominant. The clinical presentation of pneumonia had changed, many cases with radiological changes showing no consolidation. Of cases in which consolidation was present 20 to 50% had no pathogenic organisms in the sputum, but their response to chemotherapy was no different from that of the cases which yielded pathogens; a viral aetiology was therefore not to be assumed in these cases, and chemotherapy should begin at once if there was consolidation. Pneumococci were the commonest infective agents, and clinical trials had shown that penicillin, the tetracyclines, and chloramphenicol had similar therapeutic value in pneumococcal pneumonia; penicillin, which had the least toxicity, was therefore favoured. Streptomycin was useful for pneumonia due to coliform bacilli, and nystatin possibly useful for fungal pneumonias.

Failure of chemotherapy, as shown by the 5% of patients who died, was attributable to various factors, including age, heart disease, previous lung disease, and delay in starting treatment. In the recent influenza epidemics staphylococci were the commonest organisms associated with pneumonic complications, and many were resistant to antibiotics; but patients often died from this fulminating infection even when the organism was sensitive. Early diagnosis was aided by the examination of Gram-stained films of sputum, and treatment should begin at once with penicillin, streptomycin, and (in severe cases) erythromycin, modified later if necessary.

Apart from influenza, psittacosis, and Q fever, virus pneumonias were mostly trivial. There was little evidence that antibiotics would affect their course; penicillin and tetracycline, however, were active against the virus of psittacosis and the rickettsia of Q fever, and antibiotics should not be withheld unless infection was trivial or identifiable as "atypical" or virus pneumonia. Although acute bronchitis in children was often caused by viruses, antibiotics should, in general, be used for the control of concomitant bacterial infection. Exacerbation of chronic bronchitis in adults was not associated as a rule with any change in flora, and a virus was probably responsible. The value of chemotherapy was therefore limited, but chloramphenicol or preferably oxytetracycline was worth using, as it diminished the amount of sputum and coughing. Indications for prophylactic use of antibiotics to prevent exacerbations were more doubtful.

Chemotherapy for Pulmonary Tuberculosis

Professor JOHN CROFTON (Edinburgh) spoke on chemotherapy for pulmonary tuberculosis. He said that the right use of modern methods of chemotherapy made it possible to aim at 100% success in the treatment of this disease. Deaths from tuberculosis had fallen dramatically since the introduction of chemotherapy in 1947-8, and hospital statistics showed that the incidence of new cases was also falling. Prophylactic chemotherapy might be considered (a) in children with a positive tuberculin test as the only evidence of infection, (b) in adolescents with strongly positive tuberculin tests but no detectable disease, and (c) in

patients with lung lesions of doubtful activity. As regards the first of these indications, a controlled trial in the United States had shown that 0.7% of children under 1 year of age treated with isoniazid later developed clinical tuberculosis, compared with 3.3% of untreated controls. For these, prophylaxis was probably justifiable, but for older children and for those in groups (b) and (c) treatment was best left until signs appeared.

In active tuberculosis chemotherapy was always indicated. For mild cases with negative sputum bed rest was found, by controlled trial, to be unnecessary (provided supervision was good). Infectious cases, however, should always be treated in hospital until their sputum was negative; in many cases this would take no more than three or four months. All the patients in a series studied in Edinburgh had negative sputum after 10 months of treatment, and there were no relapses in patients who had been treated for 18 months. Tubercle bacilli could not be isolated from lungs resected more than 18 months after the beginning of treatment. The situation was quite different if the organism was resistant to two or more of the standard drugs, and an effective scheme of combined therapy was essential in order to prevent the emergence of resistance during treatment—e.g., streptomycin (1 g.) daily, and P.A.S. (5 g.) and isoniazid (100 mg.) twice daily until the sensitivity pattern was known, when P.A.S. might be omitted if the other agents were active. For treatment at home the oral drugs, isoniazid and P.A.S., were more convenient. Corticosteroids given with chemotherapy might be helpful in very ill patients.

As a result of chemotherapy, collapse therapy had been largely given up and surgery was less often required. The older methods of treatment and less effective drugs (viomycin, pyrazinamide, cycloserine, and tetracycline) were necessary if the organisms were resistant to the standard drugs. Professor Crofton concluded by saying that in no disease was good doctoring more necessary than in tuberculosis.

Intestinal Infections

Professor A. C. FRAZER (Birmingham), speaking on chemotherapy against intestinal organisms, considered first the pathogens. For the treatment of dysentery, sulphonamides were effective, but should preferably not be given in the form of poorly absorbed compounds; drugs which are absorbed, such as sulphadiazine, were more capable of reaching the organisms and probably more effective. A loading dose should be given and treatment should be continued for several days after symptoms disappeared. The tetracyclines (preferably oxytetracycline) were also effective in the treatment of dysentery; for more vigorous treatment with these drugs it was better to shorten the interval between administrations than to increase the dose. For typhoid and, to a less degree, paratyphoid fever, chloramphenicol was effective; the toxic risks had been exaggerated. Food poisoning was usually due to toxins (e.g., of *Staph. aureus*), and for these chemotherapy did not help, but for salmonella infections chemotherapy—chosen by reference to sensitivity—was desirable. For infantile gastroenteritis associated with specific serological types of *E. coli* neomycin was the drug of choice.

Professor Frazer considered next the normal flora of the large intestine. *E. coli*, *Bacteroides*, and (variably) streptococci, clostridia, staphylococci, lactobacilli, *Pseudomonas*, and *Proteus* were, under normal conditions, non-pathogenic, but dangerous if allowed to invade the tissues (e.g., at operation); non-absorbed agents (e.g., neomycin with phthalyl sulphathiazole) given by mouth provided a relative freedom from bacteria within 48 hours, and were suitable for preparatory treatment before operation on the bowel. The normal flora of the gut had various effects—the production of stercobilin from bile pigments and of cholic acid from bile salts, the depolymerization of mucin, the synthesis of vitamin B complex and vitamin K, and digestion of cellulose, sugars, and other food components. These activities, which contributed nothing significant to the

normal body economy, were inhibited by antibiotics that eliminated the gut flora. It was probably desirable to administer vitamins under these conditions, and a preparation of antibiotic-resistant lactobacilli ("enpac") might be useful in preventing the replacement of the normal gut flora by potentially dangerous resistant organisms (e.g., *Staph. aureus* or *candida*). Increased activity of gut organisms and colonization of the small intestine could be seen in sprue and other forms of the malabsorption syndrome. Persistent steatorrhoea, which sometimes followed the acute phase of sprue, could be successfully combated by antibacterial therapy; in the acute phase, treatment with folic acid was usually successful and chemotherapy valueless.

In answer to questions, Professor Frazer said that nystatin might be used in prophylactic treatment of the bowel when *Candida albicans* was abundant. Professor HOWIE said that it was better to use neomycin and bacitracin than penicillin and tetracycline for local application; bacteria did not readily acquire resistance to them, and they were not likely to be given parenterally.

THE SECTIONS

SECTION OF MEDICINE

Monday, July 14

Poliomyelitis: the Present Position

At the first session of the Section of Medicine the subject discussed was "Poliomyelitis: the Present Position." The president, Professor W. MELVILLE ARNOTT (Birmingham), asked Professor MAX ROSENHEIM (London) to take the chair.

Dr. W. RITCHIE RUSSELL (Oxford) said that the sharp increase in the incidence of poliomyelitis in 1947 had offered opportunities for clinical study of the disease, of its early signs, and of the life-saving measures used in treatment, in particular those designed to overcome respiratory failure. After 1950 the separation of paralytic from non-paralytic cases for notification purposes had yielded more reliable figures, both of incidence and of mortality, and advances in treatment had been such that there was now little difference in mortality rates between epidemics. About 20-30% of paralytic cases were "life-threatening," but the actual fatality rate was now about 5%, a reduction which posed special problems in so far as the seriously handicapped survivors were concerned.

Management of Respiratory Paralysis

Centres with very experienced staff had now been established for the reception of the most dangerously ill patients. These fell into three groups. (1) Patients with simple paralysis of respiratory muscles. For these the modern tank respirators were adequate, provided they were used before breathing became seriously embarrassed. (2) Patients with the bulbar type of disease. Here paralysis of swallowing was highly dangerous and its early recognition was extremely important. Such patients were especially suitable for treatment in special units from which a team could often be sent to supervise their removal to hospital. The patients should be transported prone or semi-prone, with the feet raised; they should be under constant supervision and suction apparatus should be available. Maintenance of a good airway required postural drainage and often tracheotomy. Good recovery was possible even from a state of profound stupor. (3) Patients with both bulbar and intercostal paralysis. Here tracheotomy with a cuffed tube was best combined with intermittent positive-pressure respiration through the tube. This was efficient, eased changes of posture for physiotherapy, and enabled the patient to be transported long distances and to be nursed more satisfactorily on a tilting bed. Splints were troublesome in life-threatening cases, and, if passive movements were carried out each day for a few months from the very beginning, tight painful muscles would not develop. Though rest was important at first, it should not be carried to the extent of

allowing weak muscles to shorten. If poliomyelitis decreased in the future, similar principles would still apply to the treatment of other diseases in which respiratory failure was a feature.

Epidemiology of Poliomyelitis

Professor G. W. A. DICK (Belfast), discussing the epidemiology of poliomyelitis, pointed out that of the three types of virus type 1 was responsible for 80% of the paralytic cases. Infection with all three types of some clinical degree was very common. Spread was by person-to-person contact, and children, in whom multiplication of the virus in the alimentary tract was greatest, were an important source of infection. There was no evidence that animals or birds played any part in the spread of the disease. After infection, virus remained in the throat for a few days and in the faeces for several weeks, and it was evident that certain families ("hot" families) were particularly susceptible to the spread of the virus and particularly capable of transmitting the disease. When one member of a family was infected practically all the others became infected, even if no clinical signs appeared, but whether infection was mainly from oropharyngeal or faecal virus had not yet been fully established. The "hot" families spread the disease with ease, but parallel with these were some clinical infections among "cold" families which were capable of producing immunity. It was not possible to prevent infection, but contact with the affected child and its siblings could be limited by quarantine. Live virus vaccination was so far suitable only for experimental purposes, since there was some evidence that when given by mouth an avirulent vaccine might show increased virulence on excretion. It was still not known why an epidemic occurred, but it was not owing to change in virus strains and was probably owing to change in the host.

Diagnostic Problems

Dr. J. F. GALPINE (Coventry) discussed three diagnostic problems of poliomyelitis. The first was the recognition of non-paralytic poliomyelitis, which was an example of an aseptic meningitis of viral origin. The C.S.F. was clear and contained 10 to 500 cells, with a predominance of lymphocytes and a slight increase in protein. Similar findings might be seen in mumps, benign lymphocytic choriomeningitis, and glandular fever. If such cases occurred in epidemic form without paralysis, then the Coxsackie or ECHO viruses might be responsible. Certain non-viral diseases, such as leptospiral infection, gave a similar picture, but the E.S.R. was high, the conjunctiva inflamed, the urine contained albumin, and antibodies were demonstrable in the blood. Tuberculous meningitis was a steadily progressive disease, with later development of cranial nerve palsies and characteristic chemical changes in the C.S.F. Partially treated septic meningitis and extrameningeal infections might also be confusing.

The second diagnostic problem was benign myalgic encephalomyelitis. This was a disease of unknown cause, but had a widespread distribution. It was not a fatal disease, but it had some sequelae and was associated with severe muscle pain, muscular twitchings, paresis and spasm, and a normal C.S.F. in over 50% of cases. The electromyogram might show abnormal grouping of motor unit potentials hitherto unknown. Dr. Galpine described an outbreak at Coventry and also the Royal Free Hospital epidemic. Occurring sporadically, these cases might often be labelled "paralytic poliomyelitis" or "hysteria." The third problem was polioencephalitis. This might occur without evidence of paralysis, with symptoms such as confusion, day-dreams, flights of ideas, and the clinical picture of an encephalitic state affecting cerebrum, brain stem, or cerebellum. As these were non-paralytic cases, the problem was how they should be notified.

Poliomyelitis Vaccine

Dr. JOHN KNOWLEDEN (London) described the present situation so far as formalin-killed poliomyelitis vaccine was con-

cerned. He drew attention to the difficulties of assessing results of vaccination if a large group of patients were subjected to such a procedure without previous careful assessment. It had taken 50 years to clarify the situation regarding typhoid vaccine. Good controlled studies of the Salk vaccine showed that, among 200,000 children vaccinated in a blind trial, attack rates of paralytic poliomyelitis were only 28% of those among 200,000 children given a placebo. Investigations with British vaccine had shown that in the younger children (up to 5½) there was 80% better protection, and in the older children (5½ to 9) 84%, but the numbers were very small. Both in Britain and in America there was hardly any difference in the incidence of non-paralytic poliomyelitis in the two groups, so that with this vaccine it was unlikely that the reservoir of infection in the community would be reduced. Vaccination was now carried out in Britain with two doses, with about four weeks between them, and it had been shown that a third dose six months later gave a bigger boost to antibody response than the second dose did. There had been no major catastrophe since the Cutter incident. It was still unknown whether the higher antibody response gave greater protection against paralytic poliomyelitis, what the optimum antibody level was, and for how long the effective antibody level remained. It would be a pity to take widespread action in ignorance of these facts, because as yet no attempt had been made to find out the answers.

In the discussion which followed Professor ARNOTT raised the question whether a centre dealing with patients with respiratory paralysis was best situated in isolation or whether it should be in closer contact with a general medical unit, bearing in mind the complex physiological problems involved.

Dr. T. W. LLOYD (Malvern) asked if vaccination should be given to those in a family who had been in contact with cases, and Professor DICK thought that this should be done.

In reply to Dr. NATHAN WALDMAN (Wolverhampton), Professor DICK said that he did not think that swimming-pools should be closed if the numbers admitted were limited and supervision prevented the swimmers from becoming physically exhausted.

Dr. R. M. S. MCCONAGHEY (Dartmouth) asked if, in view of the copious discharge of sewage into rivers and the sea, bathers were not in some danger. But Professor DICK considered the dilution factor to be far too great for this to be very real.

Dr. ROSITA R. RAMIREZ (Philippines) said that antibody studies showed that in young children from 5 to 9 there had been 95% infection. Dr. J. D. COTTRELL, of the World Health Organization, felt that in view of the high incidence of poliomyelitis in certain overseas communities immunization should be advised for all young adults going abroad.

Tuesday, July 15

The Physician and Hospital Planning

In introducing the subject "The Physician and Hospital Planning," the chairman, Professor W. MELVILLE ARNOTT, said that medical men had to take an intelligent and constructive interest in the tools of their trade, the places in which they worked, and the devices which they used. There were arrears of hospital construction to be overtaken, and it would be of great interest to hear the views of the four distinguished speakers who were to discuss the subject. They were: Dr. G. E. GODBER (Ministry of Health), Mr. L. FARRER BROWN (Nuffield Foundation), Professor T. McKEOWN (Birmingham), and Dr. J. FRY (Beckenham).

Hospital Surveys

Dr. GODBER, reviewing the early planning for hospital services, said that the most significant contribution was a series of surveys of hospitals covering the whole country and sponsored jointly by the Nuffield Trust and the Ministry of Health. One general point of great importance which emerged from the independent consideration of each of ten

surveying teams was the concept of the area general hospital. This was to provide all the ordinary range of specialties for a natural group of the population and was to be linked with regional special centres. For the first time in Britain hospital planning effectively got away from the design of a hospital of some empirically determined size and was thought of as a community service. The next attempt at large-scale planning was an office study which eventually led to the publication by the Ministry of Health of the "Memorandum on the Development of Consultant Services." That was the work of a group of senior consultant advisers drawn mainly from provincial teaching centres.

Thus regional boards had two kinds of preliminary survey to help them, but it was only from 1949 onwards that they began to have reliable statistics of the work which they were already doing and which might or might not be relevant to the work that needed to be done. As soon as statistics began to be available, wide disparities between areas in numbers of beds, of patients treated, and of use of beds were seen. The beds of one teaching hospital might each be used by twice as many patients in the course of a year as those of another. Apparently comparable hospitals showed wide variations in their bed turnover and waiting-lists, often with marked differences between the specialties.

Changing Nature of Hospital Service

The National Health Service had coincided with a period of great development in some highly specialized fields of medicine and surgery. In surgery, operations on the central nervous system, heart, or lungs, and, in medicine, the special techniques of cardiology or neurology, among others, were far past the experimental stage and had to be made available in one at least of the centres in every hospital region. Between 1949 and 1956 the numbers of admissions to beds for plastic, thoracic, and neuro-surgery increased respectively by 119%, 133%, and 82%. Patients admitted for orthopaedic and traumatic surgery increased by 70% and for gynaecological operations by 53%, compared with only 20% for general surgery. In neurology and dermatology increases were just over 50%, compared with an increase of only 24% in general medicine and a fall of 11% in paediatrics.

That change in the nature of professional services required in hospital was certainly not finished. The fact that more than three-quarters of the neurologists worked in the four metropolitan regions, where only one-third of the people lived, showed that the process of distribution of specialists was not yet complete. But, aside from the process of redistribution, medical advances were still necessitating staff changes. The medical planner, therefore, had to bear in mind not only recent developments which had already become accepted medical procedures but also the new techniques which were already coming into use in the special centres. Therefore, continued Dr. Godber, it should be a general principle of the planning of any area hospital now that it must lend itself to modification, adaptation, and possibly extension at some future time. The perfect monoblock, complete in itself for the needs which could be defined now but with no point at which addition could be made, was a medical and architectural vanity which could not be afforded.

Out-patient Services

Referring to turnover and out-patient services, Dr. Godber said that for very many years hospitals had been looked upon as residential establishments in which medical and nursing care was given. The rapid growth of out-patient services during the last twenty years had arisen largely from the improvement in diagnostic techniques. The work of hospitals was now carried on to a very large extent in the out-patient and diagnostic departments. In 1956 the out-patient and casualty departments of hospitals provided more than two-thirds of the work of radiological departments and almost one-third of the work of pathological departments. Moreover, both those diagnostic departments were steadily increasing the service they provided direct to general prac-

tioners. For every patient admitted to hospital wards, excluding obstetric cases, two were seen in out-patient departments; only about half the admissions to general hospitals were from waiting-lists, and thus little more than a quarter of the out-patients might be admitted to the wards. The hospital must therefore become more—not less—closely related to all the medical work of the area it served.

Hospital Building

Dealing, finally, with the planning of buildings, Dr. Godber said that the doctor's job was to tell the architect what amount of space was essential for his work; what special relationships that must bear to the other necessary constituents of the hospital; what kind of equipment he would want; at what points and for what purpose subsequent extension was most likely to be needed; and what would constitute a reasonable pattern of phased development if building must progress by stages. But the doctor should not insist on inessential architectural extravagances.

By way of illustration, Dr. Godber referred to the shape of operating theatres. "There is a vogue at this time in some countries for operating rooms of circular or egg-shaped design, for which are claimed special advantages in lighting and ventilation," he said. "It is by no means proved, however, that these advantages cannot be obtained in other ways, particularly in regard to ventilation; and it is hardly justifiable to insist that two theatres must be provided at a cost the equivalent of five of orthodox design, as occurred in one particular case."

The more detailed study of the actual design of buildings was perhaps outside the scope of the meeting, concluded Dr. Godber, but the physician had a large part to play in the design of the buildings and in the briefing of architects, but not in drawing the lines on paper for him.

Function and Design of Hospitals

Mr. L. FARRER BROWN (Nuffield Foundation) recalled that three years ago the Nuffield Provincial Hospitals Trust and the University of Bristol published a volume called *Studies in the Functions and Design of Hospitals* which was a record of some attempts to obtain valid evidence, tested by experiment, about the work of hospitals and the planning of their buildings. There were, he said, signs that those studies were beginning to influence hospital planners throughout the country in their approach to their task.

Mr. Farrer Brown cited three examples showing the wide range of possible future study. The first was an account of practical experiments in ward building, the second dealt with an important series of surveys of the demand for hospital care, and the third was a short account of a new study into the hospital care of children.

As to the first, at Larkfield Hospital in Scotland there had been the opportunity to test out in an experimental unit of 64 beds the ideas about medical wards developed from the Nuffield Trust studies. A comparable unit at Musgrove Park Hospital would be a testing place for the ideas about surgical wards, and also about operating theatres and central sterilization. Conclusions drawn from those studies were (1) that wards should be planned as double units within which two comparatively small units shared a central unit of ancillary accommodation. (2) A much higher proportion of single rooms than hitherto provided was necessary on medical grounds (but once that provision had been made the remaining beds might be kept in fairly large open units). (3) Three-quarters of all patients were likely to be able to get out of bed to use toilet facilities, and half would probably get up for meals; hence greatly increased provision was needed for lavatories, wash-rooms, and day-spaces. (4) Important economies in building costs, reductions in heating costs, and a reduction in nurses' journeys could be achieved if ward buildings were designed as comparatively short, thick buildings.

Demand for Hospital Care

As to the demand for hospital care, the results of two exploratory surveys of the case-load of hospitals in Norwich

and Northampton had raised a doubt whether the scale of hospital provision for a given population need be as much as was popularly supposed. A pilot inquiry in the main general hospital in one area seemed to indicate that of the patients occupying medical beds during one week about a quarter could have been treated at home or in the out-patient department, and that about half were remaining in hospital longer than was necessary from the standpoint of what the hospital could do for them. There was also some indication that if the general practitioner had better opportunities for diagnosis fewer patients would have to be sent to the out-patient department.

Thirdly, on the question of what provision should be made for children in hospitals, records made in fifteen hospital groups (five of them teaching groups) over four 6-week periods during twelve consecutive months in 1956-7 showed that of nearly 5,400 children admitted to adult wards the proportions by age groups were: under 1 year, 1%; 1 to 4 years, 10%; 5 to 9 years, 33%; 10 to 16 years, 56%. Therefore, before considering what sort of children's hospitals would be needed in the future, much more precise information was required about the total number of children admitted to hospitals, their geographical distribution, and their classification by diseases. Reconnaissances in children's hospitals and units encouraged the view that, while the need to build isolated self-sufficient children's hospitals might have passed, there was a good case for separating the accommodation of children from the rest of the hospital. If a children's unit was part of a general hospital it could share many of the expensive services such as radiology and pathology; most important, the paediatricians could have contact with other medical colleagues. But the planning needs for children were so different from those for adults that they demanded a separate children's building.

As to the future, changing practice would affect hospital buildings in various ways; but probably the best answer was found by regarding the problem as one of town planning, and thinking of a hospital design from its earliest stage in terms of traffic flow and zoning. A hospital was a living, changing entity and not a static composition, and its constituent elements would change at different rates.

Unanswered Questions

Continuing the discussion, Professor T. McKEOWN (Birmingham) said that the planning of hospitals might be said to raise two questions: How to keep patients out of hospitals, and how best to provide for those who must be admitted. Concerning himself with the second of those questions, he said that in spite of the considerable amount of research and planning which had been done some of the most fundamental questions remained unanswered. Three of them seemed to be of particular importance: (1) How to provide sufficient medical and nursing staff for mental and chronic sick hospitals, (2) how to make hospitals flexible in construction, site, and design, so that they would not quickly be out of date, and (3) how to avoid mixing patients with entirely different requirements within the same unit.

He suggested that, although they might appear to be very different in kind, those three problems and some others were attributable to the same circumstances. They were (a) the separation of hospitals for the mentally ill and chronic sick from the general hospitals, and (b) the traditional concept of the hospital as a single structure of more or less uniform design, providing a full range of services for all classes of patients.

Co-ordination of Services

Dr. J. Fry (Beckenham) said that in considering hospital planning it was very necessary to realize that it must be a part of a whole, and the planning of hospitals must be closely bound up with the planning of public health and general-practitioner services. "As a general practitioner I naturally feel that the medical centre of gravity has been moved too far over to the side of the hospitals, and that insufficient attention has been paid to the development of general practice," he added.

Dr. Fry said he would like to see unified local health areas which would be based on the main local hospital. Hospital, general practitioner, and public health services would be administered from one centre, and the three branches would be able to appreciate each other's problems more readily. No changes in the law would be necessary, and that type of experiment could be attempted now. The hospital of the future would have to be more aware of the needs of family doctors, by offering full facilities for investigations, by making available more maternity beds for general practitioners, and by encouraging a more active participation of general practitioners in out-patient departments. There would also have to be a shift of emphasis towards the projection of the hospital's services into the homes of the patients.

Among those who took part in the discussion were Dr. LOGAN (Manchester), Dr. J. D. LLEWELLYN-JONES (Malaya), Dr. J. A. MOODY, Dr. W. RITCHIE RUSSELL (Oxford), and Dr. SKENE.

SECTION OF SURGERY

Monday, July 14

Advanced Carcinoma of the Breast

The president, Professor F. A. R. STAMMERS (Birmingham), welcomed the members, and with Mr. E. C. B. BUTLER (London) in the chair the Section proceeded to consider the treatment of advanced carcinoma of the breast. The opening speaker, Dr. A. C. CROOKE (Birmingham), described the various hormonal factors influencing breast development. He stressed the complexity of the subject, pointing out that most of our knowledge was derived from study of the rat. Oestrogens alone did not induce any change in breast structure, but if combined with growth hormone development of the main ducts occurred. Progesterone and pituitary of mammothrophin (prolactin) were necessary for growth of the lobular structure. At term, lactation was induced by the sudden reduction of circulating progesterone and oestrogen in the continued presence of prolactin (together with adrenal glucosteroids). There was great variation among different species, and therefore knowledge derived from the rat must be applied to man with considerable reserve. Dr. Crooke warned against uncritical interpretation of hormone assays in the human. These substances could not be detected in blood, and only urinary estimation was at present available. Biological methods of estimating urinary oestrogens were unreliable, and chemical techniques, though sound, measured only a part of the oestrogen fraction. Present methods of pregnanediol assay were also unreliable. The 17-ketosteroid fraction was such a complex mixture of substances that its determination was almost without value (though knowledge of individual constituents might be of clinical importance). Growth hormone could not be assayed as yet. Hadfield, using a biological method, claimed to have detected a mammothrophin in human urine, but his results had been challenged, and other workers had failed to confirm them. Biological methods of assay using mice were notoriously difficult and capricious, but Hadfield's work might have important consequences; further attempts at confirmation should be made.

Adrenalectomy and Hypophysectomy

Professor L. N. PYRAH (Leeds) gave a short historical review of endocrine ablation operations. In rats, removal of sources of oestrogen secretion reduced the incidence of spontaneous breast carcinoma in cancer-bearing strains. While the administration of oestrogens increased it. Beaton in 1896 first showed that oophorectomy had a beneficial effect in the course of the disease in pre-menopausal women. More recently Huggins had shown that further improvement might be obtained by removing a further source of oestrogens, the adrenal glands. Professor Pyrah then reported the

results in 76 patients with advanced breast carcinoma who had been subjected to adrenalectomy and oophorectomy. It was not possible to predict the effect of operation either by histological study of the tumour or by response to previous hormone therapy. There were nine post-operative deaths, but most of these occurred early in the series. Case reports were presented of patients with remarkable remissions of their disease: 38 patients in all had had a remission; 11 of them were still alive, but two had developed recurrence. In some patients the disease apparently disappeared from the body, no clinical or radiological evidence of malignancy being detectable. Four patients had remissions lasting for three years or more, the longest being three years and eight months. In nine the remission lasted for more than two years; 12 survived 18 months. The relief of pain and the prolongation of life achieved by this operation made it well worth while.

The results of 100 patients treated by pituitary ablation were presented by Mr. J. M. SMALL (Birmingham). The object of the operation was to remove all mammothrophic hormones and somatotrophin from the body. To do this the pituitary must be completely removed and the pituitary stalk destroyed to prevent regeneration of hypophyseal tissue. This was technically difficult in some cases. Nine patients died after the operation, and there was some morbidity including diabetes insipidus (invariably) and minor visual field defects (in 30%); but none had been blinded. Even very ill patients withstood the operation well. The patients were divided into three groups according to their response to operation: those in full remission had complete disappearance of disease; those with partial remission were objectively improved but malignancy persisted; and, thirdly, those with no response at all. Patients with a long history who had responded well to hormone therapy, and who were just past the menopause, showed the best response. Of five patients who had had previous adrenalectomy only one went into full remission; her response to adrenalectomy had also been good. In his series 25% had a full remission and all but one were still alive, the longest survival being three years; 11% had only a partial remission and 6 of these were already dead. Half the patients had no response to pituitary ablation and had not survived more than ten months. Patients with secondary deposits in skin, glands, lung, and bone appeared to respond best to the operation; results in those with liver and brain metastases were disappointing.

What to Advise

The closing speaker, Mr. H. J. B. ATKINS (London), summed up the proceedings by asking what advice a practitioner should give a patient with advanced breast cancer. It had been customary to start such a person on hormone therapy—if she were past the menopause, with oestrogens; if before, with androgens. Oestrogens produced remissions in about two-thirds of patients over 60 years of age; the proportion was much smaller under the age of 60. Hence it would seem reasonable to commence treatment with oestrogens in the older age-group. In young women the response of carcinoma to endocrine ablation was much greater than the response to hormone therapy. Furthermore, testosterone, which was the more effective hormone in this age-group, was disappointing in its results, and side-effects, such as acne and hirsutism, were very distressing. Hence in pre-menopausal women it was probably wiser and kinder to proceed straight to operation. The injection of radioactive substances into the sella turcica to destroy the pituitary had not proved satisfactory even in the hands of its principal advocates. Mr. Atkins then proceeded to discuss the relative merits of hypophysectomy and adrenalectomy, using a series of 80 cases of each performed at Guy's Hospital to illustrate his remarks. At first it had seemed that hypophysectomy was much the better, but as more patients were treated it became apparent that the difference was not great and certainly not statistically significant. Despite the fact that pituitary ablation seemed

to give slightly better results it would be unwise to over-emphasize this at the present time because of the relative shortage of expert neurosurgeons. A competent general surgeon could perform adrenalectomy with a low mortality. If hypophysectomy was attempted on a large scale by those unskilled in neurosurgical techniques the consequences might be disastrous. The difference in the results of the two methods did not justify wholesale adoption of pituitary ablation at the present time.

In answer to a question by Mr. HUGH CARSON (Birmingham), Mr. SMALL said that all patients subjected to hypophysectomy had had previous radiotherapy or hormonal treatment. He mentioned that the response of patients with pregnancy or lactation carcinoma had been very poor. Professor H. W. RODGERS said that in Belfast radioactive yttrium was inserted into the sella after hypophysectomy to destroy the last remnants of pituitary tissue. Mr. R. V. COOKE (Bristol), Mr. HERMON TAYLOR (London), and Mr. BUTLER also contributed to the discussion.

Carcinoma of the Rectum

Under the chairmanship of Mr. HUGH CARSON (Birmingham), Mr. E. C. B. BUTLER (London) then addressed the Section on restorative resection for carcinoma of the rectum and pelvi-rectal junction. He said that since the end of the last war this operation had competed with abdomino-perineal resection for neoplasms just above the peritoneal reflection. Preparation of the bowel with sulphonamides had made anastomosis at this level much safer than previously. Technically, it was necessary to mobilize the rectum and remove its middle portion. Bowel three inches (7.5 cm.) below palpable tumour was usually free of growth. Contraindications to operation were obesity, gross extrarectal spread, and an anaplastic type of tumour. The operation was a little more difficult than abdomino-perineal resection and carried a slightly higher mortality. Local recurrence at the suture line, which was a problem in the past, had now been largely overcome by clamping the bowel immediately below the tumour and irrigating the distal segment of the rectum with mercury bichloride solution (one part in 500). If there was tension on the suture line a temporary transverse colostomy was advisable; a rectal tube was passed up to but not through the anastomosis. Eighty operations for restorative resection of the rectum were performed between 1948 and 1958, with a mortality of 7%. During the same period they had done 181 abdomino-perineal resections, with a mortality of 4.5%. Restorative operation was possible more often in women than in men because of their wider pelvis. Survival rates after the two operations were similar in growths of types A and C (60% and 20% respectively). In type B cases the five-year survival after anterior resection was 69%, and after abdomino-perineal resection only 36%. This difference might be due in part to a different metastasizing potential between tumours above and below the peritoneal reflection. Below the peritoneum there was no barrier to extensive spread into the pelvic connective tissue. Recurrence had occurred at the suture line in five patients; four of them had also had generalized metastases at the same time. Mr. Butler thought that extensive operations for excision of cancer were on the decline. The lethal factor in most tumours was blood-stream spread, which at present was untreatable. He likened the situation to staphylococcal septicaemia; the burden was on research workers to produce a therapeutic weapon which would destroy metastases. Extensive dissection of lymphatic fields was of doubtful value; the surgeon's task was to remove the primary tumour as completely as possible.

In the ensuing discussion Mr. B. N. BROOKE (Birmingham) emphasized that the operation was excellent as a palliative procedure and was especially suitable for elderly patients. In America there was a tendency to use restorative resection for neoplasms of the middle third of the rectum, and he thought that we too should extend the scope of the operation. Mr. HERMON TAYLOR (London) agreed that blood-

stream spread of metastases was the most important factor in prognosis. This usually had occurred before the start of treatment, which was the main reason why extensive lymphatic dissections were of little avail. Mr. E. G. MUIR (London) commented on some technical details of the operation; in particular he advised the use of a perineal drain situated behind the anal canal.

Pilonidal Sinus

Mr. A. J. H. RAINS (Birmingham) gave a short paper on the treatment of pilonidal sinus. On the surgical professional unit at Birmingham these cases were treated by excision and primary suture. The operation was performed with the patient on his face in the "jack-knife" position. Indigo carmine was injected into the track. After complete excision the dead space was carefully obliterated with buried catgut stitches. "Nobecutane" and wool were used for dressing and the wound was sealed off from the anus with strapping. The patient remained prone for 48 hours after operation and then was allowed up. Hair in the natal cleft was kept trimmed. Four cases had broken down owing to the formation of haematomas; and there were 11 recurrences. Healing took between 10 and 14 days on the average. Mr. E. C. B. BUTLER (London) asked whether the hairs in the natal cleft should not be permanently suppressed by irradiation. In reply to a question as to how recurrences should be treated, Mr. RAINS said that he excised them again and once more sutured the skin *per primum*.

Tuesday, July 15

Hiatus Hernia

With Mr. HERMON TAYLOR (London) in the chair, Mr. R. H. FRANKLIN (London) opened a discussion on hiatus hernia. He first discussed the mechanism of the cardiac sphincter. Perhaps the most important factor in preventing reflux was the angle of entry of the oesophagus into the stomach. Free regurgitation, which was normal in infants, might persist throughout life without causing untoward symptoms. Reflux of gastric contents into the oesophagus might be caused by hiatal defects or an increase in pressure within or outside the stomach. Prolonged recumbency, tight corsets, and pregnancy caused increased pressure on the hiatus. Pylorospasm with delayed gastric emptying increased the tendency to regurgitation, and hyperacidity such as was found with duodenal ulcer increased the corrosive effect of the regurgitated fluid. There were three ill effects of regurgitation: pain due to oesophagitis, dysphagia from spasm or stricture, and haemorrhage. Oesophagitis might result in slow bleeding and a profound anaemia; frank haematemesis was caused only by an ulcer in the oesophagus or in the thoracic stomach. Symptomless patients needed no treatment, and those with mild symptoms only conservative measures. These consisted of weight reduction, prevention of gravitational regurgitation (especially at night), and a peptic ulcer regime. Operation was needed for patients with symptoms of oesophagitis uncontrolled by medical treatment. The stomach had to be brought below the diaphragm and the enlarged hiatus narrowed. This could be combined with pyloroplasty and vagotomy. Intractable stricture was best treated by partial oesophagectomy with a high anastomosis between stomach and oesophagus; a low anastomosis was likely to be followed by stricture at the suture line. If there was duodenal ulceration as well as stricture a Roux loop of jejunum should be used.

Continuing the discussion, Mr. A. M. DESMOND (London) estimated that between 3 and 14% of the adult population had symptomless hiatus hernia (these figures were obtained from radiological examination and laparotomy). He reiterated the causative factors, adding kyphoscoliosis to those already mentioned. Patients with a functional overlay to their organic condition were difficult to treat and did not get a good result after operation. Surgical treatment

was necessary if conservative measures failed or a complication developed. Treatment should consist of repair of the hernia, preferably through the abdomen to allow detection of concurrent abdominal lesions. He had recently added pylorotomy to facilitate gastric emptying. In a series of 158 patients there had been six deaths: 85 (65%) had good results; 25 (18%) needed medical treatment to keep them free of symptoms; and 22 (16%) were failures. In closing, Mr. Desmond emphasized that hiatus hernia might be a "red herring." The symptoms might be due to carcinoma of the colon, Crohn's disease, or some other abdominal lesion. He then showed a short film on the technique of operation.

Mr. J. L. COLLIS (Birmingham) said, in discussion, that associated duodenal and gastric ulceration was rare in his experience. He used the abdomino-thoracic approach and sutured the pillars of the right crus in front of the oesophagus. In this way the angulation of the oesophago-gastric junction was re-established.

Carcinoma of the Oesophagus

Mr. J. L. COLLIS (Birmingham) then addressed the meeting on the treatment of carcinoma of the oesophagus. Lesions two inches (5 cm.) above the aortic arch and below were suitable for surgical excision. In his personal series of 150 cases the mortality had been 14%; the figure was the greater for high lesions than for those situated low in the oesophagus. After two years only a third of them were alive. He emphasized the importance of relieving the distressing symptoms of this disease if at all possible. The patient must be adequately nourished before operation was attempted, and this could often be carried out effectively by persevering with a high-calorie fluid diet; if necessary the insertion of a Souttar's tube would ensure adequate intake; gastrostomy should be used only as a last resort. Age was no bar to operation, but spread into the aorta or bronchus was a definite contraindication. If possible the bronchus should be removed *en bloc* with the left gastric tumour should be removed in 75% of cases. A tube of glands (which were involved in 75% of cases). A tube of the greater curvature of the stomach was brought up into the chest to anastomose to the oesophagus. After operation gastric reflux was no great problem, provided that gravitational regurgitation was prevented. If excision was impossible the tumour might be by-passed; failing that, a large Souttar's tube should be passed through the growth: it was imperative to restore free swallowing at all cost. Gastrostomy had no place except in the pre-operative phase. Mr. Collis ended by stressing the challenge of this exceedingly difficult disease.

Sir STANFORD CADE (London) began by saying that if he had a carcinoma of the oesophagus he would want it resected. Megavoltage radiotherapy (two million volts and above), however, had been a great advance and was very different from lower voltage therapy. There were three main megavoltage methods available—the two-million-volt generator, the four-million-volt linear accelerator, and the theratron (containing the equivalent of 2,000 grammes of radium in the form of radioactive cobalt). The source must be rotatory so that only the area to be treated received radiation in any quantity. By this means skin and vital organs such as the lungs and spinal cord suffered little injury. Sir Stanford reported the results in a series of 48 patients with squamous cell carcinoma of the middle third of the oesophagus treated by megavoltage radiotherapy; 39 patients were dead; nine were alive, but three had active disease; there have been no five-year survivals. In a number of cases radiation provided excellent palliation, the patients being able to swallow normally. Dysphagia might persist, however, despite return to a normal radiological appearance. In some cases therapy caused a stricture, in others a broncho-oesophageal fistula developed. One patient whose growth was incompletely removed at operation had had radiotherapy and survived 3½ years. Sir Stanford concluded that supervoltage radiotherapy could

not as yet compete with surgery in the treatment of carcinoma of the oesophagus, but it was much better than conventional radiation methods. In reply to a question by Mr. G. W. TAYLOR (London), he said that combined operation with radiotherapy had not yet been attempted.

Cold Legs in Young People

With Mr. HUGH DONOVAN (Birmingham) in the chair, Mr. G. W. TAYLOR (London) described the pernio group of syndromes; these are conditions which give rise to one variety or another of the chilblain lesion. Local ischaemia devitalized the tissues to such an extent that an inflammatory response resulted; fat necrosis was a typical lesion. There were two main varieties of pernio, primary and secondary. The primary group included acrocyanosis, erythrocyanosis, and livedo reticularis. They were much more frequent in women, usually commencing at the end of the second decade and after a remission reappearing at the menopause. In acrocyanosis there was a cyanotic rubor of the fingers and toes; erythrocyanosis affected the back of the calf in young women. The latter was often associated with oedema, especially in warm weather. Mr. Taylor put forward the view that there was some defect in the micro-circulation of the extremities. Lymphangiography in erythrocyanosis revealed hypoplasia of the lymphatic system in the affected limbs. These conditions were often familial. Secondary pernio might be due to the late effects of poliomyelitis, a low basal metabolic rate, or occasionally to functional disease such as hysteria. Treatment consisted in avoiding local chilling and conserving body heat. Measures designed to achieve these aims cut across fashion trends, and Mr. Taylor said that he found it difficult to persuade such patients to wear woolly underwear, thick woollen socks, and long skirts. Occasionally vasodilator drugs such as phenoxybenzamine helped. Lumbar sympathectomy was often beneficial, but did not cure many patients; it was contraindicated in the presence of oedema. In reply to a question by Professor F. A. R. STAMMERS (Birmingham), Mr. TAYLOR agreed that these patients should give up smoking. Answering another speaker, he warned against sympathectomy in those with long-standing symptoms. Exercise and physiotherapy were desirable to increase the circulation to the extremities.

Fractures of the Jaw

Mr. R. O. WALKER (Birmingham) gave an interesting paper on fractures of the jaw. He first stressed the need for universal instruction in first aid to maintain an airway; patients might die from suffocation before reaching hospital. Causes of respiratory obstruction were foreign bodies, a swollen floor of the mouth, and backward displacement of the tongue. Mandibular fractures accounted for 75% of cases, the remainder being made up of the more severe fractures through the maxilla. A barrel bandage was the best emergency splint for the lower jaw. This could be followed by eyelet wiring if the teeth were in good condition or by cap splints if the dentition was inadequate for wiring. Edentulous patients should be immobilized by the use of Gunning splints. Fractures through the maxilla were more severe injuries and more difficult to treat. The lower jaw was too mobile to use as a splint. Cap splints on the upper teeth, fixed externally to a plaster head-cap, were the most satisfactory method of treatment. Nutrition should not be a problem in these patients: there was usually a gap between the teeth, but, failing that, an adequate fluid diet could be administered through the space behind the last molar tooth. Very careful attention to oral hygiene was vital. In conclusion Mr. Walker made a plea that such patients should be referred early to the dental staff so that treatment could be begun as soon as possible after injury.

Mr. E. C. B. BUTLER (London) asked how often osteomyelitis and parotitis complicated fractures of the jaw. Mr. WALKER replied that both had been rare since the introduction of antibiotics.

SECTIONS OF OBSTETRICS AND GYNAECOLOGY
AND CHILD HEALTH

Tuesday, July 15

Problems of Neonatal Period

Dr. BERYL D. CORNER (Bristol), a vice-president of the Section of Child Health, occupied the chair at the joint session with the Section of Obstetrics and Gynaecology on problems of the neonatal period.

Obstetric Responsibility for the Handicapped Child

Dr. FRANCES BRAID (Birmingham) said that the paediatrician was confronted by many children handicapped by such disabilities as blindness, deafness, congenital heart disease, cerebral palsy, or mental deficiency. In most the origin of the disability was either unknown or beyond our control, but against others good obstetric care offered a major degree of prophylaxis. The possibility of rubella in early pregnancy causing congenital abnormality in the foetus might be reduced by the use of gamma-globulin, but the place, if any, for therapeutic abortion in these cases was still uncertain. Other virus infections appeared less dangerous in this regard. How often in this country toxoplasmosis damaged the foetus, especially its central nervous system, was unknown, but in the U.S.A. 30% of affected babies were said to be born prematurely, 27% of whom died; 12% of affected mature babies also died. Toxoplasmosis was transferred to the foetus only during the active phase of the maternal infection, so that later siblings were not affected. The outstanding example of the value to the foetus of good antenatal supervision lay in haemolytic disease of the newborn. Many babies were now being saved from death, and cerebral damage rarely occurred with proper management.

The incidence of prematurity, continued Dr. Braid, was rising (e.g., in Birmingham from 7.2% in 1945 to 9.2% in 1955), but in the majority of cases the cause of the premature birth was not known. Better antenatal care might be partly responsible, by prolonging a pregnancy beyond the 28th week or by intervening to prevent stillbirth. Better paediatric care of these small babies might increase the total number of surviving handicapped children, for cerebral palsy was more common in premature babies. The question whether babies who had early survived a threatened abortion had a high rate of abnormality remained to be answered. Turning to perinatal trauma, Dr. Braid said that primary traumatic cerebral haemorrhage was now rare, but haemorrhage secondary to asphyxia from any cause was less uncommon. Less than 10% of infants with cerebral disturbance at birth later showed evidence of brain damage, but it was impossible to foretell what residual damage might occur in an individual case.

A most exhilarating discussion followed to which Professor H. C. McLAREN (Birmingham), president of the Section of Obstetrics and Gynaecology, Mr. W. G. MILLS (Birmingham), Mr. EDWARD COPE (Birmingham), Professor IAN DONALD (Glasgow), Miss ELSIE WARREN (Kensington), and Miss V. MARY CROSSE (Birmingham) contributed.

Neonatal Cold Injury

Dr. T. P. MANN (Brighton) discussed neonatal cold injury, a not uncommon disorder with a high mortality. It usually occurred after home delivery in winter when the outside air temperature was below freezing point. Deaths from this cause were almost entirely preventable, yet the yearly number of fatalities in this country might well exceed 100. The condition was often unrecognized, the causative exposure to cold being overlooked. Prematurity did not seem an important relevant factor, but predisposing factors included asphyxia at birth, birth injury, and infection. The usual presenting features were increasing apathy, refusal of food, and oliguria, but the infant, usually a male, did not look ill. Sometimes the mother had noticed that the baby had been cold to touch for several days, but in none of his cases had the severity of the hypothermia been appreciated before

the baby was admitted to hospital. There was then noted severe hypothermia, oedema of the extremities, and skin erythema. A purulent nasal discharge was common, although sometimes not seen until after rewarming. Prolonged hypoglycaemia had also been found in a few cases. In two recent cases the platelet count had been low, which might have been related to a generalized haemorrhagic tendency. The outstanding finding at necropsy was pulmonary haemorrhage, sometimes mistakenly called "haemorrhagic pneumonia."

Dr. Mann concluded that, as treatment was often difficult in well-established cases, prevention was of paramount importance. Those conducting domiciliary confinements must be alert to the danger of cold exposure. In particular routine cleansing baths could be a menace in winter. Nursery temperature should not fall below 60° F. (16° C.) night or day in the early weeks. If the baby's temperature was recorded once daily, hypothermia would be detected early, and then rewarming was relatively easy.

Dr. W. N. LEAK (Winsford), Dr. H. L. ELLIS (Oxford), Dr. FRANCES BRAID (Birmingham), Dr. V. MARY CROSSE (Birmingham), Dr. A. J. MACLEOD (Outer Isles, Scotland), Dr. G. L. DAVIES (Brighton), and Dr. B. M. LAURANCE (Derby) spoke in the subsequent general discussion.

Respiratory Distress in the Newborn

Mr. H. L. SHEPHERD (Bristol), a vice-president of the Section of Obstetrics and Gynaecology, took over the chair when Dr. R. J. K. BROWN (Cardiff) discussed respiratory distress in the newborn. He said that, although it was still uncertain what made the newborn baby take its first breath, much had been learned about the circulatory adjustments that must also occur if its survival was to be assured. Much of this knowledge had been obtained by study of the changes occurring in the newborn lamb. The ductus arteriosus contracted partially after birth, yet permitted a considerable blood flow to the lungs from the aorta for some hours. In this way the expanding lungs obtained a plentiful blood supply during the critical phase of change-over from foetal to adult condition. Conversely, it had been shown that inadequate pulmonary ventilation might ultimately lead to shunting of blood away from the lungs through this open channel with accentuation of asphyxia. Pulmonary capillary erection might also assist the proper expansion of the alveoli at birth. Many believed that the added blood volume obtained from the placenta by delayed cord ligation assisted by gravity increased the output from the right ventricle by augmenting venous return.

There was strong evidence, Dr. Brown continued, that pulmonary hyaline membrane, the cause of many neonatal deaths, especially in premature babies and those delivered abdominally, especially from diabetic mothers, was of endogenous vascular origin. He himself thought it likely that early ligation of the cord in the presence of delayed onset of breathing was an aetiological factor. As general anaesthesia contributed to depression of the foetal respiratory centre, regional anaesthesia for caesarean section might be to the baby's advantage. It had also been suggested that hypoxia and sensory stresses at and soon after birth might stimulate the liberation of noradrenaline from the organs of Zuckerkandl to the enhancement of cardiovascular tone and the assistance of circulatory readjustments. A noradrenaline drip might therefore have a place in the resuscitation of the newborn; after all, many of the features of the syndrome of respiratory distress were characteristic of shock.

Dr. Brown concluded that the newborn baby had considerable tolerance to anoxia but very little to ischaemia. Thus successful resuscitation of the asphyxiated infant depended on rapid establishment of the adult type of circulation after birth.

Changing Fashions in Neonatal Resuscitation

Professor IAN DONALD (Glasgow) reviewed the changing fashions in the resuscitation of the newborn. From the

various forms of stimulation applied to the baby fashions progressed to more or less forceful types of artificial respiration. Next came the attitude of watchful expectancy, favoured because spontaneous recovery was the rule. The results of any technique were difficult to assess because it was difficult to ascertain the exact cause of the respiratory distress in any individual baby. Intubation was valuable, but he doubted the efficacy of gastric oxygen. Professor Donald then traced the development of a respirator which automatically augmented any spontaneous breaths of the baby or made it breathe if its own respiratory efforts were absent. He concluded by demonstrating this respirator in action on a dummy.

In a discussion on the papers by Dr. Brown and Professor Donald, Dr. W. N. LEAK (Winsford), Dr. H. C. W. BAKER (Birkenhead), Professor H. C. McLAREN (Birmingham), and Dr. V. MARY CROSSE (Birmingham) participated.

SECTION OF ANAESTHETICS

Wednesday, July 16

Spinal and Epidural Analgesia To-day

With the president, Dr. B. L. S. MURTAGH (Birmingham), in the chair, Dr. J. D. ROBERTSON (Edinburgh) presented the case for spinal analgesia. After listing the advantages, it was admitted that many were no longer valid in the presence of modern methods of general anaesthesia. However, since the mortality and morbidity rates after spinal analgesia were no greater than after general anaesthesia, it was a pity that the fear of litigation had become such an important factor in choosing between these methods. In fact, by avoiding positive-pressure ventilation and consequent interference with pulmonary circulation the hazards of neostigmine-resistant curarization, and by reducing blood loss, a real claim for the benefit of spinal analgesia could be made. Dr. Robertson reviewed the neurological complications, and found that they rarely occurred in centres where spinal analgesia was common practice. Spinal analgesia was more certain and more predictable than epidural analgesia. With the ever-present risk of inadvertent dural puncture, epidural analgesia exhibited all the possible dangers of either method. On the basis of recent work it might be considered a technically more difficult and poorly controlled form of spinal analgesia.

Dr. C. J. MASSEY DAWKINS (London) then presented the case for epidural analgesia. He claimed that epidural block replaced spinal block, and did so equally efficiently without the well-known hazards of spinal analgesia. Hypotension was the only complication common to both. Technical difficulty in locating the epidural space was no longer a valid criticism of the method. This had been achieved by the introduction of the Brooks indicator, which combined the Dogliotti technique of the loss of resistance to an advancing needle with the Odom technique of recognizing the negative pressure within the space. With the Brooks indicator, which consisted of a glass balloon blown on the end of an Odom indicator, it should be possible to find the epidural space with certainty in 98% of cases.

Dr. Massey Dawkins suggested that, if unconsciousness was required, hexobarbitone and the breathing of air were less likely to interfere with respiratory physiology than the administration of gases in a doubtful mixture from an anaesthetic apparatus.

Since the vagus nerve remained intact, a block of this nerve might be necessary to avoid hiccup or coughing. With this single drawback epidural analgesia offered ideal operating conditions with benefits to patient, surgeon, nursing staff, and anaesthetist. Dr. Massey Dawkins concluded with a detailed description of his technique based on 2,000 cases, and indicated the extent of its usefulness.

Dr. J. ALFRED LEE (Southend) spoke on a critical evaluation of the methods. Such an evaluation was based on the manner in which an anaesthetic technique satisfied certain criteria. These criteria were efficiency, controllability, ease

of induction, safety, and freedom from side-effects. General anaesthesia offered greater latitude than any form of local analgesia in terms of safety. But in skilled hands, and with proper care, spinal and epidural analgesia were as safe as general anaesthesia, and carried a lower mortality rate. The particular risks were undeniable, and hypotension and toxic reactions demanded treatment by an intravenous route. Thus an open vein—using a Mitchell or Gordh needle—was an essential prerequisite. Dr. Lee said that neurological complications, although not common after spinal analgesia, were virtually unknown after epidural block. In spite of these risks, both methods must be taught, and anaesthetists must be familiar with them. Technical difficulties should present no bar to their use, but personal preference must necessarily influence the choice of method.

In the discussion which followed, Dr. R. W. COPE (London) stated that the neurological risks of spinal analgesia were unacceptable. Dr. L. T. CLARKE (Birmingham) suggested that a full neurological and serological examination should be made before embarking on spinal analgesia. Dr. G. C. STEEL (London) thought that epidural analgesia offered the best solution to many anaesthetic problems. Professor W. W. MUSHIN (Cardiff) and Mr. BRIAN WILLIAMS (Middlesbrough) also took part.

Anaesthetists' Brains Trust

Under the chairmanship of Dr. H. W. FEATHERSTONE (Birmingham), questions submitted by members of the section were discussed by a panel consisting of Professor W. W. MUSHIN (Cardiff), Drs. T. C. GRAY (Liverpool), H. H. PINKERTON (Glasgow), J. GILLIES (Edinburgh), W. D. WYLIE (London), and V. J. KEATING (West Indies).

On the question of the use of chloroform, it was felt that it still had a place as an emergency anaesthetic, although it might be replaced by halothane. The panel were unanimous in believing that the general-practitioner anaesthetist had an important part to play in the hospital service. On economic and geographical grounds he was essential, but the manner of his employment and his training must be carefully regulated.

On the grounds of economy of gases, and also convenience, the use of soda-lime in a circuit using a high flow of gases was supported. It was thought unwise to rely on theoretical calculations for flow rates to avoid rebreathing. The use of soda-lime or a non-return expiratory valve overcame the risk of carbon dioxide retention, but members of the panel felt that too much attention was being paid to the presence of minute concentrations of carbon dioxide in anaesthetic circuits.

Steroids such as hydroxydione sodium succinate ("viadril") should be considered as agents producing basal narcosis rather than anaesthesia. They were of interest, but should not be regarded as the answer to all anaesthetic problems. Their value lay in the post-operative period, and this was probably of greater interest than their anaesthetic properties. The panel expressed divided opinions on the administration of suxamethonium and D-tubocurarine to the same patient. The effect of suxamethonium on the nerve endings probably persisted for many hours, but in the present state of our knowledge it was impossible to make a dogmatic statement on this problem.

SECTION OF ANATOMY AND PHYSIOLOGY

Monday, July 14

Posture and Health

In opening, the president, Sir SOLLY ZUCKERMAN (Birmingham), commented on how suitable was the subject of posture for discussion by the laboratory worker, anatomist, and clinician.

Sir RUSSELL BRAIN (London) opened the first symposium on some of the laboratory aspects of posture. Most modern work on postural physiology had been built on foundations

laid by Sherrington in his monumental work *The Integrative Action of the Nervous System*. The muscle spindles had now been shown to be influenced by their own efferents, the gamma fibres, establishing the concept of a "servo-loop mechanism" influencing the stretch reflex as well as Sherrington's lengthening and shortening reactions. Spinal and neuronal connexions had been traced and the physiological nature of excitation and inhibition was being elucidated. The parts played by the cerebellum, vestibular nuclei, and the central reticular formation had been profitably studied. Clinical observation had led to controversy over the role of the pyramidal pathways, and neurosurgery had been attempting to control abnormal rigidity in extrapyramidal syndromes. Disease might interfere with the foundation of posture at many points. Proper understanding necessitated a knowledge of the muscle spindles and their affection by normal and abnormal muscle states, the afferent impulses from them, interneurons and spinal-cord synapses, the efferent impulses, the myoneural junction, and the physiochemistry of muscle contraction. It was through these mechanisms that bad postures tended to be perpetuated. Superimposed were complex higher circuits involving all levels of the nervous system.

Ultrastructure of Muscle

Dr. H. E. HUXLEY (London) spoke on the ultrastructure of muscle studied by electron-microscopy and other new techniques. His paper was illustrated by electron-micrographs of exceptional quality. Each myofibril inside the muscle fibres consisted of a succession of overlapping longitudinal arrays of submicroscopic filaments. There were two types of array, thicker filaments about 100 Å diameter (1 Å = 10^{-8} cm.) and 1.5 μ in length composed of myosin, and thinner filaments about 50 Å diameter and length 2.0 μ composed of actin. In each array the filaments were spaced in a regular and parallel manner, the thicker lying about 450 Å apart in hexagonal fashion, muscle sarcoplasm filling the intervening space. The two types of array alternated along the length of each fibril, and in the overlapping region the thin filament interdigitated with the thick, forming a very regular double hexagonal array.

Muscle contraction was unaccompanied by shortening of either type of filament, but by a telescoping of the thin actin filaments between the arrays of thick myosin ones; the reverse process occurred during muscle relaxation. This appeared to be produced by a system of cross-bridges arising from the thick filaments and passing to the thin ones, seemingly drawing the latter along in a centipede-like motion. This "sliding filament" mechanism fitted in well with known biochemical concepts and could reasonably account for many physiological characteristics of striated muscle.

Spindle and Synapse

Professor RUTH BOWDEN (London), in a paper on the spindle and the synapse, first gave an illustrated summary of the distribution and morphology of sensory endings, particularly of spindles in striated muscles, and of the anterior horn cells with their complex synapses. She pointed out how often as many as 2,000 boutons terminaux made synaptic connexion with a single anterior horn cell. The functional significance of the multiplicity and variety of sensory nerve endings in striated muscle was discussed in the light of recent work by Granit, Merton, Eccles, Mountcastle, and others. Experimental evidence suggested that for limb muscles there was no afferent cortical projection pathway. Tendon organs and spindles appeared to exercise their inhibitory and excitatory functions primarily at cord level. Mountcastle had shown in cat experiments that columns of cortical neurones were not driven by the large group I muscle afferents, but certain cortical neurones were driven by afferents from joint capsules, ligaments, and periosteum. Simultaneous recording from cortical units driven by joint capsule afferents had shown that they might

respond reciprocally to alternate flexion and extension of the joint. The apparent absence of cortical projection pathways from muscle spindles had posed a great problem in understanding the mechanism of cortical control of movement patterns. However, as joints were positioned by muscular activity, Mountcastle's findings in respect of afferents from joint capsules might lead to clearer understanding of postural control and movement.

Nervous Gradation of Muscle Contraction

Professor R. J. HARRISON (London), a vice-president of the Section, then took the chair and introduced Dr. PATRICK MERTON (Cambridge), who presented some aspects of the nervous gradation of muscle contraction. He reminded his audience that ideas on this subject were now undergoing revision because muscles, long believed to have given rise through their sense organs to proprioceptive sensations, were now again thought to be insentient. Helmholtz, in 1865, claimed to have proved the absence of position sense in eye muscles; but objections, irrelevant in Dr. Merton's view, were raised by William James and Sherrington, whose views had long prevailed. Many simple experiments could be performed to demonstrate the absence of position sense in skeletal muscles. For example, it was impossible for a subject to say accurately where was the tip of his anaesthetized tongue, although the tongue muscles were known to be plentifully supplied with muscle spindles. When the hand blood supply was cut off for 75 minutes by an inflated wrist cuff, the thumb became anaesthetic to touch or movement, but the terminal joint was not paralysed, for the flexor and extensor muscles of this joint lay proximal to the tourniquet. But no feelings of position or tension could be elicited by active or passive movement of the terminal joint. Hence our appreciation of thumb position and force of movement must be derived from the joints and skin, and not from the muscles.

Muscles were controlled through automatic servo mechanisms, whose feed-back elements were the muscle sense organs, thus ensuring that the muscles did what was required of them whether the instructions came from the higher postural centres or the motor cortex. Indeed, it would appear that the higher centres did not want to know what was happening in the muscles. The muscle sense organs, by feed-back action, therefore conferred special properties on the neuromuscular machinery, rather than provided data with which the higher centres elaborated the orders to that machinery.

Central Mechanisms of Balance

Dr. D. A. McDONALD (London) then gave an interesting and amusing account of his experiments on the central mechanism of balance in relation to the righting movements of the falling cat. His talk was illustrated by high-speed cinematographs, some taken at the rate of as many as 1,000 frames per second to produce a most instructive "slow-motion" record of the sequence of body contortions in the falling animals. These body movements were of especial interest, as they involved the generation of rotation in a freely falling body. This was solved in the cat by flexion of the trunk and rotation of first the fore-part in its own axis and then the hind-part. Sequential rotation of smaller body sections, such as the head, did not seem to be physically possible in terms of the counterbalance of the forces necessary.

The dominant sense organs for informing the animal of its spatial position appeared to be the eyes. Professor J. B. S. HALDANE owned a venerable female cat which he assured Dr. McDonald suffered from congenital absence of the vestibular organs. Experiments with this borrowed "Haldane cat" proved that it turned over quite normally with its eyes open, but made no effort to right itself when blindfolded. A normal animal turned over just as well with its eyes blindfolded as with them open, except that the turn was slightly delayed and less perfectly executed.

Tuesday, July 15

Posture in the Living Subject

With a vice-president, Dr. A. C. CROOKE (Birmingham), in the chair, Mr. F. G. ALLAN (Birmingham) opened the discussion. Attempts to define the meaning of "good posture" were subject to individual interpretations. It could mean, for example, a posture which imparted an impression of radiant health, alertness, a sense of physical and mental well-being and even of beauty. Goldthwaite's definition of the head being held erect, chin drawn in, shoulders back, and abdomen drawn in was not, most people would agree, a very normal posture. But there were wide variations of posture within normal limits. What he liked to term "normal," "relaxed," and "military" postures were all examples within normal limits, although the "relaxed" posture probably most nearly approached a pathological stance. The posture of individuals was affected by mood and was also partly hereditary, being related to the body-type.

Remedial exercises aimed at developing muscles whose weakness was thought to cause the poor posture often had no permanent effect, but only corrected the postural faults during the actual voluntary performance of the exercises. If, however, a corrective plaster-of-Paris splint was applied for several weeks, during which time exercises were done only to prevent muscle-wasting, permanently improved posture followed the removal of the plaster. These results of treatment emphasized the importance, mentioned by earlier speakers, of stimuli coming from the joints and not from the muscles.

Electromyographic Studies

Dr. JACK JOSEPH (London) described electromyographic studies on the thigh and leg muscles in 25 males and 21 females and the hip muscles in 18 males of ages ranging from 18 to 42 years. He pointed out that if a very high amplification was used with either surface or needle electrodes the absence of electric potentials was very suggestive that the muscle immediately deep to the surface electrodes or in which the tip of the needle was lying was not contracting. This negative finding was stressed because of the results obtained in the investigations he was discussing.

The subjects were studied standing comfortably at ease, not tense, with the weight on both lower limbs, the feet about 12-18 in. (30-45 cm.) apart, the toes turned out at an angle of about 60 degrees, the hands clasped tightly behind the back, and the head held with eyes looking straight forward. In this posture it was found that in the great majority of subjects only the superficial calf muscles (soleus and gastrocnemius) were continuously active, although to a variable extent. The tibialis anterior, quadriceps femoris, hamstrings, iliopsoas, and glutei usually showed no detectable electrical activity. In the posture described, the perpendicular through the centre of gravity passed behind the line joining the centres of the hip-joints and in front of the line joining the centres of the knee- and ankle-joints. Both the hip- and knee-joints were so constructed that stability at these joints could be maintained without muscular activity, but in the case of the ankle-joint the body was prevented from tipping forwards by the continuously contracting superficial calf muscles.

Weight of Vertebral Column

Professor A. DELMAS (Paris) presented an illustrated paper on an original line of thought concerning the weight of the vertebral column and its relation to posture. There was a relation, he claimed, between the weight of vertebrae and posture. This statement depended on researches made on 30 sorts of mammals and 90 human subjects of each sex and of various races. After classifying vertebrae according to their position in the vertebral column, the weights showed irregularities and features which had been interpreted in a functional way. These features of the vertebral weight.

raised or lowered in some vertebrae, had been studied and related to the magnitude (varying at each level) of the forces of pressure or traction.

The idea of relative weight had been introduced in this study by calculating the weight of each vertebra as a percentage of the total weight of the vertebral column. This idea had permitted the elimination of weight variation due to an increase in total body weight. This procedure enabled one to show the part played by vertebrae or by particular groups of vertebrae in maintaining the posture peculiar to the individual.

The weight of the vertebral body increased regularly from the 1st cervical vertebra to the 5th lumbar ; on the other hand the weight of the posterior arch was very variable. Thus, in the human vertebral column, the heaviest vertebra, in all its parts, was not the 5th lumbar vertebra but the 3rd. It follows that the vertebrae below the 3rd, while of primary importance in the architecture of the static column, were not of similar importance in the maintenance of posture. A very well developed posterior arch was seen in the 2nd cervical vertebra, although this feature still occurred down through the first five thoracic vertebrae. On the other hand the posterior arches of the 3rd cervical vertebra and the 12th thoracic were hardly developed at all. These observations in man and those which had been noted in other species emphasized the functional importance of vertebral weights where certain individual features can be related to variations in posture.

Posture in the Schoolchild

The chair was then taken by Professor A. ST. G. HUGGETT (London), a vice-president, when Dr. CECILE ASHER (London) discussed posture in the schoolchild. Poor general posture in a child with no recognizable local defect was an indication for thorough physical examination and an investigation into his way of life. Postural variations or defects depended on the stage of the child's development, its age, body-type, and in some on faulty attitudes. Flat and everted feet could be regarded as normal in infancy and tended to disappear during the acquisition of postural reflexes and loss of the subcutaneous fat pad. Valgus ankle was a misnomer, as the ankle-joint was not involved. Common in early walking and unassociated with knock-knee, it often went with a high arch and gave a characteristic clinical picture. Any age or type of child was affected. Knock-knee was common under 5 years and commoner in stocky and obese children, slender children being more liable to overall postural defects. It appeared to regress with or without treatment. Lordosis, like knock-knee, was common in the obese, but it was normal in infancy when the pelvic inclination was more horizontal than in adults. Mesomorphic children had less lordosis and a better prognosis than endomorphs. Postural scoliosis in adolescents was often associated with poor overall posture.

"Good" or "correct" posture varied for different individuals and could not be standardized. Treatment should not be wasted on developmental phases but directed towards a particular end. We should remember that many athletes were flat-footed and kyphotic.

Lifting Weights

Dr. P. R. DAVIS (London) spoke on the posture of the trunk during the lifting of weights. Light weights could be lifted with the trunk in any position, but with larger weights the trunk was usually held somewhere between simple flexion and erect. With the heaviest weights it was normally held as straight as possible.

In the erect position the weight was mostly transferred from the arms to cervical and upper thoracic vertebrae. When stooping, the weight was transferred to a lower spinal level, and to a greater number of vertebrae.

Weight reaching the neck and acting in the long axis of the trunk was transmitted through the chain of vertebral bodies and intervertebral disks, little contraction of the spinal muscles being required. Lifting in the stooping posi-

tion, however, produced the following effects: (1) Strong spinal muscle contractions to counterbalance the flexing force exerted on the trunk by the load. (2) Longitudinal compression of the vertebral column by these muscular contractions. (3) Abdominal muscle contraction, which raised the intra-abdominal pressure. This pneumatic mechanism might indirectly extend the spine and so help support the weight.

Weight-lifting injuries could be divided into a spinal group and an extrusive group, the latter including lesions of the pneumatic mechanism such as herniae and prolapses. Damage in both these groups was in theory less apt to occur if weights were always lifted with the trunk held erect.

Posture in Industry

Professor G. P. CROWDEN (London) discussed the practical problem of posture in industry. Posture at work, he said, was one of many factors of physiological significance in relation to the working capacity, comfort, and health. Productive muscular effort involved dynamic and static components in varying proportions according to the nature of the task, the design of machinery, or the method of work performance adopted by the individual.

Movements of the body and limbs, and in particular the alternating contraction and relaxation of muscles in dynamic work, promoted the circulation in the working muscles themselves and in other anatomical structures involved in the performance of the task. On the other hand, continuous muscular contraction, whether due to static effort in work performance or in the maintenance of a strained posture, restricted the blood flow through the structures involved, and led to the rapid onset of fatigue, reduced capacity for work, and increased accident risk.

Examples were given by slides of bad and good postures adopted by men and women in industry while standing, sitting, and handling or carrying loads. It was pointed out that the basic physiological problem of defining optimal postures for work was the detection and subsequent reduction or elimination of static effort of long duration. The value of postural change during work and of varying the task performed was emphasized. While sickness absenteeism might come to the notice of the management, and the medical officer might deal with complaints of fatigue, backache, and other disabilities which might arise from postural strain at work, it was emphasized that the vital problem—namely, prevention—should be dealt with on the shop floor by engineers and others who were in charge of men as well as machines.

In his closing remarks Professor A. ST. G. HUGGETT (London) said how pleased he was to witness the happy symbiosis between the laboratory worker, comparative anatomist, and clinician on matters relating to the important problem of posture. He thanked all those who had given papers, particularly Professor A. Delmas, who had come so far, and the University of Birmingham for their loan of such excellent facilities for the meeting.

SECTIONS OF CARDIOLOGY AND THORACIC MEDICINE AND SURGERY

Tuesday, July 15

Chest Pain

With the president of the Section of Cardiology, Dr. OSCAR BRENNER (Birmingham), in the chair, Dr. GRAHAM HAYWARD (London), a vice-president of the Section of Cardiology, opened a discussion on chest pain by describing ischaemic chest pain. It was difficult to be sure, he said, that chest pain ever arose in the absence of coronary atheroma except in paroxysmal arrhythmias and occasionally with valvular disease. Anaemia and thyrotoxicosis were aggravating factors in some patients, when treatment resulted in disappearance of the pain. The usual pathological changes in patients with ischaemic pain were narrowing of the coronary

vessels and the development of intracoronary anastomosis. These anastomoses allowed coronary occlusion to take place without the advent of myocardial infarction. Patients with angina pectoris had often sustained one or more episodes of coronary occlusion, though the history did not suggest it.

Clinically there were three varieties of pain—angina pectoris, cardiac infarction, and acute coronary insufficiency. The diagnosis rested mainly on the history; the electrocardiogram had serious limitations. The pain was constrictive, and it was localized by the patient by laying the flat of the hand across the front of the chest. Even when the pain was unusual in distribution there was almost always a chest component. In cardiac infarction the pain built up to a maximum, was accompanied by shock, and often by cardiac arrhythmia. In angina, the pain occurred during exercise, but the occurrence of pain after meals sometimes caused confusion. In coronary insufficiency the pain lasted several hours but there was no shock. Clinical signs were often absent after infarction, but triple rhythm was sometimes heard. The initial electrocardiogram was often normal; definite changes might not occur for three days. Serial changes were most diagnostic. Occasionally acute abdominal conditions causing shock could give rise to minor alterations in the ST segments. The electrocardiogram in angina usually showed changes of ischaemia or infarction. If the tracing was normal at rest, it might alter after exertion, but there still remained a small group in whom the E.C.G. remained normal. Changes in the E.C.G. did not necessarily denote that the present symptoms were cardiac in origin. About 12% of symptomless men over the age of 50 had an abnormal electrocardiogram. The clinical history was the most helpful diagnostic aid.

There was no evidence that dietary treatment could influence established coronary disease. Myocardial infarction was best treated initially by morphine or pethidine. In the treatment of angina, trinitrin was the best drug, pentaerythrityl-tetranitrate less beneficial, and "marsilid" (iproniazid) sometimes helped. Induction of therapeutic myxoedema was indicated in ischaemic pain from aortic disease. Lumbo-dorsal sympathectomy relieved pain and probably helped the development of intercoronary anastomoses.

Dr. WILLIAM EVANS (London) condemned excessive zeal in treating hypertension and cardiac pain when there was often no real evidence of disease. The diagnosis of cardiac pain was often false. Several other conditions such as fibrositis and dyspepsia could closely mimic cardiac pain. About one-fifth of patients with chest pain were suffering from dyspepsia. Triple rhythm was an important physical sign in cardiac ischaemia; it was present in 80% of patients after myocardial infarction. The electrocardiogram had become the ultimate arbiter in diagnosis, but the tracing must be reliable and the criteria of normality strict. Reliance should be placed on the standard leads, lead III after full inspiration, and three chest leads. CR leads were preferred to V leads. The lesser recognized cardiographic signs of cardiac pain were: depression of the ST segment, a low T wave in lead CR4+CR7, blunt T waves, terminal dipping of the T wave, depression of the TU segment, inversion of the U wave, notching of QRS7, and the appearance of a Q wave in lead III after deep inspiration. Adherence to these strict criteria would save unwarranted invalidism from faulty diagnosis: a patient should never be made worse for seeing his doctor.

Dr. D. EVAN BEDFORD (London) contrasted the features of neurotic chest pain with those described by previous speakers. After Heberden had identified angina pectoris, other forms of chest pain were often held in similar dread. At one time the term "pseudo-angina" had been used. During the first world war it was realized that chest pain was common in young men. Organic heart disease was absent, and the name "effort syndrome" was introduced. In functional disorders the pain was below or above the left breast or over the left scapula. Radiation of pain to the neck and arm was not uncommon. The pain was intermittent and sharp, but left a persistent ache lasting hours

or days. Areas of tenderness could be elicited over the chest wall. The pain was aggravated by fatigue and emotional stress. Victims could exercise in spite of the pain, though symptoms often occurred at an interval after exertion. Other symptoms included dyspnoea (with a curious sighing respiration), exhaustion, palpitations, giddiness, and sweating of the hands and axillae. In civil life the symptoms were usually found in young adults and in middle-aged women with hypertension and obesity.

Differentiation from angina could be made on the clinical history. Neurotic ill-health should be diagnosed positively on the history and signs and not by exclusion. Patients required assurance about their general health as well as their hearts. Hysterical angina connoted symptoms which sounded genuine through the patient's acquaintance with the real symptoms from contact with sufferers from genuine disease. Vasomotor angina was probably the same as vasovagal syncope, and was characterized by prostration, pallor, a fall in blood pressure, and a sense of impending doom. It was almost certainly neurotic. Young patients with vague symptoms should not be referred to heart specialists, but in older patients full cardiological investigation seemed advisable.

Pleural Pain

The features of pleural pain were outlined by Dr. PAUL FORGACS (London), who affirmed that, though the lungs and bronchial tree were insensitive, the parietal pleura was particularly sensitive to pain. Pain from the chest wall, like pleural pain, was aggravated by coughing and breathing. Pain from the diaphragm could be referred to the chest, abdomen, or shoulder. Pain from the mediastinal pleura was not easy to recognize, since its features were not familiar and since pleural rub was not evident. Mediastinal pain was felt over the sternum in the mid-line and radiated to the neck; it was not aggravated by coughing or breathing. It was difficult to distinguish from the pain of pericarditis or coronary disease. The pain of tuberculous pleurisy often preceded the appearance of the effusion by many weeks. This provided a clinical guide in distinguishing tuberculous from simple sterile effusions. It was also of extreme importance, suggesting that the pain arose from a source of infection near the pleura. In some cases of chronic pleurisy the cause could not be determined; pleurisy could occur in the absence of any demonstrable abnormality in the lung.

Pain following operations on the chest was discussed by Dr. B. G. B. LUCAS (London). The reason for pain after thoracotomy was not fully understood. It seemed to vary with the patient's ability to withstand pain and with the site of operation. Pain was worst after operations on the lower and posterior parts of the chest. The pain often persisted for years; it bore no relation to opening the pleura at operation; and it was aggravated by post-operative dyspnoea. There were two groups of patients. The first group, with true intercostal neuralgia, responded to intercostal block with alcohol, phenol, or 50% ammonium sulphate. In the second group the pain was more diffuse and occurred over the operation scar. These patients were often introspective and difficult to treat. Some responded to infiltration of the painful site with ammonium sulphate. Early treatment was imperative. Of drugs, opiates gave most relief and did not depress inspiration. Morphine antagonists could be given at the same time.

Oesophageal Pain

Mr. R. H. R. BELSEY (Bristol), describing oesophageal pain, said that the commoner causes were oesophageal reflux, and trauma from foreign bodies, instrumentation, and corrosives. Malignant disease of the oesophagus was usually painless. Oesophageal reflux was more common than large hiatus hernia. In this condition the pain was burning and severe, though not intense. It was situated high in the epigastrium or over the lower sternum. The pain might be referred to the back, jaws, or down the arms:

it was aggravated by stooping or lying down. True vomiting was rare and did not bring relief. Eating varied in its effect on the pain but often brought relief. Alkalis helped temporarily. The patients had good and bad periods, rather like those with peptic ulcer. Flatulence was constantly present because of the habit of constant air swallowing in an attempt to relieve the pain. The habit, and the flatulence, often persisted after operative cure. There was no satisfactory medical treatment for oesophageal reflux. Diagnosis depended partly on radiology, though barium examination did not always disclose the reflux. Oesophagoscopy was often very valuable in demonstrating the reflux. There was no correlation between the severity of the pain and the degree of oesophagitis. Sometimes intense pain was produced by oesophageal spasm when food became impacted. In childhood, oesophageal reflux caused great distress. It sometimes caused a curious exaggerated posture and crying. This sometimes led to an erroneous diagnosis of mental deficiency. The pain from large hiatus hernias was different. Here the pain was closely related to eating, unaffected by posture, and relieved by vomiting and belching. In most cases of oesophageal reflux the clinical history should lead to correct diagnosis.

Following the opening speakers, the PRESIDENT opened the discussion by commenting on the relative importance of history and cardiographic changes in the diagnosis of heart disease. It was to be remembered, he said, that an abnormal cardiogram did not necessarily denote a cardiac cause for the symptoms for which advice was sought.

Dr. W. S. HAYNES (Mombasa, Kenya) suggested the use of intravenous alcohol in the treatment of post-operative pain. Dr. G. I. WATSON (Peaslake, Surrey) gave a colourful description of the symptoms resulting from lemon drops impacted in the oesophagus and from sustained over-exertion.

Dr. M. E. CHINNER (Adelaide, South Australia) drew attention to the occasional relief of anginal pain after tying the internal mammary arteries and from inducing therapeutic pericardial adhesions.

Dr. G. S. R. LITTLE (London), Dr. MACGREGOR (Croydon), Mr. TAYLOR (Birmingham), Dr. MAX HAMILTON (Leeds), Dr. WHITFIELD (London), Dr. DAVIS (Swansea), and Dr. ARCHIBALD FULLERTON (Batley) added to the stimulating discussion.

SECTION OF CARDIOLOGY

Wednesday, July 16

Treatment of Pulmonary Heart Disease

With the president, Dr. OSCAR BRENNER (Birmingham), in the chair, Dr. K. W. DONALD (Birmingham) opened the session with a paper entitled "Treatment of Pulmonary Heart Disease." Cor pulmonale developed in those who already had considerable disability from chronic bronchitis and emphysema. Sometimes asthma was also a complicating factor. These patients, having suffered from a super-added infection such as acute bronchitis or bronchopneumonia, quickly became seriously ill and the need for skilled treatment was urgent. When admitted to hospital they looked moribund, but if the initial treatment was skilled then many lives could be saved. The administration of oxygen was life-saving. Dr. Donald advised general practitioners to carry in their cars an oxygen cylinder and a loose plastic mask so that these patients could get oxygen while awaiting admission to hospital. The dangers of carbon dioxide narcosis had to be kept in mind, and the patients allowed out of the oxygen tent for 10 minutes each hour to ensure adequate ventilation of the lungs.

Among the other remedies Dr. Donald advocated were digitalis, antibiotics given intramuscularly, and aminophylline if any bronchial spasm was present. Emergency tracheotomy should be performed if there was an accumulation of mucus in the trachea. He claimed that in Birmingham this operation frequently proved life-saving. In the

speaker's opinion the newer diuretics such as chlorothiazide were superior to intramuscular mercurial preparations for the relief of oedema.

In the discussion Professor W. MELVILLE ARNOTT (Birmingham) stressed that carbon-dioxide narcosis caused the mental confusion so often seen in these patients. Mr. A. L. D'ABREU (Birmingham) confirmed the value of tracheotomy in urgent cases.

The Thyroid and Heart Disease

Dr. S. H. COOKSON (Bournemouth) then read a paper on the thyroid and heart disease. He confined most of his remarks to the effect of myxoedema on the heart, having reached his conclusions from a study of 36 patients with this disease. The diagnosis of doubtful cases could always be made from the electrocardiographic changes. These, he said, were a slowing of the rate, a reduction of voltage, and a flat or inverted T wave. Occasionally there was a prolonged P-R interval, heart block, and depression of the ST segment. These changes could be restored to normal within eight days with correct therapy. The blood pressure was raised in hypothyroidism, especially the diastolic reading. Dr. Cookson emphasized that the heart size was normal in 14 of his patients, while in the remainder considerable enlargement was present. Severe cases always suffered from the usual symptoms of cardiac failure.

Dr. W. BRIDGEN (London) said that thyrotoxicosis in adolescence must not be treated by surgery because of the ill effects arising from the resulting general endocrinal upset. Dr. K. W. DONALD (Birmingham) urged that cardiac catheterization be done to confirm the diagnosis in all borderline cases.

Myocardial Disease of Obscure Aetiology

Dr. BRIDGEN then read his paper entitled "Myocardial Disease of Obscure Aetiology." He included in this group damage to the myocardium by congenital fibrotic conditions, infections due to bacteria, viruses, and protozoa, collagen diseases, and amyloidosis. Nutritional factors complicated by alcoholic excess, beriberi, and lack of vitamin K were also contributing factors. The signs and symptoms were identical to those of ordinary heart disease, the most prominent symptom being excessive fatigue. The radiological appearances were characteristic, there being a generalized enlargement of the heart with no pulmonary oedema. Electrocardiographic changes could not be relied upon for diagnosis: the usual changes suggested infarction. Prognosis was poor, with sudden death frequent.

Professor MELVILLE ARNOTT reported that over 50% of all cardiac diseases in the Union of South Africa fell into these categories.

Surgical Treatment of Congenital Heart Disease

The Section then heard a paper by Dr. C. G. PARSONS (Birmingham) concerned with the selection of children with congenital heart disease for surgical treatment. He dealt with persistent ductus arteriosus, coarctation of the aorta, and atrial septal defect, being mainly concerned with the advice that should be given to the parents of these children about operation. The decision to advise operation could be reached only after carefully weighing up all the evidence in each individual case. Each recommendation would depend not only on the signs and symptoms and the results of the investigations but also on the ability and experience of the surgical team. 10% of all babies admitted to the Birmingham Children's Hospital because of heart disease had persistent ductus arteriosus. Without operation half of these infants would die in the first year of life. Operation was therefore advised as early as possible. 90% of babies with coarctation of the aorta died, and operation should therefore be attempted as soon as all facilities were available. When the diagnosis was made in older children, operation must be undertaken before puberty. Atrial septal defect had a relatively good prognosis and could exist without symptoms even in the elderly. The average life

expectancy was 37 years. Operation should be advised only if symptoms developed.

Mr. I. HILL (London) described all the surgical methods which could be used to correct these congenital conditions, illustrating diagrammatically with slides the technical aspects of each operation. Later he stressed the value of hypothermia in reducing the mortality of cardiac operations. He thought that the future for cardiac surgery was bright.

Dr. E. M. M. BESTERMAN (London) stressed that when an infant suffered from persistent ductus arteriosus operation must be undertaken before cardiac enlargement had occurred even if there were no symptoms present. Dr. R. GIBSON (London) reported a series of 70 cases operated on for atrial defects with only six deaths. Those who died had other complications. Dr. J. LEIGH COLLIS (Birmingham) agreed with all the practical points raised by Dr. C. G. PARSONS.

SECTION OF GENERAL PRACTICE

Wednesday, July 16

Changes and Trends

With the president, Dr. H. W. DONOVAN (Birmingham), in the chair occasional papers were heard and discussed.

Women in General Practice

Dr. ANNIS GILLIE (London) spoke of the opportunities for women in general practice. Women had been in this field of medicine for over half a century, and there were now probably some 2,500 women general practitioners. Two types could be recognized—the "woman for women" type who had almost exclusively female patients and the real family doctor who looked after the whole families: with time this was the trend.

In general practice there was great scope for a woman to practise medicine to the full: her normal family duties as a wife and mother need not greatly interrupt her professional work. A questionnaire some years ago showed that the loss of women general practitioners from retirement was less marked than of women in other branches of medicine. The entry of women into general practice seems to be maintained and even increasing. In 1957, of all the new principals in England and Wales, 817 in all, 95 (or 12%) were women.

Changes in Paediatric Practice

Dr. A. BEAUCHAMP (Birmingham) gave a personal review of the changes in paediatric practice over the past 30 years. These changes had been notable and numerous, yet some conditions remained unaltered. The catarrhal child was still with us and the vogues of vitamins and removal of tonsils and adenoids had not solved the problem. As always, it was far more important to look at the child as a whole rather than merely at the tonsils. Acute infections of the throat and ear were still as numerous, but much less dangerous and severe. Acute chest infections, on the other hand, seemed to be much more frequent.

Whereas 30 years ago osteomyelitis was an almost weekly occurrence, now, Dr. Beauchamp said, he had not seen a case for six years. With better conditions of feeding and hygiene marasmus and rickets had been controlled, but summer diarrhoea still occurred. Infectious fevers were much altered. Scarlet fever was no longer a specific disease, diphtheria was never seen, and the complications of measles were mild and infrequent. Congenital abnormalities had increased quite significantly, and no good reasons could be given for this.

The reasons for these dramatic improvements in child health were, he considered, three: better public health measures, more enlightened teaching of medical students, and new and powerful drugs. It had always to be remembered, however, that even in the past children recovered from the majority of common and acute infections—unnecessary abuse of the specific antibiotics should be avoided.

Acute Infection of the Ear, Nose, and Throat

Mr. CHARLES GLEDHILL (Northampton), speaking as an E.N.T. consultant, discussed the common problems of aural and nasopharyngeal infections as he saw them. Otitis externa was a difficult condition to treat. Accurate diagnosis was first necessary, with swelling and inflammation of the skin lining the meatus. It was usually a bilateral skin infection caused by bacteria of the pyocyanus-coli groups. The best treatment was local cleansing followed by applications of hydrocortisone and neomycin ear-drops. In treating acute otitis media great care was necessary to follow up all cases until the drum and hearing returned to normal. Any abnormalities required expert advice. Hazardous use of broad-spectrum antibiotics was very dangerous, and penicillin was still the drug of choice.

Pansinusitis was usually caused by penicillin-sensitive organisms, and penicillin was again the first choice together with vasoconstrictive nasal drops. Allergic rhinitis was with vasoconstrictive nasal drops. Allergic rhinitis was with vasoconstrictive nasal drops. Allergic rhinitis was with vasoconstrictive nasal drops. Allergic rhinitis was with vasoconstrictive nasal drops.

Local antibiotics were dangerous in acute throat infections, as generalized moniliasis was a risk. For quinsy he used emergency tonsillectomy under penicillin cover.

Chronic Rheumatism

Dr. L. J. BARFORD (Reigate) discussed the management of the common rheumatic problems in general practice. Empirical measures were the bases of all therapy. These were relief of pain by heat and analgesics, rest, and prevention of deformities and maintenance of muscle tone. In addition to these, local injections of hydrocortisone were now extremely useful in cases of osteoarthritis of knees and hands, tennis elbow, the carpal tunnel syndrome, and subdeltoid bursitis. In spite of all that had been written of its dangers, he still found phenylbutazone a most useful drug in ankylosing spondylitis and chronic gout. Above all else, and much more important than this galaxy of therapeutic measures, was the sympathetic encouragement of the individual patient.

SECTION OF NEUROLOGY AND NEUROSURGERY

Wednesday, July 16

Neurological Disorders in Childhood

With the president, Professor BRODIE HUGHES (Birmingham), in the chair, Dr. LUDO VAN BOGAERT (Antwerp) opened a discussion on neurological disorders in childhood by a review of acute encephalitis. He defined encephalitis as "a morbid process, inflammatory in nature and occurring within the brain, and developing in the presence of a living infective agent acting locally." He stressed the importance of early recognition of encephalitis, particularly when it accompanied or followed specific fevers. If, in a patient with an exanthem, constitutional upset was unusually severe, this often indicated an incipient meningo-encephalitis.

Recognition of Encephalitis

Dr. van Bogaert went on to describe the clinical features of meningo-encephalitis and underlined the importance of obtaining specimens for virological examination. This was particularly important in the first stage (that of viraemia) before neurological symptoms developed. The second febrile phase of the illness, in which the disease process might be largely localized to the nervous system, was easier to recognize clinically. In the early stage there was a pleocytosis in the cerebrospinal fluid, but later there was cytoalbuminological dissociation. A full understanding of many clinical and pathological features was necessary for the elucidation of some of the unusual clinical and pathological entities which had been described. For instance, Dr. van Bogaert suggested that some cases of acute serous exudation within the brain represented simply an early phase of

encephalitis and should be included in this group even in the absence of "cellular" evidence of inflammation. He went on to discuss the syndromes of brain-stem encephalitis, sero-haemorrhagic encephalitis, and the various types of cerebral venous thrombosis, which may be clinically similar, in the light of the pathological changes which had been described in such cases. He closed by mentioning briefly the prognosis of childhood encephalitis and methods of treatment which could be utilized in such cases.

The Hypertonic Child

Dr. PAUL SANDIFER (London) said that the title of his communication, "The Hypertonic Child," did not adequately define what he proposed to talk about, as he intended to deal with the general problem of infantile stiffness. The stiff baby was one whose joints did not move, nor could they be moved, with normal freedom. The cause of the stiffness or deformity might be local, in or around the joints, and might then be "fixed" or structural. This type of fixed contracture of the limbs was seen in infants with arthrogryphosis, but might also occur in childhood as a result of polymyositis or myositis ossificans. Alternatively the cause of the stiffness might lie far distant from the joints where restriction of movement was most apparent; it might in fact be in the nervous system. In such cases the stiffness was generally "unfixed" or postural.

An important cause of stiffness and deformity in the lower limbs was spinal birth injury, a condition which was often difficult to recognize when present in mild degree, but more often the causal lesion was in the brain. These children were generally referred to as "spastics." However, in cases of cerebral palsy, spasticity of the limbs was not invariable; some cases were disabled by rigidity of extrapyramidal type and some by involuntary movements, while in others the diplegia was initially flaccid in type.

Dr. Sandifer went on to discuss in detail the clinical features and differential diagnosis of these conditions; he pointed out that early diagnosis was important not so much because of prospects of effective treatment but rather in order to give the parents an accurate prognosis. In cases of all types there was generally a history of cerebral insult sustained in the perinatal period, and subsequently delay in the development of motor skills became apparent. Many diverse symptoms and signs of focal cerebral and cerebellar or brain-stem lesions might be present in such cases, a fact which increased the difficulties of differential diagnosis in early life.

The Hypotonic Child

Dr. JOHN WALTON (Newcastle upon Tyne), speaking on "The Hypotonic Child," said that few problems were more difficult than the differential diagnosis between the causes of generalized hypotonia of the skeletal muscles in infancy. The diagnosis of amyotonia congenita had fallen into disrepute, since some had used this term to describe all cases with hypotonia developing at or shortly after birth, assuming concurrently that such a syndrome carried an invariably favourable prognosis, a conclusion which was far from the truth. To others this diagnosis foretold, on the contrary, a progressive downhill course, an event which was certainly the rule in progressive spinal muscular atrophy. However, this view failed to take account of that small group of hypotonic children who recover.

In fact, the syndrome of early infantile hypotonia might result from a variety of disease processes, some grave, others benign. The commonest cause was progressive infantile spinal muscular atrophy (Werdnig-Hoffmann disease), in which paralysis and hypotonia became progressively severe and death eventually ensued. In a second large group of cases the muscular hypotonia is a symptom of a variety of muscular, neuromuscular, cerebral, nutritional, metabolic, and skeletal disorders. The third and smallest group, to which the name "benign congenital hypotonia" had been applied, was one in which improvement was the rule, some patients recovering completely, while in others some degree

of muscular weakness and hypotonia persisted throughout life. Dr. Walton stressed the importance of recognizing cases in this latter group and discussed in detail differential diagnosis by clinical means and also the place of electromyography and muscle biopsy.

Hydrocephalus

Mr. G. H. MACNAB (London) read a paper on "Hydrocephalus in Infancy." He said that much had recently been learned about the natural history of hydrocephalus. His colleague Dr. K. M. Laurence had studied a series of 186 children with hydrocephalus who had been fully investigated, but had not undergone surgical treatment, during the period from 1936 to 1956. Over 40% of the children survived, with natural arrest of the hydrocephalus, and 42% were of normal intelligence, with intelligence quotients of 85 or above.

In Mr. Macnab's series of cases, one-third were found to have meningomyeloceles, and in these cases it was common for inflammatory adhesions to block the aqueduct of Sylvius or the foramina of the fourth ventricle. The Arnold-Chiari malformation also caused distortion and adhesions in the region of the cisterna magna. Dr. Laurence, in the analysis of 100 post-mortem examinations, found that only in 14% of cases was hydrocephalus due entirely to congenital malformations; infection accounted for 47%, haemorrhage for 24%, and tumour for 4%, leaving 11% unaccounted for.

Mr. Macnab then went on to show a film demonstrating the insertion of the Spitz-Holzer valve—a valve with a uni-directional flow used to drain cerebrospinal fluid from a cerebral ventricle into the superior vena cava at a set pressure of 50 mm. of water. Special silicone material which formed the valve and catheters prevented coagulation of the blood. This technique was the first successful method yet devised of carrying formed cerebrospinal fluid directly into the blood stream. Over a two-year period Dr. Spitz had now inserted 212 valves, with 96% successful results. Mr. Macnab had now personally inserted 29 successfully.

Intracranial Tumours

In the unavoidable absence of Mr. R. CAMPBELL CONNOLLY (Birmingham), Dr. H. G. MILLER (Newcastle upon Tyne) read Mr. Connolly's paper on "The Diagnosis and Management of Intracranial Tumours in Childhood." He discussed the pathology of these tumours, illustrating his talk with slides which demonstrated the macroscopic appearances seen at operation and also histological changes discovered on biopsy or at necropsy. The differences in incidence of the different types of intracranial tumour in children and in adults were stressed. In children there was a relatively high proportion of gliomas of low-grade malignancy, and benign neoplasms were uncommon. In adults, a considerable proportion of gliomas showed a high degree of malignancy, but on the other hand innocent tumours such as meningiomas and acoustic neuromas were more common.

Mr. Connolly then gave a brief description of the symptoms and signs of intracranial neoplasms, mentioning features which were characteristic of the different types of growth. In differential diagnosis, the conditions which tended to give rise to particular difficulty were otitic hydrocephalus, tuberculous meningitis, and encephalitis. In summarizing the indications for special investigations, including lumbar puncture (which had a very limited place in view of its dangers), electroencephalography, pneumoencephalography, ventriculography, and angiography, Mr. Connolly showed a number of illustrative radiographs. He concluded by considering briefly prognosis and methods of treatment, with particular attention to pre-operative management, the scope of operation and radiotherapy, and aftercare.

Mr. J. M. SMALL (Birmingham), Dr. B. S. B. WOOD (Birmingham), Dr. A. L. WOOLF (Birmingham), Dr. W. A. ZALESKI (Bromsgrove), Dr. H. L. ELLIS (Oxford), Dr. HELEN E. DIMSDALE (London), and Dr. B. M. LAURANCE (Derby) contributed to the discussion.

SECTIONS OF PSYCHIATRY AND SOCIAL AND PREVENTIVE MEDICINE

Wednesday, July 16

Care of the Mentally Ill

The two Sections held a joint meeting under the chairmanship of Dr. ELIOT SLATER, president of the Section of Psychiatry, to discuss "Home, Hostel, or Hospital? The Care of the Mentally Ill." Professor A. QUERIDO (Amsterdam) opened with an account of the Amsterdam domiciliary service, which, he said, has now been running for 25 years, and which at present cares for about 3,000 patients in their homes. These patients would to a large extent probably need hospital treatment in the next two years, if the service suddenly ceased to exist. To explain how it worked he sketched out the mental health services of Amsterdam, since the domiciliary service is only one strand in the net. Amsterdam has no mental hospital of its own, and its people requiring such treatment are dispersed among the mental hospitals of Holland, where they occupy one bed in eleven, which is nearly the ratio of the city population to the total in the country. However, the City University Hospital and the Protestant University Hospital between them have about 300 beds for psychiatric cases for observation, investigation, and brief treatment.

Psychiatric First-aid Service

The pivot of the organization is a day-and-night psychiatric first-aid service, with an experienced male nurse and a psychiatrist always available, and a staff of 10 psychiatrists and 25 social workers to draw on—the staff who also work the domiciliary service. Any patient thought by a family doctor or a specialist, or by the police or other public or social agency, to be in need of admission to hospital for psychiatric reasons is signalled to the first-aid service, and the duty psychiatrist then visits the patient on the spot, wherever he is, and decides on disposal. He may organize admission to one of the two general hospitals, or he may call in the domiciliary service, which will continue a series of home visits, giving guidance and support and sometimes material aid.

The service does not give any psychotherapy (and hence neurotics are not accepted but referred to the special centres), nor does it give drugs: medication remains the responsibility of the family doctor. What it does is show interest, practical help, and general guidance to the family. The service also accepts patients on discharge from the University Hospitals, where they may have spent up to two months, and gives them on the average two to three years' supervision. It also accepts patients discharged from the mental hospitals, where the average length of stay has been reduced to six months.

Thus two-thirds of the service's patients are schizophrenics and others are organic cases (senile, encephalitic, paralytic, feeble-minded) or "psychopaths." The aim is to teach these chronic sufferers to be aware of their disability and to learn to live with it in the community. This saves the community money, and it is an excellent vehicle for mental health education.

The Mental Hospital and the Community

Dr. T. P. REES (London) followed with a brief survey of the changes in the functions of mental hospitals since the Act of 1808 authorized the building of public asylums. In the nineteenth century the asylum was to protect the public, like the prison: to-day it was a hospital for treating mental illness. At the same time, the pattern of all disease had changed. First the diseases of malnutrition had to be conquered, then the infections; now the mental illnesses were the challenge, and rapidly becoming a preoccupation of the medical officer of health. 40% of all N.H.S. hospital beds were in mental hospitals, and 1 person in 40 dies there. One man in 19 and one woman in 14 will be an in-patient.

Dr. Rees said that the old-style asylum produced fresh illness in the patients, institutionalization, and it was not only the patients but also the medical and nursing staff who developed this form of mental rigidity. The World Health Organization had advised that the mental hospital doctor should spend one-third of his time working out in the community. He wanted to see more part-time consultant appointments to mental hospitals, more out-patient clinics, especially in the evenings, and especially clinics for treatment as opposed to diagnosis. It was often very bad for neurotics to stop work and come into hospital. They should be able to get brief psychotherapy after working hours. At the same time he hoped that the majority of the mentally ill would continue to be looked after by their family doctor.

Needs of the Mental Hospital Patient

Dr. C. R. LOWE (Birmingham), speaking on "The Needs of the Present Hospital Population," said that, even if the schemes propounded by the previous speakers were fully applied, hospital admission was still going to be needed in the future, even for social reasons (people living alone, or in slums, or with unsuitable relations). To clarify the diverse kinds of hospital services likely to be required, he, Professor T. McKeown, and Dr. F. N. Garratt had made a study of the needs of the 3,555 mental in-patients of Birmingham in January last year. They found that 45% of these people needed no medical treatment, a further 42% needed only maintenance treatment, and only 13% were having active treatment and investigation in the same way as the patients in an acute general hospital. Again, only 8% were in bed, and two-thirds needed no nursing of any type. One-quarter were capable of doing productive work, yet only 10 were leaving hospital during the day to do a job, and occupational therapy amenities were far from adequate. It was clear that 12% of these patients were in hospital for social reasons, and could just as well have been in a hostel. The exact figures would clearly change with changing circumstances, such as better out-patient services, but Dr. Lowe thought the survey showed the need for diversity. Plans of the future should envisage different kinds of unit, hostel, acute ward, geriatric centre, and so on. Should they be geographically separate or built round a general hospital?

Opening the discussion, Dr. C. A. H. WATTS (Leicester) said that his county, Leicestershire, had 12 psychiatrists, and would need 30 if a version of the Amsterdam scheme were to be started. The alternative was to give general practitioners better undergraduate and postgraduate training in psychiatry so that they could do more and do it better, and to see that they could call on all the paramedical services (social workers, etc.) for help and collaboration. The patient discharged from hospital, whether general or mental, had to be given back his self-confidence and self-esteem and brought back into the community and everyday life. He was looking in the wrong direction if the hospital doctor and the hospital psychiatric social worker managed his aftercare.

Dr. B. MANDELBROTE (Gloucester) said that in the provinces, as distinct from London, the mental hospital was the natural hub and focus of the mental health services. He criticized Dr. Lowe's analysis, as did Dr. T. P. REES later, because it had equated nursing duties in general hospitals with mental nursing, whereas the mental hospital required nurses who could live with and talk to the patients in the right way. Dr. E. S. STERN (Warwick) thought Dr. Lowe's survey completely unrepresentative of mental hospitals in general, and therefore not a basis for planning. He hoped the future was not going to be the kind of "hospital city," cut off from everyday life, a little world of its own, as Dr. Lowe had suggested.

Dr. M. J. BROOKES (Shrewsbury) wanted to know why a recent commission in Denmark had asked for more mental hospital beds. Dr. R. A. LAMBOURNE (Birmingham) put in a plea for more use of the existing political, church, tennis,

and other clubs, and collaboration with teachers and parsons in rehabilitation, rather than creating more hospital out-patient clubs and employing more paramedical workers. Dr. M. P. NELSON (Somerset) wondered whether the public were now adequately safeguarded, and what was the effect on the family of having psychiatric cases in the home. To the second point Professor QUERIDO replied that they had found that children were not upset by psychotic parents, but it was neurotic parents who did the damage. To the first, Dr. T. P. REES said it was humanly impossible to prevent all escapes, whether from prison or Broadmoor, though the latter had a good comparative record. But the vast majority of psychiatric patients were inoffensive, and we had to be careful to balance the ill effects of repression on them against the possibility that through greater freedom one or two individuals might commit crimes.

SECTION OF OCCUPATIONAL HEALTH

Wednesday, July 16

Routine Medical Examinations

The president, Dr. R. S. F. SCHILLING (London), took the chair and in his introductory remarks said that in industry in Great Britain routine examination of workmen had been accepted as essential. Experience, particularly in the U.S.A., had raised three questions in connexion with this aspect of industrial medicine: (1) Were the industrial medical officers making the best use of their time? (2) Were they using the right techniques for the assessment of disease and of skill for work? (3) Were hospital techniques suitable for the investigation of normal persons?

The Adolescent

Dr. R. E. SMITH (Rugby) then read a paper on the examination of the adolescent. This was based on his experience of 20 years as a medical officer to two large schools for boys and to a college for trainee female teachers. At Rugby School each boy was carefully examined on entry and the parents were provided with a detailed history of the boy's previous illnesses. Thereafter no routine medical examinations were carried out. Reliance was placed entirely on getting every boy really well after an illness. Any boy who had been ill during the vacation was examined on return to school to ensure that recovery was complete. At Laurence Sheriff School the procedure was different. There entry examinations were carried out, followed by periodical examinations at two-yearly intervals. He described poor eyesight and dental caries as the main bug-bear, and these required special arrangements. Among the subjects which he had specially investigated were tuberculous infection, otitis media, and undescended testicles. He preferred Mantoux testing and B.C.G. vaccination to mass miniature radiography. The stethoscope, he thought, was outmoded. He was convinced from careful observation that the testicle often descended spontaneously at puberty and that interference by surgeons or endocrinologists before puberty was usually meddling. As to the discharging ear (which was one of the main problems), he had found that practically every case could be cleared up by drying with pledgets of sterile cotton-wool. At the onset this toilet was sometimes necessary every hour. Persistence of discharge was usually due to infected tonsils or maxillary sinuses. His conclusion was that effective treatment of illness when it occurred was superior to routine examinations.

Transport Drivers

Dr. P. A. B. RAFFLE (London) read a paper on the medical aspects of the selection and supervision of persons whose work involved public safety as exemplified by London Transport bus drivers. As an indication of the importance of the subject he recalled that the British Medical Association and the World Health Organization during the past five years published memoranda on medical standards for

such transport drivers, and these standards adequately covered most situations which involved public safety. He stated that the main criteria of fitness to drive a passenger vehicle were: physical capability for handling controls, good visual acuity and colour vision, and absence of all diagnosable conditions apt to cause sudden collapse or excessive fatigue. Careful progressive recording and assessment of the medical history of individual drivers were important. Dr. Raffle enumerated 12 causes of loss of consciousness in drivers, and among these he emphasized idiopathic epilepsy, because it might not appear until middle life, epileptiform seizures due to cerebral metastases complicating bronchial carcinoma, and laryngeal vertigo (cough syncope) in cases of chronic bronchitis. He outlined the scheme of selection and examinations for drivers in London Transport. Analysis of 18,003 pre-employment medical examinations showed that 5.5% of candidates were rejected on general medical grounds and a further 13.3% by reason of substandard vision or colour vision. He commented that patients and private doctors did not regard with due seriousness such conditions as cardiovascular disease and chronic otitis media, which was always a potential cause of aural vertigo. Continuous medical supervision was achieved by periodical examinations at certain ages, following absence on account of certain specific illnesses, and in cases of absence of 28 days or more.

Dr. Raffle focused attention on coronary artery disease. Because of considerable liability to recurrence, this was an absolute contraindication to the continued employment of a driver in this capacity. Coronary disease was usually discovered through sickness absence: electrocardiographic examination did not, at present, enable examiners to detect those who would develop this condition. He referred to a matter of great public interest—namely, diseases which might be suddenly disabling or fatal. During the quinquennium 1953 to 1957, 89 drivers were suddenly stricken and died on the day of the episode. Of these 11 were actually at the wheel at the moment of crisis: six accidents followed, but none involved personal injury. In conclusion he was of opinion that assessment of fitness for particular occupations after sickness was probably more important than routine examination.

Industrial Executives

Dr. O. B. SCHREUDER (Pan American World Airways System, New York) discussed the place of routine examinations in the promotion of health among industrial executives. He stressed that the employee was one of the most valuable assets in any company, and, of the employees, the management group or executives were particularly valuable because of their training, motivation, and high degree of technical and administrative skill. Accordingly the conservation of the health of the executives was an essential part of any occupational health service. He stated that the objective was best achieved through periodical examinations preferably carried out by the industrial medical officer. The main purpose of these examinations was the detection of disease in the early stages while the possibility of remedy existed. To succeed the scheme must have the full support of management. As to the content of the periodical examination, Dr. Schreuder listed these items: a comprehensive history; thorough physical examination, including detailed examination of vision, inspection of the fundi, and determination of ocular tension; palpation of the peripheral blood vessels; and rectal examination. Laboratory investigations should include urinalysis, haemoglobin estimation, E.S.R., blood sugar in persons over 40 years of age, radiographic examination of the lungs, and electrocardiographic examination if over the age of 40 years; other more specialized tests according to indication. In a recent consecutive series of 120 periodical examinations in the management group of Pan American Airways significant defects were discovered in approximately 50% of examinees. The most common ailments were metabolic diseases, including obesity and diabetes, cardiovascular conditions, such as hypertension and gastro-intestinal diseases, including para-

sitic infestations (due to visits to the tropics) and peptic ulcers. Dr. Schreuder directed special attention to the problems of stress and strain. In conclusion he underlined the supreme importance of careful, frank discussion of findings and counselling of each examinee.

A lively discussion, in which many members participated, followed the papers. The main subject of this was the ethical considerations which attach to examination of executives.

COMBINED MEETING OF SECTIONS OF SURGERY, MEDICINE, AND GASTRO-ENTEROLOGY

Wednesday, July 16

Peptic Ulcer

Making some opening remarks from the chair, Dr. E. BULMER (Birmingham), a vice-president of the Section of Medicine, said that as no important advances in the medical treatment of peptic ulcer had been made in the last 35 years it was unlikely that much time would have to be devoted to that aspect of the problem.

Dr. F. AVERY JONES (London) introduced the subject, and pointed out that peptic ulcer, though a common illness, was one which varied tremendously in its severity. Many patients had relatively little trouble from their ulcers, with only a bout of indigestion once or twice a year which quickly responded to routine treatment. In his experience about 25% of cases fell into this category. Diagnosis was usually easy, but there were many pitfalls. Importance should be attached to the periodic and recurring nature of the pain, which might be experienced only in the back, subternally, in the right iliac fossa, or in the suprapubic region.

Duodenal ulcers differed from gastric ulcers in many important respects. For example, in gastric ulcer the incidence was excessive in the labouring classes and low in the professional classes. As to causation, Dr. Avery Jones thought that so far as gastric ulcer was concerned ordinary wear and tear of the gastric mucosa might be important. In contrast, in duodenal ulcer there was the factor of high acid output and hypertrophy of the parietal cells, the latter feature being in part of a hereditary nature. The food habits, and in particular the type of food the patient ate, were of importance, and alcohol was well known to be an aggravating factor also.

Smoking and Ulcers

In a personal series of cases he had been able to show that tobacco-smoking delayed the healing of ulcers. If the patients were to stop smoking 83% of the ulcers showed significant healing by two-thirds or more in extent within one month. Certain drugs also aggravated peptic ulcer, including aspirin, steroids, and phenylbutazone. There was an unduly high incidence of chronic bronchitis among ulcer patients. Finally, emotional factors were well known to be important, and unless attention was paid to these the results of treatment might be poor. Rest in bed was an important part of treatment, for this increased the likelihood of the ulcer healing. Alkalis should be given for the relief of pain, but it was the speaker's impression that these and other drugs were not essential when the patient was free from symptoms, and indeed a complicated treatment regime for ulcers could be positively harmful, particularly when the patient had obsessional tendencies.

Dr. C. N. PULVERTAFT (York) drew attention to the striking geographical differences in the incidence of peptic ulcer which had been reported in several countries, notably India and Nigeria. In this country it had been found for some time that duodenal ulcer was more common in Scotland and the north of England than it was in the south of England, and that the disease was more prevalent in towns and cities than in country areas. He had made a study of peptic ulcer as it occurred in York and the surrounding

country between 1952 and 1957, each new patient being recorded. It emerged that the mean annual incidence per population at risk for the whole area was, for men: gastric ulcer: 0.58, duodenal ulcer 2.25; for women the corresponding figures were 0.32 and 0.66. Perforations occurred in only 7% of the women patients as opposed to 13% of men patients, and in the case of the latter both gastric and duodenal ulcers were found to be more frequent in the town than the surrounding country. It was calculated that the expectation of developing a peptic ulcer in males over the age of 10 was 0.258% per year. A comparison was made between his series and a recent analysis of post-mortem records of peptic ulcer made in Leeds, and a good correlation for duodenal ulcer especially was observed, though it was also noted that the gastric ulcer rate was higher in Leeds than in York. The speaker also pointed out that there had been a recent slight fall in incidence of duodenal ulcer in York, and this trend had also been noted by other observers in London and Aberdeen. The cause of the higher incidence in town than in country was obscure, but it was thought to be unlikely to be due to the higher tempo of urban life.

Role of Gastrectomy

Mr. HERMON TAYLOR (London) spoke of the role of gastrectomy in the treatment of peptic ulcer. He stressed that the loss of the greater part of the stomach was a serious blow to general well-being and digestive efficiency. It was justified by its curative effect upon the ulcer and freedom from subsequent anastomotic ulcer. In contrast, in his experience gastro-enterostomy was associated ultimately with a 30% incidence of recurrent peptic ulcer. This had only become evident over fifteen years, and it would not be revealed if the follow-up period was brief. The results of the addition of vagotomy must have regard to this.

Partial gastrectomy was not associated with recurrent ulcer, but a price had to be paid in the occurrence in some patients of post-operative symptoms of which dumping was the best known. This was due to the loss of the pylorus and could therefore follow any form of gastrectomy. The symptoms of fullness, faintness, and weakness were due to the sudden distension of the small intestine with food: they could always be avoided, therefore, by not taking large meals, with restriction of fluids during a meal. Symptoms that did not respond to simple rules at mealtime were not due to dumping: they were due to obstruction at the anastomosis, with distension of the afferent loop with bile. This was brought about by sharp angulation at the junction of the afferent loop and the gastric remnant. Acute distension of the afferent loop in the immediate post-operative period was the cause of rupture of the duodenal stump, which could be fatal: later, it was the cause of vomiting of bile which troubled many gastrectomy patients. The antecolic anastomosis added a special obstructive effect of its own in some cases owing to the liability of small gut to slip behind the anastomosis.

There was a variety of operations which could be used to correct afferent loop obstruction. However, it need not occur. Mr. Taylor described a retrocolic type of gastrectomy with a gastropasty procedure designed to avoid the obstructing angle. In his hands there had been no deaths with this operation, and no patients subsequently complained of bile vomiting or any serious degree of dumping.

Mr. R. L. HOLT (Manchester) briefly reviewed the various operations which could be performed for chronic peptic ulceration. The chronic gastric ulcer could often be handled well by performing the Billroth I type of procedure. In his opinion, for chronic duodenal ulcer, gastro-enterostomy combined with vagotomy was as good as partial gastrectomy. Indeed, in some respects it might be the better operation of the two, as digestion was relatively good and weight and energy were more likely to be maintained. The operation was successful in 89% of his cases by Visick's grading. Both operations, however, were followed by similar side-effects—for example, diarrhoea.

"dumping," anaemia, loss of weight, and lack of energy. These were mostly due to undigested food passing quickly from the stomach to the jejunum, and there undergoing incomplete digestion from faulty mixing with digestive secretions. To overcome this difficulty Mr. Holt had combined vagotomy with partial excision of the pyloric sphincter (anterior pyloroplasty). The incision was made in the pyloric region at right angles to the long axis of the gut, and about two-thirds of the pyloric sphincter and any anterior ulcer were excised. If a posterior ulcer was present, the edges were approximated by sutures. The early results had been excellent. The mortality rate had been 1% only, and this death was due to pulmonary embolism. Side-effects were infrequent and there had been no case of recurrent ulceration and only occasional bilious vomiting. Female patients had done particularly well. The speaker criticized the combination of vagotomy with a limited gastrectomy of the Billroth I type. The aim of this procedure had been to obtain achlorhydria, but in his opinion this was unnecessary and must inevitably be accompanied by a definite even if small mortality.

Professor F. A. R. STAMMERS (Birmingham) commented on the gradual diminution in popularity of partial gastrectomy in the treatment of chronic duodenal ulcer. Follow-up studies had revealed failure to gain weight and an increased incidence of pulmonary tuberculosis associated with poor nutrition. The overall failure rate was in the region of 10-12%. Not every patient was psychologically suited to this operation, and the "dumping" syndrome, stomal ulceration, and absorptive failure from mechanical causes were all recognized hazards. The precise aetiology of the "dumping" syndrome had not yet been clearly defined, but distension of the afferent loop, hypovolaemia, hypokalaemia, and hypoglycaemia had all been incriminated. Occasionally there was also a mechanical effect when an over-long afferent loop connected as a sump. He had observed cases in which adhesions had formed between the jejunum and the spleen and liver, and the sharp angulation of the bowel so caused had given rise to obstructive features. It was important always to ensure that the afferent loop was short. When a partial gastrectomy was carried out, it was possible to leave a hiatus between the anastomosis and the transverse colon through which either jejunum or omentum might prolapse, with resulting acute intestinal obstruction. The surgeon should ensure that this gap was closed at the original operation.

Opening the discussion, the chairman, Dr. E. BULMER (Birmingham), indicated that in his experience definitive surgery for duodenal ulcer would be necessary in about 5% of cases, but when a partial gastrectomy was performed the long-term results were poor in 10% of patients. In reply to Dr. E. H. L. HARRIES (Birmingham) and Dr. G. WATKINSON (Leeds), Mr. HOLT stressed that all his cases were tested for the effectiveness of vagotomy with the insulin hypoglycaemia test, and that a careful search was made to ensure that all branches of the vagus nerve had been cut. He had found his operations satisfactory in the treatment of manifest bleeding from a chronic duodenal ulcer, but did not advise vagotomy when haemorrhage was thought to originate from multiple gastric erosions.

ROUND-TABLE CONFERENCES

SMOKING AS A CAUSE OF DISEASE

The contrast in thought on smoking between the sixteenth century and to-day—in the light of the contemporary association of tobacco with lung cancer—was commented on by Professor H. SCARBOROUGH, professor of medicine at the Welsh National School of Medicine, at the Round-table Conference on the subject of smoking, held at Birmingham University.

In the sixteenth century, he said, tobacco had been regarded as a panacea for almost all ills. Tobacco leaves

were applied to wounds and tobacco smoke to the rectum. Later, in 1665, the boys of Eton had been encouraged to smoke as a prophylactic against the plague, and those who did not do so were severely beaten.

Professor Scarborough was presiding over a panel consisting of Dr. ERNEST BULMER (senior physician, United Birmingham Hospitals), Mr. W. H. BOND (radiotherapist, United Birmingham Hospitals), Dr. C. R. LOWE (lecturer in social medicine, University of Birmingham), and Professor W. MELVILLE ARNOTT (professor of medicine, University of Birmingham).

The CHAIRMAN, having introduced the members of the panel, asked them to state their own smoking habits. Professor ARNOTT said he smoked a pipe—and a cigar when he was given one. Dr. LOWE described himself as a “converted character”; he had smoked when he had been a “wealthy general practitioner” but could not afford to do so since becoming an “impoverished university lecturer.” Dr. BULMER said he had given up smoking three or four weeks ago, when he had been asked to become a member of the panel. Mr. BOND said he had been a pipe-smoker for two or three years. The CHAIRMAN described himself as “a moderate smoker of cigarettes.”

The proceedings consisted of answers by individual members of the panel to a series of written questions sent up from the audience, the first of which was: “How do you regard the evidence which has been produced about the dangers of smoking in regard to tuberculosis and chronic bronchitis?”

Dr. LOWE said he regarded it with horror. It was that sort of evidence that had put him off cigarettes. He accepted without any reservation that there was a proved association between cigarette-smoking and cancer of the lung, chronic bronchitis, tuberculosis, peptic ulcer, coronary thrombosis in middle life, and certain forms of cancer of the bladder—the sort of association that indicated that, if people did not smoke, a substantial proportion of deaths from those causes would not occur.

Dr. BULMER agreed. He regarded the evidence as overwhelmingly in favour of causal relationship between smoking and, pre-eminently, cancer of the lung, constituting a danger such that, if it were associated with an occupation, would make it virtually impossible to secure any employees unless they were paid princely danger money. Mr. BOND, “in defence of pipe-smoking,” said that emphasis in that connexion must be placed on cigarette-smoking.

Summarizing the views of the panel, the CHAIRMAN said there appeared to be evidence of causal relationship between smoking and carcinoma of the lungs and bladder but no connexion with any other form of malignant disease.

Efficiency of Smokers

To the question, “Does smoking interfere with mental and/or physical efficiency?” Dr. LOWE said he knew of no statistical evidence on the point. Some people became depressed when not smoking and smoked to bring themselves up to the mean; it was thus an addiction rather than a habit. Dr. BULMER had a strong feeling that smoking diminished intellectual and mental energy; on the other hand, increasing age could also account for that. Mr. BOND considered that mental and physical efficiency depended first on the physical effects of continuous irritation of the conjunctivae and throat. An addict had got to have a cigarette before he was up to what he recognized as his mental efficiency. The CHAIRMAN said that an American survey on that aspect had disclosed no difference between the mental efficiency of smokers and non-smokers.

Professor ARNOTT said it could be demonstrated that respiratory efficiency was not the same in smokers as opposed to non-smokers; in the case of smokers the lungs had a lower capacity with higher residual volume; the amount of work which a smoker performed in breathing was significantly higher because smoking was an irritant, causing some swelling of the bronchial lining and narrowing of the bronchial tubes, and therefore an increase in the

resistance to the passage of air. On the other hand, many people employed smoking as a trigger device to stimulate the emptying of the rectum at a time convenient to themselves.

The panel was next asked to explain why asthma sufferers claimed that smoking eased their attacks. Dr. LOWE said he had not heard that claimed, but bronchitics did say that a cigarette helped to cut the phlegm, “and if you live in a semi-detached house next to an addict there is no doubt about it.” Dr. BULMER doubted whether such a claim in relation to asthma had been proved.

Turning to the question of whether any kind of smoking was harmful to non-smokers close by, Dr. LOWE said he was unaware of any such evidence, while Dr. BULMER thought the question was a very wide one because the degree of proximity had not been specified. Pungent pipe smoke could be very annoying, and it might be asked whether it was good thing to be in the atmosphere of a cinema when the air was blue with smoke when the lights came on. Mr. BOND said it depended on which of two factors involved was regarded as the most important—the chronic bronchitic-producing effects of cigarette smoke or the carcinogenic content. If chronic bronchitis was accepted as a factor in the production of lung carcinoma, then the person next to the smoker was in fact suffering. He thought that probably the carcinogenic content might be too low to be significant. The smoker was getting the carcinoma and the person next door was getting the bronchitis.

The panel was next asked whether, in view of the infrequency of lung cancer 25 years ago—before the days of motor- and diesel-fumes—it did not appear probable that the causal relationship was between smoking and the total amount of noxious particles inhaled, smoking being perhaps the most important. Mr. BOND said that the evidence of lung carcinoma was not higher among those working continually in petrol fumes.

Dealing with the question of whether cigarette-smoking could cause amblyopia, Mr. BOND said that the high incidence of that complaint which the Belgians had experienced after the war had been associated with the use of home-grown tobacco containing the central stem of the leaf; this was not present in the imported, prepared product.

The question, “Is there any evidence of a connexion between smoking and coronary thrombosis?” was first dealt with by Dr. LOWE, who described the findings of a questionnaire filled in by 12 Birmingham general practitioners on the subject in relation to male patients of 60 and over. This showed that the evidence of chronic bronchitis and peptic ulcers was appreciably higher among cigarette-smokers than non-smokers or those using pipes. Coronary thrombosis also was higher among cigarette-smokers, but it was interesting to note that the blood pressure of smokers was consistently lower than that of non-smokers.

How Can Doctors Help?

The CHAIRMAN said that the panel's next task would be to consider how people could be discouraged from smoking, if it was considered to be a bad thing, particularly young folk.

Professor ARNOTT said that the doctor's most effective means of helping his patients was by example. It was wrong for any practising physician to smoke in the presence of his patients. It was up to every doctor who was a cigarette-smoker seriously to consider whether, in the interests of his profession and his duty to humanity at large, he should either give up smoking them or do so only in private. Dr. BULMER thought that that was putting it a little strongly; it would convert doctors into “secret smokers.” Certainly every doctor should seriously consider whether he should not refrain from smoking in public; what he did in his private life was nothing to do with his patients. Mr. BOND said the “attack” should be made from childhood, by giving the right example to children.

Dr. LOWE thought there should be some positive action by the Government as well as at personal level. The

important thing was that people should be given the facts—then they could make themselves sick if they wanted to—but so far the facts had not been given.

“I think the Government should come out from behind the ‘smoke-screen’ that tobacco addicts have put up, and be honest about it,” he said. It was quite wrong that smoking should be permitted in public places such as cinemas and restaurants or on public transport. Furthermore, the tobacco industry was not blameless. “We are submitted to a constant barrage from television, the cinema, and advertisements to smoke.” “There should be some control over advertising,” he said. It was also very bad that people in the Forces, at a young and impressionable age, should be encouraged to smoke by being given cheaper cigarettes to smoke when they were hanging around bored.

Professor ARNOTT reminded the conference that the Government raised between six and seven hundred million pounds a year through tobacco revenue and that there was no alternative commodity which could supply such a sum through taxation. Salt—a popular fiscal weapon in India—was impossible for such a purpose in an island so rich in salt deposits as Britain. All sensible people must be extremely sorry for the tobacco manufacturers and their associates and agencies throughout the world. As great industrial concerns, the tobacco industries had a splendid record of bringing prosperity to many areas which now depended heavily on them.

Mr. BOND said there were all sorts of preparations to help people stop smoking, from tablets to silver nitrate mouthwashes, but the best means of discouragement was the whispering campaign—“You are a fool,” sort of thing. To call people “addicts” was also a good thing; equally effective was the term “cigarette drunkard.” Another way of looking at it was to point to the surgery door and reflect that once a year it opened to admit somebody who would be dead in a month of lung cancer, but that if nobody smoked it would open only once every ten years to admit such a person. Dr. BULMER thought that the only hope was for a process which would remove the carcinogenic substance from tobacco.

Professor ARNOTT said he had the feeling that tobacco did not contain any carcinogenic agent at all but that the carcinogenic effect was caused by prolonged and sustained irritation, just as light would cause irritation of the skin, or as a varicose ulcer, prolonged and sustained over the years, would become malignant. The dream of getting a specific compound which could eliminate the carcinogenic element and render the whole process entirely free from risk did not seem biologically credible.

“What, if any, are the ill effects of stopping smoking?” was the last question before the panel. Dr. BULMER thought that the chief ill effect was “a most horrible, self-righteous priggishness.” (Laughter.) Mr. BOND said that was the only real effect that did arise.

The CHAIRMAN said that many who gave up smoking suddenly in middle age ate a great deal more as a result and put on weight; he sometimes wondered whether they were not going from Scylla to Charybdis. Dr. BULMER thought that such an effect was only temporary. Dr. LOWE said there was some evidence that people did put on weight when they stopped smoking. Weight was also related to evidence of coronary disease and one or two other complaints. It was possible that by stopping smoking a person laid himself open to coronary disease, but there were no data on this.

THE RIGHT AGE FOR PLANNED SURGERY

Dr. D. V. HUBBLE (Derby), a vice-president of the Section of Child Health, took the chair at this conference, in which members of the audience proposed questions to a panel comprising a thoracic surgeon, Mr. A. L. D'ABREU (Birmingham), a genito-urinary surgeon, Mr. INNES WILLIAMS

(London), a paediatrician, Dr. J. APLEY (Bristol), a general surgeon, Mr. A. GOUREVITCH (Birmingham), and a plastic surgeon, Mr. O. MANSFIELD (Birmingham).

Dr. H. M. COHEN (Birmingham) asked what was the right age for operating on undescended testes. Mr. WILLIAMS said that it must be done before puberty if full function of the testis was to be obtained. There was histological evidence of abnormality in undescended testes from the age of 6 years; in infancy there might be difficulty in diagnosis and danger of damage to the vas during operation, and his practice was to defer it until 8 or 9 years. Mr. GOUREVITCH preferred to say 6 to 8 years, despite Dr. Apley's opinion that in many cases descent would occur at puberty and that one might doubt whether surgery left testes undamaged. Mr. WILLIAMS thought that the ones which came down at puberty were the high retractile testes which could be difficult to distinguish from those which were undescended and which then provided almost the only indication for the use of gonadotrophins as an aid to diagnosis.

This controversial topic was changed for another when Dr. J. W. LITCHFIELD (London) inquired about the right age for operation in coarctation of the aorta. Mr. D'ABREU said that the real problem arose in the infantile cases presenting with heart failure and often accompanied by ventricular septal defects. He favoured medical treatment if possible until the age of 1 year, when surgery might be undertaken with good results. In cases without obvious symptoms he thought 7 years was a good age for operation. In replying to a question about the urgency of operation for persistent ductus arteriosus he again mentioned 7 as the age preferred by many surgeons: 7 was a magical number, a Biblical number, and it appealed to him, as he was the seventh child of a seventh child, but it really had nothing to do with persistent ductus arteriosus, which he preferred to treat at 3. He had seen no operative deaths at this age, and at 7 children were busy preparing for the 11+ examination. Where heart failure occurred, the ductus might be closed at any age, after medical preparation. Their youngest patient was 6 weeks old. Dr. Apley remarked that the ductus operations one regretted were those that had not been done.

Dr. BERYL CORNER (Bristol) and Dr. G. S. R. LITTLE (Greenwich and Deptford) asked about naevi, hairy moles, cervical sinuses, and fistulae. Mr. MANSFIELD thought that the surgeon must ask himself several questions in such cases: Were they technically operable at this age? Could a better result be obtained by deferring operation? If so, should one operate early to ease the mother's social life, remembering that except with some defects of the hand children were not conscious of their outward blemishes until the age of 6 or 7 years? The degree of blemish would affect one's decision: a hairy mole on the forehead which made a baby look like a Lakeland terrier needed earlier removal than a pale, hairless mole. With regard to facial palsy, which Dr. B. M. LAURANCE (Derby) asked about, he thought that nothing could be done during infancy anyway, and in older patients the plastic surgeon had little to offer except when facial deformity was grotesque.

Circumcision

In reply to a question about the indications for circumcision, Mr. WILLIAMS said that in childhood phimosis was the only medical indication, but phimosis was an uncommon congenital deformity which was most difficult to diagnose in the first two weeks of life, the age when circumcision was most easily performed. Mr. GOUREVITCH said that the crux was whether the meatus was rigid or not; what was called balanitis in infants was napkin rash.

Replying to the chairman, Mr. WILLIAMS agreed that circumcision gave almost complete immunity to penile cancer, but this might be because it occurred in men who either could not (because of phimosis) or would not (because of social circumstances) retract the prepuce and clean the glans. There was evidence of diminished cancer of the cervix among communities practising male circumcision, but it did not establish a causative relationship.

There was considerable discussion about the attitude of parents to circumcision—was it right to circumcise when the indications were social? Mr. Williams thought that in such cases the child was going to be circumcised by someone in any case, so it might be best to ensure that it was done properly; Dr. APLEY and Mr. MANSFIELD thought that one could often get the father on one's side in opposing operation; Mr. GOUREVITCH thought that too many general practitioners encouraged the parents to think circumcision was needed when it was not. A member of the audience asked whether it was agreed that stretching of the foreskin was the most unsuitable way of dealing with the problem, and the panel suddenly fused together in unanimous agreement.

Questioned about the use of "the pump" in the surgery of congenital heart disease, Mr. D'ABREU indicated his own group's concentration on the treatment of large ventricular septal defects with enormous blood flow through the lungs before pulmonary hypertension had set in. He stressed the much greater importance of people than of pumps—if you had £20,000 to buy a pump, it was better to spend £700 on tubing, etc., and use the rest to train four people to work it. Dr. APLEY agreed: "Too often someone has gone abroad to buy a pump and returned to find he's bought a pup."

Abdominal Pain

Mr. R. P. M. MILES (Chichester) wanted to know what should be done when, as so often happened, the surgeon saw a child, usually a girl, who had right-sided abdominal pain and whose doctor wanted the appendix removed. Mr. GOUREVITCH said he more often had to deal with cases of central abdominal pain; his job was to eliminate appendicitis or other organic disease, and when he had done that to say that the child would grow out of it. Dr. APLEY did not think this often happened; there was a family pattern which led to abdominal pain.

Finally the chairman asked Mr. MANSFIELD for his opinion about the age for operation on cleft lip and palate. He replied that he thought that if there was bony deformity a cleft lip should be dealt with at 3 months; if there was not it could be done at any time. A simple cleft of the palate too could be done at 3 months, and combined cleft lip and palate at 4 months if there was no deformity. The important thing was to close the nose off from the mouth—nowadays they seldom encountered deafness in patients with cleft palates.

MEDICAL RESEARCH COUNCIL ANNUAL REPORT

The Medical Research Council's 43rd annual report,* just published, covers the Council's activities during the year ended September 30, 1957. It records that during the last financial year (1957-8) Parliament provided the Council with £2,813,000. The previous year the sum was slightly less than £2,593,000. On this the Council maintained the National Institute for Medical Research, the M.R.C. Laboratories in the Gambia, 44 research units and 21 research groups, and various external scientific staff; provided numerous research grants and training awards; and supported financially in varying degree the Institute of Cancer Research, London, the research department of the Royal Beatson Memorial Hospital, Glasgow, and the research programme of the Christie Hospital and Holt Radium Institute, Manchester. The Council also administered the Public Health Laboratory Service, and the Blood Products Laboratory (Lister Institute), on behalf of the Ministry of Health. The Council's whole-time scientific and medical staff (excluding technicians, etc.) numbered 648 and there were a further 146 employed in the P.H.L.S.

The Council

The scientific members of the Council during the year covered by the report were Professor Robert Platt, P.R.C.P., and Professor E. T. C. Spooner (until April, 1957); Sir

*Report of the Medical Research Council for the Year 1956-1957, 1958. H.M.S.O., London.

George Pickering, Professor A. Bradford Hill, F.R.S., Professor G. F. Marrian, F.R.S., Professor R. C. Garry, Mr. H. J. Seddon, and Dr. J. D. N. Hill; and Professor C. H. Stuart Harris and Professor A. A. Miles (since April, 1957). The lay members were the Earl of Limerick, chairman; Sir Geoffrey Vickers, V.C., treasurer; and Mr. Richard Fort, M.P. The chairman of the Council's Clinical Research Board was Sir Geoffrey Jefferson, F.R.S.

The principal permanent officials are Sir Harold Himsworth, F.R.S., secretary of the Council; Sir Charles Harington, F.R.S., director of the National Institute for Medical Research; and Dr. G. S. Wilson, director of the P.H.L.S. In October, 1957, Sir Landsborough Thomson, second secretary, retired after almost 40 years with the Council, having served as deputy to each in turn of its three secretaries—Sir Walter Fletcher, Sir Edward Mellanby, and Sir Harold Himsworth. The Council records its great indebtedness, and that of medical research generally, to his rare combination of high administrative skill and scientific understanding.

New Research Units

During the year the Council set up four new units, and a fifth one just after the period. They were the unit at Leeds for research on metabolic disturbances of surgery (Professor L. N. Pyrah), groups at Exeter and the Western General Hospital, Edinburgh, respectively for research on carcinogenic substances (Dr. J. W. Cook, F.R.S.) and the general effects of radiation (Dr. W. M. Court Brown), and at Carshalton the virus culture laboratory (Dr. P. D. Cooper). The fifth unit was the microbial genetics research unit (Dr. W. Hayes) at the Postgraduate Medical School of London. In addition the Council on the advice of the Clinical Research Board took on four research projects formerly financed and administered through the Ministry of Health, and established them as Council units. They are now the clinical genetics research unit (Dr. J. A. Fraser Roberts) at the Institute of Child Health, the neuropsychiatric research unit (Dr. D. Richter) at Whitchurch Hospital, Cardiff, and the research group on juvenile rheumatism (Professor E. G. L. Bywaters) at the Canadian Memorial Hospital, Taplow.

ASPECTS OF RESEARCH

A Special Correspondent writes: Each year now the Medical Research Council's annual report contains a review of recent advances in some of those selected fields of scientific medicine in which work supported by M.R.C. funds is going on. This review increasingly attempts a popular presentation. The present report presents a summary of 15 separate fields in 50 pages. It might have been wiser to have covered fewer subjects and given each a little more space. This year, too, a great deal of space is given to matters of applied science and public health—the development of respirators, improved serological diagnosis of syphilis, poisoning by radioactive strontium, for instance—and by contrast rather too little to the fundamental science on which in the end all progress is based. Perhaps this shift of balance away from the laboratory sciences towards more practical and clinical problems reflects the greatly increased awareness of the value of applied science and technology in all fields of Government and administration to-day.

Respirators

Poliomyelitis and Asian influenza, and the recognition of certain other respiratory and gastro-intestinal viruses, account for a quarter of the whole review. The most interesting section of this is the account of how the "iron lung" and other respirators have been developed by organized exploitation of physiological and engineering knowledge. Poliomyelitis was the spur to the invention of these breathing-machines, the first by Drinker in the U.S.A. in 1929. This was a negative pressure machine, and experience with it suggested it might have been responsible for some deaths and for a certain amount of permanent crippling. So the M.R.C. set up a committee in 1938 to consider the whole problem, the different kinds of machines possible, and the physiological factors at work. Informa-

tion was needed on the relation between the machine's working and the patient's tidal air, vital capacity, and tendency to acidosis or alkalosis. About the same time, Lord Nuffield generously presented nearly 1,000 machines to hospitals throughout the Commonwealth. These were a modified Drinker machine, devised by Both of Australia. Then came the war of 1939-45, and interest lapsed.

Interest revived with the big poliomyelitis epidemic of 1947 in Britain. The crisis showed up the inadequacies of the situation. Many of the respirators had not been well maintained over the years, and spare parts were difficult to come by. Power failures showed that hand-pumping was ineffective, and the rubber bellows sometimes ruptured after several weeks' continuous use. The Ministry of Health called on the M.R.C. to come to the rescue.

The first step was the physiological assessment of the problem, to define the precise aid the patient needed at different stages of his illness, and the use of the spirometer as part of routine clinical study of cases. The second was consideration of two practical problems: how to keep the airway clear, and how to keep the machine working reliably. This led to a special report in 1950, and the drafting of a standard performance specification for cabinet respirators for the manufacture of these machines. A special kit was invented so that hospitals could modernize their Both

Spiral shell cuirass respirator. Reproduced by courtesy of the Medical Supply Association, London.

respirators. New patterns of cabinet machine facilitated nursing attention, while portable cuirass respirators (see Fig.) meant that patients could be weaned from dependence on cabinet and nurses, lead an independent life, and go home. Special instruments needed for proper treatment were also invented, such as the electronic stethoscope for examining the patient inside the working cabinet. These successful developments were the work of many people—motor engineers, industrial firms who voluntarily col-

Viruses and Interferon

laborated, the R.A.F., and so on, as well as medical workers—reminiscent of the way some of the big problems of the war such as radar and the atom bomb were solved through the collaboration of many skills.

Another aspect of the poliomyelitis problem, culture of the causative virus in cells in tissue culture, has led to the discovery of a number of new viruses, particularly the adenovirus group responsible for various infections such as "febrile catarrh" and some atypical pneumonias, through study of tissue cultures made from infected tonsils and adenoids. Complement-fixing antigens from these viruses appear in the fluid of such cultures and this has opened the way to the study of antibody titres in the sera of normal people and those suffering acute infections. By the tissue-culture method a number of viruses have also been isolated from intestinal contents and human faeces—poliomyelitis and Coxsackie viruses, but also some known as ECHO (enteric, cytopathogenic, human, orphan) in which the word "orphan" implied that they were not known to

cause human disease. However, one has since been implicated in benign aseptic meningitis, and it seems likely that some viruses which are normal inhabitants of the gastro-intestinal tract may on occasion produce disease epidemics.

In the field of pure science the discovery of interferon is one of the most interesting advances in virology for some time. It is well known that one virus growing in tissue culture cells prevents another unrelated virus from infecting the cells at the same time, and M.R.C. workers have discovered that this interference is brought about through a chemical substance, a product of the activity of the first virus and its cell host. This substance is now being purified, and it is thought to act by interfering with nucleic acid metabolism. So its discovery may shed new light on the biochemistry of normal and cancer cells.

A field where virology and cancer research meet is the study of leukaemia. It seems that the natural disease in mice is probably due to a virus, and the question was asked whether radiation-induced leukaemia in mice is also infective. This appeared not to be so. The precise dose and time relations for inducing leukaemia have been investigated, and it is interesting to find that something from the thymus predisposes an individual animal to get leukaemia. The thymectomized mouse is protected from this form of physical breakdown. Here then is another strange chemical substance controlling the fate of cells.

Mechanism of Fever; Arthritis

A third substance with an important physiological effect emerges from recent studies of the mechanism of fever. That bacteria which cause fever contain extractable fever-producing substances (lipopolysaccharide, usually) is an old observation. What is new is that these substances probably do not act directly on the temperature-regulating centres of the brain but act instead on the white blood corpuscles, which thereupon liberate a new hitherto unidentified substance which is the true brain agent. This agent does not paralyse temperature control but holds the thermostat at a new level.

The last few years have seen important advances in the diagnosis of rheumatoid arthritis. The Rose serological agglutination test is a positive way of distinguishing this disorder from other confusingly alike conditions. Also x-ray pictures can be used to differentiate a common form of generalized osteoarthritis from true rheumatoid arthritis. Though clinically similar, osteophytes at joint margins, and bony sclerosis, are seen in the former condition, erosion of joint surfaces and osteoporosis in the latter. Using these tests various populations have been surveyed and some interesting results have emerged. For both Wales and Lancashire true rheumatoid arthritis has been found equally common in both men and women. Clinically, and almost traditionally, women were supposed to be the major sufferers—but the excess of polyarthritis in middle-aged women is now found to be osteoarthritis and not the rheumatic condition. Also it seems that in men rheumatoid arthritis may in some way predispose to both pulmonary tuberculosis and pulmonary nodular fibrosis.

X-ray Crystallography

Finally, some progress in pure science—the structure of protein molecules. All crystals scatter x rays, and from a photograph of the scatter spots something can be deduced about the shape of molecules which form the crystal. Each atom in the molecule is responsible for a bit of the scatter. It was study of suitable crystals in this way which helped to settle the formula of penicillin, for instance. Crystalline proteins and viruses can also be studied by x rays, but since they contain a very large number of atoms and these are rather small the resultant scatter photograph is poor and difficult to interpret. The situation has been improved by introducing "marker" atoms, such as mercury, into the crystals. They combine at certain special points (where there is sulphur in the amino-acid cysteine, for example),

and the scatter to which they individually give rise can be picked out. Applying this method to a rather simple protein, myoglobin, the haemoglobin inside the fibres of red muscles, it has been possible to deduce its molecular shape and to make a model of it.

MEDICAL WOMEN'S INTERNATIONAL ASSOCIATION

EIGHTH CONGRESS IN LONDON

On July 16 the COUNTESS MOUNTBATTEN OF BURMA opened the Eighth Congress of the Medical Women's International Association. The Congress was held from July 15 to 21 at Bedford College, London, under the presidency of Dr. M. YOLANDA TOSONI-DALAI, of Milan. The British Medical Women's Federation, under its president Dr. KATHARINE LLOYD-WILLIAMS, acted as the host organization. The theme of the Congress was "The Adolescent," and during the scientific sessions the physical, endocrinological, psychiatric, and social aspects of that period of life were considered.

The Medical Women's International Association was founded in 1919 in New York at a meeting at which Dr. ESTHER POHL LOVEJOY, who attended the present Congress, was elected as the association's first president. It has the distinction of being the oldest international medical association in the world.

Lady Mountbatten's Address

LADY MOUNTBATTEN said that she came to the Congress as one who for many years had taken the greatest interest in health and welfare. For a long time she had been fortunate to work closely with the medical and nursing professions in Britain and in many other parts of the world, and that close association had been an inspiration to her. Their work was often hard and testing. But it derived its inspiration from women with the highest of qualifications who desired to render a service, the finest of all services, regardless of any restrictions which a question of politics, economy, race, or religion might seek to impose. All of them as doctors were united in the unceasing fight against disease and human suffering; they were united in that fellowship which transcends the barriers of nationality, caste, or creed.

As superintendent in chief of the St. John Ambulance Brigade and president of the Save the Children Fund she had worked with people of all nationalities, with widely differing problems and points of view. That had brought home to her very vividly the vital necessity for the fullest possible understanding between nations; and in the achievement of that understanding she was certain that the medical profession, because of its great humanitarian tradition and motive, had a unique mission to fulfil. For that caring for the sick and suffering, that deep concern for the welfare of the human being anywhere and everywhere which animated the work of the medical profession throughout the world, made it, more than any other human activity, a powerful factor for international understanding, co-operation, and toleration.

It was most inspiring to know that the Medical Women's International Association insisted that the constitution of affiliated societies must include a clause admitting to membership all duly qualified medical women, irrespective of race, religion, or political belief. "I find in the present gathering together of women doctors a most heartening example of professional co-operation at an international level. And I can think of no other group of women in a position to make such a vital contribution to the welfare of the whole world, not only as doctors but as ambassadors for peace and friendship, justice and understanding."

Special Contribution of Women Doctors

The work of women pioneers in the medical field had always had a special interest and indeed fascination. For

it was only through their courage and devotion that women doctors had to-day achieved such recognition and in most parts of the world had so consistently held a position of recognized professional equality with their colleagues. Since those early days experience had abundantly proved that women doctors had made a very special contribution to medicine and medical studies in that, being women as well as doctors, they had helped to focus attention on certain topics of special interest to women, notably gynaecological disorders, the health of mothers and children, and paediatrics generally.

That a more enlightened attitude to problems particularly affecting women was gaining ground was due in no small part to the influence and the devoted and outstanding work of women doctors in this country and abroad, and of the various national associations of medical women which were brought together in this international association. One had only to look at some of the subjects which had been discussed at past congresses—"The Problems of the Married Woman Working Outside the Home," "The Pathology and Hygiene of Housework," "Anaemia in Women," among others—to realize how much attention had been given to the special problems of women. These and the theme for the 1960 Congress, which was "The Old Woman," could only really be thoroughly and authoritatively discussed by a gathering of this kind.

This year the theme would be "The Adolescent." "I am quite certain," went on Lady Mountbatten, "that your scientific, unbiased, and womanly approach to the subject will make an extremely important contribution to a better understanding of the problems involved, and will help to clear away a lot of the muddled thinking which has obscured the whole subject."

Pioneers in India

In her travels she had had a wonderful opportunity of seeing and assessing the contribution made by women doctors in the medical field, especially in India, which she knew so well and for which she had the deepest affection. One always remembered the women pioneers who went to India in the 'seventies and 'eighties and who overcame almost insurmountable obstacles in order to lay the foundation of the Zenana hospitals, teaching institutes for midwives, and medical schools for women. She had visited those hospitals, institutes, and schools and no praise could be too high for those who were responsible for starting them.

In India she had heard on every side the names of Dame Mary Scharlieb, Dr. Margaret Balfour, and Dr. Ruth Young spoken of with the deepest gratitude. Also Dr. Clara Swain, of the Women's Foreign Missionary Society of the Methodist Episcopal Church, who was the first qualified medical woman to land in India. She came from New York in 1870 and started the first women's college in India. The courage and devotion of these women amongst others to whom India owed the medical relief given to-day to her women and children were something which could never be forgotten.

While speaking of India, it would be impossible not to make a special mention of one of the world's great international medical centres, founded at Vellore by Dr. Ida Scudder in 1902. To-day Indian women themselves were playing a vital part in the medical field and also in the organization of voluntary bodies such as the Red Cross Society and the extension of the St. John Ambulance Brigade.

All over the world medical women, because of their splendid achievements, had a higher reputation in their profession than any other professional women. And in all this they had had the tireless support of their national associations and of the Medical Women's International Association to which these were affiliated. Their association was fully equipped not only to promote the interests of medical women but to make a wonderful contribution to the welfare of other women too.

Lady Mountbatten then declared the Congress open.

To-day's Drugs

In this column we publish from time to time authoritative notes on a selection of drugs in current use.

Trypure Novo Stabilized (Evans Medical Supplies Ltd.).—Pure crystalline trypsin stabilized with a calcium salt in vials of 50 mg. or 1 g. and as a dispersible powder in an inert base.

The idea of using substances which would bring about the dissolution of necrosed tissues and of blood and lymph clot in order to facilitate drainage and debridement is by no means new. Over thirty years ago Dakin's solution was thus employed, especially in thoracic surgery, but its effect remained doubtful. In 1933 Tillett and Garner (*J. exp. Med.*, **58**, 485) showed that the filtrate of a broth culture of certain haemolytic streptococci had the power of lysing the viscous elements of pus and fibrin clots, and they isolated two enzymes—streptokinase and streptodornase—which have since been used in a wide range of conditions. The earlier name of these enzymes, fibrinolysin, should not be confused with "fibrinolysin" (thiosinamine sodium salicylate), which has been used to soften fibrous tissues and scars.

Trypure is another enzyme which can be used in the debridement of necrotic tissue and the liquefaction of purulent viscid accumulations and clots. The powder, which should not be taken internally, can be applied as such, but as it is readily soluble in water the enzyme can also be administered by local instillation or injection, or inhaled as an atomized solution. The dry powder is stable at room temperature for long periods; the solution remains active at this temperature for about 48 hours, but at 5° C. (41° F.) it can be stored for 2–3 months. Like many other enzymes it is quickly destroyed by heat above 55° C. (131° F.). It is particularly applicable in thoracic surgery—haemothorax, empyema, exudative pleurisy, lung abscess—but other closed-space suppurations such as sinusitis and subphrenic and liver abscesses can also be so treated. Among the many surface conditions which are suitable are infected necrotic wounds and burns, gangrene, and ulcers, and it may be used in the preparation of infected surfaces for skin grafting.

N.H.S. basic price: dual pack of 50 mg. stabilized trypsin and 15 ml. sterile saline, 13s. 3d.; 2 g. of 2.5% trypsin powder, 13s. 3d.

Irgapyrin (Geigy Pharmaceutical Co.).—Put up in ampoules of 5 ml. containing 30% solution for intramuscular injection, and as tablets of 250 mg., this substance contains equal quantities of amidopyrine and phenylbutazone. When first introduced in the treatment of the rheumatic disorders amidopyrine was considered the more important constituent, but because of its reputation as a cause of agranulocytosis phenylbutazone was later used alone and proved effective. Both constituents may, though rarely, cause agranulocytosis; phenylbutazone may cause gastro-intestinal disturbances, including peptic ulceration and bleeding, nausea, oedema, and drug rashes. One tablet twice or thrice daily, or one injection every 1–4 days, relieves pain in many conditions, including osteoarthritis, ankylospondylitis, rheumatoid arthritis, osteitis deformans, and metastatic malignant disease. It should be used with extreme caution if at all in patients with co-existing peptic ulceration, congestive cardiac failure, or conditions of renal or hepatic insufficiency.

N.H.S. basic price: 5 ampoules, 8s. 5d.; 50 tabs., 18s.

A *Supplement on Cancer* has been issued by the Registrar-General for England and Wales for the year 1953 (H.M.S.O., 7s. 6d.). It gives statistics derived from about 35,000 cases for cancer of the uterus, ovary, testis, penis, lip, tongue, mouth, pharynx, and oesophagus. Records for previous years are in some cases given for comparison.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Russian Vaccine for Multiple Sclerosis

SIR,—During the past few days we have had an opportunity of discussing the multiple sclerosis vaccine ("vaccine of Shubladze and Margulis") and the S.V. strain of acute encephalomyelitis virus of man from which this vaccine is prepared. We think it is clearly necessary to reinvestigate and characterize the original isolates of this virus, for recent experiments have shown that the S.V. strain in current use is similar to rabies virus.

As far as treatment with the "vaccine of Shubladze and Margulis" is concerned, it is not possible to make any further recommendation until reinvestigations have been made.—We are, etc.,

A. K. SHUBLADZE,
Moscow. Chief of Laboratory, Ivanovsky Institute of Virology,
Moscow, U.S.S.R.
G. W. A. DICK,
Professor of Microbiology,
The Queen's University, Belfast, Northern Ireland.

Imbecile Children

SIR,—I hope that your readers will not be misled by Dr. J. Burkinshaw's letter (*Journal*, June 28, p. 543) into thinking that the Fountain Hospital alone provides temporary admission for imbecile children. In 1956, 2,020 such children were admitted for temporary periods to 99 mental deficiency hospitals in this country. Only 602 were found alternative placement, and the local health authorities, in my opinion, could assist greatly in keeping children out of hospital by providing short-stay homes themselves.

I do not agree entirely with Dr. Burkinshaw's suggestions for their eventual admission. In actual fact many ineducable children do better in a hospital with a properly equipped and staffed school than they do at home, where no, or an inadequate, occupation centre is available. Our problem is not only to admit, but to discharge, children who could well live at home. Their parents, however, are delighted with their progress, take them home each weekend, but refuse, quite rightly, to take them out of hospital entirely because the community, so far, provides no comparable training. A five-day residential school centrally situated to deal with urban or county areas could obviate this.

If we are to introduce ineducable children gently to our hospitals and admit them as soon as they are too big to be the "family pet" they will be with us, in this antibiotic era, for the next fifty years at least. How are we to provide beds for that? I should rather catch them young, if they have to come to hospital, and try to train them for sheltered work, either going daily from their home circle or living in hostels. We could then give the holidays in hospital at that stage if required to do so.—I am, etc.,

Botleys Park Hospital,
Chertsey.

J. M. CRAWFORD.

Cardiac Arrest

SIR,—Dr. D. W. Blair and his colleagues (*Journal*, June 28, p. 1521) report a case of recovery from neurological sequelae after cardiac arrest. They are to be congratulated on their prompt diagnosis and the early institution of cardiac massage, which resulted in a return to a good general condition in their patient. In spite of this the patient obviously suffered severe cerebral damage and, even with cooling to reduce the metabolism of the damaged nerve cells, consciousness was not regained until the third post-operative day, and final recovery was not achieved for two months.

The knowledge that cardiac arrest, especially in the operating theatre, need not inevitably be fatal has resulted in

was the help given. This the latest German statement² shows to be an average payment of 5.860 DM. (£500) to those granted any compensation. (This sum, curiously enough, is almost exactly that granted automatically, together with other benefits, as "compensation" to most released war criminals—including Drs. Oberheuser and Hans Eisele.)³ Moreover, Germany has categorically refused to pay these victims a pension, although the International Refugee Organization stated that "the experiments left the victims with permanently impaired health."⁴—I am, etc.,

FRANCES BLACKETT,
Honorary Secretary,
British League for European Freedom.

London, S.W.1.

Rh Blood Groups and Sex Ratio at Birth

SIR,—In a series of babies born in Aberdeen Maternity Hospital, and blood-grouped as part of a research programme supported by a grant from the Scottish Hospital Endowments Research Trust, the ratio of male to female Rh(D)-positive babies is significantly higher than that of the Rh(D)-negative babies. The sex ratio of the Rh-positive babies (Table I) is 1.12 (1,964:1,754), while that of the Rh-negative babies is 0.93 (440:473), the probability of obtaining such a difference by chance being 1.3%.¹

TABLE I.—Sex-ratio of White (Aberdeen) Newborn Babies

Rh(D)-positive Babies				Rh(D)-negative Babies			
Group	Male	Female	M./F.	Group	Male	Female	M./F.
AB	52	51	1.02	AB	19	14	1.36
B	222	192	1.16	B	53	49	1.08
O	1,023	906	1.13	O	229	230	1.00
A	667	605	1.10	A	139	180	0.77
Aggregate	1,964	1,754	1.12	Aggregate	440	473	0.93

TABLE II.—Sex-ratio of White (Aberdeen) Newborn Babies

Babies ex Mothers	Number of Babies				
	Male	Female	Male	Female	M./F.
O Positive ex O Positive ...	579	520	677	609	1.11
O Positive ex O Negative ...	98	89			
A Positive ex A Positive ...	322	299			
A Positive ex A Negative ...	43	51	365	350	1.04
O Negative ex O Positive ...	93	93			
O Negative ex O Negative ...	55	62	148	155	0.95
A Negative ex A Positive ...	40	59			
A Negative ex A Negative ...	33	54	73	113	0.65

In view of Sanghvi's² finding of a significantly higher sex-ratio for O babies of O mothers than for A babies of A mothers it is interesting that in the Aberdeen series so far the O Rh-negative babies of O mothers have a lower sex-ratio than the A Rh-positive babies of A mothers (Table II). Thus, despite the high sex-ratio, so far, of the Rh-negative AB's the balance of evidence to date suggests that the Rh sex-ratio difference shown above would, if confirmed, prove independent of any ABO sex-ratio differences.¹ A detailed account of these findings, with acknowledgments, will appear elsewhere.—I am, etc.,

Aberdeen.

Suffocation in Infancy

SIR,—With reference to Dr. J. Shackleton Bailey's letter (*Journal*, July 12, p. 104), when I was coroner of Birmingham I carried out an investigation as he has suggested into sudden and unexpected deaths of infants reported to me and extending over the seven years 1938–44, and the findings were published in an article in the *Journal*¹ relating to 318 deaths so reported in which asphyxia was considered a possible cause by a general practitioner. Of these, 38 were shown to be so caused; 18 of them resulted from mechanical suffocation while in bed with some other person, and 6 from mechanical suffocation while sleeping alone. The remaining 280 deaths were definitely ascribed to natural causes, and these causes with the age of the infant were set out in detail in the report, supported in every instance by the post-mortem findings of a skilled pathologist.

In all such cases a necropsy is absolutely necessary in order to avoid mistaken diagnosis and to avoid the distress of a mother that she may have been responsible for her infant's death. The Coroners Amendment Act, 1926, gives coroners power to order a post-mortem examination, with or without the necessity of an inquest, and in my opinion no medical man is justified in hazarding a cause of death in such circumstances without a necropsy.—I am, etc.,

Birmingham.

Pilot Ampoules

SIR,—Sensitivity towards horse serum is found in an increasing number of patients, so that it is necessary to test their sensitivity before curative or even prophylactic doses of sera like anti-diphtheria and anti-tetanus sera, etc., are administered. At present, to conduct this test a little of the serum from the big ampoule is taken and diluted. This process of dilution, apart from being cumbersome, leaves the opened ampoule liable to bacterial contamination if left unprotected; and if the patient is found to be sensitive the ampoule may have to be thrown away and thus wasted. Hence it would be very convenient and advantageous if the manufacturers of these sera would provide diluted serum in 0.5 or 1 ml. ampoules. These could either be sold separately or, better still, be packed as pilot ampoules with the usual serum ampoules.—I am, etc.,

Mangalore, South India.

V. R. BHAT.

Lung Cancer and Tuberculosis

SIR,—My attention has been called to a letter by Dr. T. G. Paxon (*Journal*, April 12, p. 887) containing the sentence, "It has been maintained before and also hotly contested [reference] that tuberculosis has some relation to cancer." The reference is to an article of mine¹ and reflects a misunderstanding. So far from having contested in that article that there may be a relation between these two diseases, I quoted from Pearl,² and commented favourably with regard to its consideration as follows:

"Another quotation from Pearl (1929) is pertinent to the subject under present discussion: '... it is of interest to note that as the frequency of incidence of fatal tuberculosis of the lungs has declined in recent years there has occurred a marked increase in lung cancer, which has been so notable as to attract the attention of pathologists generally.'"

"In considering the significance of the putatively real increase of the rate at which lung cancer is developing in the population ... individuals reaching the adult cancer ages in current times are, in respect to their constitutional resistance to disease, greatly different from individuals formerly attaining these ages. The marked lowering of death rates in the early ages of life that characterizes the hygiene of the present era has resulted in having in the adult population individuals who in former years would have died in infancy or youth. It is likely that they carry with them a measure of the lower resistance to disease which was the constitutional basis of their former early death."

That statement was made apropos of the subject of smoking and lung cancer. In much of the literature on smoking and lung cancer the impression is easily gained that the increase in reported mortality from lung cancer is a very recent observation, and that smoking is virtually the only explanation that has been advanced for it. The quoted remark of Pearl reflects that an increased incidence of lung cancer was the subject of general comment even before 1929. As to the novelty and uniqueness of the cigarette-smoking theory, it is, in point of fact, Johnny-come-lately. From the time when a significant increase in cancer deaths began to be evidenced in mortality statistics, it was noted that this increase followed, and was probably related to, a decrease of tuberculosis. We find this idea clearly set forth as early as 1902 by Sir T. Cogan³ in a paper read before the Australasian Medical Congress of that year, in which he said:

"I desire now to place before you certain statistics which seem to connect, in some way, the increase of cancer with the decrease of tuberculosis. I have taken out the deaths from cancer and tuberculosis for each year of life during the last 25 years. It will be apparent that the resultant rates in each group have strikingly constant values. ... The question therefore naturally presents itself, whether persons who under the conditions of life and of medical science in 1876 would have fallen a prey to tuberculosis, but did not, have not at a later period provided some of the material from which our cancer rate has been recruited. I believe it is a medical axiom that 'morbid diathesis is necessary for the disease weeds to spread.' Then, may not the morbid condition under which in former years phthisis was produced have supplied the conditions under which cancer might, and does, flourish. In other words, are cancer and tuberculosis to be considered as complementary diseases?"

I hope it will not be concluded from my present letter that I now "hotly" advocate the theory that the increase in deaths from lung cancer which has been noted in mortality statistics is due to the concomitant decrease in deaths from tuberculosis. What I do advocate is that, in considering the theory that smoking causes lung cancer and that this explains the recent rise in its reported incidence, available data and opinion which bear against that theory be considered, as well as evidence which bears in its favour. Elsewhere I⁴ have presented, in some detail, how this principle should be applied also to some published "prospective" studies. What I do oppose—and with considerable warmth—is the issuance of pronouncements, authoritarian and intimidating, that the theory that smoking causes lung cancer is already conclusively established. What has been "proved" by the accumulated statistical data bearing on the problem is not that smoking causes lung cancer, but that it is merited to set up an investigative programme to ascertain, in a manner convincing to the general scientific community, whether smoking does cause lung cancer. Such a programme will necessarily involve many biological specialties and should be of a scope and intensity commensurate with the awesome importance and complexity of the question with which it is concerned. More important, actually, than just the fact of whether smoking can or cannot cause cancer is a knowledge of the physiobiological factors which are involved and how these operate. Only with a gain of such knowledge will scientific understanding of the disease be advanced, and, through this, the possibility of its effective control and amelioration.—I am, etc.,

Rochester, Minnesota.

Prevention of Lung Cancer

SIR,—Dr. A. C. Woodmansey (*Journal*, July 5, p. 46) may be right in calling smoking one of the less important of our psychological problems, but its sequel in lung cancer is an unpleasant way of dying for the patient in the prime of life, and a time of great stress for his wife who has to bear the brunt of the illness, and for the G.P. who has to pay numerous morale-raising visits.

Dr. Woodmansey says, "It is essential to protect young children from fire and other dangers by external means over which ... they have no control." This must continue until they are mature enough "to assess the dangers realistically for themselves." Surely it is at this time that they should be given the unpleasant facts about smoking, clearly and bluntly. But is it necessarily too late to do anything about it after that? While agreeing that deliberately frightening children is undesirable, is this true of adults? Is it not an even greater stress to learn that your husband (or yourself, or your father) has inoperable lung cancer?

Dr. Woodmansey goes on to say, "Perhaps the resistance of some smokers to repeated warnings is due ... to a compulsive need for reassurance that the danger is not after all as serious as the warnings assert," and that "rational therapy demands an understanding of underlying processes and is not achieved by merely trying to abolish symptoms." On this tenuous basis he appears ready to give up any attempt to deal with the problem in adults (and children) who already smoke, and to concentrate on adequate physical and psychological care of children in order to produce healthy adults. This is excellent in theory, but what chance have the children got when so often they see one or both parents smoking, their school teachers smoking, and even their family doctor smoking, not to mention the constant barrage of advertising? Who is going to be responsible for raising these "healthy adults" who presumably do not need the "benefits" of smoking? Surely this is an accepted practice in medicine to treat symptoms until the underlying processes can be got at. Nitrites are withheld just because the underlying cause of atheroma is unknown. In this case smoking may be a symptom like pain, but because of its unpleasant effects it should be removed.—I am, etc.,

London, S.W.12.

D. CONNAN.

Halothane Concentration

SIR,—The ether bottle from a Walton gas machine has wider gas passages and lower flow resistance than the Rowbotham bottle and on this account is more suitable for use in the closed circuit. I described this method using "V.A.M." (1 vol. vinyl ether and 3 vols. ethyl ether) in the *Journal* of August 20, 1949 (p. 436), and in practice still find it giving good results.

It was pleasant to read Dr. C. J. Massey Dawkins drawing attention to the virtues of vinyl ether in the *Journal* (May 10, p. 1116), but halothane has not yet proved itself so safe and the above method is not to be recommended for its administration. Halothane requires accurately controlled dosage, and this is best achieved with reasonable economy by passing a flow rate of two litres per minute through the "fluotec" vaporizer into a leaking closed circuit.—I am, etc.,

Bradford.

C. G. BLAKELEY.

Do Sebaceous Cysts Exist?

SIR,—

May we revive the "Wen"
Now that some clever men
Say the Sebaceous Cyst
Really does not exist?

—I am, etc.,

Epping, Essex.

PELHAM WARREN.

Tetanus Immunization

SIR,—I have recently completed a six-months appointment in the casualty department of a children's hospital where there was an average of one hundred attendances each day. In those cases of injury in which the risk of infection by tetanus bacilli was considered sufficient to warrant prophylaxis, inquiry was made as to whether the child had already been immunized against tetanus, with the intention of giving such children tetanus toxoid. (In those cases where the child was unaccompanied by a parent, the injection was withheld until the parent could be questioned about this.)

In no single case was the answer given that the child had been immunized against tetanus. There would seem to be little doubt that some parents are not aware of what their child has been immunized against.—I am, etc.,

Liverpool, 12.

P. JACKSON.

Unexpected Babies

SIR.—The report from your obstetric correspondent in your medico-legal column (*Journal*, July 5, p. 54) prompts me to record a recent case of interest.

I was called to see a multiparous woman who it was said had had twins. On arrival I learned that the 25-year-old patient had felt the need to go to stool and having gone had become aware for the first time that she was about to deliver a child. On retiring to bed she had with her husband's assistance delivered herself of a 6½ lb. (3 kg.) girl who was very shortly followed by a 5½ lb. (2.5 kg.) boy. The cords had been successfully tied by her husband. All that remained was to await the spontaneous delivery of a large placenta and to repair the lacerated perineum.

The patient had had irregular periods for three years since the birth of a previous child and had thought nothing of her amenorrhoea for four months prior to delivery. She strenuously denied having felt any movements or having noted any increase of girth. She had no pain throughout the confinement. Neither her husband (not unintelligent in these matters, to judge from his efficient conduct of the delivery) nor her neighbours admitted to having any idea of the state of affairs. The patient had had no decided views on having more children but is delighted with her twins, both of whom are thriving three months later.

—I am, etc.,

Bathgate.

DAVID M. MCCURRACH.

Compulsory Crash-helmets

SIR.—Time and again one sees the terrible havoc caused by motor-cycle accidents. Time and again the story is the same—boys and young men brought into hospital with head injuries so severe that it seems impossible that they will ever recover; in fact many do not; and all this very largely because they were not wearing crash-helmets. Surely, Sir, to make a motor-cyclist wear a crash-helmet is no more of an infringement of his personal liberty than it is to make an industrial worker wear protective clothing or to make a ship's passengers do boat-drill.

Looking at the problem from a more practical and possibly rather cynical point of view, the amount of time and money spent on the nursing and rehabilitation of these patients is enormous, and at a time when our Health Service already costs £750m. a year this extra and "unnecessary" expenditure is an outlay we cannot afford. If these young men will not take reasonable precaution to protect themselves of their own accord they must be made to do so by the community. The law would be easy to enforce—one warning and then a summons.—I am, etc.,

Worthing, Sussex.

P. J. G. SIMONS.

London Medical Orchestra

SIR.—I would crave the courtesy of your columns to bring to the notice of the musically minded the London Medical Orchestra, who are anxious to recruit players for the coming season starting in October.

There is something particularly enjoyable in the amateur orchestra, and some great figures in our profession have found it a refreshing distraction; two who come readily to mind were His and Billroth (the friend of Brahms). Moreover, the present President of the College of Physicians is at times observed performing valiantly in our ranks under the proficient conductorship of Dr. Ucko.

With the help of distinguished soloists this orchestra has raised over £400 this year for the Imperial Cancer Research Fund by public concerts, and will continue to help medical charities. Dr. E. V. Slaughter of 6, Oxford Court, London, W.3, would be glad to hear from any who are interested.—I am, etc.,

London, W.1.

A. DICKSON WRIGHT,
President,
London Medical Orchestra.

Obituary

Sir VICTOR HURLEY, K.B.E., C.B., C.M.G.
M.D., M.S., F.R.C.S., F.R.A.C.S.

Sir Victor Hurley, consulting surgeon to the Royal Melbourne Hospital and chairman of the board of the Walter and Eliza Hall Research Institute, died on July 17. He was 70 years of age.

We are indebted to Sir GORDON GORDON-TAYLOR for the following tribute: To-day Australia and especially Melbourne mourn the death of a prominent Australian surgeon. Born in 1888, Sir Victor Hurley had reached the Biblical threescore years and ten and had crowded much into his active life. Educated at Wesley College, Melbourne, and at "Queen's," "Vic" Hurley qualified in 1909 and obtained his M.S. of Melbourne University in 1913. He was a member of a most distinguished year at the university, which included men like the late Sir Alan Newton and Sir William Upjohn: with any reference to the Royal Melbourne Hospital the names of Hurley, Newton, and Upjohn come automatically to one's lips. He was a first-class surgeon in whom all reposed the greatest confidence: he was not of the "daimonic" type, sweeping aside former well-tried methods and promulgating new ones, not the pioneer, but the man whose care of his patient was a sacred trust, even if it involved repeated telephone messages from Melbourne to London over a member of the nursing profession who had been his patient. I met him first in the casualty clearing zone in France in 1917, and subsequently examined him in the anatomy part of the Primary Fellowship examination, along with a particularly able group of young Australians who had remained on in Europe after the 1918 armistice.

"Vic" Hurley was essentially a man of affairs, and from the time of the 1914-18 war, when he became Assistant Director Medical Services, Australian Imperial Forces, his administrative flair placed him in a succession of responsible offices, which included the presidencies of the Royal Australasian College of Surgeons and of the Federal Council of the British Medical Association. During the 1939-45 war he was Director-General of Medical Services of the Royal Australian Air Force and for a time was chairman of the Australian Red Cross Society. He was knighted in 1950, the year in which he was president of the British Commonwealth Medical Conference.

His connexion with the Royal Melbourne Hospital was a long and honourable one, and finally he became its president. Like Hugh Devine, Harold Dew, Henry Newland, and Henry Searby, he was elected an Honorary Fellow of the Association of Surgeons of Great Britain and Ireland. He probably lacked the Roman *gravitas* which so distinguished his friend and contemporary Alan Newton, but he was a man of transparent honesty of purpose, readily approachable, and of extreme courtesy. In the words of Horace, he was *vir tenax propositi*, and with the loyal help of the Chief Censor, Henry Searby, the Royal Australasian College of Surgeons prospered in his term of presidency.

He was married to a charming lady, who survives him, and he leaves four sons and two daughters, some of whom are in the medical profession.

F. M. B. writes: Victor Hurley was one of a famous group of young Australian surgeons who came to prominence in the first world war. My first contact with him was when I was a student in the early 1920's. That was in the Melbourne Hospital, now the Royal Melbourne, an institution with which Hurley's name will always be associated. He saw at first hand every aspect of its activity and development from his student days right up to his period of service as president of the hospital in recent years. Hurley was not only a highly competent surgeon but had a real flair for

administration, and throughout his career he carried administrative responsibilities in a variety of fields with success. His work as head of the R.A.A.F. medical services during the war and his unceasing concern for the progressive development of the new Royal Melbourne Hospital in its relation to the medical school in the post-war years were the most important. My own association with him was closest during the last five years, when he was chairman of the board of the Walter and Eliza Hall Institute. He was not directly interested in research, but he had a full realization of its importance as a leaven to the hospital's direct responsibilities for effective patient care and teaching, with which he was primarily concerned. Under his leadership the board meetings were happy and uneventful. Perhaps that was Victor's greatest gift—of preventing situations from developing. He was an immensely likable person, very good-looking, and retaining a deceptively youthful appearance right up to his last year of partial incapacitation, and with a friendly approach that always seemed to strike the right note. He was a good citizen in every sense of the word, and he was happy in the community's recognition of his work.

A. MEARNS FRASER, M.D., D.P.H.

Dr. A. Mearns Fraser, a former medical officer of health for Portsmouth, a post he held for 38 years, died in the Royal Portsmouth Hospital on July 8. He was 90 years of age.

Born at Reading on January 5, 1868, Andrew Mearns Fraser was educated at the City of London School, where he played in the school XV and was five times champion. From school he went to Edinburgh University, where he graduated M.B., C.M. in 1893, proceeding to the M.D. in 1902. At the University he was lightweight boxing champion. After experience which included that of assistant to Dr. Thresh, county medical officer for Essex, he took the D.P.H. at Cambridge in 1895. In 1896 he was appointed medical officer of health to the Borough of Portsmouth, where he remained until 1934. He acted as secretary to the Section of Public Medicine when the Association held its Annual Meeting at Portsmouth in 1899, and when the Annual Meeting was again held there in 1923 he was appointed president of the Section of Public Health. He was chairman of the Portsmouth Division of the B.M.A. from 1925 to 1927. He was also an active member of the Society of Medical Officers of Health, of which he was Fellow and at one time a member of its council.

T. E. R. writes: When appointed medical officer of health to the Borough of Portsmouth—as it then was—Dr. Fraser was the youngest of 32 doctors who applied for the position. He held office for 38 years, during which period Portsmouth more than doubled in size, the population increased by over 70,000, and in 1926 achieved the status of a city. Soon after his appointment a new era in public health began with the turn of the century, the work of the public health department, which had hitherto been concerned mainly with sanitation and environmental hygiene, was gradually extended to include not only the prevention of disease but those personal health services with which most people are to-day familiar. Fraser quickly became a pioneer in the campaign against tuberculosis, and in June, 1911, there was opened, in a gardener's cottage that happened to be empty in the Victoria Park, the first municipal tuberculosis dispensary in the country. A more permanent building was subsequently provided on an adjoining site, at a contract price of £296, as tuberculosis was then considered "the most effectual remedy for tuberculosis."

In 1912 Fraser was appointed a member of the Departmental Committee on Tuberculosis. Later, in 1925, he was associated with the late Sir John Rowland's scheme to provide treatment for children crippled by tuberculosis and other diseases at the Lord Mayor Treloar Hospital, Alton.

His campaign against venereal diseases is still remembered, mainly because his advocacy of immediate self-disinfection brought him into conflict with those who felt such preventive measures might encourage immorality. At a public conference people who had attended to demonstrate their hostility went away satisfied about the wisdom of the measures which he proposed. His recommendation of a public abattoir was one of the few which were not adopted during his period of office, but this has now come to fulfilment.

Fraser soon pressed for the purification of the city's water supply by filtration, and under a Parliamentary Bill in 1906 the present eight filter-beds on Portsdown Hill at Farlington were constructed, since when the water supply of Portsmouth has been above reproach. On many occasions he issued warnings against eating sewage-polluted shellfish. Nevertheless, 85 persons attending the mayoral banquet in 1922 suffered from illness through eating oysters. Following outbreaks of diarrhoea amongst schoolchildren in 1902 the uncontrolled tipping of refuse was discontinued. Maternity and child welfare services were established, and under slum clearance orders over 1,000 houses were demolished as unfit for habitation. During the whole period while he held office there was no great epidemic of disease, except for the outbreak of influenza in 1918, from which the whole world suffered, causing 713 deaths in Portsmouth. The decline in the death rate from infectious disease during his period of office resulted in a saving of nearly 500 lives a year, a large proportion of these being infants and young children.

Mearns Fraser was a handsome man of great personal charm and courtesy, well liked by his staff and esteemed by all with whom he associated. While he was most meticulous in his work and always expected the best, he was scrupulously fair and ever ready to give help or guidance to those who sought it. Always a keen golfer, he moved on retirement to Hayling Island near the golf course, where he spent much of his leisure. During the war years he was captain of the club and, until a year ago, its president. Carpentry was another of his hobbies, and he made a large number of artistic pieces of furniture. He married, in 1896, Freda Mary, daughter of E. W. Phibbs, and they celebrated their diamond wedding two years ago. They had two daughters.

J. WHITE, B.Sc., M.B., Ch.B., D.M.R.E.

Dr. J. White, consultant radiologist to the Stracathro and Brechin Hospital Group, died suddenly at his home in Edzell on June 1. He was 44 years of age.

James White was born at Aberfeldy on October 29, 1913. He was the son of a schoolmaster who later became rector of Bellshill Academy. He received his education at Hamilton Academy, where he was considered to be one of the finest mathematicians that had passed through the school. He then went to Glasgow University, where he graduated B.Sc. in 1934 and M.B., Ch.B. in 1938. Following a hospital resident post, he became interested in radiology and took the D.M.R.E. of Liverpool University in 1941, and worked in Liverpool Royal Infirmary and in Alder Hey Hospital until 1943. From 1943 to 1946 he worked in Stockport Infirmary and Salford. This was then followed by two years as a specialist in radiology in the Army with the rank of major. 1948 saw him back in Stockport Infirmary, and in 1950, he became consultant radiologist at the City General Hospital, Stoke. In 1956 he became full-time consultant radiologist to the Stracathro and Brechin group of hospitals, and finally made his home in Edzell.

James White was a hard worker and a keen student of his specialty, but he was interested in all other departments. He set himself high standards, and this was reflected both in the films he produced and in his reports. The limited construction of buildings during the war, with the inevitable cramped quarters and overlapping of departments, left a

post-war need for expansion and reconstruction. When Jimmy White arrived this expansion programme began to come on the horizon, and with characteristic zeal he set to, in consultation with others, making plans for a totally new radiological department; and now others will build on his foundations.

Beyond all the material things was his personal interest in his patients. He would go out of his way to explain to them what he intended doing, and would visit them afterwards to ask their reactions. Patients appreciated these things. His death in the prime of life came as a profound shock to us all. He is survived by his widow and two children. His brother, W. F. White, is a consultant orthopaedic surgeon at Law Hospital, Carlisle.—R. L.

C. J. MORGAN, B.Sc., M.B., B.Ch., D.P.M.

Dr. C. J. Morgan, consultant psychiatrist and medical superintendent of Morgannwg Hospital, Bridgend, Glamorgan, died on June 26. He was 43 years of age.

Cyril John Morgan was born at Penyarden, Merthyr Tydfil, Glamorgan, on December 22, 1914. He was educated at Cyfartha Grammar School, Merthyr, and thence he went to the Welsh National School of Medicine, Cardiff, where he graduated M.B., B.Ch. in 1939. He had obtained the B.Sc. with honours in anatomy in 1936. In 1947 he obtained the D.P.M. of University of London. Following qualification, he became R.M.D. at the Pontypool Hospital from June until September, 1947, when he joined the R.A.M.C. on the outbreak of war. After service as a regimental medical officer, he was appointed a psychiatric specialist, and served in this country and in West Africa until he was demobilized in December, 1945. He next joined the staff at Rainhill Hospital, Liverpool, where he became first senior assistant. In addition, he was lecturer in psychiatry to the Liverpool School of Occupational Therapy, and examiner in psychopathology to the Society of Occupational Therapists. In December, 1949, he was appointed deputy medical superintendent to Morgannwg Hospital, Bridgend, and in November, 1954, he became medical superintendent.

Morgan was a truly dynamic personality, and he will ever live in the memory of all who knew him for his innate kindness, his ever-ready help, his seemingly tireless energy, and his infectious enthusiasm. He was a brilliant and stimulating conversationalist, and had an exceedingly wide range of interests. His patients and staff, as well as his colleagues, had a deep and abiding affection for him, and his untimely death at the early age of 43 years is a most tragic loss to Morgannwg Hospital. Our heartfelt sympathy goes out to his widow and three young sons.

ISIDOR C. RUBIN, M.D., F.A.C.S.
Hon.F.R.C.O.G.

The obituary of Dr. Isidor C. Rubin was printed in the *Journal* of July 19 (p. 168).

Dr. BETHEL SOLOMONS writes: Isidor Rubin was indeed a beloved physician. Among his numerous attributes he was an essential humanist and had a delightful sense of humour. In the last 50 years he has been a pioneer investigator in his efforts to improve the lot of childless women, and he never ceased trying out new methods. His *Collected Papers, 1910-1954*, were published during the latter year and these 132 communications will be a lasting monument to his memory. He had resigned from the Mount Sinai Hospital, for which he had done so much, but was still in private practice. His experimental work was his chief joy. He was one of my oldest and dearest friends, and when he entertained me in New York about six weeks ago he seemed to be in splendid health and was as enthusiastic as ever. I know how lucky I was to be with him on this last occasion, for he was leaving two days later for meetings in Mexico and London. He will be sadly missed by his devoted wife and by colleagues and friends in every part of the world.

Medical Notes in Parliament

DOCTORS IN PARKING METER AREAS

Earl HOWE asked in the Lords on July 15 whether, in the rules governing the operation of parking meters in areas where they were installed, the Government intended to make any special regulations to meet the needs of professional men, their clients, or their patients.

Lord MANCROFT, Minister without Portfolio, said that no special provision for professional men, their clients, or patients was proposed by the local authority or included in the only parking meter Order so far made—the Parking Places (Westminster) (No. 1) Order, 1958, which was operating in North-west Mayfair. Any local authority proposing such an Order might include in it such exemptions under Section 21(4) of the Road Traffic Act, 1956, as they wished, but he could not anticipate the Minister of Transport's decisions on such applications.

Earl HOWE asked if Lord Mancroft did not think that in the case of people, perhaps suffering from grave injuries, who were going to see their medical advisers some relaxation of the parking meter regulations should be incorporated in any further Orders made for the same purpose. Lord MANCROFT said that what mattered was what representations were made by the local authorities to the Minister when he had heard all the interests concerned. In the particular case to which he had referred he understood that no representations were made, and on the only other Order before the Minister representations along the lines which Earl Howe suggested had been made. The matter was still under consideration. Earl HOWE said that, in common humanity, something ought to be insisted on by the Minister of Transport in any further Orders which were made on the subject. Lord MANCROFT replied that, if in common humanity the Minister was asked to do so, indeed he would consider it; but in the only case so far put into practice he had not been asked.

Lord DERWENT asked if this meant that it was impossible for the Minister to draw the attention of the local authority to the question and ask them to consider it. Lord MANCROFT said that the local authority principally concerned in the matter—namely, the St. Marylebone Borough Council, in whose area Harley Street was—did not need to have this matter drawn to their attention. They were powerfully aware of it, and they had made representations to the Minister and he was considering them.

Earl HOWE suggested that there were a number of professional men, doctors and others, living in Westminster No. 1 area. Surely the Minister could have taken action on his own account in a case like that. Lord MANCROFT agreed that the Minister could have taken action, but he did not think from the facts before him that it was necessary.

QUESTIONS IN THE COMMONS

Delays in Obtaining Treatment

Mr. W. OWEN (Morpeth, Lab.) asked the Minister of Health on July 14 if he was aware that the payment of a specialist fee by mineworkers in the Ashington area of Northumberland determined the speed of the treatment needed. Mineworkers scheduled for specialist advice, medical treatment, or surgical treatment under the Health Service were subject to unusually long waiting periods. Mr. D. WALKER-SMITH said that he knew the waiting periods for treatment at the Ashington Hospital were sometimes long and the facilities there were to be extended. He was not quite sure what Mr. Owen had in mind regarding specialists' fees: there were no pay beds in this hospital.

Mr. OWEN explained that two brothers had waited for nine weeks for an appointment for diagnosis. One paid a specialist fee of £3 and got an appointment within four days, and the other continued to wait. Mr. WALKER-SMITH said that in view of these allegations Mr. Owen had better

send him the particulars. Mr. F. POPPLEWELL (Newcastle upon Tyne, West, Lab.) said quite a lot of this sort of thing was taking place in the north-east. A miner had been waiting 14 weeks for an operation for double hernia, and was then told he would have to wait another six weeks, but that if he paid three guineas to a specialist he would be taken in at once. Mr. WALKER-SMITH undertook to look at any case sent to him.

Dr. EDITH SUMMERSKILL asked for the Speaker's guidance on the point of privilege. If a Member wrote to the Minister he would have to give the name of the physician and the details. Should he respond to the Minister's request and send the letter, which might mean defaming the consultant? The Speaker said this matter had started with a question in Parliament, of which the Member had given notice. There was no doubt that this question was a proceeding in Parliament.

Poliomyelitis Vaccine for Travellers

Mrs. EIRENE WHITE (Flint, East, Lab.) asked what arrangements were made to supply poliomyelitis vaccine to adults travelling to parts of the world where danger of infection is high. Mr. WALKER-SMITH replied that there were at present no comprehensive arrangements for this under the Health Service, but certain classes of travellers were covered by arrangements made by the Foreign Office, Commonwealth Relations Office, Colonial Office, and the Service Departments.

Mrs. WHITE suggested that something much more specific was required. There had been cases in Pakistan, Indonesia, and elsewhere where British women had gone without protection and had died, sometimes after an illness of only two days. Adequate arrangements should be made to protect people before they went to places where polio was endemic, and these should be publicized to travel agencies. Mr. WALKER-SMITH pointed out that in approaching vaccinations on a priority basis he had acted on the advice of the committee under the chairmanship of Lord Cohen of Birkenhead. He was prepared to take this point to the committee and take their advice on it.

Registrations for Polio Vaccination

Sir LEONARD ROPNER (Barkston Ash, Con.) asked the Minister what was the approximate number of children who had been registered for injections against poliomyelitis since January 1 and June 1, 1958; and what would be the total cost of these inoculations. Mr. WALKER-SMITH told him that information for these periods was not available, but the number of children who were registered between January 1 and April 30, 1958, was approximately 1½ million, and figures for the period May 1 to June 30 would be available shortly. He could not give any precise estimate of cost, including that incurred by the local health authorities, but the cost of the vaccine for two injections each for the 1½ million children was likely to be rather over £500,000.

Out-patient E.C.T.

Dr. DONALD JOHNSON (Carlisle, Con.) asked if the Minister of Health would increase the facilities for the administration of electric convulsion therapy in the out-patient departments of general hospitals. Mr. WALKER-SMITH said that these facilities were being provided by the responsible hospital authorities as their resources permitted.

Dr. JOHNSON asked the Minister to further this type of treatment. There would be an obvious saving of hospital beds if it were successful. On occasion there were complaints from people who suffered from after-effects which they attributed to rather intensive courses of treatment in hospitals—sometimes against their own will—and out-patient treatment would allow them to consult their family doctors from time to time and thus obtain an independent opinion. Mr. WALKER-SMITH said there was an increasing tendency for patients suffering from mental illness to be treated in out-patient departments. The logical corollary was that there should be more facilities for electric convulsion therapy.

Alcohol and Road Accidents

The MINISTER OF HEALTH explained in answer to Mr. SOMERVILLE HASTINGS (Barking, Lab.) and Sir FRANK MEDLICOTT (Norfolk, Central, Ind.) that the Medical Research Council report on the effect of alcohol on driving capacity was being revised by the author on the advice of the scientific panel under whose auspices the research was carried out. The object of the revision was to correct minor errors and simplify the presentation of the statistics. There was every intention of publishing the report. It might be possible to have a preliminary publication of the main findings in a form suitable for scientific journals.

Health Centres

Mr. A. BLENKINSOP (Newcastle upon Tyne, East, Lab.) asked what was the total number of health centres in operation, under construction, and planned respectively; and what action was being taken to encourage their further development. Mr. R. THOMPSON, Parliamentary Secretary, Ministry of Health, informed him that nine health centres established by local health authorities since the appointed day were in operation. Three were under construction, and another would be started this year. Nine other schemes had been proposed, and three at least of these were likely to be started in 1959-60. The Minister was always prepared to consider proposals for more of these centres within the limitations on capital expenditure, but it was right that the initiative should be taken locally.

Registration of Chiropodists

Dr. DONALD JOHNSON asked the Minister when he expected to introduce new legislation with a view to the regularizing of the present position in the chiropody profession; and if he would include in such legislation provisions to safeguard the position of those who had been earning their living as practising chiropodists and could produce satisfactory medical evidence to that effect. Mr. WALKER-SMITH said that the Secretary of State for Scotland and he had recently drawn up a revised scheme for the statutory registration of professions supplementary to medicine, which would require legislation to bring it into effect. It had recently been considered at a conference of all the bodies concerned and they were now considering the views then expressed.

Safety Branch of A.E.A.

Mr. R. MASON (Barnsley, Lab.) asked the Paymaster-General to what extent a safety inspectorate had now been formed to examine periodically and keep under review safety conditions within the atomic power stations and allied establishments; and whether he was satisfied that sufficient emphasis was being placed on this development. Sir I. HOROBIN said he was. The Safety Branch of the Atomic Energy Authority was being strengthened in accordance with the recommendations of the Fleck Committee, and the Government were preparing legislation to implement the policy of licensing and inspection already outlined.

Detergents in Sewage

Mrs. H. SLATER (Stoke-on-Trent, North, Lab.) asked the Minister of Housing and Local Government on July 15 what results there were from his examination of the new washing powder which ceases to foam once it gets into the sewage. Mr. J. R. BEVINS, Parliamentary Secretary, said that the foam problem was being studied by the standing technical committee on synthetic detergents. The committee was aware of recent reports that new materials had been discovered, and, in co-operation with the manufacturers and the Department of Scientific and Industrial Research, was investigating the claims made for these materials. The committee was not yet ready to make a further report. He hoped they would have the report before the end of the year.

Meat Inspection

Sir FRANK MEDLICOTT (Norfolk, Central, Ind.) asked the Minister of Agriculture, Fisheries, and Food on July 17 if he was satisfied with the progress of the efforts to ensure that 100% of the meat passing through slaughterhouses was inspected. Mr. J. B. GODBER, Parliamentary Secretary, stated that the replies to a questionnaire recently issued by the Ministry indicated that local authorities had made considerable progress during the last 18 months, and that as much as 90% of the meat passing through slaughterhouses was now inspected. Local authorities were to be congratulated on this encouraging rate of progress, and the Minister was satisfied that they were doing their best to maintain this progress and to raise the standard of inspection despite the great pressure on inspecting staff in many areas.

Scottish Medical Students

Mr. MALCOLM MACPHERSON (Stirling and Falkirk, Lab.) asked the Secretary of State for Scotland how many medical students in Scotland satisfactorily completed their courses at the recent final examinations; how many of these he estimated were likely to take pre-registration posts in Scottish hospitals; and how far this estimate corresponded to the number of vacancies in such posts. Mr. J. S. MACLAY said he was informed that 354 medical students in Scotland successfully completed their courses at the recent final examinations. No information was available of where these graduates would take their pre-registration training. There were some 600 house-officer posts in Scottish hospitals approved for pre-registration service. There was, however, no direct relationship between this number and the number of recent passes. Some Scottish graduates went to England and abroad for their pre-registration training, and similarly graduates from other countries came to Scottish hospitals; moreover, some of the posts were filled by graduates who qualified earlier.

New Measures at Broadmoor

The MINISTER OF HEALTH announced on July 21 that, although he had not yet received the full report of the Board of Control inquiry into the escape of Frank Mitchell from Broadmoor, he had received a summary of their main findings. They confirmed that the method of escape was as he had said, and they found that the saw used by the patient had been introduced into the institution from outside. He continued that they recommend that: (1) Search of patients after visiting-days should be intensified. (2) There should be no exception to the rule that the siren was to be sounded immediately the escape of a dangerous patient was known. (3) The strength of the night staff on duty in the block from which Mitchell escaped should be increased at once. (4) Alterations to the walls of the institution to increase their security at strategic points should be begun immediately. They had already given instructions for the implementation of these recommendations.

Mr. A. R. HURD (Newbury, Con.) said that local authorities and residents, who had been reasonable and understanding, would welcome these practical measures. He asked the Minister to see that the further suggestions they had made in their petition were fully considered by the Board of Control, and if need be have an independent inquiry. Mr. WALKER-SMITH replied that he would certainly study with sympathy and attention any constructive proposals put forward by the local authorities and residents. He doubted whether an independent inquiry could add anything material.

Psychopathic Patients

Mr. HURD asked how many of the patients at Broadmoor were classified as psychopaths with homicidal tendencies; and if further consideration would now be given to detaining them in an institution inside a prison rather than at Broadmoor, where their presence might be inimical to the cure of the majority of the patients. Mr. WALKER-SMITH replied that a psychopathic state might be associated with

mental illness or mental deficiency, and, as homicidal tendencies might arise from the associated illness, information in the form asked for was not available. The classification and disposal of patients requiring treatment in a State mental institution would be considered in the context of the promised legislation following the report of the Royal Commission. Mr. HURD asked if he would consult the Home Secretary to see whether it would not be better if the 50 or so psychopaths were put in prison where security could be the first consideration. Mr. WALKER-SMITH pointed out that the matter was not susceptible of the neat classification Mr. Hurd seemed to have in mind. He was advised that the right place for patients who had been sent to Broadmoor from prisons was in Broadmoor. Mrs. BRADDOCK (Liverpool, Exchange, Lab.) said that this type of patient was the one giving the Royal Commission the most difficult task of definition. Would it not be better to look at the recommendations of the Royal Commission and put them into operation? Mr. WALKER-SMITH agreed that this problem did cause considerable difficulty to the Royal Commission. He had been carefully studying their recommendations on the psychopathic state, in the light of the observations that had been made.

Polio Vaccination Extended

Mr. WALKER-SMITH also announced on July 21 that, having reviewed the progress that had been made in the existing programme of vaccination against poliomyelitis, the Government considered that the stage would soon be reached when it could be extended. Accordingly, they proposed that eligibility for vaccination should be extended to persons born in the years 1933 to 1942, inclusive, thus raising the upper age limit from 15 to 25; that a wider range of hospital staff and their families should be brought within the programme; and that a start should be made with third injections for persons already vaccinated with two. The Secretary of State for Scotland and he proposed to consult the local authority associations and the British Medical Association on the details of these extensions, and then to issue all necessary information about them to local health authorities, hospital authorities, and general practitioners. They hoped it would be possible for a start to be made on the new vaccinations by the autumn. Persons affected by the extension of the programme should watch for local announcements telling them when and how to apply.

Mr. A. BLENKINSOP (Newcastle upon Tyne, East, Lab.) asked if it was now possible to increase the amount of vaccine in this country. Mr. WALKER-SMITH stated that there were some supplies of British vaccine likely to be forthcoming in the near future, but still not in any great quantity for the time being. It was therefore wise for parents who wanted immediate protection for their children to opt for the available vaccine.

Medical Staffing of Hospitals

Mr. BLENKINSOP asked the Minister of Health what representations he had had from professional and other bodies regarding the composition of the working party on medical staffing of hospitals. Mr. WALKER-SMITH replied that he had had representations from the Medical Practitioners' Union, the Royal Medico-Psychological Association, and the National Council of Women. Mr. BLENKINSOP asked if the Minister was going to pay any attention to the representations that had been made, in view of the real anxiety among the large number of consultants and specialists who did their work in general hospitals that they had no representation at all on this committee, which consisted entirely of men—no doubt eminent—from teaching hospitals. Mr. WALKER-SMITH replied that all the representations he had received dealt with rather different points, and pointed to the omission of desirable membership as they saw it. If effect were to be given to all these suggestions there would be a danger of having a large and unwieldy committee.

The committee could get information from any source it wanted. Mr. BLENKINSOP said it was essential to carry the medical profession in any recommendations the committee made. How could the Minister expect to do that when it represented only one narrow section of the profession? Mr. WALKER-SMITH pointed out that this working party was a joint body, half appointed by the Minister and the other half by the Joint Consultants Committee. He could not go behind the membership they put forward.

Consultants Strength.—At the end of September, 1957, there were 3,192 whole-time consultants and senior hospital medical officers, compared with 3,170 in June, 1956. The part-time numbers were 5,813 and 5,708.

S.E. Metropolitan Hospitals.—Two hundred and thirty beds in mental deficiency units are out of commission in the South-east Metropolitan Region because of shortage of nursing staff.

Orthodontic Treatment.—During 1957 about 56,000 children received orthodontic treatment through the School Dental Service. In about 27,000 of these cases the treatment began in the year.

Medico-Legal

INQUEST QUASHED

INFANT NOT SUFFOCATED

[FROM OUR LEGAL CORRESPONDENT]

Two weeks ago (*Journal*, July 12, p. 111) we printed a note in this column to the effect that when infants are found dead in their cots their death is less often due to suffocation than is generally supposed. A good illustration is to be found in the case of *Ex parte Groome*, decided in the Divisional Court of the Queen's Bench Division on July 15 (*The Times*, July 16).

In that case a 5-months-old girl was found dead in her cot, and at the inquest evidence was given that death was due to suffocation and a verdict of accidental death was recorded. A post-mortem examination was subsequently held and this showed that the cause of death was not suffocation but toxæmia due to respiratory infection. The deputy coroner for Northampton applied to the Divisional Court for an order to quash the inquisition on the ground that the new evidence showed that the verdict was wrong and that the verdict should have been death from natural causes. The Court quashed the inquisition and ordered that a new inquest should be held. The second inquest was held on July 21 and the verdict of death from natural causes was returned (*Manchester Guardian*, July 22).

Procedure for Quashing Coroner's Inquisition

At Common Law the Court of Queen's Bench has always had the power to quash a coroner's inquisition, and its jurisdiction to do so can be brought into play on the application of anyone who is aggrieved by the verdict. The grounds on which the jurisdiction has been exercised vary from technical shortcomings in the verdict to misconduct by the coroner. It is not usual for an inquisition to be quashed on grounds of insufficiency of evidence to support the verdict or misdirection of the jury by the coroner. The Court will, however, quash in cases of evidential defects if it is satisfied that injustice has been done. The procedure is by motion before the Divisional Court supported by affidavit evidence.

In *Ex parte Groome* the verdict of accidental death due to suffocation, when in fact death was due to respiratory infection, could plainly work precisely the injustice envisaged in our recent note on suffocation in infancy. The deputy coroner's application to the Divisional Court gave the opportunity for the wrong to be put right.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending July 5 (No. 27) and corresponding week 1957.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the whole of England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

Scotland in First Quarter

The birth rate for the first quarter of 1958 was 19.7 per 1,000 population and was 1.0 above the average of the five preceding first quarters. The infant mortality rate was 32 per 1,000 registered births, which was the same as in the preceding first quarter. The death rate was 14.6 per 1,000 of the population, being 1.9 higher than in the corresponding quarter of 1957 and 0.4 above the five years' average.

Deaths attributed to the principal epidemic diseases numbered 89 and included 79 from influenza, 7 from meningococcal infections, and 3 from whooping-cough. There were 219 deaths from respiratory tuberculosis and 10 from other forms; these deaths were, respectively, 16 more and 5 fewer than in the first quarter of 1957. Deaths from violence numbered 746 and were 52 more than in the preceding first quarter. 159 of these deaths were due to road transport accidents compared with 103 in the first quarter of 1957.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1949-57 are shown thus -----, the figures for 1958 thus ———. Except for the curves showing notifications in 1958, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Week Ending July 12

The largest falls in the numbers of notifications of infectious diseases in England and Wales during the week ending July 12 were 179 for dysentery, from 919 to 740, and 115 for food-poisoning, from 342 to 227; the only large rise was 640 for measles, from 6,438 to 7,078.

The largest rises in the incidence of measles were 135 in Derbyshire, from 152 to 287 (Ripley U.D. 109, Derby C.B. 80), 111 in Sussex, from 162 to 273 (Littlehampton U.D. 87), and 110 in Staffordshire, from 137 to 247 (Walsall C.B. 81); the largest falls were 77 in Cornwall, from 226 to 149, and 73 in Somersetshire, from 210 to 137. 625 cases of scarlet fever were notified, being a decrease of 38 compared with the preceding week; there were no large fluctuations in the local returns. The notifications of whooping-cough, 816, were 4 fewer than in the preceding week, and the largest fluctuation in the local returns was a rise of 29 in Sussex, from 42 to 71. No case of diphtheria was notified; in the preceding week there were 3.

Of the 18 cases of typhoid fever 7 were notified in Dorsetshire, Melcombe Regis M.B., and 6 in Wiltshire, Warminster U.D.

The notifications of acute poliomyelitis numbered 59, and these were 5 more for paralytic and 6 more for non-paralytic cases than in the preceding week. The largest returns were Yorkshire West Riding 22 (Bradford C.B. 4, Leeds C.B. 3, Selby U.D. 3, Huddersfield C.B. 2, Moseley M.B. 2, Pontefract M.B. 2), London 4 (Kensington 2), Essex 4 (Rochford R.D. 3), Warwickshire 4 (Birmingham C.B. 4).

The largest centres of dysentery were Yorkshire West Riding 155 (Bradford C.B. 26, Leeds C.B. 20, Barnsley C.B.

19, Sheffield C.B. 18, Thorne R.D. 12, York C.B. 11), Lancashire 143 (Liverpool C.B. 34, Manchester C.B. 29), London 91 (Bermondsey 29, Islington 10), Durham 35 (Darlington C.B. 9), Staffordshire 34 (Rugeley U.D. 13), Warwickshire 33 (Birmingham C.B. 18), Middlesex 30, Surrey 22, Yorkshire North Riding 22 (Middlesbrough C.B. 21), Gloucestershire 20 (Bristol C.B. 19), and Hampshire 20.

Medical News

International Federation of Surgical Colleges.—The Federation was formally inaugurated in Stockholm on July 4. It is representative of surgical colleges, academies, and surgical institutions throughout the world, but not of individual persons. The foremost of its stated objects are: (1) The establishment and maintenance of close relations among approved surgical colleges and kindred institutions; and (2) encouragement of the maintenance of high standards of education, training, and research in surgery and its allied sciences. At the meeting in Stockholm Sir HARRY PLATT was elected president for the ensuing three years, and Dr. I. S. RAVDIN (U.S.A.) and Dr. E. DAHL-IVERSEN (Denmark) were elected vice-presidents. The executive committee in the first instance will consist of representatives from Holland, France, Sweden, Norway, Belgium, and Australasia, in addition to the president and vice-presidents. The member institutions are as follows: Academy of Surgery of Paris, American College of Surgeons, Belgian Surgical Society, College of Physicians, Surgeons, and Gynaecologists of South Africa, Danish College of University Surgeons, Dutch Association of Surgeons, Italian Surgical Society, Norwegian Surgical Association, Royal Australasian College of Surgeons, Royal College of Physicians and Surgeons of Canada, Royal College of Surgeons of Edinburgh, Royal College of Surgeons of England, Royal College of Surgeons in Ireland, Royal Faculty of Physicians and Surgeons of Glasgow, and the Swedish Surgical Society. The secretary of the Federation is Mr. KENNEDY CASSELS, of the Royal College of Surgeons of England.

Polio Vaccination.—The following information on the vaccination state against poliomyelitis in Great Britain, as at June 30, was released by the Ministry of Health this week: (1) Total registered all groups, 6,570,157 (children up to 15 years, 5,613,602); (2) total vaccinated with two doses, 4,481,937 (children, 4,396,382); (3) total vaccinated with one dose, 856,388 (children, 813,569); (4) awaiting vaccination, 1,231,932 (children, 1,217,220); (5) number of doses needed to complete registrations at June 30, 3,320,252; (6) number of doses held by local authorities at June 30, 3,766,651; (7) number of doses distributed since June 30, 500,000; (8) the registration rate for children under 15 June 30 was 53.6% (England and Wales 53.3%; Scotland 55.6%); (9) registration by persons in the existing priority groups are still being made; (10) estimated numbers in new groups: age 15-24, 6,250,000; hospital staffs and families, 500,000; (11) those eligible up to March 31, 1959, for a third injection may total 6,500,000; (12) it is proposed to ask local health authorities to make, so far as is practicable, an early offer of third injections to children who were vaccinated in 1956, about 200,000; (13) it is proposed that third injections should generally be offered not less than seven months after the second; (14) total number of doses of vaccine issued from May, 1956, up to July 20, 1958: British, 5,258,568; Salk, 10,452,417; totals, 15,710,985; (15) in-cluded in the total of Salk vaccine are 5,637,717 doses tested and licensed for use in America but not further tested by the Medical Research Council.

Ciba Laboratories Ltd.—On July 16 the MINISTER OF HEALTH, Mr. DEREK WALKER-SMITH, opened an extension to Ciba Laboratories' pharmaceutical factory at Horsham in Sussex. As part of the proceedings the Minister inaugurated production of a new drug against leprosy, Ciba 1905 (4-butoxy-4'-dimethylaminodiphenyl thiourea), which has been undergoing clinical trials for the last 3½ years, mainly in Nigeria. At the subsequent luncheon Sir ARTHUR VERE HARVEY, chairman of the Company, announced the setting up of a new Trust Fund, to be known as the Ciba Fellowship Trust. Its object is to help graduates and undergraduates from the United Kingdom and Eire to continue their scientific studies at Continental centres. The Trust will provide for 10-12 fellowships a year in chemistry, physics, or an allied subject, starting next year. The trustees are LORD HIVES, C.H., the former chairman of Rolls Royce, Ltd., Sir ALEXANDER TODD, F.R.S., and Sir ARTHUR VERE HARVEY. Congratulating the company on the extensive and protracted clinical trials to which their new product had been subjected, Mr. WALKER-SMITH said: "In my view, this sort of approach is the essence of reputable pharmaceutical endeavour." In reply, Mr. PHILIP MAIR, the managing director, said that Ciba spent nearly £3m. last year on research towards the discovery of new drugs, twice what they were spending seven years ago.

Chair of Medicine at Edinburgh.—Dr. K. W. DONALD, reader in medicine at Birmingham University, is to succeed Sir STANLEY DAVIDSON when he retires from the chair of medicine at Edinburgh University on March 31. Dr. Donald was educated at Cambridge and St. Bartholomew's Hospital, qualifying in medicine in 1936. After graduating M.B., B.Chir. (Cambridge) in 1938 he obtained the M.D. in 1945 and the D.Sc. (Birmingham) in 1954. He was admitted M.R.C.P. in 1946 and elected F.R.C.P. in 1952. During the second world war he served with the Royal Navy as senior medical officer to the Second Destroyer Flotilla, winning the D.S.C. at Narvik. In 1942 he was transferred to the Admiralty experimental diving unit which co-operated with the Medical Research Council's Royal Naval Personnel Research Committee in studies of under-water physiology. After the war Dr. Donald returned to St. Bartholomew's Hospital, where he was chief assistant on the professorial unit, and in 1948 he went with a Rockefeller fellowship to the United States. His next appointment was as senior lecturer at the Institute of Diseases of the Chest, London. In 1950 he became reader in medicine at Birmingham, and in 1954 was given the title of first assistant in the department of medicine there. Dr. Donald's publications have been on cardio-respiratory function, caisson disease, and resuscitation of the drowned and asphyxiated; a number of his papers have appeared in this Journal.

Peckham Diagnostic Centre.—Brigadier H. L. GLYN HUGHES, formerly senior administrative medical officer of the S.E. Metropolitan Board, has been appointed director of the proposed diagnostic medical centre at the Queen's Road Centre, Peckham. The diagnostic centre, besides being used for teaching general practice to senior students, will provide local general practitioners with facilities for radiological and pathological examinations, physiotherapy, minor operations, etc. The Nuffield Foundation is making a grant of £12,000 towards the capital cost of adapting the accommodation (estimated at £16,500), the S.E. Metropolitan Board is providing some staff and equipment, and the London County Council will meet the running costs—about £6,250 a year.

School for Educationally Subnormal.—On July 12 Dr. L. T. HILLIARD, physician superintendent of the Fountain Hospital, opened the London County Council's Rose Cottage School, Woolwich. This is stated to be only the second new school for educationally subnormal children to be built in London since the second world war. It is a day school for 150 boys and girls aged 5 to 16 years. Pupils are drawn from south-east London and north-west Kent, transport where necessary being provided by local education authorities. A speech therapist attends regularly. The school is in Welton Road, London, S.E.18, and the nearest station is Welling Station.

Royal Society of Medicine.—At a general meeting of fellows held on July 15 the following were elected honorary fellows of the Society: Mr. L. R. Broster, Dr. M. G. Candau, Professor William B. Castle, Professor Andre F.

At the subsequent luncheon Sir ARTHUR VERE HARVEY, chairman of the Company, announced the setting up of a new Trust Fund, to be known as the Ciba Fellowship Trust. Its object is to help graduates and undergraduates from the United Kingdom and Eire to continue their scientific studies at Continental centres. The Trust will provide for 10-12 fellowships a year in chemistry, physics, or an allied subject, starting next year. The trustees are LORD HIVES, C.H., the former chairman of Rolls Royce, Ltd., Sir ALEXANDER TODD, F.R.S., and Sir ARTHUR VERE HARVEY. Congratulating the company on the extensive and protracted clinical trials to which their new product had been subjected, Mr. WALKER-SMITH said: "In my view, this sort of approach is the essence of reputable pharmaceutical endeavour." In reply, Mr. PHILIP MAIR, the managing director, said that Ciba spent nearly £3m. last year on research towards the discovery of new drugs, twice what they were spending seven years ago.

Cournand, Professor D. Denny-Brown, Professor F. de G. d'Allaines, Professor Herwig Hamperl, Professor G. Miescher, Professor Newell Philpott, Professor Georges Portmann, and Dr. F. Parkes Weber.

Faculty of Ophthalmologists.—At the council meeting on July 11, the following were elected officers for 1958-9: *President*, Mr. L. H. SAVIN; *vice-presidents*, Mr. E. G. MACKIE and Professor G. I. SCOTT; *hon. treasurer*, Mr. A. MCKIE REID; and *hon. secretary*, Mr. E. F. KING.

Royal College of Surgeons of Edinburgh.—At a meeting of the College on July 15 the honorary fellowship was conferred on Dr. WARREN H. COLE, professor of surgery at Illinois University, and on Dr. I. S. RAYDIN, Barton professor of surgery at Pennsylvania University. The following were admitted F.R.C.S.Ed.:

S. M. S. Ashraf, D. W. Blair, R. C. Buchanan, P. Burgess, B. N. Chatterjee, M. C. Chenoy, J. S. G. Clark, J. T. F. de Graft-Johnson, E. J. England, D. S. Grewal, W. F. Hasan, G. Kerr, G. C. Liggins, J. McLennan, P. S. Mathur, G. Muttuhamy, K. N. Nambudripad, K. J. O'Connor, S. L. Paton, G. R. A. Raad, E. F. Reye, M. C. R. Solling, J. W. W. Thomson, M. A. T. Tolley, M. P. Trivedi, D. D. Verma, R. E. D. Williams, J. S. Winter, and N. K. Yong.

Public Welfare Foundation Prize.—The College of General Practitioners is awarding this year six prizes of £40 each to senior medical students in the United Kingdom and Eire for the best case history, with suitable commentary, of one or more patients seen in general practice. Further information about the competition may be obtained from deans of medical schools, to whom details have been sent, or from the College of General Practitioners, 41, Cadogan Gardens, London, S.W.3. The closing date for entries is August 1.

Purchase Tax on Crash-helmets.—The Finance Bill has been amended so as to make helmets designed to protect the head from injury not chargeable under Group 3 (Headgear) of the Purchase Tax Schedule as from July 17. This relief applies to protective helmets fitted with an inner cradle (e.g., crash-helmets and firemen's helmets), and also to other kinds of protective helmets (e.g., for policemen). It does not extend to specially reinforced headgear other than helmets (e.g., huntsmen's bowlers); nor does it cover helmets suitable for use only in sports.

Procedure in Criminal Courts.—Dr. T. C. N. GIBBENS, senior lecturer in forensic psychiatry at the Institute of Psychiatry, is the sole medical member of the interdepartmental committee, under Mr. Justice STREATFIELD'S chairmanship, recently appointed by the Home Secretary to review the business of the criminal courts. One of the committee's tasks will be to advise on existing arrangements for providing the courts with the information necessary to enable them to select the most appropriate treatment for offenders.

London University.—The title of emeritus professor of physiology has been conferred on Professor K. J. FRANKLIN, F.R.S., on his retirement from the chair of physiology at St. Bartholomew's Hospital Medical College. The title of professor of pharmacology and therapeutics has been conferred on Dr. R. S. STACEY in respect of his post at St. Thomas's Hospital Medical School, and the title of professor of pharmacology on Dr. ELEANOR ZAIMIS in respect of her post at the Royal Free School of Medicine.

Leeds University.—Mr. F. W. SHEA has been appointed tutor in orthopaedic surgery for an initial period starting on August 16.

N.W. Metropolitan Board.—Dr. F. J. FOWLER is to succeed Dr. H. M. C. MACAULAY as senior administrative medical officer. Dr. Macaulay retires on July 31.

Queen's Commendation.—Dr. N. J. JACKSON, of the Minehead and West Somerset Hospital, has received the Queen's Commendation for Brave Conduct for services when a youth fell down a cliff.

COMING EVENTS

Rheumatic Fever and Rheumatic Heart Disease.—Symposia for 30 consultant physicians, September 22-25 at the Postgraduate Medical School and the Canadian Memorial Hospital, Taplow. The fee is four guineas. Further details are given at p. 46 of the advertisements.

Société Française d'Otorhinolaryngologie.—Annual congress in Paris, October 20-23. Main subjects will be cancer of the tongue, and cortisone and corticotrophin. Details from the secretary-general, 6, Avenue MacMahon, Paris.

American Public Health Association.—36th annual meeting, October 27-31, in St. Louis. Details from the association, 1790, Broadway, New York, 19, N.Y.

Artificial Limbs and Appliances Centre, Roehampton.—Courses for orthopaedic consultants from October 13 to 17, and for physical medicine consultants October 29 and 30. Details from the Centre, Roehampton House, London, S.W.15.

NEW ISSUES

SPECIALIST JOURNALS AND ABSTRACTS

British Heart Journal.—Issued quarterly (£3 annually). The new issue, Vol. 20, No. 3, includes:

HEART: 1909-1958. LOUIS GALLAVARDIN. HAEMODYNAMIC CONSEQUENCES OF CORONARY HEART DISEASE. Othar Muller and Karl Rorvik. THE DIAGNOSTIC USE OF AN EAR OXIMETER IN CONGENITAL HEART DISEASE. C. R. Woolf, W. Paul, and R. W. Gunton. THE DIAGNOSIS OF MITRAL INCOMPETENCE FROM LEFT ATRIAL PRESSURE CURVES. Bertrand G. Wells. CLINICAL AND RADIOLOGICAL ASPECTS OF CALCIFICATION OF THE MITRAL RING. Eino Linko and Erkki Sysimetsä. ATRIAL DISSOCIATION. Mario Gomes Marques. DIRECT LEFT ATRIAL PRESSURE TRACINGS AND THE DEGREE OF MITRAL OBSTRUCTION. Stanley R. McCampbell. EVIDENCE FOR PULMONARY VASOCONSTRICTION IN MAN. Richard Gorlin, Frank B. Clare, and Joseph J. Zuska. A SURGICAL STUDY OF COARCTATION OF THE AORTA. Rowan Nick. ELECTROCARDIOGRAMS WITH SHORT P-R INTERVAL AND ABERRANT QRS COMPLEX. L. M. Santhvi and S. N. Misra. VENTRICULAR SEPTAL DEFECT WITH PULMONARY STENOSIS AND AORTIC REGURGITATION. D. M. Collins, T. East, M. P. Godfrey, P. Harris, and S. Oram. THE AORTIC SYSTOLIC MURMUR DEVELOPING WITH INCREASING AGE. D. L. Bruns and L. G. Van Der Hauwaert. VENTRICULAR SEPTAL DEFECT WITH PULMONARY STENOSIS. L. Brotmischer and Maurice Campbell. THE ROLE OF VENOUS CONSTRICTION IN CIRCULATORY DISORDERS. János P. Radó, Endre Gonda, and Erwin Kovács. PULMONARY FUNCTION IN PULMONARY HYPERTENSION. M. B. McIlroy and G. H. Adgey. THE RIGHT VENTRICLE AND THE SMALL PULMONARY ARTERIES IN COAL-WORKERS. Arthur J. Thomas and W. R. L. James. CORONARY ARTERY CATHETERIZATION DURING THORACIC AORTOGRAPHY. A. M. Johnson and William D. Logan. THE ELECTROCARDIOGRAM IN PROGRESSIVE MUSCULAR DYSTROPHY. G. W. Manning and G. J. Clodd. CASE REPORTS: PATENT DUCTUS ARTERIOSUS WITH VENTRICULAR SEPTAL DEFECT. G. L. Higgins. PATENT DUCTUS ARTERIOSUS WITH MITRAL STENOSIS. J. Mackinnon and R. M. Briggs. INCOMPLETE RUPTURE OF THE ASCENDING AORTA WITH SECONDARY ANEURYSM. John Wedgewood. INCOMPLETE CONGENITAL BICUSPID RIGHT ATRIO-VENTRICULAR VALVE. N. Coulshed.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Persey.—On July 11, 1958, to Mrs. Joyce and Alex. Persey, of Nottingham Road, Long Eaton, a sister for Nicola—Janet Celia Sinclair. —On May 23, 1958, at Zomba, Nsaland, to Mrs. Olive and Wilfred Sinclair, a son—Richard William Fleming. **Wolffson.**—On July 1, 1958, at Dudley Road Hospital, Birmingham, to Nancy, wife of L. J. Wolffson, F.F.A.R.C.S., a daughter.

DEATHS

Brathwaite.—On July 5, 1958, at his home, Daisy Bank, Woolfold, Bury, Lancs., Percy Frank Brathwaite, M.B., aged 81. **Chitty.**—On July 9, 1958, at his home, Eastcote, Chaddesley Corbett, near Kidderminster, Worcs., Keith Chitty, F.R.C.S., aged 38. **Fraser.**—On July 8, 1958, as the result of an accident, Andrew Mearns Fraser, M.D., D.P.H., of Curra, Hayling Island, Hants, aged 90. **Murley.**—On July 6, 1958, David Ronald Murley, M.R.C.S., L.R.C.P., D.R.C.O.G., of Mullion, Cornwall, aged 35. **Sharpe.**—On July 9, 1958, Edward Stevenson Sharpe, M.B., Ch.B., of 227, Shipley Road, Shipley, Yorks, aged 79. **Wishart.**—On July 18, 1958, George Macleat Wishart, M.D., F.R.E.P.S., of Glasgow, aged 62.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Analgesics for Incurable Carcinoma

Q.—What combinations of analgesic drugs have been found to be most useful in the relief of pain in cases of incurable carcinoma?

A.—A combination of morphine 15 mg. (gr. $\frac{1}{2}$) with chlorpromazine (25 mg.) is often very valuable. The latter, besides alleviating any nauseating effect produced by morphine, also potentiates its sedative action. The following prescription is often remarkably effective in relieving pain and raising the morale: morphine, 15 mg. (gr. $\frac{1}{2}$); cocaine hydrochloride, 10 mg. (gr. $\frac{1}{4}$); sodium phenobarbitone, 30 mg. (gr. $\frac{1}{2}$); gin, 16 ml.

"Sarkomycin"

Q.—What is sarkomycin?

A.—Sarkomycin is one of several extracts made from *Streptomyces erythromyces* that have antibacterial properties and are also active against certain experimental tumours. Umezawa *et al.*¹ reported temporary regressions in cases of carcinoma of the stomach, thyroid, and oesophagus. Magill *et al.*² at the Sloan Kettering Institute, New York, tested sarkomycin in 26 patients suffering from advanced malignant disease. They gave the maximum tolerated dose in every case. Anorexia, nausea, and vomiting were severe and all patients complained of pain at the injection site. Sarkomycin was given intravenously, and spasm of the vein and thrombosis or thrombophlebitis were common. Five patients showed minor subjective improvement difficult to assess, but in no instance was objective benefit recorded. The series was small and the disease extensive in all cases, but in view of the severity of the side-effects and the poor therapeutic results sarkomycin does not seem a promising agent in the treatment of malignant disease.

Hooper *et al.*³ attempted to purify sarkomycin. They obtained samples of which the active biological constituent was 2-methylene-3-oxo-cyclopentane carboxylic acid. This substance was antibacterial and also inhibited the growth of the Ehrlich ascites tumour in mice. The reduced form of the compound lacked antibacterial activity, but retained its action against the tumour. The purified samples were considerably more active in experimental conditions than the preparations that had been used in clinical trials. The pure substance does not yet appear to have been tested clinically.

Barrier Creams

Q.—What is the best barrier cream against chemicals such as phenylbenzolate, benzoylchloride, and various aldehydes used in scent-making, particularly one which would be proof against the various aldehydes?

A.—This is a difficult question. There are two main types of barriers, one water-soluble and the other water-repellent, and it is among the various examples of the former type that one might be found to give some protection against the risk of dermatitis principally from organic solvents and aldehydes. However, in the work indicated—which does carry a risk of dermatitis—it would be

better to rely on minimum (or no) skin contact than to pin any great faith on any barrier, however cunningly compounded. Careful washing after work combined with the principle of minimum contact is the best safeguard, and in addition the use after work of a skin-conditioning cream will probably prove effective for all but the especially susceptible worker. Ideally, medical supervision should be added to fit the cloak of protection.

Carpal Tunnel Syndrome

Q.—Is hydrocortisone injection advised for the carpal tunnel syndrome?

A.—Injection of hydrocortisone for the carpal tunnel syndrome is not advised. The results of operative treatment are so good, and the operation itself so trivial, that conservative treatment is probably never in the patient's best interests. It is difficult to see what hydrocortisone could do to relieve compression of the median nerve in the carpal tunnel, and the indiscriminate and unscientific use of hydrocortisone in conditions for which it is clearly not indicated is to be deplored.

Hepatitis and Plasma Transfusion

Q.—What is the average incidence of hepatitis due to the icterogenic virus following the intravenous administration of plasma? Why is human serum albumin not used more in Britain?

A.—The incidence of hepatitis attributed to the transfusion of plasma has usually been based upon the occurrence of jaundice in the recipients 40 to 50, occasionally 200, days after transfusion. The incidence can be ascertained with reasonable accuracy only by follow-up surveys of recipients six months after transfusion; however, it is often difficult or impossible to decide whether the disease is to be attributed to other parenteral injections or to infection with the virus of infectious hepatitis. The association of several cases of jaundice with one batch of plasma may assist in making the decision.

Since 1945 all the plasma made for distribution in England and Wales has been dried small-pool plasma, which is prepared from not more than ten donations of blood; each pool yields four to five bottles of dried plasma, so that a pool cannot be given to more than this number of individuals and will very often be given to a smaller number or to only one individual. It is frequently, therefore, impossible to investigate more than a few patients associated with any given batch; the differentiation between homologous serum jaundice and hepatitis due to other causes is thus rendered more difficult. Most patients also receive, in addition to plasma, whole blood which may itself transmit the causative agent. In the most recent survey¹ the incidence of jaundice after transfusion of dried small-pool plasma with or without blood was found to be little different from that after whole blood alone—slightly less than 2 per 1,000 patients followed up.

Human albumin was first made in the U.S.A. during the second world war for the United States Navy for the treatment of casualties suffering from wound shock, because it could be prepared as a concentrated solution and its containers therefore occupied relatively less space than an equal number of bottles of plasma or dried serum. While it could be used with good results instead of plasma for the restoration of plasma volume, it was found desirable to give fluids such as glucose-saline simultaneously, especially in the presence of dehydration. It was first prepared in Britain after the war.² Its preparation is expensive, and about 60-70% of the theoretical yield is obtained. The expectation that albumin would be of especial value in the treatment of nephrosis has not been fulfilled. Its value in treatment of cirrhosis of the liver is still being investigated.

Brucella Abortus in Milk

Q.—What should be done when samples of tuberculin-tested, unpasteurized milk are found to contain *Brucella abortus*?

A.—There is no obligation on local authorities to take any action when milk is shown to contain *Br. abortus*, although they are obliged to do so if the organism found is *Br. melitensis*: the usual course in that uncommon event is to prohibit marketing of the milk pending further investigation.

A proceeding which safeguards the consumer, and should involve no hardship to producer or retailer, is to require that milk from the infected source be pasteurized. Investigations can then be made to trace the exact source of the infection. The "ring" test, an extremely simple test for *Brucella* agglutinin in milk, will serve to identify first the herd and then the individual animal(s) responsible. Final results may be verified by the whey agglutination test and culture or guinea-pig inoculation. If only one or two animals are affected, and the herd is a good one and well protected against reinfection, the elimination of these animals is in the farmer's interests as well as in those of the public health.

Resistance to Insecticides

Q.—What is the difference between a mosquito's "tolerance" and "resistance" to an insecticide? How can mosquitoes be controlled if they develop tolerance or resistance?

A.—There is no universally accepted terminology for resistance to insecticides, but certain facts are generally agreed. As is the case with other insects, some kinds of mosquito in their natural state are found to be more difficult to kill with insecticides than others; so that one can say that one species is more susceptible and another more tolerant. There is evidence that natural tolerance can be augmented, to some degree, by breeding from the strongest individuals; this produces a race showing "vigour tolerance" towards all kinds of poison.

The word "resistance" is now usually employed to describe a rather high degree of specific immunity to a particular type of insecticide. In several instances it has been shown to be due to a single gene, inherited in a normal Mendelian way. Whereas vigour tolerance can often be overcome by increased dosage, true physiological resistance generally protects the insect from poisons of a particular kind, so that an entirely new sort of insecticide must be employed. Thus, D.D.T.-resistance generally involves resistance to similar compounds, such as methoxychlor, etc. B.H.C.-resistance protects insects from chlordane, dieldrin, and other cyclodiene insecticides. A third type of resistance, to the organo-phosphorus compounds, is less well understood, but appears to involve a number of insecticides of this kind. Apart from changing to a different class of insecticide, there is nothing that can be done about resistance at present other than to revert to control methods in vogue before the introduction of the new synthetic insecticides.

Treatment for Roundworms

Q.—What is the most effective treatment for roundworms?

A.—In eradicating roundworm infections there is little to choose between hexylresorcinol and piperazine adipate or hydrate. Both are administered in a single dose, but hexylresorcinol must be given in a cachet, otherwise it would cause irritation of the buccal mucous membrane. It is therefore unsuitable for administration to children who are too young to swallow a cachet. It is also important that the cachet should be made of rice paper or other readily dissolved medium, for the drug would not otherwise be liberated until it had possibly passed so far down the

intestine that it had passed some of the worms and was therefore unable to act upon them. Piperazine salts are more expensive than hexylresorcinol. The adipate is dispensed in tablets and is therefore suitable for administration to adults; piperazine hydrate is dispensed in the form of an elixir and is therefore a convenient preparation for administration to children.

Tetrachlorethylene is also effective against roundworms, but stimulates them to considerable activity, and in heavy infections damage and possibly even perforation of the intestinal wall could occur.

Dosages suitable for the treatment of adults suffering from roundworm infections are hexylresorcinol 1 g.; piperazine adipate 25 mg. per kg. and piperazine hydrate 50–75 mg. per kg. of the patient's body weight; and tetrachlorethylene 4 ml. emulsified in mucilage. All are given in the morning, the patient having had nothing to eat since approximately 4 p.m. on the previous day. One hour after the administration of the anthelmintic a saline purge should be given.

NOTES AND COMMENTS

Thin and Greasy Hair.—Dr. AGNES SAVILL (London, W.1) writes: For the treatment of early baldness in young men ("Any Questions?" June 7, p. 1365), rubbing and massage must be clearly distinguished. Correct massage does not involve "friction between the fingers, the hair, and the scalp" ("Notes and Comments," July 5, p. 62). For correct massage the tissues over the skull must be lifted and given rapid vibration. In my book¹ I give records of successful cases. On page 91 the method of correct massage and vibration is described. The treatment must be followed every day for 15–20 minutes. A downy regrowth results, but falls again when treatment is arrested. Naturally, few have the perseverance to continue this treatment for long periods. Supplementary treatment at intervals with ultra-violet light and a small high-frequency glass electrode also promotes a downy regrowth. Many years ago this was so promising that my patients believed the problem had been solved, but in the majority of cases the down again fell away.

REFERENCE

¹ Savill, A., *The Hair and Scalp*, 1952. London.

Corrections.—In our report of Dr. N. W. HORNE's remarks at the meeting of the Section of Thoracic Medicine and Surgery at Birmingham (July 19, p. 154), the word "helpful" in the third line should have been "harmful," and "renal" in the last line should have been "adrenal."

In the report of Dr. GWEN HILTON's contribution to the Seventh International Cancer Congress (*Journal*, July 19, p. 161) it was stated that, of 38 patients treated by radical radiotherapy alone, 8 had lived for 15 years without recurrence. This should have been 5 years, not 15 years.

Collected Articles from the "British Medical Journal"

The following books are available through booksellers or from the Publishing Manager, B.M.A. House. Prices, which include postage, are now the same for both inland and overseas.

Emergencies in General Practice (26s. 9d.).

Refresher Course for General Practitioners, Volumes 2 and 3 (26s. 9d.).

Clinical Pathology in General Practice (22s. 3d.).

DEPRESSIVE STATES: THEIR AETIOLOGY AND TREATMENT*

BY

GERALD GARMANY, M.B., B.Sc., F.R.C.P., D.P.M.

From the Psychiatric Department of Westminster Hospital

Depression is a large subject, and the purpose of this paper is to discuss merely a few aspects of it. Some years ago a front page to the out-patient notes of psychiatric patients attending Westminster Hospital was devised which was intended to give the essential facts of the case when the patient came up on subsequent occasions. It was envisaged, of course, that the data collected might be examined, for the hospital is fortunate in having a records officer and a Powers-Samas machine; but no particular piece of research was in mind at the time. These points are mentioned since it is relevant to notice that the original observations were made without any motive save of a very general kind, and the results, being computed by a machine, should be free from the unconscious distortion that can sometimes mar such retrospective studies. Data of this kind could be produced for any psychiatric syndrome, and a study of anxiety states on somewhat similar lines has already been published (Garmany, 1956).

A group of 525 consecutive cases has been chosen, comprising depressive states of all kinds. In each of these an effect of sadness would be both dominant and primary, and the series should not include, for example, anxiety states with depressive features or schizophrenia presenting with depression. At the time each patient was seen the depressive was classified as endogenous, reactive, or involutional, and this classification is preserved in the data which follow. In considering, as we must, how the vast distinction was made, it may be noted that the majority of the assessments were made by me. It is not suggested that this fact confers upon them any quality save a relative uniformity of approach.

Classification of Depression

Endogenous depression, as its name suggests, is a depression coming from within, which means much the same as idiopathic and essential in other contexts—namely, that we do not know why it happens at all. Coming without apparent cause, it usually runs a self-limited course of six to nine months, and this period can be greatly shortened in the large majority of cases by electroplexy. The family history is often positive, and there is some correlation between the tendency to develop this form of depression and the possession of a pyknic habitus, of which the familiar picture of John Bull is a typical example. The well-known work of Kretschmer in this context has not been an unmixed blessing to psychiatrists, many of whom have a strong

resistance to the recognition of endogenous depression in those of asthenic habitus. Sometimes these patients are suspected quite unjustly of concealing important psychopathological data, or, alternatively, much time may be spent in working on material which is present but irrelevant.

In making a diagnosis of endogenous depression I have been influenced by many factors. An absence of precipitating causes is clearly *prima facie* it is implicit in the definition of the disease. A history of periodic attacks with recovery in between, either in the patient or in members of his family, is important. Equally so is the presence of a temperament known to predispose to the disease, whether it be depressive, hypomanic, or cycloid—moving between the two extremes. Finally, I have been influenced by the cross-sectional picture which has been regarded as typical of endogenous depression. Such a picture would include remorse and self-blame about the past, hopelessness about the prospects of future recovery, and psychomotor retardation. In very few cases would all these things be present, but enough would usually be there for a confident diagnosis to be made. To what extent such confidence was justified is one of the questions to be considered.

Reactive depression is regarded as a progressive reaction to events, in the Meyerian sense, and not as a disease entity, as is endogenous depression. It is therefore in theory traumatic, and, as was noted during the war, trauma is more effective in producing the illness when it is slight but sustained than when it is acute but short-lived. The diagnosis is therefore made when a depressive illness follows upon sustained trauma, and it is particularly liable to follow a long period of tension (Curran and Garmany, 1944). The cross-sectional picture is traditionally a different one from that presented by an endogenous depression.

Psychomotor retardation is not present, and blame of others for his plight is more usual than remorse. Hopelessness about recovery is uncommon, and so, for the same reason, is suicidal preoccupation. The diagnosis is sometimes influenced by the probable or known results of treating the patient with electroplexy, on the basis that if the patient responds his illness could not have been psychogenic, a conclusion which is neither logical nor true.

In making a diagnosis of *involutional depression* I have used far stricter criteria of a classical kind. To fall within this group the patient had to be of an age ranging from one corresponding with that of the menopause in women and extending up to old age. The

*A shortened version of an address to the Folkestone Medical Society on April 24, 1958.

pre-morbid personality had to be of a rigid and rather obsessional kind, quite dissimilar from the likable pyknic of tradition. There should have been no previous attacks, and the clinical picture should show both agitation and hypochondriasis. I think it is true to say that these five criteria have been accepted in psychiatry for a long time, though in clinical practice they are seldom followed strictly. I have followed them myself, however, largely in order that I should know in the future what I meant when I saw the patient. The comparatively small number of involutional depressions in the series is probably to be attributed to this rather purist approach, and illustrates very well the difficulties in making comparisons in psychiatry when the criteria of diagnosis can vary so much.

Distribution between Endogenous and Reactive Depression

There has for many years been dissension among psychiatrists regarding the reality of the distinction between endogenous depression and reactive depression, and regarding the existence of involutional depression as an entity at all. Lewis (1934) in a paper which is now securely ensconced among the classics of psychiatry, attempted to answer the first of these problems. In a very careful study he was unable to satisfy himself that there was any real difference between reactive and endogenous depression, at least in terms of symptoms. Mayer-Gross *et al.* (1954), on the other hand, take the opposite view, and feel that, though the distinction may be difficult to make in many cases, it can and should be made. The problem is one of exceptional difficulty because of the universal human tendency to seek causes for the effects it witnesses. Thus it happens that both the patient with the endogenous depression and his relatives may produce all kinds of apparent aetiological factors, many of which are really the results or content of the illness rather than its cause.

Life is full of troubles, and it is statistically not unlikely that, whenever an endogenous depression begins, some traumatic incident will have preceded it, so that the one is regarded as the result of the other. The psychiatrist himself may be in a dilemma too, for if, as is usual, he regards a certain clinical syndrome as being typical of a constitutional illness—namely, endogenous depression—he may disregard dynamic external factors which are important. Thus I feel no doubt at all that influenza frequently precipitates a depression which is clinically of an endogenous type, and yet that fact should not be so if our description is correct.

A similar problem arises in the case of reactive depression. Traumatic events may precede the illness and yet we may be dealing with a temporal coincidence. A notable example is the prolonged grief reaction following death in the family circle. Depressive manifestations occur physiologically for about three months, and yet the same picture may be evident perhaps five years after the death. While on the face of it such a depressive is reactive, it is noteworthy that a considerable proportion will respond to electroplexy.

The distinction, if any, between endogenous and reactive depression is often posed as a problem which seems only verbal. Nevertheless there are certain very real questions to be answered. Firstly, we ought to know whether depressions generally can be divided into those in which constitutional factors are all-important and environmental factors of little account, and others in which the reverse applies. Secondly, and supposing the first question is answered affirmatively, we must know whether it is true that endogenous depression should be treated by E.C.T. and reactive depression by psychotherapy; for that is the usual assumption. Everyone would agree that a few cases fall clearly into one group or the other, but we must know whether the distinction is a valid one for the group as a whole. The results which are here reported bear principally upon these two questions of aetiology and treatment.

In some respects, and particularly when considering treatment, the results reported have certain limitations. They are derived from the out-patient population of a London teaching hospital and cannot be representative of the population as a whole. Many general-practitioner colleagues recognize and treat depressions on conservative lines without referring them for an opinion. Many potential patients do not become actually so because they cope with their own affective disturbances. For these reasons the patients seen probably exclude many minor cases, but, as will be apparent, this lends greater point to some of the inferences made. In London the urgent disposal of acutely suicidal patients is facilitated by the highly organized public health service, so that with such patients the doctor may often send for a duly authorized officer himself. I am inclined to think that the deviation of patients in this way is probably small in the case of depression, while it might be quite considerable in the case, say, of acute schizophrenic episodes.

Aetiology

Table I shows the incidence of constitutional loading in 525 consecutive cases of depression seen at Westminster Hospital. The cases are broken down into three

TABLE I.—Incidence of Constitutional Loading in 525 Cases of Depression

	Endogenous Depression	Reactive Depression	Involutional Depression	Anxiety States
No. of Cases	295	194	36	
Notable	98	40	5	61%
Possible	107	67	12	
Unlikely	85	70	13	38%
Not stated	5	17	6	3%

categories, and for interest the corresponding percentages are shown for anxiety states and taken from the paper to which reference has been made. Constitution means the general mental and physical make-up of the patient, and "loading" has been inferred from a number of factors. Thus a pyknic habitus, a positive family history, and a history in the patient of previous unprovoked attacks were taken as indications of constitutional predisposition. The word "notable" means that such indications have been marked and unmistakable. The word "possible" has not in fact been used in the sense I originally intended—namely, to indicate a state of doubt. In practice it has meant "likely," and so in assessing the results I have added these two columns together. It will be seen that, although the loading is greater in the endogenous cases, it is nevertheless very high in all three categories. Bearing in mind that the presence of such loading has to some extent influenced me in diagnosing endogenous depression at all, I do not feel that the difference between 70% and 55% is enough to warrant much support for a clear differentiation between the two types of depression.

Table II shows a list of stress factors enumerated at the time the cases were first seen. They were present at the time the illness developed and were considered to be aetio-

TABLE II.—Stress Factors

	Endogenous Depression	Reactive Depression	Involutional Depression	Anxiety States
No. of Cases	295	194	36	
Personal	170 (58%)	115 (59%)	24 (66.6%)	70%
Domestic	83 (28%)	94 (48%)	3 (8.3%)	35%
Work	38 (13%)	35 (18%)	8 (22.2%)	20%
Other social	15 (5%)	17 (9%)	0	10%
Financial	13 (4.3%)	20 (10%)	1 (3%)	9%
Housing	11 (3.6%)	8 (4%)	0	9%
Physical	51 (17%)	80 (41%)	3 (8.3%)	27%
None found	64 (21%)	11 (5.5%)	8 (22.2%)	9%

logically important in its development and perpetuation. Thus if after influenza a depression developed with a typical "endogenous" appearance, I would mark the illness as being associated with a physical stress factor, since to do

otherwise seems against reason and good sense. Similarly, if a man developed an endogenous depression with motor retardation and told me that the illness arose after his wife had left him, then I would mark this as a domestic stress factor rather than dismiss it as mere content of his illness. The personal stress factor requires some explanation, since it has been used in a special sense, and it must be distinguished from constitution.

Constitution refers in this context to an inborn loading which predisposes to depression. Personal stress factors mean those facets of personality structure which make living less easy, but do not of themselves predispose to depression. Thus an overactive conscience may be acquired in a strictly religious family, and would make life in a stockbroker's office more of an exercise than it would be in a vicarage. This would be recorded as a personal stress factor. The meticulous obsessional character creates what to others may seem to be unnecessary burdens for itself. It delegates badly, it concerns itself overmuch with trivia, and it sets out to live up to standards of performance which are abnormally high. This is not depressive loading, but it certainly constitutes a stress factor of some magnitude. These then are the senses in which I have used these two expressions, and it is because others might use them differently that I feel I should describe them.

It will be noted in Table II that the percentages add up to more than 100 because, of course, several factors might be operative in one particular patient. There is no doubt that the incidence of stress factors, other than personal ones, is higher in the reactive group than in the endogenous group. Nevertheless it is high in both columns, and the group. Intrapersonality stresses were the same in both. I was extremely surprised to find that domestic stresses had been thought to be important in almost one-third of the cases of endogenous depression seen and in nearly half of the cases of reactive depression. Had I been given these figures before they were computed I would have thought them exaggerated. This is perhaps an interesting example of how superior old traditions can be when contrasted with the newer psychiatry. Most women regard development of depression in a husband as a serious personal reflection, and it would appear that in a large proportion of cases they are right. Because of a rather unhappy oversight when the transcriptions were drawn up, the machine has proved incapable of sex differentiation, and I cannot therefore give figures which would inculcate husbands.

The important role of physical factors in reactive depression is noteworthy, though this must, in some measure at least, be the result of work done in a general hospital, since nearly half the patients seen come from colleagues who may have been dealing with associated physical anomalies. In the Financial difficulties and the housing shortage, as in the case of anxiety states, appear to play little part in aetiology. It is interesting to note that in only 20% of cases did endogenous depression seem to come "out of the blue"—that is to say, without external factors, and, interestingly enough, this is almost exactly what Rennie (1942) found. It may, of course, be said that I have mistaken content for cause, for this criticism was made of Rennie's figures. I cannot for this criticism was made of Rennie's figures. I cannot prove that this is not so, but can only emphasize that I counted these stress factors only in those instances where temporal coincidence suggested that I must. To have done otherwise would have been to assume the truth of a proposition that I hoped to investigate.

Although diagnosis was made largely on the cross-sectional picture, it is likely that it was influenced in some measure by the presence or absence of stress factors. Thus here, as with constitutional loading, the assessments are in some degree biased. There is no way of measuring this bias, but, making allowance for it as fairly as I can, there does not seem to be any gross dissimilarity among the three groups.

Table III shows the age distribution of the three groups compared with that of anxiety states. The figures are much the same as those given by others. It will be seen that the

TABLE III.—Age Distribution on 10-Year Groups

	0-21	21-30	31-40	41-50	51-60	61-70	71-
Endogenous depression	—	51	73	76	57	35	3

Involutional depression	—	36	66	8	17	9	2
Anxiety states	8	—	—	28	15	4	1

risk from depression extends over a much longer period of life than does that from tension, which is at its peak in the fourth decade.

Treatment

The treatment set out in Table IV represents what was decided at the first interview. Subsequent experience of the patient may in some instances have required modification of the course first chosen. Thus a patient selected for

TABLE IV.—Treatment

	Endogenous Depression	Reactive Depression	Involutional Depression	Anxiety States
Consultation	15	28	3	
Counsel	10	18	1	50%
Support	42	55	6	
Intensive	7 (2.3%)	17 (9%)	1	11%

urgently	16 (5.3%)	4 (2%)	3 (9%)	—
Hospital otherwise	47 (15.6%)	20 (10.5%)	3 (9%)	3 cases
E.C.T.	109 (36.3%)	9 (4.5%)	4 (39%)	—
Drugs	57 (19%)	59 (29.5%)	1 (1%)	33%
Other	—	2	1	4 cases
Total	322 (295)	233 (194)	45 (36)	

psychotherapy may have deteriorated later and required E.C.T. I venture to hope that usually the course chosen will have been proved by events to have been correct, but with the figures available to me I cannot prove that this is so. Even if others, as is possible, have less confidence in this than I have myself, then at least clear information is given about the advice tendered at the first interview. It will be noticed that the totals at the foot of each column do not quite correspond with the total number of cases seen, which is shown in brackets. The intention was that only the major treatment should be indicated, but in some instances I forgot this and ticked two.

It is interesting to note that electroplexy was selected for immediate use in out-patients in only just over one-third of the cases of endogenous depression. If all cases of depression are taken together, then about 25% were given this treatment. If it is assumed that all cases severe enough to be sent to hospital were given E.C.T., then I believe that about 50% of all cases of depression referred to our out-patient department received this treatment. I am sure this is a clinical finding without bias, for I have no conscious revulsion against E.C.T. comparable, for example, with my dislike of leucotomy. It will be seen that E.C.T. was employed relatively rarely in those cases called reactive depression. The disparity is so great that I think it can be explained in only one way—namely, that the diagnosis was materially affected by the clinical judgment of probable response to E.C.T.

It is important to be clear what this means. It proves nothing about the constitutional loading present or about the incidence of stress factors. It merely indicates that there is a group of depressions rarely requiring E.C.T., and another group (described here as endogenous and involutional) where E.C.T. is required in something between one-third and one-half of the cases. If there is a fundamental distinction between the groups it is to be found in the quality which is considered in the difficult or borderline case. This quality is, I am sure, *reactivity* or the readiness with which the patient will respond emphatically to changes of mood in the examiner. This quality is used to determine the need for E.C.T., the risk of suicide, and, as has been indicated, the diagnosis. Yet if we describe some depressions

as showing less reactivity than others, we mean much the same as when we say the depression is deeper. This is quite different from saying that the depression is more endogenous.

Only a very small number of patients (4.5%) were sent to mental hospitals urgently because of acute depression. A larger number (about 13.5%) were admitted, mainly to Westminster Hospital, for a variety of reasons. Elderly patients and those with certain associated physical diseases would be admitted, particularly if they had long distances to travel or lived alone. Patients showing severe associated tension or depersonalization are much better treated as in-patients, so that E.C.T. may be given under a heavy blanket of sedative. Those who have lost much weight will not usually do well with out-patient E.C.T. and should be admitted so that modified insulin can be given as well. Nevertheless a patient referred to hospital with depression can be assured, as these figures show, that he has four chances in five of being treated as an out-patient.

The figures given for treatment by drugs are misleading in that, rather arbitrarily, they were regarded as subsidiary forms of treatment when associated with E.C.T. or with psychotherapy. As a result they would often be omitted from the transcription sheet. The incidence of associated pharmacological therapy must in fact have been very high.

Summary

A study has been made of 525 patients suffering from depression divided into the three traditional categories of reactive, endogenous, and involutional depression.

The constitutional loading in patients developing these illnesses is in all cases high, but the incidence does not suggest any qualitative difference among the three types.

Stress factors are important in all groups, and stresses produced by abnormal personalities are especially so. Again, a study of these stress factors does not suggest a distinction worth making among the three groups.

Domestic stresses appear to be highly important in the genesis of reactive depression, of considerable importance in endogenous depression, and of small importance in involutional depression.

Endogenous depression, despite its name, appears to come "out of the blue" in only 20% of cases.

Of all cases of depression referred to hospital, 25% need E.C.T. straight away, and a further 25% after admission to hospital.

Very few cases of reactive depression received E.C.T., and it is believed that these patients were characterized above all by their "reactivity" to outside stimuli.

It is concluded that the distinction between these three forms of depression, and particularly between the reactive and endogenous varieties, is an unreal one. Constitutional predisposition and the incidence of stress factors appears to be much the same in these groups.

The distinction traditionally made appears to be a distinction between those depressions which show more reactivity, are less severe, and infrequently require E.C.T. and those depressions showing the reverse features.

It is believed that this resolves itself into a distinction between mild and severe depression.

I gratefully acknowledge the help given to me by Mr. G. J. Copleston, records officer at Westminster Hospital, in providing me with the figures on which this paper is based.

PROGNOSIS OF TROPICAL SPRUE

BY

O. K. HAZARI, M.B., B.S., M.R.C.P., D.T.M.&H.

AND

A. W. WOODRUFF, M.D., Ph.D., F.R.C.P.
D.T.M.&H.

Hospital for Tropical Diseases, London

There has long been doubt regarding the prognosis of tropical sprue, some regarding it as a seriously chronic disorder in which those affected suffer severe and protracted disablement, remain continually susceptible to relapses, and seldom recover completely (Low, 1928). Stitt (1945) gives a typical opinion in stating of sprue: "Unless adequately treated, however, severe cases are ultimately fatal within a period varying from about one to fifteen years." A further relatively unfavourable prognosis is expressed in a recent textbook (Mackie *et al.*, 1954), where of sprue it is written that "more commonly fats in the diet must be restricted permanently and parenteral injections of liver continued at intervals of one to two weeks." Others (Rodriguez-Molina, 1943; Woodruff, 1949) have produced evidence that the disease has a more favourable prognosis.

The reason for this apparent divergence of views may well be that in different studies different types of cases have been followed, that those with a poor prognosis have been patients affected with idiopathic steatorrhoea or non-tropical sprue, and that those with a satisfactory prognosis have been suffering from tropical sprue. The question might, it was thought, be resolved by ascertaining the ultimate outcome of the disease in patients affected with tropical sprue during the last war. If these patients are still suffering from symptoms of sprue, then the tropical variety of this disease must indeed be one with a protracted course and may well have much in common with idiopathic steatorrhoea, which is generally held to be a chronic disorder. If, on the other hand, tropical sprue is followed by only a short period of disability, then a point of difference of considerable diagnostic and aetiological importance would be established. The point is also of importance in the management and disposal of patients suffering from the disease and concerning the advice to be given them regarding diet and consumption of fats.

A Previous Study

Woodruff (1949) carried out a study in which patients invalided from India to Britain with tropical sprue were followed for 2½ to 3 years. Ten years have elapsed since that study was carried out, and it is therefore possible to review the prognosis of some of those patients, using a longer time scale than was possible in 1949.

The patients were originally diagnosed, treated, and invalided from a mobile R.A.F. field hospital in the Arakan; they have now become widely dispersed throughout Britain, the United States, and a number of Commonwealth countries, and therefore it has not been possible to examine them personally. A detailed questionnaire has accordingly been sent to them, and this report is based upon the answers given in it. Of the 47 patients reported in 1949 (Woodruff, 1949) it had been possible to follow up 34 at that time. Further letters were recently written to these patients and 17 replies were received.

Original Condition of the Patients

The clinical features of the 47 patients with sprue have previously been described (Woodruff, 1949). The records of the 17 patients who replied to the recently issued

questionnaire have been reviewed and their original symptoms have been found not to differ notably from those of the remainder of the series. Thus among the original 47 patients diarrhoea had been present for a mean duration of 3½ months; among the 17 whom it has been possible now to trace, diarrhoea had originally been present for a mean duration of three months. Tongue lesions, including glossitis, with inflamed and atrophic mucosa and ulceration, were present in 12 of the 17 now followed up, as compared with 39 of the 47 in the complete series. The average amount of weight lost among the 17 now followed up was 21 lb. (9.5 kg.), as compared with 28 lb. (12.7 kg.) for the complete series. The mean haemoglobin values of the original 47 patients and of the 17 now followed up were respectively 12.2 and 11.9 g. per 100 ml. The faecal fat in those now followed up averaged 32.6 g.% of the faecal dry weight, compared with 37.1 g.% among the original 47 patients.

Present Condition of the Patients now Followed Up

Capacity for Work.—All 17 patients reported that they were able to carry on their full work. Their employment varied widely; nine were doing sedentary work, four were on moderately heavy work, and four were employed on heavy manual labour.

Weight.—Since returning to the United Kingdom in 1944–5, 15 of the 17 had gained in weight, the average gain being 11 lb. (5.0 kg.); the remaining two had each lost 1½ lb. (680 g.).

Diarrhoea.—Since their condition was reviewed 10 years ago, 11 of the 17 patients had been completely free from diarrhoea, three have had single attacks lasting 48 hours during these 10 years, another has had a single attack lasting 96 hours, one has had occasional attacks lasting 24 to 48 hours, and one states that he has had many attacks lasting 48 to 72 hours. All state that normally they pass one to two stools a day and that the faeces are formed, inoffensive, and of normal colour and size.

Glossal Ulceration.—Three of the 17 had had some glossal ulceration during the past 10 years. Two had had one or more ulcers of the tongue present for 2 to 10 days and associated with attacks of diarrhoea; the third patient had had a buccal ulcer lasting for two to three days on one or two occasions during this period.

Appetite.—Three patients reported that they still have a disinclination to eat fatty or fried foods, but the remaining 14 stated that their appetite was normal and good.

Abdominal Discomfort, Distension, and Flatulence.—Two patients stated that a minor degree of these symptoms has been present almost continuously throughout the past 10 years, and a third stated that they occurred after ingestion of fatty and fried foods. These symptoms, however, have not been severe enough to limit the patients' activity in any way, and in view of their subjective nature their connexion with the original sprue is doubtful. Similar considerations also applied to two patients who still complained of lassitude after undue exertion but who nevertheless were able to carry out their full work. No patient now complains of cramps.

Discussion

If the 17 patients recently followed up are representative of the whole series—and there is no reason to believe that they are not—then it appears that the long-term prognosis in tropical sprue is good and that after treatment with a high-protein, low-fat diet a patient may be expected to be restored to full health. Alimentary symptoms, except possibly glossal ulceration, in such patients appear to be no more frequent than is to be expected among persons who have not had sprue. Those followed up in this study have been living on a normal diet without any restriction on consumption of fats, so that in tropical sprue protracted dietary limitation appears to be unnecessary.

All the 17 patients were treated before the introduction of folic acid or vitamin B₁₂, and thus their satisfactory return to health demonstrates that, at most, administration of large amounts of these substances shortens the illness but that they

are not essential to recovery. This observation emphasizes a difference between sprue as encountered in the East and that reported in the Caribbean region, where folic acid and/or vitamin B₁₂ have been used extensively for treatment and they or liver extract may be essential for it. Woodruff (1952) drew attention to these differences, particularly to the severe degree of anaemia usual in Caribbean cases and to the common absence of reference to steatorrhoea in reports on sprue from this region. He suggested that the condition commonly described there as "sprue" is nutritional megaloblastic anaemia, with which some alimentary symptoms may be associated and thus be a source of confusion. The satisfactory recovery without the aid of specific haematinics of the patients here followed up further supports this view.

The chronicity of idiopathic steatorrhoea or non-tropical sprue and its failure to be influenced other than temporarily by treatment indicate, firstly, that assessment of the history and/or observation following a period of treatment afford valuable means of differentiating between tropical sprue and idiopathic steatorrhoea, for patients with the former will recover and remain well, while those with the latter will not. Secondly, the difference in course between the two conditions suggests that they are separate aetiological entities; tropical sprue being characterized by a temporary upset in bowel function and in fat absorption, whereas in idiopathic steatorrhoea or non-tropical sprue this upset is permanent. By means of jejunal biopsy, Shiner (1956, 1957), Doniach and Shiner (1957), and Sakula and Shiner (1957) have demonstrated that in idiopathic steatorrhoea mucosal atrophy is present, and a permanent change of this kind with loss of enzyme function in the tissues affected and a similar temporary disturbance in tropical sprue, perhaps secondary to changes in the intestinal bacterial flora, might well account for the difference in course and in prognosis of these two conditions.

Summary

Doubt concerning the prognosis of tropical sprue has arisen probably through confusion between it and idiopathic steatorrhoea or non-tropical sprue, which, it is generally agreed, is a relatively chronic disorder. The prognosis of tropical sprue has therefore been studied by following up patients who contracted it in India and Burma during the 1939–45 war and who were invalided to Britain. It has been difficult to contact the patients because so many of them have changed their residence several times or have emigrated since 1945. Of 34 patients followed up, however, three years after invaliding, it has now been possible to contact 17. It is appreciated that there are pitfalls in drawing conclusions from so small a proportion of the original number of patients, but they are believed to be representative: it is known, for example, that several emigrated in good health.

Those contacted have all been found to be in good health, to be carrying on their full work, and to have gained an average of 9½ lb. (4.3 kg.) in weight. Attacks of diarrhoea, glossal ulceration, abdominal discomfort, and distension have been infrequent.

The long-term prognosis of tropical sprue appears to be good and to contrast favourably with that of idiopathic steatorrhoea. This contrast in course affords one means of differentiating the two disorders and suggests that they are separate aetiological entities.

CONTROLLED HYPOTHERMIA

RECENT DEVELOPMENTS IN THE USE OF
HYPOTHERMIA IN NEUROSURGERY

BY

PAMELA M. HELLINGS, M.B., F.F.A.R.C.S.

Recently Research Anaesthetist to the Neurosurgical Unit
of St. George's Hospital, London

Hypothermia is a technique of comparatively recent application, and may be described as a method of reducing the normal body temperature of the whole patient. The method was first practised by Smith and Fay (1939) in the attempted treatment of neoplasms, with a view to slowing the rate of tumour growth at lowered temperatures.

More recently McQuiston (1949) used hypothermia during cardiac surgery carried out on hypoxaemic children. Further interest was taken in this when Bigelow *et al.* (1950) suggested that the lowered oxygen demand of the brain during hypothermia would protect it against ischaemia during intracardiac operations. Since then the method has been used extensively as an aid to cardiac surgery.

The application of hypothermia to neurosurgical conditions is of more recent origin. Rosomoff and Gilbert (1955) noted a reduced brain volume when experimenting with dogs under hypothermia, and accordingly recommended its use in neurosurgery. Loughheed *et al.* (1955) followed with a report on two cases in which hypothermia had been used for the surgical treatment of vascular lesions, and Botterell *et al.* (1956) reported on the use of hypothermia in the management of 22 cases of intracranial aneurysms.

The Investigation

Thus the value of hypothermia in the treatment of neurosurgical conditions had been established on a broad basis by the end of 1956, when work was begun with a view to developing a practical and routine method for use with a busy neurosurgical unit.

From November, 1956, until December, 1957, 123 patients whose ages ranged from 6 to 78 years were treated under hypothermia. This paper shows how the routine method was evolved and established.

At the outset an unselected series of ruptured intracranial aneurysms and angiomas were treated surgically under hypothermia; later, when it became evident that the method was safe and the value of the improved operating conditions was appreciated, confidence grew, and the method was used

FIG. 1.—Chart of Case 6.

during other intracranial procedures, particularly for meningiomas.

The danger of repeated subarachnoid haemorrhage in cases of ruptured intracranial aneurysms is well known. Thus to avoid a further bleed before operative treatment could be carried out, and also in the hope that the patient's condition might improve, the first five cases in this series were cooled over a period of 5 to 19 hours, using the "lytic cocktail" combined with sodium amylobarbitone to prevent shivering. Fans played upon the patient continuously and body surfaces were kept constantly moist with a dilute solution of cetrimide in water, the former being added to reduce surface tension, thus allowing a film of moisture to remain on the skin for a longer period than would water alone. At the time chosen for operation the temperature lay between 30 and 31° C., and a general anaesthetic was then given. This was discontinued at the end of the operation, when warming was begun with electrically heated blankets. This method has the following disadvantages:

1. Shivering occurred even though large amounts of drugs were administered. In one case 180 mg. of chlorpromazine, 100 mg. of promethazine hydrochloride, 190 mg. of pethidine, and 900 mg. of sodium amylobarbitone were given and slight shivering was still present, which increased if the patient was moved or disturbed in any way. Rosomoff and Gilbert (1955) pointed out the need for adequate anaesthesia in these cases because of the rise in C.S.F. pressure which occurs with shivering.

2. As a result of the large quantities of drugs administered the blood pressure was not easy to control. A steep drop in blood pressure was apt to occur on moving the patient, on tilting to a head-up position, and again after only a small blood loss. This fall was not compensated for immediately, and the blood pressure tended to remain low for long periods. This reduced blood flow to the already damaged brain, which, even though the temperature was low and the tissue oxygen requirements were diminished, might well have proved to be insufficient. There was also considerable danger of cerebral thrombosis if the blood pressure remained low for any length of time.

3. The fall in temperature was difficult to control, and a further fall tended to occur after induction of general anaesthesia.

In view of the foregoing difficulties it was decided to take advantage of the strong anti-shivering action of nitrous oxide, as described subsequently by Parkhouse (1957).

Accordingly the sixth case in the series—a ruptured intracranial aneurysm—was treated by hypothermia under prolonged general anaesthesia. When the temperature had reached the required level the nitrous oxide was discontinued, and the effect of this, together with its reintroduction, is illustrated in Fig. 1. The pulse rate rose, and the blood pressure rose steeply as shivering became more marked, and both settled dramatically to their former level when the nitrous oxide was reintroduced. A slow rise in temperature occurred later as a result of the increased heat production on shivering, and further cooling was necessary to reduce the temperature to the required level again. Intravenous drugs were given during the initial cooling process—thiopentone 250 mg., pethidine 60 mg., "tubarine" 30 mg., sodium amylobarbitone 500 mg. in all were given. No further drugs were needed to prevent shivering after reintroducing nitrous oxide.

This case was of interest because the patient had undergone haemorrhage from a ruptured posterior cerebral aneurysm on four separate occasions during the three weeks prior to admission to hospital, the last haemorrhage

occurring within the 24 hours before admission. Further rupture was prevented by ligation of the neck of the aneurysm at operation, and the patient eventually made a complete recovery.

occurring within the 24 hours before admission. Further rupture was prevented by ligation of the neck of the aneurysm at operation, and the patient eventually made a complete recovery.

It became evident that the advantage of prolonged hypothermia, preventing further haemorrhage, did not outweigh the disadvantages of prolonged anaesthesia, and therefore the remaining cases were operated upon as soon as the temperature had been reduced to the required level under general anaesthesia.

The following method of producing a state of hypothermia at a temperature level between 31 and 30° C. was used for the remaining 117 cases.

Procedure

Anaesthesia

The patient was given promethazine, pethidine, and atropine as premedication. One hour later anaesthesia was induced with thiopentone, suxamethonium, and pethidine, and was maintained with nitrous oxide and oxygen, together with additional doses of pethidine and thiopentone. If this proved insufficient to prevent shivering, suxamethonium was given in repeated intravenous injections, or, alternatively, tubarine was given in small doses until shivering was controlled. Respirations were aided or controlled as required.

Hypothermia

Hypothermia was effected by means of surface cooling, using ice, after the induction of anaesthesia. Ice packs were placed above and below the trunk of the patient, and also

over the large arteries which run near the surface of the skin—that is, the carotid, femoral, and axillary arteries. In order to avoid too great a drop in their temperature the limbs were not cooled directly. The skin in contact with the ice packs was massaged at frequent intervals to assist the circulation of the cooled blood; this was of particular value in the case of the obese patient, as it reduced the temperature gradient between the centre and the surface of the body.

The main difficulty was to obtain toleration of the cold applied without depressing the vital centres or producing apnoea by giving large doses of relaxants: the temperature of the surroundings was found to be of little importance when ice was used, provided the ice was replaced as it melted. As the blood supply to the damaged brain had already been reduced by spasm of the supplying vessels, and would be further reduced by hypotension, care was taken not to depress the blood pressure until this was required during operation. Apnoea was produced during the process of cooling in those cases where relaxants were necessary to control shivering, but it was essential to ensure that respirations were present during the neurosurgical procedure, as a guide to the surgeon.

The ice packs were removed at 33–32° C., and the patient was then ready for operation. Before the main part of the operation had been completed the temperature had continued to fall to 31–30° C., 30° C. being the lowest temperature level required.

This further drop in temperature after the removal of the ice occurred more quickly and to a lower degree in the thin patient than in the obese, because of the insulating effect of fat against cold. Hence the steeper the fall in temperature during cooling the greater the "after-drop" expected. Thus when a thin patient was cooled rapidly the ice had to be removed at between 34 and 33° C. to avoid too profound a final drop in temperature. This point is illustrated in Figs. 2 and 3.

Temperatures

Rate of Temperature Fall.—When hypothermia was produced by the method described, the time taken for the temperature to fall was proportional to the weight and surface area of the patient. As a rough guide, the time taken for the temperature to fall from normal to 33° C. (when the ice was removed) was calculated on the basis of one hour per 6 stone (38 kg.) weight. Thus a 12-stone (76 kg.) patient would take approximately two hours, the time varying slightly according to the patient's surface area—that is, the tall and thin would take a relatively shorter period than shorter patients of the same weight.

Temperatures were recorded from the rectum and from the nasopharynx, using glass alcohol thermometers. In 28 cases the brain temperature was also recorded during operation, and Table I shows the variable degree of correlation of the rectal temperature compared with the brain temperature.

Nasopharyngeal temperatures were not recorded during operation, as access to the nose, using glass thermometers, was impossible.

TABLE I

Case No.	Weight in Kg.	Temperature (°C.)		Case No.	Weight in Kg.	Temperature (°C.)

Warming

At the end of the operation anaesthesia was discontinued, and no active attempts were made to rewarm the patient unless the temperature tended to drop post-operatively. Normal temperatures were usually regained within eight hours of the operation. Promethazine was given to reduce shivering, and, if the patient was conscious and complaining of cold, pethidine was given. Consciousness was regained at low temperature in cases where brain damage had been minimal and anaesthesia had been light; one patient was capable of answering questions at 29.5° C.

The rate of temperature rise post-operatively gave an indication of the neurosurgical state of the patient. If brain damage had been slight there was a rapid rise within a period of three to five hours, but when brain damage had been severe the temperature would take as long as two to three days to reach normal, with little or no shivering occurring. This slow rise in temperature in the very sick was of definite advantage, as the oxygen requirements of the brain remained low for a long period.

Blood Pressure

The common pattern of the blood pressure is illustrated in Fig. 4. The initial fall after induction of anaesthesia was followed by a rise due to vasoconstriction of the peripheral vessels, as a result of cooling. This was followed by a gradual fall due to diminished cardiac output, which was

FIG. 4.—Pattern of blood pressure on cooling.

not profound if temperatures were not taken below 30° C. Bigelow *et al.* (1950), experimenting with dogs, found a similar pattern in blood pressure on cooling.

With this method of hypothermia, the blood pressure was little disturbed on moving the patient. All operations were carried out with the patient lying with a head-up tilt.

In the first six cases described, this tilting produced falls in blood pressure of between 20 and 80 mm. Hg, whereas using the second method the fall was rarely more than 10 mm. Hg, thus giving greater control over the blood pressure.

This was an advantage, because, although it is safer at low temperatures to lower the pressure due to diminished oxygen requirements (Dundee *et al.*, 1954), it was considered advisable in these cases of brain damage with spasm of the cerebral vessels to limit this low pressure to the shortest time possible.

Thus the blood pressure was lowered only when necessary by using trimetaphan camphorsulphonate ("arfonad").

Trimetaphan Camphorsulphonate

Operations were performed in nearly all cases at a blood-pressure level of 70–80 mm. Hg. Trimetaphan was given by

intravenous infusion at a concentration of 1 mg./ml. normal saline. In common with other drugs trimetaphan takes longer to act at low temperatures. The sensitivity of patients to this drug varied at low temperatures as at normal temperatures, and consequently time had to be allowed to assess the sensitivity of the patient to the drug by giving it at a very slow drip-rate for three to five minutes. If this was not done a profound drop in blood pressure would occur when the trimetaphan took effect on a sensitive patient. This profound drop in pressure might be prolonged because the compensatory mechanisms for hypotension do not act normally at low temperatures. Prolonged diminished blood supply to the damaged brain might thus occur.

The total amount required to maintain hypotension was found to vary as much in cold patients as in patients at normal temperatures, and large amounts of trimetaphan

FIG. 5.—Showing effect of trimetaphan. (1) Lead II. Temperature, 30.8° C.; blood pressure, 95 mm. Hg. (2) Lead II. Temperature, 30.8° C.; blood pressure, 60 mm. Hg with trimetaphan. (3) Lead II. Temperature 30.8° C.; blood pressure, 60 mm. Hg; trimetaphan discontinued.

(200 mg. or more for a period of one to two hours during operation) might be necessary.

Trimetaphan was given in 74 of the 123 cases, and was effective in all but one of them. In every case there was a slight rise in the pulse rate, usually 10 to 20 per minute, even at temperatures just below 30° C. In the one resistant case a drop of only 5 mm. Hg could be obtained at a temperature of 29° C; whereas the pulse rate rose from 48 to 130 a minute and returned to 80 a minute a quarter of an hour after trimetaphan had been discontinued.

It was observed that a fall in blood pressure was difficult to obtain when the brain underwent retraction, and at low temperatures retraction of the brain caused a marked rise in blood pressure when trimetaphan was not being given.

Fig. 5 shows the electrocardiogram at a temperature of 30.8° C. when trimetaphan was given to lower the blood pressure from 95 to 60 mm. Hg.

Some Findings

Blood Loss.—At low temperatures patients did not compensate well or quickly for loss of blood. This was shown by the almost immediate drop in pressure, while there was little or no rise in pulse rate. A loss of only 250 ml. of blood could cause a severe drop in blood pressure, which did not return to the original level even when blood was replaced. If flattening of the operating table was not effective, small intermittent intravenous injections of nor-adrenaline, combined with blood replacement, were given to raise the blood pressure.

Pulse.—Increasing bradycardia occurred as the temperature fell; usually the rate was below 60 a minute at 30° C. The lowest value obtained was 36 a minute. Atropine, 0.3–0.4 mg., was given intravenously if the rate dropped below 50 a minute. This usually, but not always, caused

an increase in the pulse rate, which gradually fell again. The cases which did not respond by an increased pulse rate were those in which the sino-auricular node was directly depressed by the effect of cold (Cookson and Di Palma, 1955). Irregularities of the pulse were encountered during cooling, but these remained for only short periods. Moving the patient was the most common cause of these irregularities, which often appeared when transferring the patient from the operating table after anaesthesia had been discontinued: the pulse became regular again after a rise in temperature of a few degrees. Thus moving the patient under light anaesthesia should be avoided. Auscultation of the blood pressure always became difficult as the temperature fell, owing to vasoconstriction of the vessels. The radial pulse could be palpated throughout hypothermia in all but three cases. To reduce the vasospasm in these three cases, a stellate ganglion block was performed at the beginning of the operation, which proved effective in each case. Thus it was possible to keep a record of the systolic blood pressure by palpation of the radial pulse in every case.

Electrocardiographic Control.—The one almost constant finding, apart from lengthening of the whole complex, was the appearance of the "Osborn effect" (Osborn, 1953). This is a secondary wave closely following the S wave—so closely that it appears to be part of the QRS complex. Osborn looked upon this finding as a bad prognostic sign, as it usually preceded fibrillation by about half an hour. G. R. Graham (1957) pointed out that this change in the electrocardiogram under hypothermia is almost constant, and of no serious significance. This was found to be true in this series of cases.

Respirations.—Respirations were controlled, or aided as necessary, with a high flow of gases (4 litres of oxygen to 6 litres of nitrous oxide) without absorption of carbon dioxide. Respirations could not be controlled during operation because their presence and character were a valuable guide to the surgeon. Thus large doses of relaxants for abolishing shivering could not be used. The respiratory rate fell with the temperature in every case. The operation of clipping the anterior cerebral artery in the treatment of anterior cerebral aneurysm at normal temperatures sometimes produces apnoea which appears almost immediately the artery has been occluded. This apnoea was also produced at low temperatures, but might take five to six minutes to appear after the artery had been clipped. One case remained apnoeic for 30 minutes, after which time breathing restarted. Neither this case nor other cases of apnoea from the same cause under hypothermia suffered any lasting ill effect.

Operating Conditions and Selection of Cases

Haemorrhage from the scalp was usually reduced, but in 5 of the 123 cases haemorrhage was greater than at normal temperatures, and it was concluded that the process of cooling had probably interfered with the effective clotting of blood in these cases. Haemorrhage inside the dura was reduced in all cases, including the five which had increased scalp bleeding.

Intracranial tension was lower than normal in 97 of the cases operated upon, normal in 15, and raised in 8. Some of the 97 cases had large intracranial clots, and the tension was low only after these had been removed.

Vascular spasm of the cerebral vessels was present in many of these ruptured intracranial aneurysms at normal temperatures, as demonstrated by the arteriogram. This condition was not abolished by hypothermia, as spasm of these vessels could also be demonstrated at temperatures of 30–31° C.

Selection of Cases.—Operation took place as soon after admission as possible, and no patient was considered too ill for surgery. Many were already dying from the effects of the haemorrhage they had recently suffered; such cases were classified as category A, and the remaining cases were

divided into categories B and C according to the length of time since the last bleed from the aneurysm. There were 29 moribund patients, of whom 16 died in spite of treatment. These cases were unselected both from the neurosurgical and the general condition. Among this series were many chronic hypertensive patients and many with left ventricular hypertrophy and coronary disease. There were two cases of diabetes mellitus and two cases of syphilitic aortitis, one of which had a ruptured aortic valve and was at the time under treatment for cardiac failure.

Post-operative Complications

Bronchopneumonia was a problem in all cases of continued coma or drowsiness, and particularly if there had been pre-operative signs of chest infection. Antibiotics were given to all cases undergoing hypothermia.

Tracheotomy was performed in every case of continued coma to facilitate suction of secretions from the trachea and bronchi.

There was one case of pulmonary embolus, one of deep calf-vein thrombosis, and one of thrombosis of the long saphenous vein as a result of the intravenous infusion.

Seven cases were reopened post-operatively. In five of these only cerebral oedema was found, and the remaining two cases had subdural haematomata.

Ice was used in packs directly in contact with the skin in 117 cases, and no post-operative damage to the skin occurred in any of these cases.

Summary of Results

The results obtained are shown in Table II.

TABLE II

Category	No.	Died
Category A aneurysms	29	16
Categories B and C aneurysms	60	12
Angiomas	10	2
Meningiomas	13	None
Primary intracerebral haemorrhage	2	2
Head injuries	3	2
Pituitary tumours	2	1
Gliomas	2	None
Acute subdural	1	None
Excision of abscess capsule	1	None

No deaths occurred during the process of hypothermia or during operation. Many of the deaths occurred weeks or even months after operation.

Summary and Conclusions

The method of producing hypothermia described was evolved from the treatment of 123 cases, 117 of which were treated by surface cooling, using ice, which has the following advantages: (1) it is simple to operate in so far as the minimum of assistance and of complicated equipment are required; (2) control is good, because the time to cool can be predicted; and (3) only a limited number of drugs are necessary.

During the whole of the series no death occurred that was directly attributable to the use of hypothermia, and it is therefore concluded with some certainty that, provided the body temperature is not lowered below 30° C., the improved operating conditions produced by hypothermia may be obtained at a small increased risk, when compared with the use of a general anaesthetic alone.

In view of this, hypothermia was later used successfully for other intracranial procedures, such as angiomas and meningiomas, where the improved operating conditions were considered to be of value.

This procedure has become routine for all such cases at the Atkinson Morley's Hospital, where this work was undertaken.

I thank the consultants and all members of the staff of the Atkinson Morley's Hospital for their help and co-operation in conducting this research work, which was made possible by a Research Fellowship awarded by St. George's Hospital.

PREVENTION OF RHEUMATIC FEVER RECURRENCES

BY

E. G. L. BYWATERS, M.B., F.R.C.P.

AND

G. T. THOMAS, M.B., M.R.C.P.

From the Rheumatism Research Unit, Canadian Red Cross Memorial Hospital, Taplow, Berkshire, England

Sulphonamides were first used in the prevention of rheumatic fever recurrences nearly 20 years ago (Coburn and Moore, 1939; Thomas and France, 1939). In 1941, Thomas, France, and Reichman published their results in a controlled series that had been followed for four years. They found that the frequency of throat cultures positive for Group A haemolytic streptococci was less in a group of 55 patients protected by daily sulphanilamide and that none in this group had had acute streptococcal throat infections or further attacks of rheumatic fever. In the control group (67 patients) there were 15 major attacks of rheumatic fever and four deaths. Rosenberg and Hench (1946) summarized the results of 10 controlled series published between 1939 and 1946, involving over 1,000 person-seasons in each of the two groups: the recurrence rate in the protected series was 2.2% per patient-season and in the unprotected 13.7%.

In 1947 Burke published the first results with penicillin. One group of 10 patients had been given 1,500 Oxford units by mouth daily, and another group of 10 were studied as controls: both had been followed for one year after discharge from hospital. There was a higher incidence of infection of the upper respiratory tract in the unprotected group, and one relapse occurred in this group but none in the protected. There have been many American studies in the past 10 years (summarized by Stollerman, 1954), but only few from this country. Pitt Evans (1950) gave 100,000 units of penicillin daily by mouth to one group of 155 children in a convalescent home; another 145 children were studied as controls. Both groups were followed as in-patients for an average period of 22 weeks. The incidence and duration of the Group A haemolytic streptococcal carrier state was approximately four times greater in the unprotected than in the protected group, and clinical pharyngitis and tonsillitis was over seven times more frequent. There were no relapses of rheumatic fever in the 155 protected patients and four in

the 145 unprotected. Gale *et al.* (1952) observed 73 patients for eight months after discharge from hospital: 41 were given 200,000 units of penicillin daily: the remaining 32 received lactose and glucose. Throat swabs were taken every two weeks. There was a lower incidence of positive throat cultures in the treated group, and, whereas two rheumatic relapses occurred in the 32 controls, there were none in the 41 treated.

Prophylaxis was not used on any large scale in this unit until 1951. We relied instead on isolation (and, if necessary, treatment) of all new admissions until their throat cultures were known to be negative for haemolytic streptococci, and on weekly throat-and-nose swabbing of all patients and staff; anyone with a positive throat swab was isolated and given intramuscular penicillin. In this way the number of streptococcal infections was kept at a very low level and the recurrences in hospital were few. Experience in this country indicated that recurrences of rheumatic fever after discharge from hospital were much less frequent than had been reported in the U.S.A., where estimates ranging from 40% per year (Wilson and Lubschez, 1944) down had been reported. Up to 1951, therefore, in view of possible toxic effects from long-continued administration and of the low recurrence risk, our patients had not been put on to prophylaxis on discharge from hospital.

Present Investigation

In the years 1949 and 1950 there were 96 patients in this unit who were diagnosed as having rheumatic fever: none were put on to prophylaxis in hospital. All fulfilled the criteria for diagnosis of rheumatic fever as defined by Duckett Jones and modified by the American Heart Association (1955). They had, therefore, either two major and one minor, or one major and two minor, criteria (major criteria: polyarthritides, chorea, nodules, erythema marginatum, and carditis; minor criteria: fever, arthralgia, prolonged P-R interval, raised sedimentation rate, evidence of preceding haemolytic streptococcal infection or previous history of rheumatic fever or rheumatic heart disease). Four patients died in hospital. The remaining 92 were not put on to prophylaxis at the time of discharge from hospital. They were seen for follow-up examination at three-monthly intervals for the first year, and thereafter once each year. At each examination a careful history was taken, with special reference to sore throats and limb or joint pains; a complete physical examination was carried out; and blood was taken for sedimentation rate. All 92 were seen at one year, 91 at two years (1 defaulter), 89 at three years (3 defaulters), 87 at four years (4 defaulters) and 1 patient who had died in a recurrence at three years, and 85 at five years (2 more defaulters). Thus there were six defaulters by the fifth year and one had died at three years.

In view of the mounting evidence of the efficacy of prophylaxis and the low incidence of toxic reactions, we started to use prophylaxis as a routine measure for both in-patients and out-patients in 1951 as stipulated in the U.S.-U.K. treatment trial in which we were participants (Co-operative

TABLE I.—Comparison Between Protected and Unprotected Groups on First Admission into Hospital

Group	Total No.	Sex		Age in Years on Admission		Degree of Carditis on Admission			Duration of Disease Activity on Admission in Days		
		M	F	0-10	11-16	None	Pres. 1st Attack	Pres. 2nd or Later	0-14	15-43	43+
1949-50 (unprotected)	96	53	43	46	50	28	42	26	50	22	24
1951-52 (protected)	88	44	44	38	50	13	49	26	30	32	26

Clinical Trial, 1955). In the years 1951 and 1952, 88 patients were admitted with rheumatic fever, all of whom fulfilled the same diagnostic criteria as the previous group. The two groups were also similar as regards age and sex incidence, degree of heart involvement, and duration of disease before admission (Table I).

All 88 patients admitted in 1951 and 1952 were given prophylaxis in hospital (tablets containing sulphathiazole, sulphadiazine, and sulphamerazine ("sulphatriad"), 1 g. daily). Two patients died in hospital. In the remaining 86 prophylaxis was continued after discharge. These 86 patients were seen for follow-up examination at six-monthly intervals for the first two years and thereafter once each year. They were interrogated and examined in the same way as the previous group, and blood samples were taken for packed cell volume, sedimentation rates, and anti-streptolysin O titres. Urines were also tested for sulphonamide (La Rosa, 1945). 85 were seen at one and two years (1 defaulter), 81 at three years (5 defaulters), 79 at four years (6 defaulters), and 71 at five years (6 defaulters and 9 not yet due for follow-up).

Results

Recurrences were defined as further episodes of rheumatic activity after discharge from hospital in which the criteria for diagnosis were again fulfilled—that is, there were two major or one major and two minor criteria. None had more than one recurrence in any 12-months period.

In the unprotected group of 92 patients admitted between 1949 and 1950, 18 patients had recurrences during the first five years of follow-up. 17 of them had further attacks of rheumatic fever: 14 had one such attack, 2 had two, and 1 had three. Thus the 17 patients had a total of 21 recurrences. The remaining patient had three attacks of chorea. There were therefore 24 episodes of fresh rheumatic activity. Of the 86 in the protected group, 5 had further attacks of rheumatic fever.

Table II shows the number of recurrences in the two groups at or before each annual follow-up. In the unprotected group, 9 of the 17 with recurrences of rheumatic

TABLE II.—Number of Recurrences Per Year at Annual Intervals in Cases that Survived

Years from Admission:	0	1	2	3	4	5
Unprotected group:						
No. at risk	92	92	90	86	81	77
% of recurrences	—	5.4	6.7	5.8	4.9	5.2
Protected group:						
No. at risk	86	85	85	81	79	71
% of recurrences	—	1.2	1.2	0	2.5	1.4

fever were put on to prophylaxis during their readmission to hospital; none of them had further attacks. These cases have therefore been excluded from the "number at risk" after their discharge from hospital, as they were then receiving prophylaxis. At one year there were 92 unprotected "at risk"; at two years 90 (1 defaulter and 1 on prophylaxis); at three years 86 (3 defaulters and 3 on prophylaxis); at four years 81 (4 defaulters, 1 dead at three years in a recurrence, and 6 on prophylaxis); and at five years, 77 (6 defaulters, 1 dead, and 8 on prophylaxis). In the protected group, 85 were seen at one and two years (1 defaulter at each); 82 at three years (5 defaulters); 79 at four years (6 defaulters); and 71 at five years (6 defaulters and 9 not due for follow-up).

The mean incidence of recurrences per patient-year was 5.6% in the unprotected and 1.2 in the protected.

Discussion

Whilst the number of recurrences during the 12-months period after discharge from hospital was consistently and considerably less in the protected group, the reduction is less than reported in American series. This is because the recurrence rate in the unprotected was much lower than seems to be the usual experience in the United States. The

total mean incidence of recurrences per patient-year in our unprotected group was only 5.6%. Wilson and Lubschez (1944), in New York, found an overall recurrence rate of 25% in children aged between 4 and 13, and Fischel's unpublished figures from another hospital in New York (quoted by Stollerman, 1954) showed that of 239 unprotected patients 43 (18%) had recurrences during the first year.

Such large differences in recurrence rate in unprotected populations may depend on different criteria for recurrences or on other factors. Thus, out-patient prophylaxis is less stringent and effective than in-patient prophylaxis. In our protected group, of the five that had recurrences, one was known to have stopped taking sulphonamide two months previously and in another it was probable that the drug had been discontinued. Under barrack conditions (and some of the American figures come from Service camps) the risk of contracting streptococcal infection is greater than in the home, and the attendance of patients for illness may be different in different countries. However, most of the American series seem to agree on a high incidence of recurrences in unprotected series of whatever age, while in the few series reported in this country the incidence has been low (Pitt Evans, 1950; Gale *et al.*, 1952; present series). This difference may account in part for prophylaxis being taken up less enthusiastically in this country than in America.

Although the two groups of cases in this series were not run concurrently, the five-year period of study overlapped by two to four years in the two groups. In both groups the recurrence rate was similar during each of the five years of follow-up. This is of considerable interest, for Wilson and Lubschez reported that the risk of recurrences in the year following an attack was 38.7%, whereas the risk after one year's freedom from attacks was only 11.7%. In our series the recurrence rate has remained at a similar level throughout the five-year period despite the fact that the children were getting older and were further from their initial attack. Furthermore, Wilson and Lubschez found an overall recurrence rate of 25% in children aged 4 to 13, and only 9% in those aged 14 to 16. In our unprotected cases the age distribution on admission to hospital was 46 patients up to and including the age of 10, and 50 between 11 and 16. Of the 46 up to and including the age of 10, 7 had recurrences; of the 50 aged between 11 and 16, 10 had recurrences. There is manifestly no great falling off of recurrence rates after puberty.

Objections that have been raised to prophylaxis have been discussed in a previous publication (Bywaters *et al.*, 1957). Among these have been the fear of toxic reactions (agranulocytosis, drug rashes, and renal damage) and of streptococcal resistance to sulphonamide. In this series, though patients were given sulphonamide over periods of four and five years, such reactions were few. Two in the protected group complained of lassitude during the first year after discharge. One, a girl of 12, was found to have a white blood cell count of 3,850 per c.mm. with 25% polymorphs. She was admitted to hospital and sulphonamide prophylaxis was changed to penicillin. One week later she had recovered: the white-cell count was 7,450 per c.mm. with 70% polymorphs. The other, a boy of 5, had a white-cell count of 2,000 per c.mm. with 20% polymorphs at the sixth month follow-up. Penicillin prophylaxis was substituted, and, although the white-cell count remained low for some months before returning to normal, prophylaxis continued uneventfully.

No patient in this series developed agranulocytosis, although another of our patients (not included in this series because she was over the age of 16 on first admission) developed agranulocytosis at the eighth week; she responded satisfactorily to intramuscular penicillin. One patient in the series developed urticaria after 10 weeks on sulphonamide. The drug was stopped after four days and penicillin prophylaxis substituted. The rash persisted for another four days and then subsided. No instance of streptococcal resistance to sulphonamide was encountered,

though in another patient (not included in this series because he had chorea only) haemolytic streptococci resistant to sulphonamide were found in routine weekly throat swabs after eight weeks of treatment. The patient was treated with bactericidal doses of intramuscular penicillin, a tonsillectomy was performed, and prophylaxis was then continued with oral penicillin.

Since that time, all patients with rheumatic fever or chorea have been given sulphonamide or penicillin prophylaxis in hospital, and this has been continued after discharge (sulphatriad, 1 g. daily, or penicillin G, 200,000 units twice daily). Our original impression of the efficacy of this prophylaxis has been confirmed, and toxic reactions have been few in number and harmless. Most have occurred within a few weeks of starting treatment—that is, whilst the patients were still in hospital. Prophylaxis has then been changed from one drug to the other and there has been no further trouble.

We have no data available on differences in the recurrence rate between cases treated with sulphonamide and penicillin. Assuming both drugs to be equally effective, penicillin would be the one of choice, for there is the possible though small danger of agranulocytosis with sulphonamide. The slight extra cost of penicillin (3.6d. a day as compared with 1.6d. a day for sulphonamide) does not seem important, and storage of penicillin presents no problems, for the tablets retain their potency for three months if kept in an airtight tin in the cool. Injections of benzathine penicillin have been advocated by some as preferable to penicillin by mouth. Though this method ensures that prophylaxis is carried out, it is difficult to impose a regime of weekly injections on children in the knowledge that this must be continued for years. The Rheumatic Fever Committee of the Royal College of Physicians (1957) recommends 200,000 units of penicillin G twice daily, or 120 mg. of penicillin V twice daily, and that benzathine penicillin should be used if for any reason oral prophylaxis cannot be given. With this we concur.

Finally, for how long should prophylaxis be continued? This is a matter for individual judgment, taking into account parental attitudes and circumstances. It is our belief, based on these figures for recurrence rates, that prophylaxis should continue for at least five years after the last attack or until the child has left school, whichever period is the longer (Rheumatic Fever Committee of the Royal College of Physicians, 1957). If, after leaving school, patients are exposed to an increased risk of streptococcal infection—that is, should they enter a university or one of the Services—then prophylaxis should be continued for a further period. If liability to reinfection is based on M antibody level, it may be that even more prolonged prophylaxis will be necessary.

Summary

Two comparable groups of patients with rheumatic fever were followed for a period of five years. One group of 96, admitted in 1949–50, were given no prophylaxis either in hospital or after discharge. The other, comprising 88 patients admitted in 1951–2, were given 1 g. of sulphonamide daily in hospital and after discharge. The period of follow-up in the two groups overlapped by two to four years.

The mean incidence of recurrences per patient-year was 5.6% in the unprotected and 1.2% in the protected. There was only small variation from year to year in each group, and no tendency for the recurrence rate to decrease with time. The reasons for the relatively low incidence of recurrences in the unprotected group and other differences between this and American series are discussed. Toxic reactions were few: none were serious. The duration, dosage, and merits of various forms of prophylaxis (sulphonamide, oral penicillin, and long-acting penicillin by intramuscular injection) are discussed.

DESENSITIZATION TO BEE STINGS
BY INTRACUTANEOUS INJECTIONS
OF WHOLE-BEE EXTRACT

BY

DAVID ORDMAN, M.B., Ch.B., D.P.H.
The South African Institute for Medical Research,
Johannesburg

Reports of more or less severe reactions to bee stings are not infrequent in South Africa, and deaths therefrom are occasionally reported in the lay press. Our own information about bee-sting sensitivity and the effects of bee stings derives largely from many physicians in various parts of the country who, describing more or less severe reactions in their patients, inquire about the possibility of prophylactic desensitization.

Persons sensitive to bee stings commonly manifest local reactions in redness and swelling at the site of the sting and general reactions in rash, urticaria, oedema of face and glottis, and often anaphylactic shock, with collapse, unconsciousness, and even death. There may also be malaise, vomiting, dyspnoea, or bronchospasm. These effects appear within minutes after the sting or reach their climax some hours later.

The majority of patients who show a high degree of sensitivity to bee stings have suffered symptoms of progressively increasing severity after each sting, following a longer or shorter period of freedom from significant reactions after the initial sensitizing sting, which may have been many years ago. The following examples are given in illustration:

A farmer 44 years old had frequently been stung, as a boy and young man, with more or less severe local reactions after each sting. When he was stung again in 1952 there was little local reaction, but within three minutes he became unconscious and remained so for two hours. On recovery he had a "choking" sensation, with headache and malaise continuing for a day or two.

A medical man with no family history of allergy was stung at the age of 3½ years by about a hundred bees. The stings were removed and he suffered no ill effects. When he was 12 years old he was stung on the hand and developed a swollen face. Two years later he was stung between the toes. This resulted in swollen eyes, oedema of the glottis, and extreme dyspnoea requiring urgent medical attention. At the age of 29 he was stung once on the forearm, and, although he was injected with adrenaline within 20 minutes and with three further injections at hourly intervals, he had to have treatment at hospital, where he was detained for some time. He was stung again 10 years later, and, although adrenaline was administered within 10 minutes, he developed alarming swelling of the face.

A physician wrote from the Transvaal: "A patient of mine was stung by a bee in the soft tissue around his eye and had a severe systemic reaction. He became semiconscious and vomited profusely; rapid heart, with fall of blood pressure. He had never been affected by a bee sting previously although stung many times."

As a result of our advice and recommendations concerning the possibility of desensitization, however, patients are

Details of 24 Persons Sensitive to Bee Stings Submitted to Desensitization.

Case No.	Sex and Age	Otherwise Allergic	Reactions from Bee Stings	Whole-bee Extract Skin Sensitivity and Treatment Series	After Desensitization	
					Reactions from Bee Stings	Outcome
1	M 6	Urticaria from insect bites	Progressively more severe reactions from stings. Was stung recently and had to be treated with corticotrophin	1 unit 0.5–250 units	Stung twice during course of desensitization with hardly any effect from second sting	Successful
2	M 48	Migraine	For the past 2 years had developed palpitations, pallor, faintness, and prostration with every sting	50 units 25–500 units	Stung on finger: local oedema lasting only a few hours	"
3	M 36	Vasomotor rhinitis from inhalation of mohair dust	Local swelling and severe itching, worse with each successive sting. General reaction not marked except slight swelling of eyelids and listlessness	500 units 250–2,000 units	Local spot only. No general reaction	"
4	M 9	Not	Had become increasingly sensitive to stings. Last sting produced a marked local reaction and a very severe general reaction, including urticaria with oedema of glottis	1,000 units 500–3,000 units	Recently stung repeatedly with, at most, a slight local reaction. "This has been a most gratifying result"	"
5	F 56	"	Severe urticaria and palpitations	250 units 100–1,500 units	"Only mild reactions"	"
6	M 5	"	At age of 2 years was stung on face, gross oedema developing there. At age 4 was stung on left thumb and within a minute there was oedema of face with gross tachycardia, oedema of the larynx occurring 5 minutes later	250 units 100–1,000 units	After three separate stings on the one leg the only reaction was a local swelling	"
7	M 32	"	Stung at age 6 years and again at 13: no serious local reaction and no general effect. Recently stung by 5–6 bees on hands, with slight local swelling and itching of whole body 15 minutes later. Stung again 2 weeks later by 4–6 bees with slight local swelling but marked general itching and marked swelling of loose tissues of throat, eyelids, and armpits, with generalized urticaria and vomiting. "I firmly believe that I would have died from oedema of the throat and glottis if I did not inject myself with 1 ml. adrenaline immediately I realized that my tongue was getting thick." The patient is a physician	1 unit 0.5–25 units	Stung 6 months later on finger with only slight local swelling and itching	"
8	M ?	"	When stung on neck or face became pulseless, icy cold, and collapsed. Often found on ground by his family deathly pale after a single sting	500 units 250–1,500 units	Sting on arm: no untoward reactions	"
9	F 41	"	Always very sensitive to stings. Marked shock, breathlessness, fainting, and palpitations. The patient, a trained nurse living on a farm, gives herself adrenaline after a sting	250 units 100–1,500 units	Discontinued injections after 100 units owing to distance from doctor. Stung 9 months later, with only mild local erythema and no general reaction	"
10	F 60	"	Both grandmother and grandson reacted similarly to stings, with rash, tachycardia, and oedema of glottis. A sting in either patient meant an emergency call to the doctor	1,000 units 500–2,000 units	Only 6 injections of 500-unit extract. Stung 2 months later: no bad reaction	"
11	M 3			1 unit 0.5–25 units	No reaction after sting 2 months later or after sting one year later	"
12	M 7	"	Several episodes of anaphylactic shock with patient in very critical condition	50 units 25–3,000 units	No shock at all after recent sting	"
13	M 50	"	Severe anaphylactic type of reaction, with vomiting, urticaria, and collapse	500 units 250–2,000 units	After two recent stings only slight swellings. One sting on neck resulted in only mild flushing. "No doubt this man has benefited very considerably from desensitization. He is extremely happy at result"	"
14	M ?	"	Increasing sensitivity to stings. On last occasion, acute oedema of glottis and unconsciousness. The oedema developed so rapidly that he was unable to give himself an injection of adrenaline	5 units 2.5–3,000 units	Small urticarial weal at site of sting. No general reaction. "Naturally the patient is delighted"	"
15	F ?	"	The physician provided a general account of five cases under his care. "Same history in each case: Patient feels unusually bad after first sting; after second sting, urticaria with slight oedema of glottis. One patient became unconscious by the time he reached hospital. Another was laying out a golf course and was seriously thinking of giving up his job owing to the increasingly severe reactions from bee stings"	50 units 25–500 units	"The injections were given according to the suggested dosages in the pamphlet accompanying the treatment extracts. Since desensitization all the patients can walk among bees with impunity"	"
16	F ?			500 units		"
17	M ?			250–1,500 units		"
18	M ?			500		"
19	M ?	"	Stung from childhood onwards with no effect at first, but later with progressively severe reactions. Recent stings resulted in swollen face, body rash, and "feeling of pins-and-needles in body"	250–1,500 "	Swelling of hands and arms continue, but no longer that "queer feeling" Patient feels that he is better after stings now	Some improvement
20	M ?			1,000 "		
21	F 21	Not	Large areas of local erythema with massive swelling as well as general malaise and urticaria	10 units 5–100 units	Moderately severe local reaction with weal, urticaria, and swelling	Not successful

Details of 24 Persons Sensitive to Bee Stings Submitted to Desensitization—Contd.

Case No.	Sex and Age	Otherwise Allergic	Reactions from Bee Stings	Whole-bee Extract Skin Sensitivity and Treatment Series	After Desensitization	
					Reactions from Bee Stings	Outcome
22	M 43	Not	Twice stung in the past, with severe anaphylactic reaction each time	10 units 5 and 10 units only	Desensitization in June and July, 1953. Stung again in May, 1956, with bronchospasm and severe anaphylactic shock	Not successful
23	F 48	..	Tachycardia, vomiting, and mental confusion within 2 minutes after a sting	10 units 5-100 units	Stung some months later; had nausea, vomiting, tachycardia, and body pains	..
24	M 52	..	After a sting he became mentally confused, dyspnoeic, intensely red in the face, and developed tachycardia and unconsciousness	1,000 units 500-1,500 units	A sting received 4 months later produced tachycardia, mental confusion, and collapse	..

ordered for that purpose by physicians and are issued in a series of graded strengths referred to as "treatment sets." In this way, 50-60 treatment sets for desensitization purposes were issued annually in 1951-5, 86 sets in 1956, and 115 in 1957. These figures do not, of course, indicate the incidence of serious reactions to bee stings in the country, but merely reflect the spread of knowledge regarding prophylactic desensitization.

In our experimental and clinical studies extracts of whole bees have been employed instead of material from the sting apparatus, because our earlier investigations had shown that in persons sensitive to bee stings intracutaneous testing with extract of whole bee and with extract of sting-venom sac produced similar reactions, indicating, at least, the presence of a common antigen. From a practical point of view, in the large-scale preparation of extracts the removal of venom sacs with stings from large numbers of bees does not seem warranted when the preparation of the equally useful whole-bee extract is so simple.

Progressive skin tolerance to the injection of gradually increasing strengths of whole-bee extracts is the rule, and, as shown below, a parallel state of clinical hyposensitization is similarly attained.

Preparation of Whole-bee Extract

In the preparation of whole-bee extract many hundreds of bees are removed from the hive into a closed container, where they are killed with chloroform. The dead bees are washed in a colander under a flow of cold running water for the removal of honey and debris, and spread out on sheets of blotting-paper for superficial drying. The bodies are weighed and ground in a mortar to a thick paste, which is extracted with a moderate excess of Coca's fluid in the cold for 48 hours, with frequent stirring. The mass is squeezed through a clean, fine double-muslin bag, and the filtrate, collected and preserved with 0.5% phenol, is submitted to paper filtration followed by Seitz filtration. The clear straw-coloured fluid is controlled for sterility, and constitutes the "whole bee" extract.

Standardization of Whole-bee Extract

The "standardization" of the whole-bee extract is arbitrarily based on the total protein nitrogen content of the fluid. The figure thus obtained, and referred to as the "unitage," is taken as the basic "strength" of the particular batch of extract. It is of course no criterion of the allergenic value of the extract, and merely serves as a convenient guide to dilutions which may later have to be made.

Preliminary Skin-testing of the Patient

Skin-testing is regarded as a necessary preliminary to the desensitization process that is to follow. The object is to determine the degree of the patient's sensitivity in "units" to the particular batch of bee-protein extract in use. A "bee-venom skin-test outfit" is issued to physicians, consisting of a series of capillary tubes containing the whole-bee extract in the following graded strengths: 1, 10, 50, 100, 200, 500, 1,000, and 2,000 units per ml.

The skin tests are carried out as follows. With a tuberculin-type syringe, 0.02 ml. of the lowest-strength

extract (1 unit) is injected into the skin of the volar surface of the forearm. Injections are continued in this way with the stronger extracts in the skin test outfit until the occurrence of a local reaction is just apparent—a weal about 1 cm. in diameter with a surrounding area of erythema. No further skin tests are done, but the "unitage" of the extract producing this reaction is noted. All test injections are given by the intracutaneous route in a fresh area of skin each time at intervals of 10 to 15 minutes to allow for the development of any reaction that might occur. In our experience, skin sensitivity is variously shown by sensitive patients to 1-250 units per ml. of fresh whole-bee extract.

A suitable treatment set for desensitization purposes is now prepared on the basis of the skin-test reaction.

Desensitization with Whole-bee Extract

Desensitization is carried out with injections of whole-bee extract by the intracutaneous route. This route is advised because the reactions are plainly visible and easily gauged, and dosage can accordingly be suitably regulated. Further, as the amount injected each time is relatively small there is a local reaction only, and, in our experience, no constitutional or other untoward reactions need be anticipated.

The treatment set provided for desensitization purposes consists of a series of dilutions of whole-bee extract of the same batch used for the skin testing in 2-ml. rubber-capped bottles in increasing strengths and commencing at a dilution somewhat less than the reaction-strength noted in the preliminary test.

The intracutaneous injections of each extract dilution are given in doses of 0.05-0.25 ml. at intervals of 2-4 days, with dose increments, when indicated, of 0.05 ml. It is desirable to obtain a weal 1-2 cm. in diameter after each injection. Increase of dosage or use of higher-strength extracts is indicated only when the weal reaction is beginning to diminish in size. It may happen that five, six, or more injections are given from the same extract before proceeding to higher strength.

Example: A positive reaction was obtained in the preliminary skin test with the 10-unit extract. The treatment set is prepared with a series of extracts containing 5, 10, 25, 50, 100, and 250 units per ml. When this course is completed a further series of stronger extracts from 250 units per ml. upwards is issued as indicated. It is desirable to continue desensitization with gradually increasing doses of extract until the patient is receiving injections of extracts of about 1,000 units strength with a local reaction only after each injection. When this final "unitage" of extract is readily tolerated, with the production only of a local weal of 1-2 cm. diameter, maintenance doses of 0.25 ml. each are injected thereafter at gradually increasing intervals until the patient is receiving such an injection once every three to four months. It has not been found necessary to use strengths of extracts higher than 2,000-3,000 units per ml. for effective desensitization. In highly sensitive persons—that is, those reacting to 1-10 units by skin test—it suffices to use a desensitizing extract not stronger than about 1,000 units (corresponding to 1,000-100 times the original skin reaction strength). This final

dosage is reached as a rule in 2-3 months. As in all "desensitization" procedures, it is inevitable that the state of hyposensitization attained will in due course be lowered if not lost. It is for this reason that maintenance doses as described should be continued for as long as thought necessary, especially in bee-keepers and others who cannot avoid contact with bees.

Results of Desensitization

A description has been given (Ordman, 1951) of three persons sensitive to bee stings in whom effective desensitization had been achieved with the use of whole-bee extract administered intracutaneously. Since that time 19 further instances of successful desensitization by this method have come to notice, bringing the total to 22. These 19 cases have emerged from a study of 47 satisfactorily completed reports by physicians who had submitted their bee-sting-sensitive patients to adequate desensitization. In 23 instances the patients had not been further stung by bees, and it is in the remaining 24, where stinging had followed desensitization, that these 19 persons were found to be fully protected (see Table).

It may seem surprising that only 22 authenticated instances of successful desensitization can be quoted when material for prophylactic desensitization had been supplied over the years for some hundreds of persons. The explanation is, firstly, that most people subjected to bee stings in South Africa live in the rural areas and information about them must be obtained by correspondence with their doctors, leading all too often to little or no details about patients in spite of follow-up letters. Secondly, in the bulk of the replies that do become available the information is vouchsafed that, although the patients had been properly desensitized according to our instructions, they had not subsequently been stung by bees.

Details are given in the Table of the 24 cases which had been submitted to desensitization and about which full reports were obtained. Effects of bee stings before and after such desensitization, results of skin-sensitivity tests, and the desensitization procedure itself are described for each case.

It will be observed that in 19 of these cases (1-19) the results were highly satisfactory, as no reactions, or very mild reactions only, were now occurring in persons who were originally very severely affected by bee stings. In Case 20 "some improvement" only was claimed. In Cases 21, 22, 23, and 24 it was reported that desensitization procedures had produced no benefit at all—that is, reactions after bee stings were now as severe as they had been previously.

Cases 21, 22, 23.—These patients were highly sensitive by skin test to whole-bee extract (10 units). Desensitization was carried out to only 100 units or less instead of to the required 3,000-4,000 units. Desensitization in each of these cases was obviously inadequate, and satisfactory results could not be expected.

Case 24.—For some reason this patient does not appear to have been highly skin-sensitive to whole-bee extract (1,000 units) by test, and desensitization should have gone on with strengths up to 4,000 units or even higher.

It becomes clear from the study of the Table that desensitization with whole-bee extract by the intracutaneous method is a very satisfactory procedure if properly carried out.

Summary and Conclusions

A procedure is described for the prophylactic desensitization of persons sensitive to bee stings by the use of increasing strengths of whole-bee extract administered intracutaneously.

A preliminary intracutaneous skin test is performed to determine the degree of the patient's sensitivity to the extract that is to be used for subsequent desensitization.

Successful desensitization is reported of 19 persons originally highly sensitive to bee stings.

THE POLYSACCHARIDE BEHAVIOUR OF CANCER ANTIGENS

BY

JACK G. MAKARI, M.D., D.T.M.&H., Sc.M.

Research Department, Muhlenberg Hospital, Plainfield, New Jersey, U.S.A.

The high degree of accuracy in the detection of antigens in the sera of patients with carcinoma obtained by use of the Schultz-Dale method has already been reported (Makari, 1955a, 1955b). Recently Burrows (1958) confirmed these results in a thorough investigation of the test. The chemical nature of cancer antigens remains an unsolved problem. However, in studying host-tumour relationships it is extremely important to know the exact nature of these cancer antigens. In an effort to elucidate this problem, Burrows and Neill (1958) have investigated the nature of the immunologically active constituent of serum of patients with carcinoma. They attribute the antigenic activity of such sera in the Schultz-Dale test to the presence of a polypeptide.

The following application of the Schultz-Dale method leads us to believe that cancer antigens behave like polysaccharides and that the activity observed by Burrows and Neill in the polypeptide of the serum is probably due to an associated polysaccharide antigen.

Methods

Details of the Schultz-Dale method, the preparation of antigens, and the testing procedure have been described (Makari, 1955b). Tumour and normal tissues are homogenized in 0.2N saline solution (one part of tissue plus four parts of saline) with a Sorvall homogenizer immersed in cracked ice. This procedure is allowed to continue for 10 minutes with the rheostat set at 115. The homogenate is then centrifuged twice at 3,000 r.p.m. at 5°C. for 10 minutes. The sediment is discarded and the supernatant is further centrifuged for 30 minutes at 10,000 r.p.m. at the same temperature. This sediment is separated and resuspended up to volume with normal saline solution. It is to be noted that this sediment differs from that used in my earlier work (Makari, 1955a, 1955b) in that the latter was obtained between 3,200 and 4,000 r.p.m. The sediment used in the present study—that is, that obtained between 3,000 and 10,000 r.p.m.—was chosen because it was found to have antigens in common with various tumours (Makari, 1958a).

The resuspended sediment and its supernatant comprise the antigens used in this study. They are used both in this form and after treatment by a procedure described by Chang (1953) and Chang, Snyder, and Murray (1953) in their preparation of an erythrocyte-sensitizing substance from rickettsial antigen which was thought to be polysaccharide in nature. In this procedure an equal volume of ether is added, with vigorous shaking for five minutes. It is then left undisturbed, to allow separation into ether and aqueous phases. The aqueous phase is mixed with alkali in the following proportion: nine volumes of the aqueous phase to one volume of 2N NaOH. The mixture is kept in a water-bath at 100°C. for 30 minutes. It is cooled and dialysed for two hours at 0 to 4°C. against several changes of isotonic phosphate saline solution (Na_2HPO_4 , 0.81 g.; KH_2PO_4 , 1.04 g.; NaCl, 6.8 g.; distilled H_2O , 1,000 ml.; pH=6.8). The active material found inside the dialysis bag is then shaken with an equal volume of chloroform for 20 minutes and centrifuged at 2,000 r.p.m. for 15 minutes. In this study the chloroform layer is discarded and the clear aqueous phase containing the sensitizing substances (which are referred to as S.S.) is used. These behave as polysaccharides, being non-dialysable, resistant to boiling and alkalis, and giving a positive Molisch test.

In an effort further to evaluate the polysaccharide nature of cancer antigens another method was used which is very similar to that described for the preparation of pneumococcal polysaccharides (Whistler and Smart, 1953).

In this method, melanoma antigen (fraction O), in equal amounts, is added to 95% ethanol chilled at 0° C. This is centrifuged and the supernatant discarded. The sediment is suspended in 80 ml. of acetate buffer (157.5 g. of NaC₂H₃O₂·3H₂O in three litres of distilled water and the pH adjusted to 6.05 with glacial acetic acid). This is then ground slowly at 0° C. and centrifuged.

From the supernatant, the polysaccharide (fraction A) is precipitated by the addition of 5 volumes of cold isopropyl alcohol. The residue from the first grinding is again suspended in 80 ml. of acetate buffer and ground at 0° C. The suspension is centrifuged and the supernatant precipitated with isopropyl alcohol (fraction B).

Fraction A is removed by centrifugation and dissolved in 100 ml. of cold distilled water. The resulting turbid greenish solution is deproteinized by the Sevag method in which 50 ml. of chloroform is added in 10 ml. of butyl alcohol for each 150 ml. of solution, and agitated from time to time in a homogenizer at 3° C.

The resulting emulsion is centrifuged, and the aqueous layer containing polysaccharide is separated. The aqueous layer is then adjusted to a concentration of 3% sodium acetate with saturated sodium acetate solution brought to pH 6 with acetic acid.

One half-volume of cold isopropyl alcohol is added to precipitate the polysaccharide, and the suspension is left overnight. The Sevag procedure is repeated until the material is completely deproteinized, after which the polysaccharide is centrifuged. This polysaccharide-like substance is referred to as P.L.S.

Immunization of guinea-pigs is passive with rabbit antiserum (I.V.) in Section A, and is active in others.

Virgin female guinea-pigs are immunized, by the help of Freund's adjuvants, either with S.S. or with the original antigens obtained from neoplastic tissues. Control antigens and their corresponding S.S. are prepared from "normal" sections of the same organ from which the cancer tissue is obtained, and also from similar organs of a young healthy adult.

In three to four weeks the guinea-pigs are sacrificed and their uterine horns are used in a Schultz-Dale bath. Rabbits similarly immunized are bled and their sera used for passive *in vitro* or *in vivo* (intravenous) sensitization. To release the local *in vitro* anaphylactic reaction of the uterine muscle, various tissue antigens, their S.S. and P.L.S., are used, as well as sera from normal blood donors and from patients with cancer.

These reactions are recorded in mm. in Tables I and II. In Table III results are shown in terms of contraction index (C.I.). This is the ratio of the specific contraction in mm. to that resulting from 10 µg. of histamine base.

TABLE III.—Immunological Activity by the Schultz-Dale Method of a Polysaccharide-like Substance (P.L.S.) and Its Two Fractions A and B Prepared from Melanoma Antigen. (Results are Recorded in Terms of Contraction Index (C.I.). 0.1 ml. was Used to Release the Reaction)

Results

In general, the same result is obtained from guinea-pigs immunized with both S.S. and the original antigens. Furthermore, S.S., P.L.S., and original antigens release the Schultz-Dale reactions equally well.

In fact, the polysaccharide-like fractions, A and B, give a higher contraction index than does the original melanoma antigen (fraction O), fraction A giving the highest figures (see Table III). Desensitization is possible with these reactions.

Some typical reactions are shown in Tables I and II. After desensitization to normal serum and normal tissue antigens, the uterine horns from the cancer-immunized guinea-pigs still react positively in response to sera or tissue antigens from carcinoma or related tumours. Table I shows this phenomenon clearly. Thus, in Table I.A the uterine horns of guinea-pigs immunized to S.S. carcinoma of the colon (Ag.-SS.195 (Handy)) reacted specifically (after desensitization to normal serum in reactions A1 to A14) with sera from carcinoma patients (reactions A15 and A17), but not with sera from normal donors (reactions A16 and A18). On the other hand, control uterine horns of guinea-pigs immunized to S.S. "normal" colon (Ag.-SS.194 (Handy)) did not react to these same sera from carcinoma patients or from normal donors (after desensitization to normal serum).

The immunological specificity of these positive reactions is strongly suggested by desensitization procedures in which the sensitized uterine horns initially exposed to a positive reacting serum or a tissue antigen fail to react to the same antigen after these horns are washed and exposed again. This indicates specific neutralization of antibodies fixed to

the horn by their specific antigens and excludes the possibility of a non-specific pressor effect. For example, Table I shows a marked reaction to serum from carcinoma case 18053 in A15; a weaker reaction to serum from another carcinoma, 18077, in A17; and no reaction at all on second contact with carcinoma serum, 18053, in A19.

Table I.B shows a similar behaviour of the uterine muscles from guinea-pigs immunized to the native original antigens—that is, carcinoma of the colon (Ag.195 (Handy)) and "normal" colon (Ag.194 (Handy)), as was shown for their S.S. counterpart. In addition, the comparative strength of various antigens in releasing the reaction is shown. Ether extraction of antigens 194 and 195, for example, improved their antigenicity, as shown by their ability to release the reaction in the Schultz-Dale bath (Table I.B, 14, 15, 16, and 17). Furthermore, the capacity of these antigens to immunize guinea-pigs was well preserved even after their ether extraction (Table II.D). It is also apparent that after centrifuging at 10,000 r.p.m. the supernatant fraction of the antigen is much more effective in releasing the reaction than the sediment even when the latter is ether extracted (see Table I.B: 3, 4, 16, 17, and 18).

Table II further reveals the parallel behaviour of S.S. and of original antigen. It also shows the behaviour of autologous antigens (wherein neoplastic and "normal" tissues are taken from the same patient) as, compared with homologous antigens (wherein the neoplastic and the control normal tissues are taken from a carcinoma patient and from a healthy accident victim respectively). In the case of autologous antigens the so-called "normal" tissue is not altogether normal immunologically. Although it shows mostly normal tissue components for the most part when the full antigen is used for immunization of guinea-pigs (Table II.C, 1 and 5; D, 1 to 12), it does show carcinoma components when S.S. is used for immunization (Table II.A, 6 and 8) and for releasing the reaction (Table II.C, 5 and 6). In the latter case both "normal" colon (Ag.194-S.S. (Handy)) and carcinoma of the colon (Ag.195-S.S. (Handy)) possess the same abnormal components although they are present to a lesser degree in the "normal" tissue. Furthermore, desensitization indicates that these abnormal components are antigenically similar to the carcinoma antigen. Thus we see that prior addition of "normal" colon (Ag.194-S.S. (Handy)) to the carcinoma horn (Table II.C, 5) desensitized it completely to further addition of carcinoma of the colon (Ag.195-S.S. (Handy)). However, the same amount of Ag.195-S.S. did react specifically with another similarly sensitized horn (Table II.D, 13). This was not the case, however, when autologous tissue antigens were used from a healthy person. This is shown by Table II.B, in which tissue antigens are prepared from the kidney of a patient with acute leukaemia and control antigens are prepared from the kidney of a young victim of a car accident. Only normal tissue antigens were found in the healthy kidney.

The common antigenicity between various types of malignant tumours is shown in Table I.A, 15 and 17; between fibrosarcoma and carcinoma in Table I.B, 19 and 20; between various types of carcinomas and melanomas in Table II.A, 3, 4, 6, and 8; and between leukaemia, Hodgkin's disease, and carcinoma in Table II.B, 9 and 10. This aspect will be studied in other articles (Makari, 1958a, 1958b).

Discussion

The immunologically active substances in the serum and tissues of cancer patients behave like polysaccharides when studied by the Schultz-Dale test. They are precipitated by isopropyl alcohol, and their activity is maintained, and even improved, after deproteinization with chloroform and butyl alcohol. Burrows and Neill (1958) showed that acid hydrolysis resulted in complete loss of activity. This does not contradict the polysaccharide nature of these antigens, since acid hydrolysis of polysaccharides is known to destroy their antigenicity. Extraction with 2N NaOH, however, hydrolyses

the bonds between carbohydrates and proteins (Meyer and Rapport, 1951), while heat to 100° C. denatures the proteins. This probably explains why treatment with heat and alkalis does not destroy their ability to immunize guinea-pigs or to release the Schultz-Dale reaction. The fact that such activity persists after ether extraction tends to refute the lipid nature of cancer antigens. The slight improvement in antigenicity resulting from ether extraction is again consistent with a polysaccharide nature, since polysaccharides have a great affinity for lipids.

Moreover, the polysaccharide nature of the antigen explains the greater activity of the supernatant, as compared with the sediment, in releasing the Schultz-Dale reaction. The less soluble and less active components are probably the result of gradual drying of tissues. This, according to Whistler and Smart (1953), occurs when highly hydrated polysaccharide material is air-dried. The gradual removal of water molecules allows neighbouring polysaccharide molecules to come together and establish strong bonds which later restrain the separation of molecules. This reduction in surface area and in the number of active available sites on the polysaccharide molecules could be regarded as a form of polymerization, and would account for the *in vitro* reduction of antigenic activity—that is, its capacity to release the reaction in the Schultz-Dale bath—of the sediment as compared with the supernatant.

These studies also raise the question of the relatively "normal" nature of the healthy colon tissue obtained from the patient Handy, who did have a carcinoma of the colon. Is pathologically "normal" tissue necessarily immunologically "normal"? Is the better control tissue to use in this case "normal" colon from the same patient or from a young healthy accident case?

The above findings indicate the presence of the specific carcinoma polysaccharide-like antigens in these so-called "normal" portions from the carcinoma patients, although to a less extent than in the neighbouring neoplastic tissue. They also indicate that this soluble polysaccharide-like antigen is present not only in the cancerous tissue but also in the blood and other tissues, even those that appear pathologically "normal." This was the reason for the use in later studies of homologous tissues from a healthy individual rather than from the cancer patient himself.

The polysaccharide nature of cancer antigens could easily explain why mast cells and tissue polysaccharides are the predominating elements in the development and growth of connective-tissue tumours as shown by Sylvén (1945), Holmgren and Wohlfart (1947), and Gersh and Catchpole (1949). It could also explain the greatly increased amounts of polysaccharides always found in the serum of cancer patients. Furthermore, it throws new light on the finding of high levels of hyaluronidase inhibitors in the blood of patients with disseminated cancer by Kiriluk *et al.* (1950) and with certain leukaemias and lymphomas by Hentstell and Freedman (1951).

The association of polysaccharides with polypeptides is well known. Morgan (1941) and Partridge and Morgan (1942), for example, were able to make artificial complexes using "polypeptide-like" substances isolated from Shiga, and carbohydrates such as group A substance from commercial pepsin. It was found that these "polypeptide-like" substances appear to have a special power to form antigenic complexes with polysaccharides.

It is our belief that the activity of the polypeptide found by Burrows and Neill (1958) in the serum of cancer patients is due to an associated polysaccharide antigen. The finding by Winzler (1953), referred to by Burrows and Neill, of an increase in polypeptides in the serum in carcinoma, and specifically of mucopolypeptides, strengthens this possibility.

Polysaccharides are less complex to study immunologically than are proteins. This finding, therefore, of the polysaccharide nature of cancer antigens should give us a little more reason for optimism in our attempts to understand the cancer problem and a greater hope of its solution.

These results are preliminary in nature, and work along these lines is being continued at the Muhlenberg Hospital. Further evidence for the polysaccharide nature of cancer antigens, using another immunological technique, will be published elsewhere.

Summary

Substances distinctly polysaccharide-like in nature have been prepared from cancer and normal tissue antigens by two procedures: (1) by precipitation with isopropyl alcohol and deproteinization with chloroform and butyl alcohol (P.L.S.); and (2) by heat and alkali treatment (S.S.).

The specific immunological activity of cancer antigens seems to reside in these polysaccharide-like substances.

I thank Mr. H. D. Hamilton, of the Muhlenberg Hospital, for his help in preparing the manuscript. This work was done at the University of Texas.

DETECTION OF ANTIGENS IN SERA OF PATIENTS WITH NEOPLASTIC DISEASE BY SCHULTZ-DALE TEST

ITS POSSIBLE USE AS A SCREENING PROCEDURE FOR TUMOURS

BY

JACK G. MAKARI, M.D., D.T.M.&H., Sc.M.

Research Department, Muhlenberg Hospital, Plainfield, New Jersey, U.S.A.

In search of a specific diagnostic serological test in cancer we have looked for a high degree of positive results in known cancer cases and a high degree of negative results in non-cancerous disease. Dunn and Greenhouse (1951) tentatively set limits of 90% accuracy in cases of cancer and 95% accuracy for patients with non-cancerous disease.

Makari (1955) described the use of the Schultz-Dale test for the detection of carcinoma antigen in the serum of patients with carcinoma. It was shown that, when the carcinoma antigen used for immunization of guinea-pigs was the sediment obtained between 3,200 and 4,000 r.p.m., this test would conform to the criteria set up by Dunn and Greenhouse—that is, it was positive in 96.8% of proved carcinoma cases and negative in 95.2% of non-cancerous lesions.

Recently Burrows (1958) was able to confirm our results in a large series of 508 patients, and recorded an accuracy of 96.7% in proved carcinoma cases and of 96.7% in non-cancerous lesions. This establishes the

use of such a procedure as a *diagnostic* test, but the need still remains for a *screening* test which would detect not only carcinomas but other tumours as well. Such a screening test, however, should not be subject to some of the criteria established by Dunn and Greenhouse for a diagnostic test—for example, the requirement that there be not more than 5% of "false-positive tests" (a test which is positive, although the patient does not have a clinically apparent cancer). The principal aim of such a screening test would be the detection of tumours in this preclinical stage. In fact, a good screening test should show more of these so-called "false positives," and, to be a practical test, it should detect not only carcinomas but all tumours.

Working on the hypothesis that the change from a state of carcinogenesis to pre-tumour, tumour, and tumour differentiation is associated with a gradual increase in the size of the antigenic particles (as these particles become incorporated with certain components of the host), and that such a change is accompanied by an increase in specificity, one would expect that, by using antigenic particles smaller than those used in our previous work, components which are less group-specific and which have a wider antigenic spectrum would be found.

In fact, by the use of carcinogens as immunizing antigens to guinea-pigs, it should ultimately be possible to reach the lowest common denominator of all tumours, and to detect in the serum of patients carcinogen-like substances in the early stage of carcinogenesis before clinical cancer develops. In this and in another paper, evidence is presented in support of this hypothesis. The purpose here is to show that, by using for immunization of guinea-pigs antigens with smaller particles than those I previously used, it is possible to detect antigenic components in the serum which are common to patients with various types of neoplastic disease, and to show that such a procedure might be utilized as a screening test for tumours.

Some aspects of immunological relationships between various tumours are also referred to.

Method

The technique employed is essentially the same as that used by Makari (1955), except that an antigenic fraction with smaller particles is used for immunization of guinea-pigs.

A 20% aqueous emulsion of a tumour is made in 0.2N saline solution. The sediment II previously used was obtained by centrifugation at 3,200 r.p.m., equivalent to an R.C.F. of 1.5 kg./g., and recentrifugation at 4,000 r.p.m., equivalent to an R.C.F. of 2.3 kg./g. Sediment III (also used before) was obtained by centrifugation between 4,000 and 10,000 r.p.m., equivalent to an R.C.F. of 10.3 kg./g. In this study a modified sediment III, to be referred to as sediment IIIB, is used. This is the sediment obtained by centrifugation at 3,000 r.p.m., discarding the sediment, and recentrifugation at 10,000 r.p.m.—that is, between 3,000 and 10,000 r.p.m. This sediment (IIIB) is suspended in normal saline solution (to original volume) and is injected subcutaneously with Freund's adjuvants into young virgin female guinea-pigs. These guinea-pigs are sacrificed after one month and used in a Schultz-Dale bath. For passive sensitization, rabbits are similarly immunized but are given a second dose two weeks later. This is followed by a third dose a week afterwards. They are bled 7 to 10 days after the last injection. The rabbit antisera are adsorbed with guinea-pig kidney (to remove Forssman antibody) and are then either injected intravenously or diluted (1 part to 250) with Tyrode's solution, and allowed to come in contact with

a uterine horn from a non-immunized guinea-pig for one hour at 5° C. and with air bubbled into the mixture.

Carcinomas of varying types were used for immunization of guinea-pigs. These were carcinomas of the breast, rectum, colon, and stomach, and squamous carcinomas of lung and oesophagus. Other tumours were also used: fibrosarcoma, melanoma, acute leukaemia, and lymphoma.

One further modification was introduced for the evaluation of these reactions. For a test to be regarded as a true positive, evidence of desensitization was required—that is, it should be possible to obtain decreasing reactions or no reactions at all to the same serum when the uterine horn is washed and re-exposed to it at the same dose level. Those cases which did not fulfil this criterion were included with the questionable group. Uterine horns not adequately sensitized and not reacting with a known positive serum were discarded. Sera added to the horn at the end of the run and not followed by a known positive reaction could not be evaluated and are not included in this series.

For certain studies of antigenic relationships between tumours, two experiments are reported. In one, segments from the ileum of one guinea-pig were used instead of the uterine horns, and Tyrode's solution with full-strength calcium was used instead of the half-strength we use with uterine horns. Passive sensitization *in vitro* was done with antisera from rabbits immunized with various types of tumours. The reactions were triggered by the addition of supernatants—that is, where sediment at 10,000 r.p.m. was removed. In another study the uterine horns from guinea-pig 415 actively immunized against carcinoma of the colon (antigen 70) were used. The two horns from the same guinea-pig were divided into four segments, which were used in separate baths. To release the reactions, various dilutions of carcinoma and sarcoma supernatants were used, one horn receiving carcinoma supernatant, another carcinoma sediment, the third sarcoma supernatant, and the fourth sarcoma sediment. Each horn was then completely desensitized to the antigen added to it, and the releasing antigens were reversed so that sarcoma was added to the horn receiving carcinoma, and vice versa. This experiment was carried out in collaboration with Dr. P. Krag, of the State Serum Institute in Copenhagen, while he was visiting our laboratories.

Results

By the use of a modified Schultz-Dale test for tumour screening—that is, where carcinoma sediment IIIB (between 3,000 and 10,000 r.p.m.) was used as immunizing antigen—the following positive results were obtained in 444 individuals (Table I): 90.2% of 215 proved carcinomas; 62.0%

TABLE I.—Schultz-Dale Reactions in 444 Individuals and in 704 Normal Serum Specimens Using a Modified Test for Tumour Screening with Carcinoma Sediment IIIB as the Immunizing Antigen for Guinea-pigs

Cases Studied	Result of Test			Total
	Negative	Questionable	Positive

Antigens for rabbits with the exception of Ag. 51 are made up of sediment III B. Ag. 51 has in addition sediment at 3,000 r.p.m. included. Figures in parentheses represent contraction indices (ratio of specific contraction to histamine contraction). Figures 1 and 2 outside parentheses indicate whether contraction occurred in the first or second half of the run. * Strong maintained reaction. † Desensitization with normal serum and normal tissue antigens was done before the addition of cancer antigens, but is not reported in this table.

17 sarcomas, 85% of 33 carcinomas, and 75% of 8 melanomas. Two cases of lymphoma were positive, but one case of Hodgkin's disease was negative (see Table II). When three melanoma sediments IIIB (between 3,000 and 10,000 r.p.m.) were similarly used as immunizing antigens, the following results were obtained in 61 cases: 75% of 16 cases of melanoma were positive with the amelanotic Ag., 86% of 7 cases of melanoma with melanotic Ag. 158, and 87% of 15 cases of melanoma with melanotic Ag. 80. Eight out of 10 cases of carcinoma were positive and four out of five cases of sarcoma were positive. Two out of three cases of leukaemia were positive, but one case of Hodgkin's disease was negative. In other studies Hodgkin's disease was shown to have common antigenicity with leukaemia. The overall percentages of positive reactions were as follows: 89% of 262 carcinomas, 73% of 130 malignant tumours other than carcinomas, 94.2% of 35 benign tumours, 77.9% of 59 cases with pre-cancerous lesions and suspected tumours, 12.5% of 80 healthy donors, and 12.6% of 704 serum specimens from the blood bank.

Some studies on antigenic relationships among tumours are shown in Tables III and IV. The results indicate a spectrum of common antigenicity which is narrowest in carcinoma of the breast and widest in lymphoma (see Table III). Results of the second experiment (shown in Table IV) demonstrate some antigenic relationships between carcinoma of the colon and sarcoma. It was found that the supernatants gave a reaction in a higher dilution than the sediment. Furthermore, desensitization was easier to perform with the sediment than with the supernatant. Desensitiza-

tion to carcinoma reaction prevented the appearance of a sarcoma reaction, while desensitization to sarcoma allowed the later appearance of a carcinoma reaction.

Discussion

It is apparent that by the proper choice of the immunizing antigen one can utilize the Schultz-Dale test both as a type-specific diagnostic serological test for carcinoma, or also, as shown in these studies, as a serological screening

test for all kinds of tumours. The finding that benign tumours and pre-cancerous lesions (such as hyperkeratosis, hyperplasias, etc.) give as high a percentage as malignant tumours indicates the further usefulness of this procedure as an early screening test for tumours.

A negative test would mean that the presence of a tumour is unlikely, while a positive test is a signal indicating the presence of a benign or malignant growth, or even a pre-cancerous lesion which should be further investigated. Therefore the significance of such a test from the point of view of early detection is much greater than the test we described earlier, but is less useful for establishing a definite diagnosis. It is of interest to note that malignant tumours other than carcinoma gave fewer positive results than benign tumours, including even early hyperplasias or suspected tumours. This finding by itself suggests the usefulness of such a test for early detection of tumours and for screening purposes.

It is of interest to note that, although this screening procedure detects common antigens in various tumours, it still detects its own type of tumour to a greater extent—that is, type-specificity is not completely lost. Thus when sarcoma sediment IIIB is used, the highest percentage of positives (88%) is still in sarcomas as compared with carcinomas and melanomas. When melanoma sediment IIIB is used (from melanoma 158 and 80), 86% and 87% positive results are obtained with melanomas. The persistence of type specificity is due in part to the inclusion of cancer-specific antigens sedimented at 3,200 to 4,000 r.p.m.—that is, sediment IIIB from carcinoma, sarcoma, and melanoma, this test could possibly detect all these tumours equally well and to a greater degree of accuracy than 90%.

It also seems feasible that by further fractionation of sediment IIIB one could hope to obtain a fraction which would distinguish malignant tumours from benign tumours. This, too, would be of great clinical usefulness. Sediment IIIB from an amelanotic melanoma with metastasis to the omentum was an exception; with this antigen both carcinomas and sarcomas were detected to a greater extent (80%) than were melanomas (75%). Could this observed difference in antigenic specificity be related to metastasis?

Studies with polysaccharide-like sensitizing substances (S.S.)—prepared from carcinoma sediments IIIB and used for immunization of guinea-pigs—show a broad antigenicity similar to that of its parent antigen. For example, a polysaccharide-like S.S. prepared from adenocarcinoma of the colon (sediment IIIB) shows common antigenicity with adenocarcinomas of the colon, breast, lung, and stomach, squamous carcinomas, melanomas, and fibrosarcoma. These studies are reported in the accompanying article (Makari, 1958).

The study of antigenic relationships between tumours is very fascinating but is still in its infancy. Two examples are given here to show how the Schultz-Dale test could be most helpful in such studies. In the guinea-pig immunized with carcinoma of the colon sediment IIIB (see Table IV) it was found that desensitization to carcinoma antigen prevented the sarcoma reaction, but that desensitization to sarcoma antigen allowed the later appearance of carcinoma reaction. We may assume that the two antigens have components in common, and that the horns immunized actively with carcinoma also contained, besides this antibody in common with sarcoma, another antibody or group of antibodies reacting only with carcinoma antigens.

In the second example (Table III) a few observations are of interest. Listing the tumours studied in order of their immunizing capacity, we find the spectrum of antigenic composition increasing in the following order: melanoma, carcinoma of the breast, carcinoma of the lung, squamous-cell carcinoma of the mouth, lymphosarcoma, fibrosarcoma, and, finally, recurrent lymphoma. If the supernatants are studied for antigenicity, however, we see a reversal of the order shown above, with the antigenic spectrum widening as

we go from fibrosarcoma to lymphosarcoma and then to carcinoma of the lung and oesophagus. Melanoma of the skin is an exception. The sediment from carcinoma of the liver (secondary from breast) was prepared differently from the others by including the sediment at 3,000 r.p.m. to that at 10,000 r.p.m. It is surprising, however, that, despite this addition, there seems to be some loss of antigenicity of the sediment as compared with the other carcinomas tested. Again one wonders whether this difference may be due to the fact that the carcinoma of the liver is a metastatic lesion compared with carcinoma of the lung and carcinoma of the oesophagus, which are primary.

One more question: What should be the management of an individual with a positive tumour-screening test with no localizing symptoms or signs and in whom a thorough check-up is negative? One could still follow a "wait and see" policy and keep such a person under strict surveillance until the first signs and symptoms appear. This would necessarily mean a loss of both precious time and an excellent opportunity for cure. There is, in my opinion, another alternative—namely, the detection of circulating antigens from tumour-damaged organs by use of the Schultz-Dale test.

In preliminary experiments we have found it possible to detect liver antigen, kidney antigen, etc., in the serum by the use of normal liver and kidney antigen for immunization of guinea-pigs. On finding evidence of circulating kidney antigen—for example, in conjunction with a positive tumour-screening test or a positive diagnostic test—it becomes possible to diagnose not only the presence of a tumour and its type but also its location. In this way, despite the limitations of our present surgical techniques, operative intervention at such an early phase would result in much better chances of a cure.

Summary

The Schultz-Dale test described earlier (Makari, 1955) has been modified by immunizing guinea-pigs with carcinoma sediment obtained between 3,000 and 10,000 r.p.m. instead of 3,200 to 4,000 r.p.m. This modification has been studied in 566 individuals and 704 serum specimens obtained from blood-bank sera.

89% of 262 carcinomas, 73% of 130 malignant tumours other than carcinoma, and 94.2% of 35 benign tumours were accurately diagnosed. 77.9% of 59 pre-cancerous lesions and suspected tumour cases were positive, while only 12.5% of 80 healthy donors and 12.6% of 704 serum specimens obtained from the blood bank were positive.

This modification can be useful as a tumour-screening procedure, while the original method described by Makari and confirmed by Burrows would serve as a specific diagnostic test for carcinoma.

Some antigenic relationships between various tumours are also discussed.

I thank Dr. Peter Krag, of the State Serum Institute, Copenhagen, for his collaboration in the experiment shown in Table IV, and Mr. H. D. Hamilton, of the Muhlenberg Hospital, for his help in editing the manuscript. This work was done at the University of Texas.

COMPLICATIONS OF CANDIDA ALBICANS INFECTION IN INFANCY

BY

J. M. WAGNER, M.B., M.R.C.P.

AND

I. KESSEL, M.R.C.P., M.R.C.P.Ed., D.C.H.

Department of Paediatrics, University of the Witwatersrand

Thrush was first described in 1764 by Rosén von Rosenstein, who mentions a disease of the mouth, more severe if it spreads into the lungs. Thrush infections were later described by Langenbeck in 1839, Berg (1841), and Robin (1853). Robin called the organism *Oidium albicans*, and in 1890 Zopf renamed it *Monilia albicans*. From then until the present time the organism, now known as *Candida albicans*, has been adjudged to be responsible for disease in man. During recent years, since the discovery of broad-spectrum antibiotics, increased interest has been paid to the severe effects which may be produced. In infancy, thrush has long been known as a common disease occurring especially in sickly and undersized children. The majority of cases present an oral disease of varying severity, but many reports have been written of far more serious consequences of invasion by the fungus. These usually involve local spread to the gastro-intestinal or respiratory systems, but monilial septicaemia with metastatic disease is also described.

The purpose of this paper is to present four cases of thrush oesophagitis and to review previous writings on the complications and treatment of *Candida albicans* infections. Three of the cases present a very definite syndrome which is due to thrush, though the oesophagitis cannot be proved with certainty, and the fourth is a fatal case of thrush oesophagitis proved at necropsy.

Case 1

A male infant aged 26 days was admitted to hospital on November 10, 1956, with a history of cyanotic attacks and difficult breathing for five days. He had a full-term normal delivery but difficulty in sucking from birth. On the day of admission severe thrush was noted.

On admission he was a well-nourished infant weighing 7 lb. 2 oz. (3.2 kg.). He was very dyspnoeic (rate 60 a minute), was cyanosed, and had marked stridor and intercostal recession. His temperature was 98.4° F. (36.9° C.). There were rhonchi throughout both lung fields. He had a grade III systolic murmur in the fourth left interspace suggestive of a ventricular septal defect, but no signs of congestive cardiac failure.

He was nursed in an oxygen tent moistened with "alev-aire" and given penicillin, 250,000 units six-hourly, streptomycin, 75 mg. twice daily, nystatin, 100,000 units six-hourly, and 0.5 ml. injections of vitamin B complex on alternate days. He was offered feeds of expressed breast milk.

X-ray examination of the chest (Fig. 1) revealed bilateral bronchopneumonia. A blood count showed a haemoglobin of 15.3 g. per 100 ml. and 11,700 white cells (polymorphs 47.5%, monocytes 0.5%, lymphocytes 51%, eosinophils 1%). An oral swab grew candida.

For a few days the child improved generally, though the thrush remained obvious. He then deteriorated rapidly, was cyanosed outside the oxygen tent, and had very pronounced blue attacks, mainly during feeding.

A "lipiodol" swallow examination on November 21 (Fig. 2) showed pooling of the oil in the pharynx with spill-over into the lungs. An aspiration pneumonia affected the major

portion of the right lung and the mid-portion of the left. It was then decided to take him off all oral feeds and medicines and to give him an intravenous drip. This treatment was continued for 10 days—the fluid containing appropriate electrolytes and vitamins, and plasma was given daily. His condition improved, his colour became pink, and all chest signs disappeared. On one occasion—three days after this treatment was started—he was fed and became extremely cyanosed. On November 30 a repeat lipiodol swallow (Fig. 3) showed easy passage from pharynx to oesophagus with no spill-over. The lung fields had almost cleared.

From December 1 slow oral feeding was resumed and he made an uninterrupted recovery (Fig. 4).

Case 2

A male infant aged 15 days was admitted to hospital on March 17, 1956. He had been quite well until he was 8 days old, when he developed thrush. This became worse in spite of treatment, and for a few days before admission he had been breathless and had vomited some of his feeds.

FIG. 1.—Case 1. Chest radiograph before treatment.

FIG. 2.—Case 1. Radiograph of lipiodol swallow before treatment.

On examination he was apyrexial but extremely ill, cyanosed, and dyspnoeic, and frothy mucus was bubbling from his mouth. His mouth was swollen and showed severe thrush with some ulceration. Chest examination revealed recession, and on auscultation rales and rhonchi were heard throughout both lung fields. On attempting to swallow he became very blue and regurgitated most of what was taken. A lipiodol-swallow examination showed a spill-over into the trachea and that some of the oil would not enter the stomach through the cardiac sphincter. This was thought to be due to reflex cardiospasm due to oesophagitis. Treatment was instituted immediately; oral feeding was entirely stopped and intravenous drip, penicillin, streptomycin, and nystatin (100,000 units, four-hourly) were given.

Two days later the child was a little better but still extremely ill, and hydroxystilbamidine, 10 mg. intravenously daily, was started. On March 24 oral feeding was again

FIG. 3.—Case 1. Chest radiograph after treatment.

FIG. 4.—Case 1. Radiograph of lipiodol swallow after treatment.

tried, but there was immediate deterioration. X-ray examination at this stage (Fig. 5) showed a right basal pneumonia. Intravenous therapy was again started, though small oral feeds were continued. The condition improved very gradually. On April 8 lipiodol-swallow examination was repeated, and on this occasion the oil passed rapidly from mouth to stomach without spill-over or hold-up.

The patient was discharged well on May 5.

Case 3

A female patient aged 5 weeks was admitted to hospital on January 7, 1954. She had a normal history until 3 weeks of age, when she developed thrush of the mouth, which was treated daily with 1% gentian violet without improvement, and then unsuccessfully with chlortetracycline. She had been very difficult about taking feeds throughout this period. For one day she had had a cough.

On admission her temperature was 101° F. (38.3° C.), but she appeared to be fairly well. She was not cyanosed or dyspnoeic, but she dribbled continually from her mouth. Her chest was clinically quite clear. There was very marked thrush of the mouth. She was treated with penicillin, "bejectal," and local gentian violet. Two days later the mouth was worse and local chlortetracycline was tried. The mouth remained unhealthy, and on January 15 signs of severe pneumonia were present clinically and were con-

FIG. 5.—Case 2. Radiograph taken during treatment.

firmed by x-ray examination (Fig. 6). The plates were reported as being unlike moniliasis of the lungs. Following this, her condition deteriorated rapidly in spite of oxytetracycline and chloramphenicol. It was noted that feeding caused marked distress and cyanosis. She died on April 22. Unfortunately necropsy was refused.

Case 4

A male infant aged 9 months was admitted to hospital on April 21, 1952. His history was of a normal child until four days before admission, when he developed vomiting and an acute diarrhoea. These symptoms were not improving, so he was brought to hospital. On examination his temperature was 102° F. (38.9° C.); he was dehydrated and showed signs of malnutrition. His weight was 12½ lb. (5.7 kg.). Other positive signs found were severe thrush of the

mouth and pharynx and rhonchi throughout the lungs. Both the liver and the spleen were just palpable.

He was given intravenous fluids, intramuscular penicillin and streptomycin, and gentian violet was used locally. Oral feeding of skimmed milk and water was begun after 24 hours. Initially he improved on treatment, but the thrush never cleared. On April 30 he was noticed to be jaundiced, rather chesty, and cyanosed, and his chest was full of rales. His temperature rose to 103° F. (39.4° C.). After this his condition rapidly worsened, and he died two days later.

Necropsy showed a dehydrated child, with marked thrush of mouth and pharynx. The lungs showed basal congestion. The oesophagus was thickened and the surface covered with thick white granular membrane which stopped short at the entrance to the stomach. Histology of the oesophagus showed acute inflammatory changes with exudation and superficial necrosis, and on Gram's stain the presence of *C. albicans*.

FIG. 6.—Case 3. Radiograph of chest.

Aetiology and Frequency of Moniliasis

C. albicans may be found in the normal mouth flora, especially in older children and adults. In the newborn and infants, where the oral pH is high, it is usually introduced from the exterior and causes disease. There is an increased incidence in children of mothers suffering from vaginal moniliasis. This has been observed many times, and one experiment was done to prove that vaginal thrush could be introduced into the mouth of the newborn, producing disease (Hesseltine *et al.*, 1934). Some nurseries have reported an incidence of infection as high as 18.2%. Apart from vaginal thrush as a cause, many cases must be produced by direct spread due to nurses' fingers, bottle teats, dummies, etc. Any trauma to the oral mucosa will increase the likelihood of infection. Airborne infection seems to play no part in the spread.

In any age group the use of broad-spectrum antibiotics has increased the incidence of moniliasis.

Complications of Moniliasis

Oral thrush, which in itself can be a severe disease interfering seriously with nutrition, can spread to cause three types of disease: (1) spread into the gastro-intestinal tract, especially the oesophagus; (2) spread into the lungs; and (3) systemic spread.

Gastro-intestinal Spread

As gastro-intestinal spread is the main topic of this paper it is dealt with in more detail than the other complications, especially as regards oesophagitis. The diagnosis of oesophagitis in Cases 1-3 cannot be proved. However, the syndrome which they represent is a definite one whether it be due to actual spread to the oesophagus, as some authorities have felt, or to an incoordination of swallowing due to thrush of the posterior pharynx, either leading to inhalation of food and aspiration bronchopneumonia. This syndrome may be described as one in which a baby with oral thrush becomes very toxic and sometimes dehydrated, has difficulty in swallowing, and during feeds is noted to choke and become cyanosed. Within a short period a severe bronchopneumonia develops, and without active treatment death may easily follow, as happened in Case 3. To substantiate the diagnosis x-ray films of the chest will show marked bronchopneumonia, and lipiodol swallow an incoordination of swallowing either at the upper (Case 1) or at the lower (Case 2) end of the oesophagus. Culture of the oral flora can show that *C. albicans* is present, but not at what level of the gastro-intestinal tract. Some authors working on adults with similar clinical pictures have performed oesophagoscopies on their cases, and shown that the oesophagus is involved in a disease similar to that in the mouth (Stenderup *et al.*, 1956). Such an investigation was not thought safe in these very ill babies.

In the literature this syndrome is well described. Ebbs (1938) performed necropsies on 28 infants under 10 months of age, the average being 4 months, all of whom had died of oesophagitis: 22 had thrush oesophagitis. The clinical picture in these children was very similar to that described above. Reye (1941) found that of 150 necropsies 10 showed oesophagitis, which was the cause of death in seven and in five was due to thrush. Henderson (1943) reviewed 163 cases of thrush during a three-year period, and 13 of these had oesophagitis and seven died from its effects. Adams (1944) described five fatal cases of thrush pneumonia in infants with a similar clinical picture. Lederer and Todd (1949) did routine necropsies on 28 infants under 4 weeks and on 176 under 1 year of age. In seven of the former and 19 of the latter moniliasis was thought to have caused death. Clinically a syndrome of vomiting and dehydration with aspiration of vomit and septicaemia is described. Six patients died suddenly from blocking of the respiratory passages.

Wolff *et al.* (1955) describe two cases identical with our Cases 1-3. Both responded well to similar treatment. Andrén and Theander (1956) and Geiger *et al.* (1946), writing on two adults, mention typical x-ray changes of oesophageal moniliasis. Both had been on long courses of antibiotics and were x-rayed because they had oral thrush with dysphagia. The entire thoracic oesophagus was irregular and ragged, and was made up of numerous small indentations and protrusions. Longitudinal folds were discernible and the lumen became distended on passage of a large bolus. Stenderup *et al.* (1956) had three adult patients with thrush, and in two oesophagoscopies showed thick coating of the oesophagus with monilia-like lesions.

Two authors mention intestinal moniliasis. MacGregor and Henderson (1943) examined two children found dead at home in whom marked intestinal thrush was present, and Zimmerman (1950) quotes a personal communication from Dr. Sydney Farber of five cases of disseminated moniliasis in childhood in which the primary site was the oesophagus or the intestines.

Thrush oesophagitis is a reasonably common disease, and, though for many years it was thought to be diagnosable only at necropsy, there is no doubt that it can be diagnosed and treated during life.

Broncho-pulmonary Moniliasis

Much controversy has arisen whether primary moniliasis of the lungs exists or not. From the first mention of the

condition by Castellani in 1905 until now, many authors have published reports of cases. Many, however, feel that there is no such disease and that where moniliasis is found in the lungs it is a secondary infection. Actual proof of moniliasis is made difficult by two factors—that it is hard to prove that a positive candida culture comes from the lungs when oral moniliasis is present, and that after death moniliasis is a common secondary infection of tissues. There is no doubt, however, that at any age oral thrush can be complicated by pneumonia, which is not always due to inhalation. Some cases—for example, that described by Beckmann *et al.* (1955) with prompt response to nystatin, and the fatal case described by Falkner and Wising (1955)—are very convincing cases of primary broncho-pulmonary thrush. Sahni (1957) describes a case without primary lung disease in which the patient responded adequately to treatment with potassium iodide and nystatin. It seems that pulmonary moniliasis must be regarded as a serious complication of the oral disease.

Systemic Moniliasis

A number of cases have been described of septicaemic spread of candida infection, with widespread lesions developing. References to the following cases were found:

Two patients with monilia meningitis, one of whom was found to be quite well after a four-year follow-up (Fine *et al.*, 1955; Carnu and Charanis, 1954).

A patient who died of thrush and was found at necropsy to have a perinephric abscess, thrombosis of the inferior vena cava, and bronchopneumonia, all growing pure *C. albicans* (Brown *et al.*, 1953).

A patient who at necropsy had multiple abscess of the brain, myocardium, and kidneys due to monilia (Brown *et al.*, 1953).

Two further cases quoted by Brown *et al.* were found at necropsy to have monilial abscesses of myocardium, kidneys, and lungs. Blood culture grew *C. albicans* in one case and *C. tropicalis* in the other. Both cases had had long courses of broad-spectrum antibiotics.

Zimmerman (1950) quotes the case of a patient who died of mycotic endocarditis, and mentions a personal communication from Dr. Sydney Farber quoting five cases of disseminated moniliasis in children being treated with various chemotherapeutics, and at necropsy there were widespread fungus lesions. The primary site in all was the oesophagus or intestines.

Geiger *et al.* (1946) quote another fatal case of *C. albicans* endocarditis.

Although these are not a vast number of cases, they do present a frightening aspect of the possible outcome of thrush.

Pathology

Case 4 illustrates the pathology of thrush oesophagitis. The organism grows as patches of greyish-white membrane on the mucous surfaces, this membrane consisting of a tangled growth of Gram-positive hyphae with spores produced at the junctions of the segments. Permeation and destruction of the epithelium occur and often there is secondary bacterial growth. The oesophagus is either primarily involved or involved through secondary extrusion from a contiguous lesion. There may be either superficial erosion or actual pseudomembrane formation with mycelial threads found in the tissue sections.

Treatment of Moniliasis

In the majority of simple cases of not very ill children with oral thrush local measures will suffice. These consist of gentle handling so as not to traumatize the mucosa, and swabbing with at most three daily applications of 1% gentian violet solution. If this is ineffective, and in more severe cases, drug therapy should be started. The possibilities in this direction are:

Nystatin, an antifungal agent derived from cultures of *Streptomyces noursei*, in doses varying from 50,000 units four times daily in the newborn to 500,000 units in adults, has proved a very powerful antimonilial weapon. It has eliminated or reduced

the number of candida organisms in the stools of 25 adult patients in 48 to 72 hours (Sternberg *et al.*, 1953-4). It is poorly absorbed from the gastro-intestinal tract and is mainly of use locally. There are few or no toxic effects.

Hydroxystilbamidine, which is one of the aromatic diamidine compounds and has been used in various mycotic infections, was found useful by Wolff *et al.* (1955) in two cases of thrush oesophagitis. The dosage suggested is 5 mg. per kg. given 12-hourly for four to six days. Toxic effects, such as trigeminal neuralgia and renal damage, which are common with stilbamidine therapy, have not been reported. There is a marked tendency to thrombophlebitis of the veins used for the intravenous injection, and there are reports of weakness and even circulatory collapse following the injection. In a series of three cases in adults pentamidine was found very effective (Sutcliffe *et al.*, 1954).

Brilliant green has been successfully used locally, intravenously, and by aerosol in cases of pneumonia. The suggested dosage for intravenous use is 0.16 to 0.5 mg. per kg. daily, and by aerosol 2 ml. of 0.1 to 0.2% solution in 50% propylene glycol by oxygen inhalation.

Potassium iodide has been effectively used in many cases, but largely in conjunction with other drugs.

"Paraben" (parahydroxybenzoic acid) has been used experimentally in moniliasis caused by chlortetracycline and found to be effective. So far it has not been found useful therapeutically, but it may be in the future. It is a substance used to prevent fungus growth in foods.

Recently other chemotherapy has been successful in some cases. (a) 1,2,3,4-Tetrahydrofluorenon (T.H.F.) was tried with excellent results in a child with lung thrush following a skin infection (Lindquist, 1957). He reports a series of 30 cases treated by A. Frisk with favourable results in 50%. (b) 2,2-Dihydroxy-5,5-dichlorodiphenylsulphide has been used systemically with success in one case. It was previously used only locally (Richter, 1950). (c) Sodium caprylate has been used in two cases (Keeney, 1946).

Additional and supportive therapy varies according to the complication present. Difficulties of feeding are obvious in cases of oral thrush, as is the need for oxygen in pneumonia. The vital stopping of all oral feeding in cases such as those described here must be borne in mind and instituted before fatal inhalation pneumonia occurs. Intravenous therapy must be continued until a lipiodol-swallow examination shows the baby is able to swallow properly.

Summary and Conclusion

Four cases of thrush oesophagitis are described; two patients survived and two died. An attempt is made to describe the clinical syndrome related to this complication of thrush and how it should be treated. There is a review of cases described with one or more of the complications of oral thrush and their outcome. The possible therapy and the pathology of the condition are outlined.

Whilst oral thrush is an extremely common condition in newborn and infants' wards, the severer complications are not so well known, and as therapy may be life-saving, especially in cases of oesophageal spread, an attempt is made to review some of these complications. Thrush oesophagitis, or a syndrome as cited to it, is fairly common, and often fatal if unrecognized or incorrectly treated. The entity of monilia bronchopneumonia definitely exists, whether as a primary or a secondary disease. Rarer complications, especially monilial septicaemia, are worth remembering, though they are mainly diagnosed at necropsy.

One feels that no case of oral thrush should be regarded light-heartedly until all traces of the disease have cleared up and one is certain no complications have developed.

We thank Dr. Seymour Heymann, head of the department of paediatrics, for his permission to publish these cases, and Dr. S. Javett, Dr. J. Parnell, and Dr. H. Falcke, who were the physicians

ber 28:—Morphine, 50 mg. q.i.d.; amiphenazole, 20, 100, 100, 10 mg. Brighter, no longer drowsy, and able to converse with visitors and read easily. November 30:—At this point amiphenazole was discontinued and he became drowsy again and unable to stay awake for visitors or to read. December 3:—Restored to amiphenazole, 40, 120, 120, 10 mg., and again became bright. This patient's level of alertness could be altered at will by altering the dose of amiphenazole which accompanied his morphine.

Case 8.—Married woman aged 56. This patient had risen slowly to a dose of morphine, 110 mg. q.i.d., with amiphenazole, 40, 40, 20, 20 mg. She was taken off amiphenazole; after 10 days on this dosage of morphine alone, she appeared normal except for slight nausea and tremor. However, further questioning and administration of the Wechsler memory scale showed gross confusion and disorientation of a type typical of a brain lesion or toxic psychosis. She was incapable of performing any task properly. She was given amiphenazole, 60, 60, 40, 40 mg., and over a week she recovered until she became indistinguishable from a normal person. Her Wechsler memory scale corrected score rose from 66 to 98 over that week. It was thought unethical to repeat withdrawal of amiphenazole. This patient has continued medication with morphine and amiphenazole until the time of writing (May, 1958), and at no time has there been a recurrence of an episode similar to that when taken off amiphenazole.

Case 9.—Married woman aged 55. For some weeks this patient was maintained successfully on morphine, 15 mg. q.i.d., with amiphenazole, 50 mg. q.i.d. The patient's liver became enlarged and jaundice appeared, soon after which there was a sudden onset of drowsiness. Amiphenazole was increased from 100 mg. to 150 mg. to 200 mg. q.i.d. with no effect. Respirations dropped to 6 a minute. Death occurred one week after the onset of the drowsiness. At necropsy the liver weighed 2,800 g. and showed almost complete replacement by growth.

Case 10.—Man aged 60. For some weeks maintained successfully on morphine, 15 mg. q.i.d., with amiphenazole, 80 mg. q.i.d. A sudden onset of drowsiness coincided with a very tender enlarging liver. Morphine was discontinued except occasionally at night, but amiphenazole continued. No improvement occurred and the liver continued to enlarge. Death occurred just under one week after the onset of drowsiness. At necropsy the liver weighed 2,150 g. and showed diffuse nodular secondaries.

Up to date, five cases which closely follow the pattern of Cases 9 and 10 have been observed. In the latter cases, after the enlargement of the liver the onset of drowsiness could be predicted in each case, and this was not controlled by an increase in the amiphenazole dosage.

Discussion

The 10 case histories given are illustrative of the results which have been obtained with 500 patients over a period of four years. The following points can be made with a considerable degree of certainty.

In the presence of amiphenazole: (a) Morphine may be given in large doses (200 mg. q.i.d.) without any risk to the patient, provided the usual small doses are given at first. The dosage can be increased rapidly over a few days. (b) Drowsiness does not develop unless there is gross liver damage. The degree of alertness of the patient can be controlled by varying the dose of amiphenazole. (c) Addiction to morphine does not develop. This can be stated for the following reasons: (1) euphoria is absent, (2) no patient has ever expressed a craving, and (3) in at least four cases in which morphine (over 65 mg. q.i.d.) has been given for months there were no withdrawal symptoms on abrupt cessation of morphine administration. (d) Complete analgesia for 24 hours in the day can be obtained. The psychological value of the patient's never experiencing pain cannot be stressed too much. (e) It is necessary to reduce the dose of amiphenazole at night, otherwise the patient will complain of insomnia. (f) In certain cases, where the patient

becomes aware of the hopelessness of his condition and when the downhill progress is rapid, it is necessary to omit the amiphenazole.

The mechanism of the combined role of morphine and amiphenazole is still unknown. A tentative hypothesis is that morphine and amiphenazole combine, probably in the liver, to form a non-narcotic analgesic substance. The evidence for this is that (1) the beneficial effect of the addition of amiphenazole to a drowsy patient already receiving morphine usually takes several hours to become apparent—for example, amiphenazole has only limited value in controlling the respiratory depression and vomiting induced by single doses of morphine (Christie *et al.*, 1958); (2) patients with liver damage do not derive benefit from amiphenazole; (3) patients suddenly deprived of morphine do not show withdrawal symptoms—that is, they are not really deprived of morphine but of the new compound (morphine and amiphenazole), and this deprivation does not lead to withdrawal symptoms; and (4) a similar suggestion would explain the lack of addiction.

This hypothesis, if correct, would indicate the method to be employed in the post-operative use of morphine and amiphenazole. About two days before the operation several small doses of morphine and amiphenazole should be given. Then immediately in the post-operative period the dose of morphine (with amiphenazole) could be increased to the desired degree to produce complete analgesia for intervals of six to eight hours as long as the pain continues (see Weber, 1958).

It should be particularly noted that the doses of amiphenazole used at present are much greater than those previously recommended. As much as 200 mg. may be given t.i.d. or q.i.d., either orally or intramuscularly.

More recently (Gershon *et al.*, unpublished) it has been shown that large doses of amiphenazole (up to 200 mg. a day) will relieve mild depressive states. This action would offer another explanation for the anti-narcotic effect of amiphenazole.

Summary

The beneficial effect of amiphenazole in preventing drowsiness or narcosis when large doses of morphine are administered in intractable pain of terminal carcinoma has been confirmed.

Addiction does not develop, so that the morphine may be withdrawn at any time without the production of withdrawal symptoms.

Case histories supporting the above conclusions are presented.

A tentative hypothesis for the mode of action of amiphenazole is advanced.

This work was partly carried out by means of a grant from the National Health and Medical Research Council, Australia, and the Mental Health Research Fund, University of Melbourne. We thank Dr. W. Moon, medical superintendent, Austin Hospital, for his ready co-operation. We also thank Dr. Kaye Scott and Mr. Victor Stone for their enthusiastic support and permission to publish the case material. Supplies of morphine and daptazole were generously made available by Burroughs Wellcome (Aust.) Ltd. and Nicholas Pty. Ltd. respectively.

PETROL-VAPOUR POISONING

BY

READ AIDIN, M.D., D.C.P.

Pathologist, Worthing Hospital

In view of the widespread use of petrol it is surprising that deaths from inhaling the fumes are so rare. Petrol or gasoline vapour has been known for many years to be poisonous. In the reports of the Chief Inspector of Factories for 1937-47 four deaths due to gassing by petrol vapour have been recorded (Ministry of Supply, 1952).

I have been unable to find an account of death from petrol vapour in British medical journals, and so think the following accident worth recording, as many workers both inside and outside the medical profession are unaware of the lethal properties of the vapour.

Case Report

At a non-medical research laboratory in which petrol was used experimentally it was the custom for laboratory assistants to go to a hut 20 yards (18 metres) from the main building and fill a 2-gallon (9-litre) can with petrol. The petrol was kept in a poorly ventilated hut in a 40-gallon (180-litre) metal drum. The drum stood 33 in. (84 cm.) in height and was kept covered with a tightly fitting metal lid.

At 2.30 p.m. on a hot day a youth of 17, 5 ft. 6 in. (167 cm.) in height, was sent to fetch petrol. As he had not returned at 3.15 p.m. a messenger was sent, who found him dead, slumped with his head, shoulders, and arms over the edge of the drum. There was 9 in. (23 cm.) of petrol in the drum, and the youth had apparently placed the can inside the drum and had been ladling petrol with a beaker into the can.

At necropsy irregularly shaped areas were present on the right forearm and wrist where the superficial epithelium had disappeared, leaving dark-red areas. These excoriations involved areas on the upper arm and round the elbow, and resembled the raw areas seen on the body of a macerated stillborn foetus. Several similar smaller areas measuring up to 1 cm. in diameter were present on the forehead. There was slight bruising over the right anterior-superior iliac spine and on the right side of the abdomen, probably caused by pressure from the edge of the drum.

The body was pale and cyanosed; there were no external haemorrhages. The stomach contained semi-digested food, and the oesophagus and the trachea regurgitated stomach contents. Nothing else abnormal was found. There were no petechial haemorrhages in the lungs, heart, or thymus, nor were there any other signs of asphyxia. The internal organs were not congested. No smell of petrol was noted from the lungs. Microscopically the lungs, liver, heart, and kidneys were normal.

Inquiries showed that other workers, when getting petrol from the drum, left the can on the floor and ladled petrol out without stooping down and putting their heads into the drum. The dead lad could not do this, as he was not tall enough, but apparently had to bend his head and shoulders into the drum.

Discussion

Machle (1941) exhaustively reviews the subject of death from inhalation of petrol vapour and gives many references to American and Continental sources.

Petrol is a mixture of hydrocarbons of varying volatility and toxicity. Octane, which is present in high proportions in some petrols, is very toxic. N-octane is about seven times as toxic as pentane (Lawrence, 1945). Some commercial petrols contain benzene and other aromatic hydrocarbons which are of still greater toxicity. In Great Britain

petrol contains 0.8 ml. of tetra-ethyl lead (T.E.L.) per litre (Ministry of Supply, 1952).

Poisoning by petrol vapour occurs rapidly by inhalation but slowly by ingestion. There is probably some skin absorption, but this is generally masked by the accompanying absorption through the lungs, which is the main factor in poisoning. Vigdortschik (1933) states that a concentration as low as 110 to 450 parts per million may produce symptoms in susceptible persons. Fieldner *et al.* (1921) found that 7,000 p.p.m. when inhaled produced definite intoxication in five minutes. Rambousek (1913) states that higher concentrations of the vapour cause almost immediate unconsciousness and death from respiratory arrest.

Machle (1941) records that men exposed to 1,000 p.p.m. showed drowsiness, dullness, and numbness at the end of 15 minutes, followed by vertigo, ataxia, and slight nausea after an hour. Symptoms occurred much more quickly after exposures to 3,000 p.p.m., while exposures to 7,000 p.p.m. caused intoxication in five minutes. Little is known about the concentration of petrol vapour that causes death in man after a short exposure. Machle records that a concentration of 10,000 p.p.m. is rapidly fatal in experimental animals. If the concentration of the vapour is high, absorption through the lungs may be very rapid and symptoms may appear within a few minutes of exposure. The type of coma appears to depend on the chemical nature of the petrol; paraffin hydrocarbons produce quiet coma, as shown by animal experiments, while unsaturated hydrocarbons cause convulsions (Haggard, 1920). The inferential evidence seems to be that the vapour contains a poison affecting the central nervous system. After a few minutes' exposure to a high concentration of vapour the victim passes into coma and dies without any respiratory struggle or post-mortem signs of anoxia (Machle, 1941).

The day of the accident was warm, favouring the formation of petrol vapour. Since the vapour is heavier than air, it seems certain that a heavy concentration formed in the closed drum. This was confirmed by the following test. In the early afternoon of a warm day in circumstances similar to those of the day of the accident an operator about the same height as the dead youth was equipped with an antitoxins hose mask apparatus; the free end of the breathing hose was placed well outside the hut. The concentration of the petrol vapour was measured by a Poole combustimeter. So as to obtain samples of air from a wider area than that occupied by the end of the rubber suction tube the end of the tube was attached to a 2½-in. (6.3-cm.) funnel. The funnel was then attached to the operator so that the opening of the funnel was within a few inches of where his mouth and nose were when covered with a mask. The lid was removed from the drum, which contained 9 in. (23 cm.) of petrol. The operator then proceeded to fill the can with the beaker. To do this he had to keep his head and shoulders well in the drum. Fifteen seconds after the lid was removed the petrol-vapour concentration was found to be 25,000 p.p.m. During the next 80 seconds, while the can was being filled, the concentration of petrol vapour varied from 8,000 to 35,000 p.p.m., averaging about 20,000 p.p.m. The higher values were obtained when the operator was pouring petrol into the can and some spilt in the process. Four minutes after the lid had been removed and one minute after it had been replaced the concentration of petrol vapour 3 ft. (91 cm.) from the drum was found to be 2,500 p.p.m.

At first the cause of death seemed debatable. It was suggested that the lad might have been struck by lightning. About the time of his death there had been a thunderstorm; however, the evidence seemed to be that the storm did not reach the area until after his death. There were no burns such as might be found on a body that had been struck by lightning. The excoriation of the skin was due, it is believed, to clothing soaked in petrol, which may cause severe blistering unless the clothing is quickly removed and the skin well washed. Presumably the process went

on after death. There is some evidence that the skin lesions may have been caused by T.E.L. in the petrol (Ministry of Supply, 1950). When leaded petrol evaporates about half of it evaporates before any of the lead comes off. Absorption is rapid through the lungs and unbroken skin. It is stated that T.E.L. has a specific toxic effect on the central nervous system. Death may occur within 10 minutes of exposure to a heavy concentration. A degree of consciousness and sensation is said to persist almost to the time of death.

Fifteen deaths from this cause are recorded by Bini and Bollea (1947). It seems, however, difficult to determine whether these deaths were due to petrol vapour or T.E.L. Cassells and Dodds (1946) describe chronic poisoning from T.E.L. but mention no acute cases. Machle (1941) states that T.E.L. is not a factor in acute poisoning. The possibility of vasovagal inhibition had to be considered, but there was no evidence of any painful stimulus. Nor was there any evidence of pressure on the carotid body or evidence to support such a questionable diagnosis as status lymphaticus or of death occurring in an epileptic fit.

The pathological changes found at necropsy are not specific in death from petrol vapour. If death is not immediate the lesions may be due to the irritant and lipolytic action of the vapour. There may be damage to the lungs, hyperaemia, petechial haemorrhages, subpleural extravasations, and sometimes gross haemorrhage into the lungs. Bronchitis and pleural effusions may be present. Severe acute exposure will cause sudden collapse; death may follow without loss of consciousness. In view of the great concentrations of petrol vapour, well over lethal level, that were demonstrated when the accident was reconstructed, there seems to be no doubt about the cause of death.

Summary

A case of accidental death due to inhalation of petrol vapour is described; the surprising rarity of this kind of accident is mentioned and the post-mortem findings are recorded. The reconstruction of the tragedy is described, showing that the concentration of petrol vapour must have been at a highly dangerous level. The literature is reviewed.

I thank Mr. D. E. Woods and Mr. A. J. Taylor for the estimation of the vapour concentration obtained at the reconstruction of the accident.

A grant of £50,000 has been made by the King Edward's Hospital Fund for London to assist the North-east Metropolitan Regional Hospital Board in their plans for developing St. Clement's Hospital, Bow, as a modern psychiatric hospital. The hospital already provides to some degree for the mentally sick, in that it has an observation ward and a small unit for psychoneurotic cases. The board consider that in future this hospital will no longer be needed to play any part in providing for the general hospital needs of the area. They have therefore decided to extend the psychiatric work undertaken there, with a view to establishing a modern neuropsychiatric centre for East London. The aim is to provide full facilities for the investigation and treatment of all types of acute mental illness, as well as providing teaching and research facilities.

Medical Memorandum

Spontaneous Rupture of Haematocolpos

Atresia of the hymen is a comparatively uncommon condition and receives but brief mention in most gynaecological textbooks. The possibility of spontaneous rupture of the occluding membrane is not considered in any of the standard works of reference; the following case is described in which this very rare occurrence was encountered.

CASE REPORT

The patient, a girl aged 13, was admitted to hospital on April 30, 1957, because of severe vaginal haemorrhage. Since January she had suffered from attacks of acute urinary retention at approximately monthly intervals, but these had apparently settled readily after the administration of a simple diuretic mixture. Accompanying these episodes there had been some complaint of backache and abdominal pain and a feeling of general malaise. On the evening of admission she had suddenly begun to bleed profusely from the vagina.

On examination her face was pale, but the mucosae were well coloured and there was no evidence of shock. She was afebrile, with a pulse rate of 100 and a normal blood pressure. Inspection of the perineum revealed a bluish swelling just posterior to the urethral orifice; this swelling occupied the normal site of the vaginal introitus and from it a small quantity of dark blood was trickling. Closer examination confirmed that the vagina was occluded by a membrane in which there was a tear, about 3 mm. in diameter, immediately proximal to its anterior border.

Under general anaesthesia the membrane was incised in a cruciform manner, releasing a moderate amount of retained blood. The vagina was greatly distended, the cervix being just palpable at the limit of digital examination. Following operation she was given a course of oxytetracycline extending over five days. Her progress was uneventful, and on May 7 she was re-examined under an anaesthetic before being discharged. By this time the vagina had contracted to a size approximating to normal and the uterus could be easily palpated bimanually; it did not appear to be enlarged. In the pouch of Douglas a moderate quantity of soft clot could be felt, but, as she was symptom-free, no attempt was made to evacuate this. She was allowed home the following day, and has remained well since that date.

COMMENT

The preoperative diagnosis in this case might have been suggested by the history of recurrent attacks of urinary retention, but the picture was complicated by the unusually early age of onset and by the ready relief of symptoms on administration of a diuretic mixture. It is generally accepted that the retention of menstrual blood in cases of haematocolpos is almost invariably due to a membrane situated above the true hymen (Bourne, 1955). Spontaneous rupture of this membrane must be excessively rare, and the only previous reference to this occurrence appears to be an article by Puech (1878) entitled "Imperforation de l'hymen: accidents dépendant de la rétention des menstrues se terminant au bout de dix-huit mois par la rupture spontanée de l'obstacle." In the present case there had been no history of trauma, and it seems likely that rupture was due simply to the effect of increasing intravaginal tension on an abnormally thin area of the obstructing membrane.

RONALD P. CUMMING, M.B., F.R.C.S.Ed.,
Late Senior Surgical Registrar, Aberdeen General Hospitals.

Reviews

POLYMYOSITIS

Polymyositis. By John N. Walton, M.D., M.R.C.P., and Raymond D. Adams, M.D. (Pp. 270+x; illustrated. 32s. 6d.) Edinburgh and London: E. and S. Livingstone Ltd. 1958.

During the last ten years renewed attention has been given to disorders of the voluntary muscles, and the authors of this monograph—Dr. Walton at the Royal Victoria Infirmary, Newcastle upon Tyne, and Dr. Adams at the Massachusetts General Hospital, Boston—have both made important contributions in this field. Although the name "polymyositis" was introduced in 1863 by Wagner, comparatively little interest has been taken in the condition till recently, and, apart from florid cases of dermatomyositis, the diagnosis has only rarely been made. This monograph is based on 40 patients, 25 of whom have been examined by one or other author, the remainder coming from the case-records of the Massachusetts General Hospital; in all of them muscle biopsy specimens were available. The cases in the series vary considerably in their clinical characteristics and to some extent in their pathological features, but the authors consider that in most there is "a single basic disease process related to the other collagen diseases." There is an excellent review of the relevant literature as well as a good clinical analysis, but the outstanding chapter is on the pathology as shown by muscle biopsy. Interpretation of muscle pathology is difficult and often open to more than one conclusion, but this chapter makes the authors' findings quite clear, and the reproduction of photomicrographs, some in colour, is of the highest quality. It seems likely that in the next few years the clinical, pathological, and electrical characteristics of polymyositis will become clearly defined, and possibly even the aetiology discovered. If this should be so, it will be partly the result of this monograph, which is highly recommended to anyone interested in disorders of muscle.

J. W. ALDREN TURNER.

DUSTS, SMOKES, AND MISTS

Particulate Clouds: Dusts, Smoke and Mists: Their Physics and Physical Chemistry and Industrial and Environmental Aspects. By H. L. Green, M.A.(Cantab.), F.Inst.P., and W. R. Lane, B.Sc.(Birm.), F.Inst.P. (Pp. 425+xix; illustrated. 70s.) London: E. and F. N. Spon, Ltd. 1957.

This book comes from the Physics Section of the Chemical Defence Experimental Establishment at Porton, where so much classic work on particulate clouds has been done, and by virtue of its parentage alone the volume would command respect. Part I is concerned with the basic physics and physical chemistry of suspended particles, special attention being paid to the genesis and examination of dusts, smokes, and mists. In Part II theoretical principles are applied to environmental and industrial problems. No clinician can be wholly unconcerned about the nature of aerosols, since many substances of known or suspected physiological action are dispersed in this form. Bacteria, pollens, radioactive substances, tobacco tars, air pollutants, industrial dusts and fumes, agricultural chemicals, and many therapeutic agents may be suspended in the air, and the properties of such systems are fully discussed. The lucid style of the authors is never abandoned in the face of the complexity of their subject. The foreword contains a timely warning against repetitive work and pointless publication, and in the light of this expressed opinion the extensive bibliography—the chapter on health hazards is followed by 126 references—may be regarded as authoritative.

To attempt in these columns to assess the stature of this work as a textbook of applied physics would be an impertinence. The authors say that they have endeavoured to

systematize their subject and "bring to it some coherence where only distantly related topics appear to exist," and in the admirable fulfilment of this modest claim they have made, incidentally, a valuable contribution to the literature of clinical science.

P. J. LAWTHOR.

EFFECTS OF RADIATION

Medical Radiation Biology. By Friedrich Ellinger, M.D. (Pp. 945+xxxiv; illustrated. £7 10s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1957.

The results of the Japanese atomic explosions and further developments in the warlike and peaceful uses of atomic energy have invested radiation effects with a new importance, and clinicians in most branches of medicine must now be expected to have some knowledge of radiobiology if they are to be able to exercise an informed judgment on problems in which the effects of radiation may play a part. Not only physicians, but also dermatologists, ophthalmologists, haematologists, and others are encountering these problems with increasing frequency, and the need has been felt for a comprehensive work on radiation effects, their mode of production and clinical diagnosis. The present volume has been designed to meet this need, and it may be said at once that it succeeds well in doing so. It covers the whole field of radiation effects on cells and on living tissues, in health and disease, as they appertain to man.

When a subject of this extent and complexity is compressed within the confines of a single volume, from the pen, moreover, of a single author, it is only to be expected that there will be some variation in the coverage of the different aspects of the subject. Thus the sections on fundamental radiation biology are sometimes more in the nature of a summary than of a complete discussion, while those on the effects on human tissues and organs are, generally speaking, full and detailed. The chapters on the effects of ionizing radiations on the skin and its appendages are outstanding. Of special importance at the present time are the chapters on the biological effects of ionizing radiation originating from sources within the body (such as ingested radium and radiostrontium) and that on ionizing radiation as a health hazard. There is an extensive bibliography comprising no fewer than 5,000 references covering the literature up to 1955.

Written as it is primarily for the clinician this is an important and valuable book, and in spite of its high cost in this country it should find a place on the bookshelf of every physician and of those others who may have to deal frequently with problems of radiation effects.

AN UNUSUAL THERAPIST

Recovery from Schizophrenia: The Roland Method. By John Eisele Davis, Sc.D. (Pp. 162+xi. 36s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1957.

This book, which consists mainly of extracts from papers, describes the Roland method of treating chronic schizophrenia. Mr. Roland's qualifications are in physical education. After the war he worked with Dr. Karl Menninger at Topeka, Kansas, and became interested in the application of physical activity to the treatment of "regressed" patients—that is, chronic catatonic schizophrenics. The book is noteworthy for the manner in which it conveys Mr. Roland's enthusiasm—one might say evangelical zeal. We are told that the therapist must feel deep down that his own well-being is in some significant way linked with that of the patient, and hints are given on the handling of the "strong interpersonal relationship" which develops between the patient and the therapist. The therapist, indeed, appears to be actively involved emotionally with the patient, a procedure which would seem to be fraught with risks, especially as the therapist apparently receives no psychiatric training.

The method involves "an intensive, continuous, and sustained programme occupying all the patient's waking hours day after day." It can perhaps be illustrated by describing the initial stages. The patient, who is naked apart from his socks and shorts, lies upon the relaxation table. The therapist, whose voice should be soft, kind, understanding, and demonstrate love and acceptance, says such things as, "I am here to help you," or, "I know you can't talk, but I will help you." He then massages the spine, the neck, the face, saying from time to time, "Relax . . . relax." The patient slowly begins to co-operate. The author gives an example to illustrate the dramatic results which can be achieved. One patient after five weeks' treatment assisted the therapist when he held the patient's arm and patted a piece of clay with it, the therapist meanwhile reciting the nursery rhyme, "Patty cake, patty cake, baker man."

The data on the results of this method are sketchy. The main investigation was the Downey evaluation, by a committee of psychiatrists and psychologists. They comment on "the marked discrepancy between the stated objectives of the programme and the results achieved," and would presumably regard "recovery from schizophrenia" as somewhat hyperbolic. It is well known that hospitalized chronic schizophrenics tend to get "bogged down" in stereotypes of thinking and behaviour, and that their behaviour degenerates so that they become dirty, mute, open masturbators, and so on. This is a tendency which has to be combated according to the methods developed by Bleuler and his school. If this deterioration in behaviour has not been combated, any physician who pays attention to these patients will achieve improvements in behaviour, often to a startling degree. It is probably by virtue of this rather than any specificity of his method that Mr. Roland achieves his results. The patient certainly does receive a great deal of attention; one therapist, with his "aides," is fully occupied treating three patients.

The book includes a revealing biography of Mr. Roland. We are told that his "Rohrschach [sic] tests have shown underneath the surface much anxiety and tension," and "his tendency to overstrive and overintellectualize is largely a compensatory mechanism." He "has good intellectual potentialities," but "intellectual judgment may suffer at times due to the disrupting and disorganizing components in the personality." Biographies such as this are perhaps a useful innovation.

A. W. BEARD.

MEDICINE AND TOWN PLANNING

Medizin und Städtebau: Ein Handbuch für Gesundheitlichen Städtebau. Edited by Paul Vogler and Erich Kühn. Two volumes. (Volume 1: pp. 700+ix; Volume 2: pp. 727+ix; illustrated. D.M.190.) Munich, Berlin, Vienna: Urban and Schwarzenberg, 1957.

This so-called "handbook" on medicine and town planning, edited by Professor Paul Vogler, a distinguished physician, and Professor Kühn, a distinguished architect, consists of two volumes of Teutonic thoroughness that are weighty in both mental and physical senses. The relationship between health and the environment in which we live is no new subject, and this work does not, it is felt, set out to be original—rather to collate all the evidence from all over the world proving the harm that has been done in the past and indicating the potentialities that may be realized in the future.

While the work is of special interest to architects and town-planners, the medical aspects are dealt with in some detail. For example, diseases of childhood, of the upper and lower respiratory tracts, and of old people can have an obvious connexion with environment. Town planning which uses the land artistically and scientifically is seen as a potent ally in the prevention of disease, and authoritative contributors from many countries have been enlisted in order to prove this.

The late Professor John Ryle, when he transferred his energies from clinical medicine to the newer field of social

medicine, deplored that medicine, while profiting over the last quarter of a century from modern scientific and technical advances, had in the process fallen out of tune with some fundamental human needs. The partnership between medicine and town planning is a reform such as he would have visualized. Social planning as here advocated echoes his plea that the basic causes of disease should be in the first line of defence, and their conquest would lead to economies which would make possible a National Health Service in fact as well as in name.

Impressive as are these two volumes, one doubts whether the best-intentioned public-health authority would find the time to study all 1,400 pages. Unfortunately, also, as a book of reference it loses some of its value in having no bibliography, which would facilitate a follow-up of many of the subjects discussed. The illustrations, culled from primitive lands to the newest housing schemes of Scandinavia, warrant unqualified praise, and the index is conscientious and helpful. As befits a work dealing with two specialties ordinarily widely separated, a glossary enables specialists in one field to understand the technical language of the other.

Many of the contributors are not known in this country, but to judge by the high reputation of the two English contributors—E. G. S. Eliot, of the Ministry of Housing and Local Government, and Otto Königsberger, of the London School of Tropical Medicine—they are one and all of the first water, and each deals with his particular subject lucidly and in detail.

The work of the editors must have been stupendous. In the face of such a mammoth achievement one hesitates to ask, Was it worth while?

PHILIP ELLMAN.

TRUTH ABOUT CANCER

Cancer and Common Sense. By George Crile, jun., M.D. (Pp. 143. 10s. 6d.) London: Robert Hale Limited, 1957.

For those who really want to know the truth this is an excellent little book. It is very simple and very sensible, but it is, naturally, written primarily for the American public, who are known to be much more knowledgeable about cancer than their British counterpart. It is of interest to learn, therefore, in view of the efforts which are being made in this country at the present time, especially by the B.B.C., to educate the public about disease in general and cancer in particular, that this same education has had some disturbing effects in the United States. Dr. Crile has, it would seem, thought it necessary to write this book in order to dispel "the fear which those responsible for telling the public about cancer have chosen to use as a weapon." It will come as a surprise to most of us in Britain to read that "the American College of Surgeons has been attacking this group [of surgeons] who exploit fear in order to do unnecessary operations and has been driving them out of many hospitals."

Before leaving this book on their waiting-room tables, doctors should ponder well whether the whole truth about cancer, as stated here, should be told. Dr. Crile himself says that "the harsh facts, at the moment they are revealed, may seem unbearable," and indeed a layman will get little comfort, if that is what he is seeking, from many of the pages of this book. He will learn, for instance, that:

"Our present diagnostic tests are totally inadequate to detect internal cancers at a stage when they can often be cured."

"Our efforts in the last twenty years have failed to reduce the death rate from cancer."

"The most important factor in the survival of a patient is the type of cancer that he happens to have."

Maybe this is the sort of thing that an educated man or woman in 1958 ought to be aware of. But one can foresee quite a bit of trouble for doctors if patients cross-examine them on these lines. For doctors this is a first-class book; for patients it is, in our present state of knowledge, probably better not to know the worst.

FOETAL BLEEDING

Severe anaemia in the baby at birth is most often due to haemolytic disease, in which the diagnosis of rhesus incompatibility is easily made. Severe anaemia developing soon after birth may also be due to external haemorrhage, usually from the bowel or umbilical cord, which can hardly escape notice. It is less widely known, however, that a non-haemolytic anaemia may be present at the time of birth because of haemorrhage during foetal life. This may not have been visible, or, if visible, the blood may have been misinterpreted as a sign of maternal bleeding. Foetal bleeding constitutes a serious emergency which if not immediately recognized is likely to cost the infant his life. Bruce Chown¹ has recently reviewed the circumstances in which the foetus may develop the anaemia of haemorrhage.

Most common is haemorrhage following incision of the placenta during caesarean section. This hazard has been recognized for many years and is greatest when the lower-segment operation is performed for anterior placenta praevia. Various workers have suggested methods of avoiding damage to the placenta during delivery by this route.^{2,3} The foetus may also bleed severely *in utero* from rupture of a blood vessel on the foetal aspect of the placenta, so that the resultant anaemia may have been present for some hours before its birth.⁴ This catastrophe should be suspected if during labour bright red blood flows suddenly and in quantity from the vagina. Chown¹ considers that the obstetrician must reach and treat the baby within 3½ hours if its life is to be saved. On the other hand, loss of blood from the foetus via the vasa praevia, or into the placenta itself,⁵ may be much less severe. If bright red blood trickles

from the vagina before or early in the course of labour it should be tested for foetal (alkali-resistant) haemoglobin.^{6,7} A strongly positive result is proof that the blood comes from the foetus and is a warning that treatment may be urgently called for.

The need for prompt recognition of post-haemorrhagic anaemia in the newborn cannot be overstressed. Where blood loss has been severe the infant will be pale and shocked, but the onset of respiration is usually spontaneous and the heart rate is rapid.¹ This contrasts with the slow heart rate and the ineffectual gasps of the infant in a state of asphyxia pallida, who is usually covered with meconium. Hepatosplenomegaly and jaundice are absent. The blood volume returns to normal remarkably quickly after massive haemorrhage in the newborn, and serial estimations of the haemoglobin level in the baby's skin-prick blood afford a relatively reliable assessment of the magnitude of the haemorrhage. G. A. Neligan and J. K. Russell² regard a haemoglobin level below 90% (13.3 g. per 100 ml.) as an indication for immediate transfusion. In fact, the need may be so urgent that the normal process of blood-grouping must be forgone. Chown¹ wrote: "The blood that can be obtained *most quickly* is the *right* blood. . . ." In most British maternity hospitals group O rhesus-negative blood would be immediately available.

In the circumstances so far considered, the loss of blood from the foetus is observable before or during delivery and may be classified as overt. By contrast, it may be classified as occult when the foetus bleeds across the placenta into the mother's circulation, a situation first postulated in a case reported by A. S. Wiener.⁸ Chown¹ was the first to prove beyond doubt that a severe non-haemolytic anaemia in the newborn could arise in this way. Two instances of transplacental haemorrhage from the foetus have recently been reported from Dundee by H. B. Goodall and his colleagues.¹⁰ The clinical picture is one of gross pallor, tachycardia, hypotonicity, and weakness at birth. The liver and spleen are not enlarged and respiration is regular. Blood from the cord or the infant shows the microcytic hypochromic picture of haemorrhage of some weeks' duration. The presence of normoblasts in fair numbers excludes congenital hypoplastic anaemia. When a rhesus-negative mother has been immunized against the foetal red cells by previous rhesus-positive pregnancies, the entry into her circulation of foetal blood has been reported to cause a rigor during labour.^{5,10}

Proof of transplacental foetal haemorrhage is to be found in the mother's blood, which should be taken for testing as soon after the infant's birth as

possible. Direct serological proof may be obtained by differential agglutination.^{5, 9, 10} This entails extensive grouping of the bloods of both mother and infant in the hope of finding some antigenic differences which will allow small numbers of the baby's cells to be recognized in the mother's circulation. The maternal blood is incubated with serum containing the appropriate antibodies in saline and in albumin, and the indirect Coombs test is performed. With both techniques the maternal blood will show scattered clumps of agglutinated foetal cells in a background of many unagglutinated maternal cells. Strongly presumptive evidence was obtained in one case by detecting the adsorption of anti-D by a rhesus-negative mother's blood containing D-positive cells from the foetus. Moreover, this mother was shown, after delivery of the foetus, to develop antibodies against D with a positive indirect Coombs test.⁹ Goodall and colleagues¹⁰ obtained support for the concept of foeto-maternal transfusion in their two cases by examination of the buffy coat in the mother's blood. In one, who had previously given birth to two infants with haemolytic disease, evidence of the entry into her circulation of incompatible foetal blood was found in the presence of marked erythrophagocytosis. In the other, not previously sensitized to the rhesus factor and not herself anaemic, the buffy coat contained many small ring-stained erythrocytes and tiny normoblasts similar to those seen in her infant's blood and presumed to have come from this source. Direct chemical evidence of transplacental bleeding may also be obtained from the estimation of the alkali-resistant haemoglobin in the mother's blood by a quantitative technique. A gross increase in foetal haemoglobin in the maternal blood is proof of foeto-maternal bleeding, but a level just above that found in normal controls is only suggestive unless supported by morphological and serological evidence.

Finally, mention should be made of another form of occult foetal haemorrhage, in which one twin bleeds through the placenta into the other.¹¹ In consequence, one twin is born with anaemia which may be severe enough to require transfusion, whereas the other is polycythaemic and may in fact have to have blood removed.

AMERICAN DOUBTS ABOUT B.C.G.

Of the few trials of B.C.G. vaccine on groups of the general population, four have been outstanding. The first is that of J. D. and C. F. Aronson in North American Indians with low standards of living and high tuberculosis rates.¹ About 1,500 tuberculin-negative subjects, from infancy to 20 years old, were

given B.C.G. and a similar number left unvaccinated; the tuberculosis morbidity, judged by annual radiography, was studied for 11 years and the mortality for 20 years.² The protection against death from tuberculosis was good, about 80%, though, since very few deaths had occurred towards the end of the observation period, it was difficult to be sure that this was maintained beyond the first 10 years. The non-tuberculous death rate was similar in the two groups. The second notable trial is that proceeding under a committee of the Medical Research Council in which 56,000 volunteer schoolchildren, aged 14½–15, in three English urban areas were x-rayed and tuberculin tested; those with negative reactions to 100 tuberculin units (T.U.) were given B.C.G. vaccine (14,100), vole bacillus vaccine (6,400), or were left unvaccinated (13,200). The follow-up is by postal and personal contact, annual chest radiography, and ascertainment of clinical cases routinely diagnosed through the National Health Service. The first progress report³ covered 2½ years and gave an annual incidence of tuberculosis of 1.9 per 1,000 among the unvaccinated, and 0.4 both in the B.C.G. and in the vole-bacillus-vaccinated groups—that is, about 80% protection. There has been no waning of protection by either vaccine up to at least 4 years.^{4, 5} No death from tuberculosis was reported in any group within 2½ years. The third and fourth trials are taking place under the United States Public Health Service in Puerto Rico, where the tuberculosis rates are still very high,⁶ and in two adjacent counties in the states of Georgia and Alabama, where the rates are probably lower than in the catchment areas for the British trial.

A report from the U.S. Public Health Service covering a follow-up period of 6–7 years is now available,⁷ the authors being Carroll E. Palmer, L. W. Shaw, and G. W. Comstock. In Puerto Rico nearly 200,000 volunteers aged 1 to 18 were enrolled and tuberculin tested; those negative to 10 T.U. were given B.C.G. vaccine (50,600) or were left unvaccinated either because they refused vaccination (31,600) or through the process of random selection (27,300). Those vaccinated and the controls received an additional test of 100 T.U. In Georgia and Alabama about 64,000 volunteers aged 5 and upwards were x-rayed and tuberculin tested; those negative to 5 T.U. were vaccinated (16,900) or left unvaccinated (17,900). The follow-up in both trials is confined to the routine notification of cases to the local health authorities. No periodic re-examinations are undertaken. The most important reason for this omission is now given as the avoidance of bias in the diagnosis of cases, though from an earlier report⁸ it seemed that lack of

time, staff, and money were mainly responsible. The calculated incidences of tuberculosis take no account of migration; the true incidences would be underestimated because of this, and also because of using routine notification as the sole method of ascertainment. These factors may indeed provide some explanation for the finding in the Puerto Rico trial that the annual incidence of tuberculosis was only 0.43 per 1,000 among the unvaccinated controls in an environment where 21% of the children entering in the trial aged 6 were already reactors to 10 T.U. In the B.C.G. group in Puerto Rico the annual incidence was 0.30—giving a protection by vaccination of 31%, which is statistically significant. For Georgia and Alabama the corresponding rates were 0.22 (controls) and 0.14 (vaccinated) per 1,000—that is, a protection of 36%, which, however, is not statistically significant. The morbidity ratios between controls and vaccinated in each trial had changed little over the period of follow-up.

The effectiveness of B.C.G. vaccination in the non-reactors to the initial tuberculin tests in these two trials by the U.S. Public Health Service is poor compared with the results obtained in the American Indian study and in the Medical Research Council's trial—and indeed runs contrary to previous experience in trials of varying statistical quality in America and elsewhere.^{9, 10} Some explanation for this disturbing finding must be sought. Two vaccines from different mycobacterial species—B.C.G. and natural vole bacilli—were used in parallel in the Medical Research Council's trial: in Puerto Rico and in Georgia and Alabama vaccines different from those used in Britain and from each other were used. Did the differences in performance reflect differing post-vaccination tuberculin sensitivities? The American authors point out that, while both vaccines in the British trial produced strong post-vaccinal tuberculin sensitivity and gave good protection, the inferior protection observed in the two American trials was given

by one vaccine producing sensitivity of the same high order as in the M.R.C. study and by another with mediocre powers of sensitization—although this in its turn was about the same as in Aronson's successful vaccinations made many years previously. Hence, on the conventional view that the protective efficacy of a vaccine is related to its average sensitizing potency—a theory based on animal experiments^{11, 12}—the poor results in the American trials cannot easily be ascribed to low-potency vaccines. On the other hand, this explanation cannot be entirely excluded, since it is possible experimentally to sensitize without protection and vice versa.^{13, 14} To have known the proportions of subjects with local vaccination lesions would have provided a useful check, but these were not systematically ascertained. Viable counts of the vaccines would be even more valuable if they were available. If the cause of the American results should indeed be deficient antigenicity it would emphasize the urgency of improving the means of accurately differentiating a good from a less good vaccine. The tests on mice described by G. P. and A. S. Youmans¹⁵ might serve as a useful addition to the usual animal tests of protection. It is worth noting that freeze-dried B.C.G. vaccine has recently been accepted by the Ministry of Health¹⁶ for optional general use in Britain on the basis of its sensitizing potency in man.¹⁷

Discussing other possible causes for their results, Palmer and his colleagues mention what they consider to be statistical faults in the Medical Research Council's trial; but of the two trials the British would appear to be the more carefully conceived and executed—a true model, according to one authority.¹⁸ For example, no attempt was made in the Puerto Rico study to verify the accuracy of the notifications of disease or death. However, the general high quality of both American and British trials makes it difficult to see how the differences in the degree of protection afforded to the vaccinated groups can be attributed to statistical shortcomings, and there will no doubt be general agreement with Palmer and his colleagues that other reasons are probably responsible. Apart from differences in the vaccines, differences in the populations might have led to divergent results. In the British trial, reactors to 100 T.U. but not to 3 T.U. were excluded from the random selection of those to be vaccinated, and their separate follow-up showed a lower incidence of tuberculosis than among those who were negative to 100 T.U.—though not so low as the incidence among the vaccinated. This may have been due to natural protection. In the American trials vaccination was on the basis of a negative reaction to 5 or 10 T.U., and

because there was a particularly high regional prevalence of persons reacting to 100 T.U. only, large numbers of these must have been included in both vaccinated and control groups. This inclusion of persons already partially protected might have reduced the contrast in the incidence of tuberculosis between these two groups. Palmer and his colleagues discuss this possible explanation but are unable to come to a firm conclusion on its authenticity. They have not considered another possibility: could it be that a booster to B.C.G. by natural tuberculous superinfection is required to maintain full effectiveness, and that this superinfection is less common under the conditions of the American than of the British trial, because of a lower prevalence of infectious cases in the communities concerned?

The authors of the American report are at one with the Medical Research Council's workers in recognizing the importance of the yield of cases of tuberculosis from the non-vaccinated group of tuberculin-positive reactors. Estimates of the benefits of vaccination in a community must take note of the proportion of positive reactors to tuberculin and of the estimated future incidence of tuberculosis among them as well as of the infection rate and estimated incidence among the negative reactors, vaccinated and non-vaccinated. Chiefly owing to the 30% effectiveness of vaccination in the negative reactors in the American trials, in contrast to the British 80%, Palmer and his colleagues estimate that only 10% of the total number of cases of tuberculosis in their study populations could have been prevented by vaccination, compared with the estimate of more than 40% over a shorter period of follow-up in the British trial. On this basis, and for other reasons, the American authors believe that in most circumstances in the U.S.A. to-day the disadvantages of B.C.G. vaccination as a means of controlling tuberculosis outweigh its advantages. This generalization may be correct, for infection rates in the U.S.A. are low. But to the further argument that B.C.G. cannot help those already infected it could be answered that earlier vaccination might forestall this,¹⁹ though Palmer would doubtless reply that in his hands effective vaccination has not been evident at any age. His views on the use of B.C.G. in the U.S.A. coincide more or less with those of a distinguished advisory committee of his own service under the chairmanship of Dr. E. R. Long,²⁰ but differ sharply from those expressed by another equally distinguished advisory committee with Dr. G. P. Youmans²¹ as chairman. Whatever the reason for the differences between the results of the American and British trials, the usefulness of the current British scheme for the B.C.G.

vaccination of 13-year-old children need not be doubted, at least while morbidity from tuberculosis retains its current importance.

PULMONARY ALVEOLAR PROTEINOSIS

From the U.S.A. comes news that another clinico-pathological entity has been split off from the ill-defined group of chronic diffuse pulmonary infiltrations. In the last five years three distinguished pathologists¹ have collected twenty-seven cases of a disease which "consists of the filling of the alveoli by a PAS-positive proteinaceous material, rich in lipid. This material appears to be produced by the lining cells, which slough into the lumen, ultimately becoming necrotic and yielding granules and variable laminated bodies to the alveolar content." The constancy of the histological structure and the high lipid content of the affected alveoli were remarkable, and only after laborious microbiological, chemical, and spectrographic studies were the authors forced to the conclusion that "pulmonary alveolar proteinosis" represented a distinct entity.

Of the twenty-seven patients, sixteen were studied at the Armed Forces Institute of Pathology. Their ages ranged from 2 to 57, only two being under the age of 19; of the civilians, fifteen were males and six females. Although almost one-half had a premonitory pneumonia-like illness, the exact time of onset could not be determined in the majority. The principal symptoms were slowly progressive dyspnoea, cough, and sputum; when the disease progressed, lassitude and loss of weight were usually apparent. The radiological features, upon which the diagnosis ordinarily rested in the first instance, were strikingly uniform and consisted of a "fine, diffuse, perihilar, radiating, feathery or vaguely nodular, soft density, resembling in its butterfly distribution the pattern seen in severe pulmonary oedema." Since the first patient was diagnosed less than five years ago, the clinical course of this chronic disease cannot yet be fully described, but on the evidence available serial radiographs have shown that eight had improved, thirteen had persistent infiltrations of varying intensity, and eight had died with signs of progressive dyspnoea and cyanosis. Studies of the morbid anatomy were based mainly on biopsy specimens, which showed nodules of yellowish-grey material up to 2 cm. in diameter, from which a milky, pus-like substance oozed on gentle pressure. Necropsy material from seven cases revealed large masses of confluent consolidation.

The problems posed by this newly described disease are manifold. Having been detected in a laboratory, the pathological aspects have received the greatest attention so far. At first, a fungal aetiology was suspected, but exhaustive researches have been unrewarding. The interstitial plasmocytic pneumonia attributed to infection by *Pneumocystis carinii* has been considered in great detail, but numerous staining techniques have failed to show any cysts; the cellular structure is different and the lipid content of the foci is even greater

¹ Roser, S. H., Castleman, B., and Liebow, A. A., *New Engl. J. Med.*, 1958, 258, 1123.

than in that disease. No bacterium or virus has been incriminated, nor have chemical analyses revealed any causative agent; no excess of beryllium, cadmium, nickel, zinc, or mercury was found on spectrographic examination. From the clinical viewpoint the occupational histories may be significant—four patients worked in or about timber works; two were in the vicinity of broken fluorescent tubes, but no beryllium was found in subsequent tissue analysis; and several were in contact with the newer industrial products such as volatile solvents, plastics, aerosols, and detergents. This range of experience might be expected in an industrial nation, but the cases derived from all parts of the United States, and, of the twenty-seven under review, one each was discovered in Canada, England, and Italy. Whatever the causative agent may be, whether living or inanimate, careful microbiological, chemical, and epidemiological studies must be undertaken, for the disease seems not to be rare. As the lesions appear to be limited to the lungs and possibly the draining lymph nodes, they may well derive from inhaled material, and the possibility that they are a non-specific response to a variety of agents is worth bearing in mind.

This most stimulating paper is bound to cause much interest. The suggested title is somewhat unwieldy in its present form. Perhaps the word "pulmonary" might be omitted, leaving "alveolar proteinosis," which is a big enough mouthful in all conscience, but is probably acceptable to most physicians until more is known of its cause or causes.

PUBLIC HEALTH ON THE ROADS

What is coming to be recognized as one of the great public-health problems of the day¹—road accidents—was prominent in several different discussions held at the B.M.A. Annual Meeting recently. They caused 5,500 deaths and over 60,000 serious injuries in Great Britain last year. But the attention that these deaths and injuries evoke among medical men is not, unfortunately, to be found among lay people. As Mr. E. J. Dodd, chief constable of Birmingham, said at the meeting,² "the sad thing is that road accidents are no longer 'news' and nobody cares about them." And Mr. G. F. Rowbotham saw here the duty of the medical profession to examine and explain this apathy.

Meanwhile a certain amount of technical research goes on into the mechanical causes of accidents, and some of it is outlined in the report issued last week of the Director of Road Research.³ Owing perhaps to the greater acceleration and smaller wheels of modern cars, skidding is reported to be increasing as a factor in accidents. Figures given for three years show that skidding played a part in 13% of personal-injury accidents in 1954, 14% in 1955, and 15.5% in 1956. Of special interest in the wet summer that we are experienc-

ing is the observation that skidding is more frequent on wet roads in hot weather, so that more skids due to wet roads are seen in summer than winter.⁴ But it would seem that at least part of this might be due to the greater impatience of some drivers on congested roads. At any rate, a careful watch is kept for dangerous sites, and the road surface is altered when found to be defective on test. The report refers also to special "on-the-spot" studies of accidents being carried out in Buckinghamshire, Berkshire, and Middlesex. They have given some results of interest. Among them is the finding that car seats are sometimes badly fixed and injuries have been aggravated in consequence. Secondly, a yielding rather than a rigid steering column will reduce the severity of the injury to the driver. Thirdly, toughened safety glass is safer than the laminated variety. And, fourthly, the doors of British cars do not tend to fly open in a smash as do those of American cars.

In relation to the damage done by road accidents the amount spent on research into them—something over £70,000 a year⁵—does seem small, though mechanical safety is probably only a small part of the problem. Many would agree with the speaker who said at the Birmingham Meeting that "inconsiderate, inexperienced, careless, and over-confident motorists are the sinners."

ON TAKING A CUBIT FROM THE STATURE

Society has of late been kinder to tall women. An association ensures that the stores contain the clothes and shoes they need; models, it is said, are taller than they were and some new styles are designed for tall women rather than for short. The Victorian cult of the little woman, whether brave or sweet, has departed. However, most mothers would still prefer that their daughters should not be more than about 5 ft. 10 in. (178 cm.) tall; and if it was possible by medical means to prevent this happening there would undoubtedly be some demand for treatment. On the other hand, there would be little enthusiasm among parents for a treatment destined to prevent boys growing taller than 6 ft. (183 cm.).

Before therapy is undertaken to prevent girls from growing excessively tall two conditions need to be satisfied: first, that ultimate height can be predicted with reasonable accuracy; and, secondly, that such treatment is not harmful. The prediction of ultimate height depends on a consideration of the relation of the present height both to age and to skeletal maturity.⁶ The assessment of skeletal maturity is made by x-ray examination of epiphyses, and the most accurate methods of doing this have been the subject of much investigation.^{6,7} If a girl's height at the age of 12 years is 6 in. (15 cm.) above the 50 percentile, although the skeletal maturity

⁴ *Road Research 1956*, H.M.S.O., 1957.

is consistent with her age, then an ultimate height of 70 in. (178 cm.) may be predicted. The accuracy of these measurements is subject to many variables, and the forecast has a considerable margin of error. It would therefore be justifiable to give treatment only if the excess above average height promises to be considerable.

Oestrogen, in doses of 2.5 to 5 mg. of conjugated oestrogens daily, has been used^{8,9} to reduce ultimate height with apparent success. Its action may depend both on antagonism to the growth hormone (which stimulates linear growth by acting on the epiphysal cartilage) and also by supplying a direct stimulus to epiphysal development. In terms of bone physiology, chondroplasia would thereby be slowed and oestrogenesis would be advanced; linear growth is retarded and ultimate height reduced by more rapid epiphysal development. Oestrogen to produce these effects would have to be given for two or three years, or until the fusion of the epiphyses with the long bones is complete. Uterine haemorrhage may be expected to occur, but the testimony of M. A. Goldzieher⁸ and S. C. Freed⁹ is that regular menstruation was established in their patients, sometimes before, and always after, therapy was withdrawn. Certainly the evidence seems to be that little permanent harm comes from using the "target" hormones such as oestrogen, testosterone, cortisol, and thyroid. The corresponding anterior pituitary action is temporarily suppressed, but both the pituitary and the target glands appear to recover without damage from their atrophic state, provided it is not too long continued. Conservative endocrinologists and gynaecologists, however, would not recommend that oestrogens should be given to adolescent and pubertal girls to reduce ultimate height without careful consideration of the two conditions here discussed.

MENTALLY HANDICAPPED YOUNG PEOPLE

Three years ago the department of Public Health and Social Medicine at the University of Glasgow produced a useful survey of a group of mentally handicapped girls. A complementary survey on a group of boys has now been completed.¹ Together these surveys trace the history of some 400 boys and girls from the time of leaving special schools for the mentally handicapped in Glasgow until reaching their early twenties. How do they fare?

On the whole their employment record is surprisingly good when the level of intelligence quotient (as estimated at school) exceeds 50 for girls and 60 for boys. About 75% of the girls in this group had a record of at least five years in continuous employment, while only 8 of the boys were unemployed. The girls succeeded rather better than the boys in occupational grade, for about half of them were in semi-skilled jobs compared with only 20% of the boys. However, 13 out of 162 boys had successfully served an apprenticeship and reached the status of skilled craftsmen. Clearly mental handicap is not

necessarily incompatible with manual skill. But the picture is not wholly bright. Half of the girls and the majority of the boys were in unskilled, and in many cases unsuitable, jobs. "Often the lads found their way into jobs which were dirty, unpleasant or heavy, or which, from their nature, were not likely to be of universal appeal." One girl in five was found in "general labouring work, often dirty, sometimes in foundries." When I.Q. fell below 60 for boys, or 50 for girls, the record was more often of unemployment.

The marriage rate was about half that for the general population of Glasgow, though when the I.Q. was below 50 the prospects of marriage were more remote. It is much too early to look for information on size of family. A more disquieting feature is the frequency with which the boys run foul of the law. By the age of 22 some 30% had one or more convictions—a rate twice as high as that for a group not suffering mental handicap and for whom figures were available. The pattern showed an increasing rate of delinquency as I.Q. increased. When I.Q. exceeded 70 the proportion convicted exceeded 40%.

Nevertheless the general picture is better than might have been expected. Many of these mentally handicapped young people seem to be leading useful and contented lives. The most difficult problems centre round the virtual unemployability of those with a low I.Q., the ease with which the lesser handicapped are led into crime, and the unsuitability of many of the jobs which the young people accept. Those in the first category will probably always remain a dependent group, but more could be done to help the others. Some local authorities, but by no means all, have set up a special department of their youth employment service to cater for the needs of handicapped children. If this special service were extended, and if industry could be persuaded to co-operate, many of the problems of unsuitable employment might be well on the way to solution. The problem of delinquency is more intractable, and seems likely to remain a serious problem for many years to come. No solution is in sight. Personal supervision has helped in some cases, but the available skilled staff are far too few to make more than a small contribution. The problem must, however, eventually be tackled in a wider context, for a growing body of evidence points to social environment as a major factor. It has frequently been shown that the more depressed areas of our large cities contribute much more than a proportionate share of these unhappy cases. In the legal sphere we are moving towards a doctrine of "diminished responsibility" without waiting for any counterbalancing attack on the social and psychological problems of prevention.

Underlying the whole range of problems is the importance of the home. In the Glasgow surveys, where the home background was assessed as "good" there was a record of less unemployment, higher-grade jobs, and less delinquency. It may be that the best efforts of both central and local authorities, and the whole apparatus of the Welfare State, can provide no adequate substitute for a good home.

NUCLEAR WARFARE AND THE TREATMENT OF MASS CASUALTIES*

BY

G. D. KERSLEY, T.D., D.L., M.D., F.R.C.P.
Consultant Physician, Royal National Hospital for
Rheumatic Diseases, Bath; Area Hospital Officer

The apathy in this country, and perhaps especially among the medical profession, towards Civil Defence and education in protection from nuclear warfare is very evident. One is told either that "it can never happen" or "that nothing can be done about it." Both these statements should be carefully examined.

It is hoped that, in the cause of brevity, some dogmatism will be excused.

Apart from conventional weapons there are three hazards of total warfare—chemical, biological, and nuclear. In the first category, in addition to the well-known blister gases, there is now "G" gas, a colourless, odourless liquid which antagonizes cholinesterase, allowing accumulation of acetylcholine, a few drops causing immediate contraction of the pupil, followed by convulsions and, within four minutes, death. Apart from being under cover or wearing a gas-mask, some protection can be provided by the immediate injection of atropine, 2 mg., and experiments are being made with pyridine aldoxime methiodide (P.A.M.), which may prove more effective.

Biological warfare, which could be so well exploited by saboteurs, has fearful potentialities—incubation periods, mixed infections, and the infection of animals and crops all adding to its danger. Hygiene, knowledge of home nursing, and stockpiling of vaccines and antisera seem the only antidotes.

But it is nuclear warfare that perhaps merits most attention—destruction by blast, burns, and radiation liberated by either fission or fusion of the atom.

Mechanism of Nuclear Bombs

The atom bomb (Fig. 1A) consists of two "sub-critical" masses of uranium-235 that can be pressed

FIG. 1.—A: Atom bomb (fission bomb). B: Hydrogen bomb (fission-fusion bomb). C: Uranium bomb (fission-fusion-fission bomb).

together by a charge of T.N.T., the whole being surrounded by a reflecting tamper. In the "safe" position a shield rests between the two masses of uranium. This is a true fission bomb.

The so-called hydrogen bomb (Fig. 1B), a fission-fusion bomb, is an atom bomb surrounded by hydrogen isotopes which fuse under the influence of the intense heat to form inert helium with release of more energy—a comparatively "clean" bomb if exploded well off the ground.

*Presidential address to the Bath, Bristol, and West Somerset Branch of the British Medical Association, 1957.

This bomb can receive yet another coat of uranium-238, which, though less radioactive than the ²³⁵U needed for the atom (A) bomb, can be "split" by the large number of neutrons liberated by the hydrogen bomb. The fall-out from this fission-fusion-fission bomb (Fig. 1C) will be radioactive even if no dust is sucked up from the ground and irradiated.

Within minutes of an atom or hydrogen bomb being dropped on the free world, planes would take off with nuclear weapons from hundreds of bases. There would be a few days of holocaust, during which every activity would cease except for attempts to survive, and at the same time to destroy the enemy. After this there would be a long, long period attempting to make the world again a place in which it would be possible to exist.

There are two things that will reduce the risks of such a disaster—being strong, and being prepared for the worst. The latter in particular concerns us, and includes planning for dispersal and the teaching of self-help, first aid, and hygiene. Such preparation, costing nothing, but requiring medical backing, would more than halve the casualty rate—it might in the long run even decimate it. But more of this later.

We have said a word about the mechanism of nuclear bombs, but what of their effect? One "nominal" atomic bomb is equivalent to 20,000 tons of high explosive, more than a quarter of the total tonnage expended on the United Kingdom in five years. One H bomb of 10 megatons is equivalent to 500 times the A bomb or more than 100 times the weight of T.N.T. which fell on this country in the whole war.

Effects

The effect of either the A or the H bomb varies greatly according to the height of the burst, terrain, and weather, but the former would normally be an air burst to obtain maximal blast effect and would then be "clean," with negligible fall-out and with radiation effects only from the flash. The H bomb might well be a ground burst, and, in addition to perhaps some fall-out from an outer casing of ²³⁵U, it would draw up in the mushroom cloud behind its fire ball of expanding incandescent gas many tons of dust, in which it would induce radioactivity. The radioactive flash from the H bomb loses its significance, as anything in its area of influence would also be both blasted and burnt to death.

On the burst of a bomb, the sequence would be a fantastic light flash, causing temporary blindness, radiation effects, and intense heat of short duration, igniting material depending on its constitution, colour, and screening. This would be followed by the blast effect many seconds later, allowing time to take cover under a table to seek shelter from glass and rubble. The blast would also fan fires started by the original flash.

With the "nominal" A bomb, the size of that dropped on Hiroshima and Nagasaki, almost total destruction would occur within a radius of $\frac{1}{2}$ mile (0.8 km.), severe blast, burns, and radiation effects for 1 mile (1.6 km.), and houses largely uninhabitable for $2\frac{1}{2}$ miles (4 km.). With the 10-megaton H bomb—on all targets except the large conglomerations of population a 2-megaton bomb might be more realistic—total destruction might be expected over a $3\frac{1}{2}$ -mile (5.6 km.) radius, severe damage up to 10 miles (16 km.), and slight damage up to 20 miles (32 km.). With the 2-megaton bomb there would be only slight damage at 10 miles (16 km.). In spite of the "magnificence" of the H bomb, the A bomb is still likely to be used for military purposes, where ground must later be occupied by the attacker and for some small objectives such as air fields.

Medical Organization

The medical services that must cope with this situation will be civilian augmented by the Services. Broadly speaking, the medical organization will consist of headquarters,

forward medical aid units, hospitals (acute, auxiliary, and home cover), ambulance-car organization, and medical stores.

The hospital service and mobile units, until called out, will be administered, under the regional senior administrative medical officer, by an area hospital officer, who will be responsible for the direction of casualty admission within his area of some ten thousand beds. The principal medical officer at regional level will advise the Civil Defence Controller.

The first-aid teams, consisting of a medical officer, one S.R.N., and eight or nine auxiliaries, are "mobile"—ready to go to an incident and help to deal with serious emergencies and triage (the sorting of casualties)—or "static," to be situated at each acute hospital and helping to screen it from the less seriously injured cases and, in fact, provide a service for the walking wounded. The mobile first-aid unit is equipped with a car, 10-cwt. (500-kg.) truck, and motor-cycle. Both types of first-aid units are an integral part of the hospital service, but will be assisted as necessary

FIG. 2.—Suggested layout of a forward medical aid unit. SB₁ = Squad for off-loading. SB₂ = Squad for internal movement. SB₃ = Squad for on-loading. Triage by team of one senior medical officer, one clerk, and one nursing orderly.

by a casualty-collecting party from the Civil Defence Service. Until called out, both will work in the hospital to which they are attached, and will continue to be maintained by that hospital, but the mobile unit will be at the disposal of the Civil Defence Controller when required.

The tendency is now to group together some four mobile first-aid units to form forward medical aid units of much greater value and potentialities. With these larger units some serious attempt at sorting casualties may be made, and a suggested layout is here given (Fig. 2). On arrival patients would be "frisked," if necessary, with a geiger counter in the ambulance to see whether they need pass through decontamination, to be stripped of their clothes and washed, before entering triage. One or two medical officers of considerable experience should do the actual sorting, each accompanied by one or possibly two clerks and a nursing orderly. One medical officer might superintend both the first-aid section, from which light cases would be passed on to welfare or home, and the holding section for the very sick, though most of the care of the latter would be under the direction of a senior member of the nursing service. Two medical officers will be required in the urgent treatment section, where haemorrhage would be checked and correctable respiratory defects dealt with, and where compound fractures would receive attention. The evacuation section would require only a couple of nursing orderlies. An administrative officer could relieve medical staff of some duties and stretcher-bearers would be in three squads—one

for off-loading, one for on-loading, and one situated in a corner of the triage section for internal transportation. Two stretcher-bearers would stand by a stretcher case from its entrance, until it had been taken to first aid, holding, treatment, or evacuation, and they would then return to their rendezvous. Ambulances, after discharging cases, would proceed to an ambulance park, to be cleansed if necessary, pick up new stretchers and blankets, and then await orders.

Documentation must be of the simplest. A casualty label should be attached to the patient, if this has not already been done, with name, main diagnosis, symbols of M for morphine (with dose and time), T for tourniquet (with time), X for priority, H some haemorrhage, and R, C, XX, and P for contamination with radioactivity, blister, nerve gas, or phosphorus. Immediate disposal must be marked on the label in writing or by tabs, and if time is available the patient's address and where he was found should be added. Tabbing could be of five colours: (1) urgent, acute hospital; (2) urgent treatment and then acute hospital; (3) acute hospital not urgent; (4) hold; (5) first-aid and welfare. For the unit record, all that is required is a nominal roll of name, main diagnosis, and disposal.

An "acute hospital" will be any hospital with operating facilities expanded up to its maximum and possibly augmented by the addition of a tented extension provided by the Army. Nursing will be largely by auxiliaries supervised by S.R.N.s. These hospitals will be supported by auxiliary hospitals with approximately an equal number of beds, set up in stores, factory buildings, and the like, under the charge of a general practitioner and relying almost entirely on auxiliary nurses. They will deal with the less seriously ill cases both before and after admission to the acute hospital. In "target areas" only small "home cover" hospitals of not more than 15% normal capacity will be retained to deal with accidents and emergencies, and they will be staffed on a rota basis from one of the acute hospitals in the periphery.

All ambulances and commandeered vehicles for movement of casualties will come under the ambulance and collecting section of the Civil Defence organization. It seems likely that a key point, where a senior ambulance officer should be situated, may be the forward medical aid unit. Here, obtaining reports from ambulances arriving and keeping in the closest contact with the Area Civil Defence Controller, he will be in an excellent position to co-ordinate and control the forward "hauls" and those back to the hospital area.

Medical stores will be stock-piled at strategic points, and it is presumed that they will be under the control of the regional board.

The Army will keep in close liaison with the Civil Defence Authority, and field ambulances, when available, will make ideal forward medical aid units, while military hospitals can open hospital extensions of 200 beds within four hours, if suitably situated.

It is estimated that about 40% of casualties are likely to be due to blast—many caused by flying glass—and that about 60–70% will have suffered some burning. In the later stages radiation casualties will become a problem—perhaps 15 to 30%—but most of these will have to be treated at home.

Sorting

Triage is, of course, of the very first importance. Let us first consider the ideas of forward sorting of casualties and the experience of a large-scale exercise carried out in America in 1956, and then the ideas arising from the United Services Symposium held at the Royal Society of Medicine in June and at the Mayo Clinic in September, 1957 (*Proc. Mayo Clin.*, 1958).

A mobile team with one triage, three resuscitation, and one holding and four surgical sections dealt with 250 "casualties," 90 miles (145 km.) from their base. The "make-up" of the casualties was: major lacerations, 35%; uncomplicated burns, 29%; wounds to the ex-

trémities, 13%; head and nervous system injuries, 8%; chest and abdominal cases, each 5%; faciomaxillary, 3%; and ophthalmic, 2%. Of the total, 55% had some burning. The planning took 23 days, but as the result of this the units started work full blast within five hours of the alert.

Many lessons were learnt, but in particular the importance of the sorting section, which was staffed by four physicians of great experience. This section was hardly big enough, and it was felt that, with overpowering numbers, many of the hospital sections would have to drop their work and take over sorting and resuscitation. The whole advance station was organized into (1) triage, (2) resuscitation, (3) holding, and (4) evacuation of sections. The motto "The greatest good for the greatest number" had always to be kept in mind. Every effort had to be made not to overload the "acute hospital" section—even with relief teams the number of cases that can be operated on in the first 24 hours is very limited, and General Drummond suggests that a surgeon can operate on only 12 serious cases per day for any prolonged period. Only cases of really top priority must be thus labelled. Head cases did not as a rule merit urgent treatment. All cases were graded into (1) emergency surgery, mainly to check haemorrhage and remove devitalized tissue, (2) resuscitation, and (3) holding (non-urgent, slight injuries, and moribund).

About 50% of cases were sent to the acute hospital, 25% to distant hospitals for less urgent treatment, and 25% kept in the holding unit.

The main lessons learnt from the "exercise" were the importance and magnitude of triage and the need for a very large supply of tracheotomy tubes and blood and blood substitutes. It seemed likely that tracheotomy might very often be required in multiple injuries with C.N.S. involvement and especially when there was the complication of burns.

The Filter Unit

In the recent symposium on the treatment of mass casualties, Colonel Ahern (1957) dealt with triage and the possible use of a filter unit. He envisaged a 10-megaton bomb on a city with a million inhabitants. There might be 210,000 immediate casualties, excluding the dead. Of these, 60,000 would be light cases and 150,000 seriously hurt. Of the latter, 100,000 would be trapped and some be released, dead or alive, within a few days. There would thus be 50,000 untrapped serious casualties to be evacuated to hospitals as soon as possible. This was the debit side of the ledger. On the credit side there were over 50,000 hospital beds at distances of from 5 to 15 miles (8 to 24 km.) from the edge of the devastated area—just enough to care for the untrapped serious cases, but not enough for the trapped cases. A filter unit might consist of 10 doctors, 120 to follow. A filter unit might consist of 10 doctors, 120 nursing personnel, and 160 stretcher-bearers and "police." It that is, one field ambulance plus a company of infantry. It could filter 6,000 cases in 24 hours (allowing two minutes per patient for sorting and nine minutes for emergency surgery). It is estimated that 40% would be minor injuries, 20% urgent cases, 20% requiring delayed expert treatment, and 20% "write-offs"—labelled expectant treatment.

The unit would first turn away, after first aid, all walking wounded to a Civil Defence Welfare Centre. The remainder, wounded to a Civil Defence Welfare Centre. The remainder, after being monitored, and if necessary cleansed, would pass to the sorting department, and would then be divided into almost equal groups for immediate treatment, evacuation, and holding. This unit should therefore divert from the neighbouring acute hospitals approximately two-thirds of the cases that found their way to the sorting department.

On arrival at hospital, General Drummond (1957) suggests direct admission to the ward of cases filtered elsewhere—in this way 100 patients can be bedded down in 60 minutes. He stresses the hopelessness of overloading a hospital beyond the capabilities of its staff, and recommends the "locking of the gates" when it is full. One medical company can, however, open and admit an additional 100 patients within two hours of arriving at a hospital to which it may be

attached. If, however, casualties have not been already sorted, this must be carried out in as large a hall as possible at, or adjacent to, the hospital. In the first instance, with minimal documentation, casualties must be sorted by experts into (1) fit to go home at once or after first aid, (2) for transfer to an auxiliary hospital, (3) cases requiring admission and treatment "at leisure," (4) cases requiring urgent treatment and resuscitation, and (5) moribund.

The serious but treatable cases to be admitted to an acute hospital fall into two categories: the very urgent—easily accessible haemorrhage, correctable respiratory distress, crush injuries of limbs, and open fractures—and the less urgent—15 to 40% surface burns, major closed fractures, and damage to the central nervous system.

Types of Casualty

All who dealt with casualties in the last war will be familiar with the danger of flying glass. Much can be done in prevention by screening and sandbagging windows and taking cover. Only the most severely injured would be able to be admitted to acute hospitals. There would be no scope for professional individualism.

Burns would be on an unprecedented scale, and again only for those where expert treatment is necessary to save life and where life can probably be saved will transfusions and infusions be available—they would largely be reserved for 15 to 40% surface burns, perhaps one-third of the cases. For the remainder, sedation—sodium phenobarbitone, 3 gr. (0.2 g.)—analgesics, copious saline by the mouth, and possibly oral antibiotics and a clean covering for the wounds, will be all that is likely to be possible. Exposure to air with the burnt part raised is, however, perhaps best if practicable. The value of early amputation of a badly burnt limb must not be forgotten. Treatment for anaemia later must also be remembered.

An interesting "help yourself canteen" for the treatment of the less serious burns cases is envisaged by Hunt (1957). Instead of a bun, the customer would collect the appropriate burns dressing; for a drink there would be saline and bicarbonate of soda; and at the cash desk would be some simple printed instructions.

For abdominal casualties, treatment of shock and minimal disturbance before urgent surgery are indicated. Intravenous infusion, gastric suction, antibiotics, and sedation will probably, however, be required. Chest cases may need closure of sucking wounds, release of tension pneumothorax, aspiration from the pleural cavity, maintenance of airway, fixation of a floating chest, and, of course, infusions, oxygen administration, and antibiotics. Lower-limb fractures may indicate skeletal traction by insertion of a Steinmann pin under local analgesia through the tibial tuberosity or os calcis. For the upper limb temporary splintage is all that is required, with no attempt to reduce displacement until later. Waterson (1957) outlines the principle of treatment of fractures by the application of standard plasters, none of which surround the limb or can obstruct the circulation, and which can be put on immediately by pairs of trained orderlies as soon as the medical officer has made the diagnosis.

Radiation Treatment

In the treatment of radiation casualties a selection will have to be made of those most deserving of expert help. Prognosis is therefore the first essential. Some guide to the amount of radiation a person has absorbed can be obtained from calculation of the intensity of radiation, duration of exposure, distance from radioactive particles, and screening factors. Screening and distance factors are illustrated by the fact that 6 in. (15 cm.) of concrete quarters the dose, occupation of the centre ground-floor room of a two-storied house reduces the dosage factor by 40, and staying in a cellar by as much as 300. Intensity of radiation from fall-out at first decreases rapidly, so that an area showing a reading of 1,000 r per hour, one hour after an explosion, will have that reading reduced to 100 r per hour

in 8 hours, to 10 r per hour in 48 hours, and to 1 r per hour in three months. It must be noted that the drop in radiation is much slower in the later stages because this latter radiation is due to isotopes with much longer half-lives. 50 r in 48 hours is considered a permissible dose for rescue workers in an emergency. 100 r will produce some morbidity, 200 r 50% casualties but little if any mortality, and 400 r 50% mortality.

Prognosis on these physical factors is, however, both difficult and uncertain, as some people can absorb nearly twice as much radiation as others without serious harm. The very old and very young are the most susceptible. Pathological examinations would not only be largely impracticable but of little use. We come eventually to old-fashioned clinical medicine and observation, and particularly to timing of onset of symptoms after exposure, for our real guide. If there are no symptoms for 24 hours after exposure and then they consist only of slight vomiting and nausea, the prognosis is good. If persistent vomiting occurs within two hours (a victim may be sick because of shock or other causes), fever before seven days, or purpura or loss of hair before three weeks, the prognosis is probably hopeless. Treatment consists of rest and sedation and a bland nourishing diet with plenty of fluids. In the more severe cases intravenous fluids and antibiotics of the erythromycin wide-spectrum type, to be started after the fifth day, when the leucopenia becomes manifest, may be helpful if available.

The distribution of medical and all rescue planning will have to be governed by "fall-out." As stated before, when a nuclear explosion takes place on or near the ground a large quantity of dust is sucked up and irradiated. This will be carried by the prevailing air currents at the levels it traverses and will gradually settle again downwind. Meteorological observations will give some indication of likely areas of fall-out, but a zone some 50 miles (80 km.) across and perhaps 200 miles (320 km.) long may be expected. Weather conditions will also determine how long a warning there may be before the fall-out settles—in some areas there may be perhaps an hour. The intensity will be at once plotted and zones demarcated on this information. The policy in the whole area must be to "go to ground," and the critical time for moving again is 48 hours. The reason for this is, as mentioned before, that the degree of radioactivity falls off rapidly for about this time and then much more slowly, and that this time is about as long as it is considered feasible to keep the population under cover. After this two-day lapse, in the periphery the population may be allowed out about half the day, a little more central for two hours, and in the centre, where there is still more than 10 r per hour radioactivity, everyone must be evacuated—but again not till 48 hours after the burst.

Conclusions

What do we learn of practical importance from these sketchy remarks?

Firstly, plans must be made in advance for dispersal of population and voluntary partial evacuation by families in target areas. As the warning period is likely to be short, previous planning is essential. As part of this evacuation, about 80% of all patients would be sent home from all hospitals and the hospitals in the target areas would be completely cleared.

Secondly, enrolment, organization, and teaching of auxiliary nurses is of paramount importance, as on these we shall largely have to rely.

Thirdly, more information must be given to the public on the grounds of reducing panic. The unknown is the worst of all, and besides this there is some reassuring information that can be given. For instance, when a nuclear bomb has dropped it is unlikely that there will ever be another in that area; that flash blindness is often temporary though lasting hours; that mild face burns may cause loss of vision due to oedema for 24 to 48 hours only.

Fourthly, the "stay put" policy must be completely accepted; not only will evacuation after an incident increase risk to the individual from fall-out but it will hamper rescue, and also there may be nowhere for the evacuee to go. A badly bombed but just habitable house is better than none at all.

Fifthly, the population as a whole must learn some first-aid, home nursing, and self-help. Not only will there be no medical services available to deal with the minor casualties, but for those in a fall-out area no help can be obtained from outside for the first two days.

Finally, everyone should know something of hygiene. With concentrated populations in "safe" areas, burst water and sewage systems, and reduced resistance, resulting perhaps from both malnutrition and radiation effects, the results of epidemics might be worse even than the immediate bomb burst. As rigid a standard of hygiene as possible would be essential. Here again the Army Medical Services, with their vast experience, will be invaluable.

I should like to express my thanks to the D.G.A.M.S., Lieutenant-General Sir Alexander Drummond, and to General Lethbridge, Civil Defence Controller of the South-western Region, for reading this paper and for valuable comments, and to officers of the South-western Regional Hospital Board for encouragement and help.

ADAPTATION TO STRESS CONFERENCE OF BEHAVIOURAL SCIENTISTS

[FROM A SPECIAL CORRESPONDENT]

The Mental Health Research Fund held a conference on "Research on Stress in Relation to Mental Health and Mental Illness" from July 15 to 18 at Lincoln College, Oxford. Its purpose was to arrive at a synthesis of the concepts used in different branches of the behavioural sciences when discussing stressful situations and stress effects, or at least to clarify the differences between the ways these terms are used. Physiology, endocrinology, biochemistry, ethology, psychology, and psychiatry each had one or more representatives, and the conference brought together some 40 scientists, American, Canadian, and British, under the chairmanship of Sir GEOFFREY VICKERS, V.C., the chairman of the Fund's research committee.

Finding a Common Language

The fare was rich and varied. It was hardly surprising, therefore, that, suffering from indigestion, some participants should have expressed doubts about the feasibility and even the desirability of achieving a useful degree of synthesis. They tended then to argue that each branch of science requires to work out its own conceptual models, and that models worked out in other branches lose their precision and usefulness if they are incautiously extended. However, there were few who were not in sympathy with the thesis, argued cogently by Professor R. W. GERARD, of the Neuropsychiatric Institute, Ann Arbor, in a final summing-up, that the behavioural sciences form a unity, and that the processes of adaptation, whether to the physical, biological, or interpersonal environment, have a great deal in common; the similarities are more impressive than the differences. Several speakers had asserted that psychosocial stressors are very different from biological stressors because their meaning and therefore their effects depend upon past experience, which differs from one individual to another. Professor Gerard countered their arguments by pointing out that biological individuality is no less evident than psychological individuality and depends as much upon residues of past experience, remote as well as recent, and that in any event if there were only individuality and idiosyncrasy there would be no science, for the purpose of science is to show what is common to a number of individual instances.

The variety of meanings given to the term "stress" was a source of difficulty in the earlier sessions, for it was used to describe not only factors in the physical, biological, or social environment but also the disorders they produce. The conference soon discovered that confusion could be avoided by speaking of stressors or stressor agents, following Professor HANS SELYE (Montreal University), or stressful situations, on the one hand, or stress effects, stress processes, or distress on the other. Alternatively, the difficulty could be avoided by speaking of a defence reaction, for instance, instead of a stress response.

Restraint and Bereavement
